Biosphere ecology	Biosphere	Regional ecosystems	Through climate, atmosphere, etc.	Productivity, sustainability, disturbance

Cybernetic Principles in Biosystems

Adaptation and self-organization are impossible without information and controlling processes, that is, without realization of cybernetic principles. Cybernetic mechanisms can be found at all the levels of life, from biochemical processes to biosphere.

Self-regulation is a process of changing functionality of the system directed at its conservation. It is development of property of inanimate systems expressed by the Le Chatelier principle (1884) – external influence on the system's state is compensated by internal processes, influenced in the opposite direction. The law's version for open systems can be formulated as the following: an increase of the system's input leads to corresponding increase of its output. This reaction is passive and does not need energy.

For biological systems, it is very typical to use active methods to keep the system's steady state (maintain `homeostasis'). One of the ways is to follow the cybernetic principle of `negative feedback'; the output of some part of the system must influence its input – if the output is too large, the input is decreased, and vice versa.

Nature of Life: Mathematical, Physical, and Chemical Approaches

The multilevel and multimedium nature of life necessitates considering it in different aspects, in the framework of different sciences. Really, many definitions of life have no structure as ``Life is …,'' but only as ``Life can be considered as…." Probably, one can expect gradual synthesis of various approaches to the life problem, but, for the time being, the integrated picture has not been formed.

Mathematical View on Life

Mathematics is a tool for abstraction, a way to the core of scientific knowledge. Mathematics is not interested in details; for it, life is a kind of complex systems with special relations between elements. For the description of different properties of life, there are various mathematical models. Probably, it is impossible to design a universal model of life; each model has its own field of application and level of approximation. Attractiveness of mathematical models does not consist in their complexity, but in their lucidity and explanatory power. According to Einstein, ``Models should be as simple as possible, but not more so."

One of the first biological models was the Malthus model of exponential growth (1800). It was developed for the field of population dynamics by the Lotka–Volterra models (1925–31). Models of life were proposed by J. von Neuman, R. Tom, H. Meinhard, and others; mostly they were differential models. Their use was very productive; in particular, they are a basis for the nonlinear analysis.

Another interesting mathematical tool for life description is the theory of cellular automata. This kind of discrete model has a property to be chaotic at the microlevel and ordered at the global level. In principle, one can imagine the world as a cellular automaton with elements – physical particles. The well-known Game of Life of Conway (1970), which really reflects some features of real life, is also a cellular automaton.

Usually mathematical methods are numerical, but it seems to be a very perspective way to use topological and algebraic approaches also. The above-mentioned topological theory of ecological niches can be considered as an example of this way.

Physical Principles of Life

According to J. S. Mill (1806–73), laws of life cannot be something other than laws of behavior of molecules, interacting as parts of a living organism. But, because of emergence of biological systems, it is not easy to reduce biological laws to physical ones. Such a way, called `reductionism', does not always give practical results, but it is important as the theoretical basis for searching borders of the possible for living objects. It is not easy to predict fundamental consequences from fundamental laws; each forecast of possible effects is a discovery.

Biology is a continuation of physics and chemistry and chemistry is a continuation of physics. One can understand biology as `new physics' and pose a problem to find its form, which corresponds to physical traditions. Particularly, physics of life is possible only under very special values of the world constants; traditional physics `does not know' what life is, and cannot explain these values. It is necessary to use the `anthropic principle': our existence as intellectual beings, studying the world, presupposes its features ensuring origin of man.

In biology, as well as in the other sciences, the problem of energetic balance is very essential. It gives a general estimation of the process of life functioning. As open systems, living objects need permanent energy income; they use it step by step and finally transform it to thermal energy of the environment. The main source of energy for life as a whole is the radiation of the Sun (and, insufficiently, energy of the Earth's interior: chemical, thermal, and, probably, radioactive). Plants (`phototrophs') use the solar energy for chemical synthesis of organic substances (the process of photosynthesis), supporting their own existence and providing chemical energy for all other forms of life: `heterotrophs' (herbivores and carnivores) and `saprotrophs'. Physically one can say that the solar energy in the course of photosynthesis raises energetic levels of electrons in some atoms of living matter; then the electrons gradually and purposefully descend, executing chemical and mechanical work.

Life directs energy flux to itself and uses it. According to the I. Prigogine theorem, an open system, in the case of linearity of the energy flux through it, produces minimum likely entropy. Life is an inconvertible process, going in a linear area of forces–flow rates; it endeavors to keep this linearity. But irreducible small nonlinearity produces stochastic noise, finally destroying each living organism.

Contrary to general physical tendency, postulated in the second thermodynamic law, life as a global process is characterized by gradual decrease of entropy. (Separate organisms also decrease its entropy during most periods of their life, but after their death the entropy `gains revenge'.) The paradox was already pointed out by the father of statistical physics L. Boltzmann (1844–1906), and later was deeply analyzed by A. J. Lotka (1880–1949). In 1944, the Nobel Prize winner physicist E. Schrödinger (1887–1961) published his famous book *What Is Life*? devoted to this problem.

The general explanation why entropy can be decreased in living systems is evident; these systems are open; they use external energy to decrease their own entropy and, at the same time, increase entropy of the environment. In general, both first and second thermodynamic laws hold true. But the ways of converting the energy income to entropy reduction (or maintaining order) is not so clear. According to E. Schrödinger, organisms `drink orderliness' from a suitable environment. He explains about flux of `negative entropy' (negentropy) to organism, which compensates natural increasing entropy. He does not explain the process in detail, but stresses that life's tools for this aim are `aperiodic solids' – the chromosome molecules. Schrödinger's book had an essential influence on molecular biology; particularly, it stimulated J. D. Watson and F. Crick to discover the DNA structure (1953) and explore in that way, the physical explanation of life.

It is not very clear yet what Schrödinger's negentropy is – free or stored energy, information, organization, or something else? Probably, a perspective conception is the idea about necessity for life of two coupled processes. The first (energetic) one accepts energy from environment and provides it to the second (information) process, which is responsible for the living system's development. A disproportion of entropy takes place; the second process presupposes decrease of entropy; the first one, correspondingly, increases it. Such processes are observed in inanimate nature; for example, explosion of an ultranew star transforms it into a primitive clot of neutrons, but, at the same time, heavy elements of the periodic system (prerequisites of life) are synthesized and spread in the universe. High-ordered entropy disproportion in living organisms presupposes very exact coordination of biological processes; in accordance with Schrödinger's opinion, information DNA molecules play the role of the coordination center.

Life is not contradictory to the second thermodynamic law, but uses it in a special way. Excluding from reproduction all the descendants of a couple except two of them, death of prey killed by predator, extinction of species in the course of evolution – all these events on the one hand increase entropy, but on the other hand they lead to general progress, to ordering matter in some local areas (from which, because of reproduction, the new forms spread as widely as possible).

As for inanimate nature, many scientists see in unidirectionality of the entropy change the basis of the time phenomenon; the tendency of entropy reduction in living systems can give a key to understanding of the general laws of living matter evolution. A. J. Lotka in the article `Contribution to the energetics of evolution biology', published in 1922, proposed to consider energetic power of organisms as the main criterion maximized in the course of evolution. Later, he called this maximum power principle, the `fourth thermodynamic law'. The approach is still under discussion; it was supported and developed by such prominent scientists as V. I. Vernadsky and H. T. Odum.

The law is based on the consideration of species' evolution, when in conditions of ``the struggle for existence, the advantage must go to those organisms whose energy-capturing devices are most efficient in directing available energy into channels favorable to the preservation of the species'' (A. J. Lotka). A capability of better assimilation of solar energy or energy collected by other organisms is a prior evolutional advantage.

It is quite right at the level of ecosystems, when stochastic fluctuations and individual peculiarities at the level of species are integrated and averaged out. More and more effective populations are involved into biological cycling, increasing its intensity. As a result, the ecosystem power (consumed energy per unit time) permanently grows. It is mainly the result of competition from plants (producers), which are forced to maximize production for keeping their place in the ecosystem. Another extremely important factor is the activity of animals (consumers). They withdraw producers' biomass and additionally intensify cycling. Probably, the global role of consumers in biosphere consists exactly in the spinning up of ecological cycles.

At the level of concrete species, classical power is not the only parameter determining its evolutionary perspectives. One should take into account, for example, the efficiency of the species in limitation of entropy growth. As a result, it is more reasonable to speak not about all the available energy, but about `exergy'. The latter shows an ability of the organism to make the work relative to the surrounding; it is the `co-property' of a system and a reservoir.

Another important aspect, influencing vitality of the species, is the integrated character of energetic abilities of living organisms. H. T. Odum proposed a concept of emergy (embodied energy) as ``a measure of energy used in the past'' and stored in the system's structure. The concept is being developed by S. E. Jørgensen and others. The maximum `empower principle' is proposed by H. T. Odum as ``a unifying concept that explains why there are material cycles, autocatalytic feedbacks, succession stages, spatial concentrations in centers, and pulsing over time.'' Generalization of the approach is possible by way of taking into consideration `population strategies' of species. For example, one can base on the r/K concept or its modification the r/C model (in the context of which population preferences in division of its energetic recourses between the processes of growth and competition are considered).

Information Basis of Life

The notion about the information nature of life is generally accepted. At the same time, even the term `information' is interpreted in biological literature in various ways. Starting from the classical works of the founders of the information theory, C. Shannon (1948) and J. von Neumann (1951), different directions of the generalization of the term were proposed.

Concerning the information character of internal biological processes, a reasonable approach is based on I. I. Shmalhausen's views (1968) about the resonance nature of biological information. Most of the relations between elements in biological systems are based on special resonance organization of living objects. Very often, an energetically weak influence of one element on another one produces its powerful reaction. This interaction cannot be interpreted as pure energetic; we call it `information interaction'. In this context, information cannot be transmitted; it is a relation between two elements. There is connection between exergy as the object's energy with relation to its surrounding and the possibility of the object to realize information actions.

For realization of an information action, the initial influence (signal) must exceed some critical value: `excitability threshold' or `reobase'. For example, the maximal tension of cell electric discharge is 0.1 V; its reobase is 10% of this value. Sporadic resonance effects take place in inanimate nature too, but for living matter it is its basis; there are special mechanisms of energy charging for the creation of prerequisites for resonance (information) action. From the level of cells, there are extremely complex structures of signal relations, separated from processes of energy and matter transmission. In multicellular organisms and ecosystems, special information subsystems were originated. They influence each other by means of special media (substances and fields), bearing precisely signal character. Special systems of coding and decoding become more and more sophisticated. Information is the main instrument in all homeostatic processes; it is the main way to organize negative feedbacks in living systems.

Physically, the resonance is realization of potential energy; mathematically the same is bifurcation, nonlinear effect of steady-state (attractor) change. One can interpret information processes in a living system as a sequence of `internal bifurcation'. As life is an information process, it exists near separatrixes, divided areas of steady states' attraction in the space of system parameters. It is a mathematical illustration of life's fragility: directed small changes of system critical parameters can easily upset its dynamic equilibrium.

Quite often, the concept of information is used in biological literature for designation of a measure of living matter ordering. In this case, information is the opposition to entropy, something like Schrödinger's negentropy. In the course of life development, its information content gradually grows. The philosophic question about the origin of information in the universe is still open. There are two main opinions: either the Big Bang in the result of a symmetry breach created all existing information and it is gradually sowing up, or its quantity equaled zero at the beginning and it is in the process of permanent growth. In the second case, the information creation is bound with Darwinian natural selection. According to G. Kastler ``the information creation is storage of random selection.'' It happened also in the inanimate nature, but became much more intensive in the living one. The history of the universe is characterized by exponential growth of information.

General Chemical Principles of Life

Living matter is a direct sequel of the chemical level of organization. It is not invariant to its chemical composition; the material determines key properties of life.

Chemical reactions in living systems are cyclic and autocatalytic. According to the hypothesis of S. Kauffman (1993), big chemical systems of interacting polymers, which reach a critical level of complexity, necessarily become autocatalytic and self-replicating. Their elaboration can be ordered by natural selection. As examples of autocatalytic reactions, one can consider Calvin's cycle (`propagation of sugar phosphates') or replication of ATP, also connected with photosynthesis. The cyclic chemical reactions discovered by A. Szent-Györgyi and represented by the famous Belousov–Zhabotinsky reaction can play the role of `soft clocks' in living organisms.

Life is a positive connection between information molecules and proteins. The most important chemical cycle is the following: DNA produces enzymes, which, in their turn, ensure its replication.

Organic macromolecules are not thermodynamic objects; they have no aggregate state and are naturally far from a steady state. It is a prebiological stage of matter development. According to Schrödinger's simile, a living organism as well as a pendulum clock are not thermodynamic objects; because of solidity of the clock and stability of the hereditary substance of the organism, room temperature for them is practically equivalent to zero.

Polymerization as well as enzymes decrease entropy, and thereby decrease molecules' freedom to move and select their co-reactants. A principal difference of life chemistry from ordinary one is the matrix synthesis. For living matter, contrary to inanimate one, a strict order of extremely long chain of reactions is possible.

Life Is a Way of Matter Self-Organization

It is common knowledge that life is the manifestation and result of a general tendency of matter to self-organization. The difference between opinions consists in understanding of the predetermination of self-organization steps. Really, this difference is not so essential: on the one hand, random mutations in pure Darwinism lead to realization of more or less predetermined process of adaptation to existing conditions, whereas on the other hand, a `vital force' is needed in some mechanisms (why not stochastic?) to conduct their programs. The self-organization algorithms must have some physical basis (self-organization can be considered as a physical principle according to M. Eigen); it is not an opposition to Darwinian selection.

Self-organization is a process of forming order from disorder. It is possible in the following conditions: (1) there is a big quantity of simple components; (2) the components can constitute mutual relations; (3) there is a source of energy, supporting the

relations formed; (4) external conditions are suitable for stability of the new system; and (5) the systems can play the role of elements in the process of forming systems of a next level. Evolution of living matter is a combination of rising tendency, connected with growth of complexity, and descending one, connected with tendency to stability.

There are no special biological fundamental forces or elementary particles. Life is the continuation of the inanimate world; it uses all opportunities given by the laws of nature, particularly nonlinear scenarios such as phase transformation, hysteresis effect, the formation of dissipative structures, etc. All the possibilities should be groped for, probably by accident.

Biological Self-Organization as a Process of Niche Creation and Filling

Life can be considered as existing in its own space of possibilities (a `space of life'). Mathematically, this space can be called as a `phase space'. Potential wells in this nonlinear space are occupied by different forms of life; they are the so-called ecological `niches'. Usually the niche of species is defined as a set of environmental factors corresponding to the needs of the species. A linear world (without sources of energy) would have no niches. The inflow of energy creates or allows to create wells in the life space, where life can consolidate. The situation is similar to the physical picture of the world; elementary particles, probably, exist in potential wells and the world space is furrowed by some fundamental processes (e.g., the energy conservation law can be approximate, and leaking energy furrows space).

Evolution is a process of optimization. Biological systems evolve to a steady state or, in other words, optimize some criterion (Lyapunov's function), looking for a potential well (a niche) in a phase space. One of the optimization criteria is entropy production, which must be minimal in a state of dynamic equilibrium in accordance with the Glansdorff–Prigogine theorem.

In a niche, the system possess properties of homeostasis; after small distortions, it will return to the initial state. The evident discrete character of the steady states' set produces separateness of niches. Heterogeneity of the life space explains existence of strictly separated species and other taxonomic units. Living organisms are substantially casts of their niches. There are many examples of convergence, when similarity of niches leads to similarity of organization of living beings.

Tendency of nonlinear systems to keep in equilibrium is well known as a general systems property of `equifinality', postulated by L. Bertalanfy. It is a spontaneous reaction of the system; it is an important factor of evolution, but it does not direct the life progress. Optimality does not mean progressive character; the level of amoeba fitness is not lower than that of man. Evolution uses the gradient method, which allows finding a local extremum only; for improving living conditions, species must jump over unacceptable ones. According to I. Prigogine, self-organization is a process of step-by-step loss of stability. The change of a steady state can be a result of either essential external influence upsetting the system from a previous equilibrium and forcing it to transit to a new one, or a gradual change of system parameters leading to a change of the phase space topology, to disappearance of the current steady state. Both of these ways were combined during life history; the model corresponds to the saltation conception about evolution as a sequence of catastrophes. External influences (geological, cosmic, anthropogenic) cause disappearance and reorganization of niches. New niches stimulate evolution of their potential hosts, which fill them because of reproductive abilities producing `pressure of life' (see Fig. 3). Species, which have lost their niches, should progress or become extinct.

In accordance with another topological model, catastrophes (and accompanying biological innovations) create new dimensions of the life space. In the niche (a point of local minimum), a new dimension appears; correspondingly, the host of the niche loses its stability and gets a possibility to find a better position in a new direction. At the result of such step-by-step changes, the development trajectory of the species is formed as a chain of orthogonal line segments. The path of progress can be compared with a `bobsleigh track'.

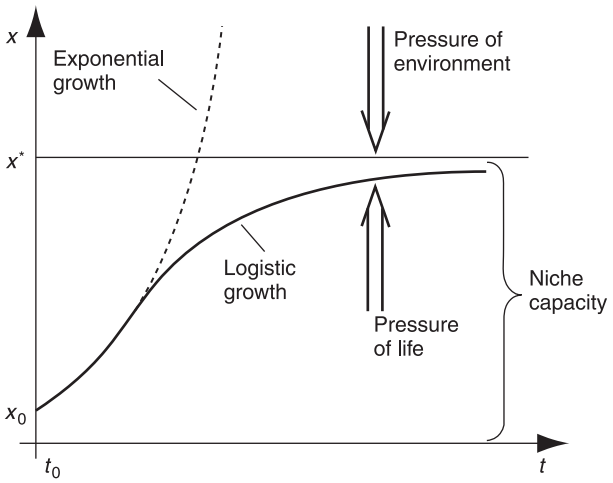

Fig. 3 Niche capacity as a result of dynamic equilibrium between pressure of life and pressure of environment.

Can evolution proceed under the constant conditions of environment? Darwinism does not exclude this possibility; the development of life organization can go on in the course of successive small improvements (decreasing entropy), but this movement is very slow. Usually it does not presuppose essential change of phase space topology; although it can sometimes stimulate radical changes: for example, the development of photosynthesis brought to the oxygen revolution and total reorganization of the system of niches. As a rule, a host of a stable niche slowly evolves and can meet competition only from the side of kindred species or, quite rarely, introduced ones. The Black Queen hypothesis about the necessity of permanent improvement of all species (``to stop means to die'') is not true for stable niches. This fact is illustrated by the existence of a great number of primitive species formed millions and billions of years ago. For continuation of the race, it is necessary to change topology of the phase space, to disturb the system.

Relatively fast evolution of life has become possible because of general instability of niches. The history of life is a sequence of actions of forming and filling niches. As a result of divergence, niches bifurcate; the process of `niche proliferation' takes place. Quite fast processes of niches interaction are ecological successions, when niches regularly change and supplement each other. Often infill of a niche creates a number of new ones, and, importantly, the complexity of the derived niches is usually higher than that of the initial one. It creates prerequisites for progressive evolution of life, an increase of its complexity. Newer forms of life produce newer local worlds, up to virtual worlds in the human mind, which are entirely real as both processes in brains and a plan for the real world change. Man with his imaginary worlds creates principally new powerful niches, particularly, for the development of artificial `electronic beings'.

Principally, the evolution process concerns not separate organisms, but the biosphere as a whole. The optimality of organisms is not an absolute value; it has a sense in the context of environment including other organisms. In other worlds, self-organization of life cannot be understood at the level of organisms; it is necessary to consider the general life space, separated species in corresponding niches, and their interference.

General Evolutionary Rules

1. Evolution is irreversible (the principle of L. Dollo, 1893). Why does the return to former conditions not lead to recurrence of old forms? There are at least two explanations. First, energetic innovations found during the previous stages of the evolution will not be lost if they are effective. Second, change of a living form is reflected in surrounding ones; the form can regress only together with its community. It is not so probable, although sometimes an ecosystem can degrade – not because of degradation of developed forms, but as a result of their elimination and return to the forefront of primitive forms.
2. Evolution is a movement from simple to complex, but the simple is not destroyed – it is included in the new structure of life. According to A. Szent-Gyorgyi, life never revises what has been made, but it builds above the existing. The cell is similar to a lot of archeological diggings, where one can see a number of strata – the older, the deeper. The structure is not optimal, but is reliable; the damage of upper layers is not fatal – ancient mechanisms can smooth the blow.
3. Complexity growth stimulates self-organization process. As is shown by J. von Neumann's model of self-organizing automata, the ability to self-organize depends on complexity of the object. There is a critical level, beginning from which automata can reproduce more complex forms than themselves. During its development, life also passed through critical levels, which forced its tendency to progressive evolution.
4. Evolution has often a binary character. Evolving systems can consist of two closely connected parts such as DNA–proteins, cell–nucleus, male–female, etc. During active stages of evolution one part outstrips the other; the first one becomes an object for experiments, and the second one guarantees preservation of attained level.
5. Life uses for its self-organization, natural frequencies (modes) of component systems. Some modes can intercept incoming energy from other ones and intensify themselves. This effect has resonance nature and is close to information phenomenon. Octave principles can take place – structures are formed by series on multiple frequencies. It is one of the ways of forming hierarchy of living systems.
6. Spatial self-organization of life can be considered as a process of dissipative structures' formation – one of the nonlinear mechanisms of originating order from disorder.
7. Life evolution is directed from profound symmetry to absolute asymmetry. The main stages are ball, radial, axial, and bilateral symmetries, and triaxial asymmetry. The asymmetry is a reaction on anisotropy of the living space, for example, gravity anisotropy.
8. Evolutionary process is not so much an invention of new forms as a search for effective combinations of existing ones. Various living beings are built from the same standard bricks, which were formed during early stages of evolution.
9. Evolution evolves itself. In the history of life, there were several `evolutionary formations', characterized by special evolutionary factors and features of self-organization forms.

Basics of Darwinism

Although people have used selection of domestic animals for a long time, and first guesses about the development of life were stated in the antiquity (e.g., according to Aristotle it is driven by a special living force – entelechy), the theory of `transformism' (about changeability of living forms), which opposed the theory of creationism (about constancy of organisms, created by God), was formed only in the eighteenth century. The first fundamental theory of biological evolution was proposed by J. B. Lamarck

(1744–1829) in 1809. This theory, progressive for its time, did not include the idea of natural selection and assumed inheritance of acquired characters. In 1858, Charles Robert Darwin (1809–82) proposed a new evolutionary theory based on the mechanism of natural selection.

Darwinism includes two key ideas: undirected variation (`mutations') of discrete hereditary codes (`genes') passed from parents to children, and elimination of less-adapted individuals in the course of `struggle for existence'. The codes, better reflecting the external conditions, gradually become dominant; average characteristics of individuals are changed. Selection transfers information about environment in the hereditary code. Useful negative fluctuations of entropy are spread over the species.

The Darwinian idea of natural selection can be considered as a very general explanation of matter self-organization – the tendency of entropy decrease in particular objects. This thought corresponds to the opinions of the founders of mathematical genetics, such as R. E. Fisher (1890–1962): ``Natural selection is a mechanism for generation improbability,'' and A. Lotka: ``The principle of natural selection reveals itself as capable of yielding information which the first and second laws of thermodynamics are not competent to furnish.''

Inheritance, Variability, and Natural Selection

For Darwinian self-organization, life must be structured for discrete generations and lifetime of each generation must be limited. To be effective, transfer of hereditary information from a previous generation to the next one cannot be absolutely free. Each species is divided into more or less isolated populations, where panmixia takes place. New specimens' characters are examined at the level of populations; only in the case of success, they spread for the whole species. Sometimes there are additional levels of such hierarchy: subspecies, races, subpopulations, etc. Structural units of species, uniting closely related individuals, are partly reproductively isolated. It is still not clear whether it is a natural result of hereditary remoteness or it is a manifestation of special isolation mechanisms forming an optimal structure of the hereditary field.

An important fact is discreteness of the hereditary code; genes are indivisible. This consideration eliminates Jenkin's nightmare: a useful character cannot resolve in descendants of reiterative coenobium.

Inherited characters cannot be absolutely independent; some of them are more or less correlated. On the one hand, it is a destabilizing factor; characters are selected in the context of other ones. On the other hand, it leads to tendentiousness of genes' variability, joint manifestation of correlated characters in accordance with the homologous series law of N. I. Vavilov (1920).

Darwinian variability is a principally random phenomenon. It is impossible to predict dynamics of external conditions; evolutionary perspective living forms must have multidirectional hereditary deviations. Initially directed evolution (as Berg's nomogenesis) is not sufficiently flexible to be effective.

Genes' variability (mutations) must be within reasonable limits. If it is too small, the progress will be too slow and can stop far from a local extremum. If the variability is too big, it will lead to system's chaotic behavior. These parametric effects are well illustrated by mathematical models based on the well-known `genetic algorithm'.

Darwinian natural selection examines the character of different specimens: stability, amativeness, reproductive potential, etc. It is not always a struggle for existence; often it is a struggle for leaving sufficient number of descendants. The main criterion is birth rate. If it is less than one, the species is doomed.

There are three levels of natural selection; only such forms of life can exist, which: (1) are stable and can physiologically give a breed; (2) allow origin of intellectual man (the anthropic principle); and (3) survive in the course of competition with other species (Darwinian selection). Evolution eliminates evidently defective individuals; other ones are not really exterminated, but rather `squeezed' from the ecosystem because of low birth rate.

Natural selection can be classified into three forms: stabilizing (supporting existing adaptations in stable environment); motivating (producing new adaptations); and disruptive (leading to separation of the population in condition of heterogenic environment).

Selection leads to harmony of the organism and its environment. Similar conditions produce similar organism's forms of adaptation to them. This effect is called `convergence'. Adaptation can follow a limited number of ways; in particular cases, it is not evident whether this form is a result of selection, or it is a direct consequence of physical laws.

Evolution can be divided into micro- and macroevolution. Microevolution consists in accumulation of hereditary changes in the population. At this stage, the most essential effects are the change of statistical distribution of different genes within the population and a search for their optimal combinations. The main factors of population evolution are maintenance of genetic heterogeneity, population size fluctuations, reproductive isolation, and natural selection.

Macroevolution is the evolution at the level of ecosystems; its result is the origin of new species. Its nature is not absolutely clear yet. It can be explained by either multistep microevolution or a random essential change, appearance of `perspective freaks'.

New Tendencies in Darwinism

The modern evolutionary theory is an elaboration of the classical Darwinian theory. Apart from such extremely important fields as `genetics', Darwinism accepted a number of new ideas such as genetic drift and recombination, cooperative evolution, and global biospheric context of evolution.

Mutations do not so often revolutionize populations; mostly, they support its genetic heterogeneity. In accordance with modern views, genetic mutations are not obviously new forms of genes. Usually they are recombinations of existing hereditary material, at the molecular, cellular, organism, and ecosystem levels. Such recombinations can produce a fast evolutionary leap forward. There is a common genetic pool of life; similarity of genes does not necessarily mean cognation.

According to Kimura's theory of `genetic drift', genes can exist and even breed in a latent form and then rapidly declare themselves. The effect does not contradict Darwinism; it only proposes a broadened understanding of mutations and their formation.

Variability as a result of genetic change is quite typical at the lower level of life. In cells, there is dissipated genetic material, which does not influence its characters, in silent parts in DNA (introns), in cellular parasites, viruses and plasmids (DNA molecules in the cellular protoplasm, which can be transmitted not only to descendants, but also to neighboring cells).

Although multicellular organisms are protected from genetic material damage by special mechanisms, cases of genetic material transfer can take place for them as well: by viruses, as a result of distant hybridization, etc. Besides, genes, reflecting environment, reflect genes of neighboring organisms. Thus, hereditary units (genes) of all living beings form a closely connected system, a general `gene pool' of biosphere.

One of the factors of horizontal genetic transfer, great importance of which has been understood lately, is the formation of symbiotic beings. A well-known example of symbiotic organisms is lichen, consisting of two species, fungi and alga, which, in principle, can exist separately. Because of long-standing coevolution, these two species have adjusted their biochemistry and synchronized reproduction. There is a small green sea worm *Convoluta roscoffensis*, feeding on symbiotic algae; algae germs transfer to the next worm generation through gametes. Most animals need symbiotic microorganisms for effective digestion, luminescent organs of animals are a result of symbiosis with bacteria, etc. One of the most important revolutions in the history of life was the origin of eukaryotic cells as a result of step-by-step symbiotic integration of several prokaryotic ones that finally shared their genes.

A subject of competitive selection can be a symbiotic system, unifying initial forms, which before had struggled for existence separately. The symbiotic evolutionary theory complements Darwinism with a deeper appreciation of the fundamental cooperative processes, which accompanied the origin and evolution of life.

Each organism has its own place in the biosphere. It cannot evolve separately; it should coordinate its change with connected species. Particularly, evolution of separate organisms should not damage biogeochemical cycles. In the course of evolution, the cycles, as well as the biosphere, reproduce themselves as comprehensive wholes.

Although the natural selection operates at the level of individuals, increase in information takes place only at the levels of species and ecosystems. Evolution of the biosphere is a grand process of information collection. The main source of the information storage is the biospheric gene pool.

Summary

Although life is an extremely complex phenomenon, including processes of different levels, nature, and duration, modern science has elaborated general approaches to its understanding. First of all, it is the systems approach which allows describing multilevel structure of life and modeling some general principles of its dynamics. The physical view on life is interesting due to understanding of biological laws as continuation of physical ones and the energy approach to living systems, particularly, investigation of role of entropy, exergy, emergy, and so on in biological evolution. Another interesting subject is the information nature of life, which is, finally, the main manifestation of universal information processes.

Dynamics of life is a permanent process of self-organization. A few very general principles of this process can be formulated: equifinality of biological processes; development of life as a process of niches proliferation; and Darwinian natural selection. There are a lot of questions science has no answers for, but general scope of the life phenomenon problem becomes more or less clear now.

Phosphorus Cycle☆

Y Liu and J Chen, Tsinghua University, Beijing, China

Introduction

Phosphorus (P) is important because it is a nonsubstitutable element in sustaining all life and food production on our planet. It is one of the three macronutrients needed by all crops (together with N and K). Human activity has quadrupled the mobilization of phosphorus, and although the availability of this nonrenewable resource does not seem to pose a problem at the moment, there are other aspects of our phosphorus metabolism that do require our attention, namely, the wastes (water and soil sinks) and how we affect the biogeochemical cycle of phosphorus on Earth. Throughout the metabolism of phosphorus in our economy, there are large amounts of wastes and emissions as will be shown later. P sources coming from industry, farmland, animal feed, and household consumption are all main contributors to overnutrient water bodies, causing eutrophication. For the soil sink, P is accumulated in both agricultural and natural soils due to fertilizer application exceeding crop assimilation and due to dumped industrial, agricultural, and animal wastes, which slowly leach into the soil. Thus, a huge amount of P is immobilized in soils, which results in deterioration of farmlands and the inefficient use of P resource.

The Human-Intensified Phosphorus Cycles

Inorganic Cycle

Phosphorus circulates through the environment in three natural cycles. The first of these is the inorganic cycle, which refers to phosphorus in the crust of the Earth. In geologic time, phosphorus has moved slowly through the inorganic cycle, starting with the rocks, which slowly weather to form soil, from which the phosphorus is gradually leached from the land into rivers and onward to the sea, where it eventually forms insoluble calcium phosphate and buries in aquatic, primarily oceanic, sediments (Follmi, 1996). There it remains until it is converted to new, so-called sedimentary rocks as a result of geologic pressure. On a timescale of hundreds of millions of years, these sediments are uplifted to form new dryland and the rocks are subject to weathering, completing the global cycle (Schlesinger, 1991). In addition, some phosphorus can be transferred back from the ocean to the land by fish-eating birds whose droppings have built up sizable deposits of phosphate as guano on Pacific coastal regions and islands and by ocean currents that convey phosphorus from the seawater to these regions. A simplified schematic of the global phosphorus cycle is presented in **Figure 1**.

The global cycle of phosphorus is unique among the cycles of the major biogeochemical elements in having no significant gaseous compounds. The biospheric phosphorus flows have no atmospheric link from ocean to land. A little phosphorus does get into the atmosphere as dust or sea spray, accounting for 4.3 million metric tons of phosphorus per year (MMT P $year^{-1}$) and

0.3 MMT P year^{-1}(Richey, 1983), respectively, but the amounts are several orders less important than other transfers in the global phosphorus cycle. The amount 4.6 MMT P year^{-1} of atmospheric phosphorus deposition, being balanced by the phosphorus carried by the wind and the sea spray, cannot offset the endless drain of this element from the land due to erosion and river transportation. Fortunately, increased anthropogenic mobilization of the element has no direct atmospheric consequences.

Nearly all the phosphorus on land is originally derived from the weathering of calcium phosphate minerals, especially apatite [$Ca_5(PO_4)_3OH$]. Around 13 MMT P year^{-1} of this is released to form soils each year (Emsley, 2000). However, this amount cannot offset the annual losses of phosphorus from the land. Taking into account all four forms of phosphorus (dissolved and particulate and organic and inorganic), the total amount of annual phosphorus losses from the lithosphere into freshwaters is estimated at 18.7–31.4 MMT P year^{-1} (Compton et al., 2000).

The uncertainty in the estimate is mainly due to a lack of knowledge on the biogeochemical processes of the particulate inorganic phosphorus, which constitutes the major component in the total loss. Not all of the eroding phosphorus can eventually reach the ocean. About 3.0 MMT P year^{-1} is carried away by wind into atmosphere, and at least 25% of that is redeposited on adjacent cropland and grassland or on more distant alluvia (Smil, 2000). Consequently, the amount of phosphorus transported by freshwaters into the ocean is probably in the range 12–21 MMT P year^{-1}. This result agrees with the most likely value of 17–22 MMT P year^{-1} given by some previous estimates (Emsley, 1980; Richey, 1983). The river-borne transport of phosphorus constitutes the main flux of the global phosphorus cycle. The loss, as a result of erosion, pollution, and fertilizer runoff, must be considerably higher than it was in prehuman times. It can be argued that the human-intensified phosphorus flux caused by wind and water erosion is at least two or even three times its prehistoric level (Compton et al., 2000; Smil, 2000).

Organic Cycles

Imposed on the inorganic cycle are two organic cycles that move phosphorus through living organisms as part of the food chain. These are a land-based phosphorus cycle that transfers it from soil to plants, to animals, and back to soil again and a water-based organic cycle that circulates it among the creatures living in rivers, lakes, and seas. The land-based cycle takes a year on average and the water-based cycle organic cycle only weeks. It is the amount of phosphorus in these two cycles that governs the biomass of living forms that land and sea can sustain.

The amount of phosphorus in the world's soils is roughly (90–200) $\times 10^3$ MMT P according to various estimates (Emsley, 1980; Filippelli, 2002). While the total phosphorus content of soils is large, only a small fraction is available to biota in most soils. This constitutes an available phosphorus pool containing 1805–3000 MMT P, most likely 2000–2600 MMT P (Emsley, 1980; Richey, 1983). A larger amount, in the range (27–840) $\times 10^6$ MMT P, can be found in the oceans. The surface seawater contains (80–3097) $\times 10^3$ MMT P and the rest is accumulated in deep seawater (Paytan and McLaughlin, 2007).

It is estimated that the oceanic residence time of dissolved P is between 20 and 100 kiloyears, although P is extensively cycled within the ocean on much shorter timescale. The ocean water loses phosphorus continually in a steady drizzle of detritus to the bottom, where it builds up in the sediments as insoluble calcium phosphate. Despite the geologic remobilization, there is a net annual loss of millions of tons of phosphate a year from the marine biosphere. Thus, the ocean sediments are by far the largest stock

in the biogeochemical cycles of phosphorus. Estimates of total P burial in open ocean marine sediments range from 2.8×10^3 to 10.5×10^3 MMT P per year, and the total marine sediments is estimated to be 840×10^3 MMT P(Paytan and McLaughlin, 2007). The majority of this burial flux is reactive P, with most of the nonreactive P having been deposited in the continental shelves.

Global Phosphate Consumption

The phosphate rock is initially converted to phosphoric acid (P_2O_5) by reaction with sulfuric acid. The phosphoric acid is further processed to produce fertilizers, food-grade and feed-grade additives, and detergents. Other marginal applications include metal surface treatment, corrosion inhibition, flame retardants, water treatment, and ceramic production. Despite such widespread use, the latter applications represented only ~3% of the total consumption of various phosphates in the 1990s (CEEP, 1997).

The global consumption of all phosphate fertilizers surpassed 1 MMT P year^{-1} during the late 1930s. After reaching 14 MMT P year^{-1} in 1980, the world consumption of phosphate fertilizers has been relatively stable. It was 14.8 MMT P (34 MMT P_2O_5) in statistical year 2002–03 and increased to 19.8 MMT P (45.4 MMT P_2O_5) in statistical year 2009–10, roughly accounting for 81.1% of the global extraction of phosphate rock (FAO, 2013). The top three economies, including China, the United States, and India, accounted for one-half of the world consumption. The area of the world current cropland is about 1.4 billion ha, implying that the global fertilizer application intensity averages 14 kg P ha^{-1}. The application rate varies significantly among continents, ranging from about 3 kg P ha^{-1} in Africa to over 28 kg P ha^{-1} in Asia. Annual P application in Western European countries was 24 kg P ha^{-1} in 1965, peaked at 34 kg P ha^{-1} in the 1980s, and then gradually decreased to 17 kg P ha^{-1} in 2007 (Sattari et al., 2012).

Crop Harvests

The use of phosphates to nourish agricultural soils aims to replenish the removal of phosphorus from soil by harvests and erosion losses. Adopting the average phosphorus contents in crops and the harvest index, the global crop production harvested 13.9 MMT P from soils in 2010 as shown in **Table 1**. A study of Chinese phosphorus flows suggested that the national harvest in 2004 removed 3.2 MMT P from croplands, based on a set of 'domestic' data for the phosphorus contents and the harvest index (Liu, 2005). These two estimates agree that (1) cereals accounted for a major part of the harvested phosphorus, that is, 70% at the global level and/or 68% in China, and (2) about two-thirds of the annually harvested phosphorus is contained in grains and the rest is contained in straw and other agricultural waste.

Since natural weathering and atmospheric deposition, as discussed elsewhere, cannot compensate the amount of phosphorus uptake from soils, application of phosphates, in both inorganic and organic forms, becomes essential to sustain today's harvests. There are several means of organic phosphorus reuse. The most direct means is to recycle crop residues *in situ*. Assuming roughly half of the annual output of crop residues (mostly cereal straw) is not removed from fields, the amount of the direct reuse of crop residues is about 2.4 MMT P year^{-1}.

Livestock and Animal Wastes

Animal wastes have been applied as organic manure in traditional farming and remain a relative large source of recyclable phosphorus in modern agriculture. According to the latest estimate from China, beef cattle, dairy cattle, swine, and poultry

Source: FAO (2013). *FAOSTAT*. Statistics Division, Food and Agriculture Organization of the United Nations; Smil, V. (1999). Crop residues: agriculture's largest harvest. *BioScience* **49**(4), 299–308; Liu et al. (2005).

produced 4.9 MMT P contained in animal manures in 2004 (Chen et al., 2008). The livestock population in China accounts for about 30% of the world total in 2004 and the proportion has remained fairly constant (FAO, 2013). On this basis, the global production of animal wastes would be 16.0 MMT P $year^{-1}$. However, the real figure may be somewhat larger, because the animals in China are not so well fed compared with developed countries. For this reason, the estimate of global production of 16–20 MMT P $year^{-1}$ in animal wastes, applying an average concentration of 0.8–1% of phosphorus for both confined and unconfined animal wastes, is probably more accurate.

Only the phosphorus in confined animal wastes is considered to be recyclable for croplands, while unconfined animal wastes mainly return to pastures. Assuming that animal biomass remains relatively constant, the amount of phosphorus in animal wastes is equal to the consumption of phosphorus contained in all kinds of feeds. In 2003, livestock consumed 36% of the harvested cereals (excluding the amount of cereals processed for beer), 21% of the harvested starchy roots, and 20% of the harvested pulses (FAO, 2013). Consequently, the annual livestock consumption of phosphorus in the harvests is accounted as about 2.4 MMT P $year^{-1}$.

Some part of crop residues is used as animal fodder. However, the reuse ratio of crop residues as fodder considerably varies globally. For instance, it was reported that the percentage of crop residues – mostly the straws of rice, wheat, and corn (maize) – used as fodder ranged from 3.6% in Shanghai to 42.8% in Gansu Province in 2000 in China, depending on crop and livestock species, farming and feeding traditions, and local economic profiles, and averaged 22.6% across the nation. Since over 70% of world livestock are raised in developing countries where commercial feeds are less used, the global recycling rate of crop straws as fodder is probably about 25%, leading to an absolute quantity of 1.2 MMT P $year^{-1}$.

Another major source of animal daily phosphorus intake is via feed additives. Around 6% of the global yield of phosphoric acid has been processed as animal feed-grade additives since 2000 (Brasnett, 2002). This constitutes an annual phosphorus flux of 1.0 MMT P $year^{-1}$ input to livestock husbandry.

Adding all the previously mentioned three sources, the global livestock consumption of phosphorus amounts to *c.* 4.6 MMT P $year^{-1}$. Taking into account the recycling of various industrial by-products and kitchen organic wastes (which is prevalent in rural family-based farms in developing countries), this figure could be as much as 20% higher, resulting in a total of 5.6 MMT P $year^{-1}$. Of course, the phosphorus flux to livestock of 5.6 MMT P $year^{-1}$ is mainly consumed by animals in confined facilities, while the world's cultivated and natural pastures provide a major source of phosphorus for unconfined animals. If one-half of the organic phosphorus in confined animal wastes is subject to recycling, animal manure is responsible for about 2.8 MMT P $year^{-1}$ returns to global croplands.

Food Consumption and Human Wastes

The third source of organic phosphorus available, in principle, for cropland is human waste. Assuming the world human body mass averaging 45 kg per capita (reflecting a higher proportion of children in the total population of low-income countries) and phosphorus content in human body averaging 470 g P per capita implies a global anthropomass contains approximately 3.0 MMT P. The typical daily consumption is about 1500 mg P per capita for adults (CEEP, 1997). This is well above the dietary reference intake (DRI), the amount human individual should take each day, as recommended by the Food and Nutrition Board, Institute of Medicine, US National Academy of Science. The US-recommended intakes are 700 mg per capita for adults over 18 years of age, 1250 mg per capita for young adults between 9 and 18 years of age, and 500 mg per capita for children.

A similar estimate for China is derived from a previous study: the individual daily intake of phosphorus was 1400 mg P per capita for urban residents and 1470 mg P per capita for rural residents in 2000. This exceeds the DRI of 1000 mg per capita recommended by the Chinese Nutrient Society. In addition, livestock products provided 30% of daily phosphorus intake for Chinese urban residents and 14% of that for rural population.

According to total protein intake and percentage of protein from vegetable sources, the mass phosphorus produced from human wastes annually on a capita basis in combined urine and feces ranges from 0.18 to 0.73 kg in 2009. Human excreta and urine contained about 3.4 and 1.7 MMT P $year^{-1}$, respectively. Urban and rural population generated 2.7 and 2.4 MMT P $year^{-1}$, respectively (Mihelcic et al., 2011).

Application of human excreta as organic fertilizer is common both in Asia and in Europe, but less prevalent elsewhere in the world. The nutrient linkage between farmers and croplands has been relatively stable, but the human wastes in urban areas are less recycled than in rural areas. For instance, less than 30% of human wastes in urban areas were recycled for agricultural uses in the late 1990s in China. This percentage dramatically decreased from 90% in 1980. In contrast, about 94% of human wastes in rural areas were returned to croplands in the 1990s. In European countries, the recycling rate of urban sewage averaged about 50% over the 1990s. Globally, it could be appropriate to assume that about 20% of urban human wastes and about 70% of rural human wastes are recycled at present. Therefore, recycled human wastes amount to 2.2 MMT P $year^{-1}$.

Adding the quantities of the phosphorus recycled as crop residues, animal manures, and human wastes, the total organic fertilizers applied to croplands amount to 6.4 MMT P $year^{-1}$. This is equivalent to 24% of the applied amount of inorganic fertilizers. Thus, the global input of phosphorus to croplands is probably 26.2 MMT P $year^{-1}$ in total or 1.9 times the amount of the phosphorus removed from the soil by harvesting. This leads to a net accumulation of 12.3 MMT P $year^{-1}$ or 7.9 kg P ha^{-1} in global soils, disregarding erosion and runoff losses.

Phosphates in Soil

The distribution, dynamics, and availability of phosphorus in soil are controlled by a combination of biological, chemical, and physical processes. These processes deserve special attention, as a considerable proportion of the applied phosphate is transformed into insoluble calcium, iron, or aluminum phosphates. On average, only a small proportion, perhaps 15–20% of the total amount of phosphorus in the plant, comes directly from the fertilizer applied to the crop. Readily available phosphorus in the soil solutions, however, provides most of the plant-available phosphorus. For most of the twentieth century, farmers in Western countries were advised to add more than double the amount of phosphate required by a crop, because these immobilized calcium, iron, and aluminum phosphates had been assumed to be permanently unavailable to plants.

Concentration of phosphate ions in the solution and the P-buffer capacity are the two main factors controlling the availability of soil phosphorus to plant roots. But the equilibrium concentration of phosphate present in soil solution is commonly very low, below 5 μmol (Condron and Tiessen, 2005). At any given time, soil water contains only about 1% of the phosphorus required to sustain normal plant growth for a season (Emsley, 2000). Thus, phosphates removed by plant and microbial uptake must be continually replenished from the inorganic, organic, and microbial phosphorus pools in the soil. These continuous processes dominate contemporary agricultural production to remove about 8.9 kg P ha^{-1} from cropland each year on a world average (based on our own estimate) and commonly 30 kg P ha^{-1} from the US and European fertile agricultural soils.

Each phosphate mineral has a characteristic solubility under defined conditions (Valsami-Jones, 2004). The solubility of many compounds is a function of acidity (pH; **Figure 2**). An increase in pH can release sediment-bound phosphorus by increasing the charge of iron and aluminum hydrous oxides and therefore increasing the competition between hydroxide and phosphate anions for sorption sites. Also, organic acids can inhibit the crystallization of aluminum and iron hydrous oxides, reducing the rate of phosphorus occlusion (Schlesinger, 1991). The production and release of oxalic acid by fungi explain their importance in maintaining and supplying phosphorus to plants.

The relative sizes of the sources and stocks of phosphate in soil change as a function of soil development (**Figure 3**). The buildup of organic phosphates in the soil is the most dramatic change. As time goes on, this becomes the chief reservoir of reserve phosphate in the soil. In most soils, organic phosphates range from 30% to 65% of total phosphorus, and it may account for as high as 90%, especially in tropical soils (Condron and Tiessen, 2005). The reasons for this are their insolubility and chemical stability. It has been noted that acid soils tend to accumulate more total organic phosphorus than do alkaline soils. This is almost certainly because organic phosphates react with iron and aluminum under acid conditions and become insoluble. Being the salts or metal complexes of phosphate esters, they release their phosphate by hydrolysis, but only very slowly. Phosphate esters can have half-lives of hydrolysis of hundreds of years. This process can be greatly speeded up by the action of phosphatase enzymes in the soil whose function is to facilitate reaction by catalyzing it. At later stages of soil development, phosphorus is progressively transformed into less-soluble iron- and aluminum-associated forms, and organic phosphorus contents of the soil decline. At this stage, almost all available phosphorus is found in a biogeochemical cycle in the upper soil profile, while phosphorus in lower depths is primarily involved in geochemical reactions with secondary sediments.

When the supply of dissolved phosphates to growing biomass is abundant, a net immobilization of inorganic phosphorus into organic forms will occur. Vice versa, inadequate inorganic phosphorus supply will stimulate the production of phosphatases and

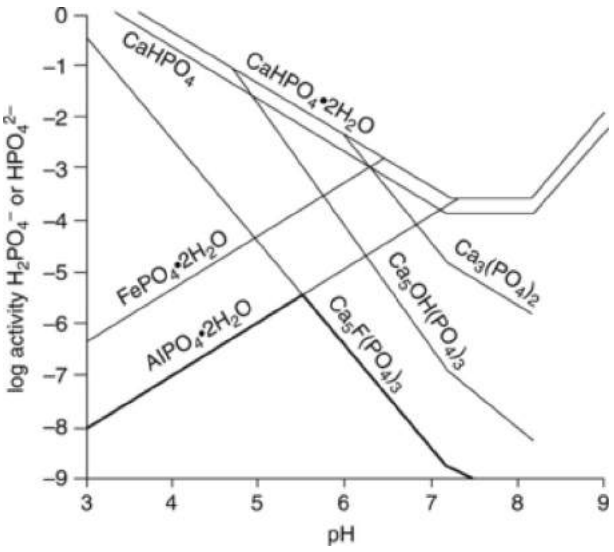

Figure 2 The solubility of phosphorus in the soil solution as a function of pH. Adapted from Schlesinger, W. H. (1991). *Biogeochemistry*: *an analysis of global change*. San Diego, CA: Academic Press.

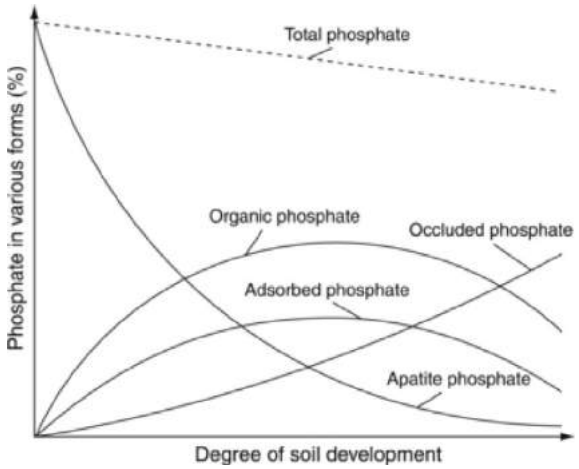

Figure 3 Phosphates in the soil vary with soil development. Adapted from Emsley, J. (1980). The phosphorus cycle. In: Hutzinger, O. (ed.) *The handbook of environmental chemistry*: *the natural environment and the biogeochemical cycles*, pp. 147–167. Heidelberg, NY: Springer.

the mineralization of labile organic forms of phosphorus for microbial uptake. A continuous drain on the soil phosphorus pools by cultivation and crop removal will rapidly deplete both labile inorganic and organic phosphorus in soils.

Allowing soil reserves of readily available phosphorus to fall below a critical value, determined by field experiments, can result in a loss of yield. The turnover of available phosphates by plants in soil solution is determined by rates of releases of phosphorus from insoluble forms to soluble phosphates. All kinds of soil particles can contribute to this process, and in some cases, it is not only the chemical balance that maintains the supply but also the action of microbes and enzymes that releases phosphate from organic debris in the soil. It is believed that the biogeochemical control of phosphorus availability by symbiotic fungi is a precursor to the successful establishment of plants on land.

However, our existing knowledge – briefly discussed earlier – cannot yet provide a comprehensive understanding of the complex movements and transformations of phosphorus, especially of its organic forms (Turner et al., 2005). This hampers the efficient application of phosphate fertilizers and the efficient control of phosphorus losses.

Phosphorus Losses

Phosphorus is lost from croplands via erosion or runoff. Quantifying phosphorus losses in eroding agricultural soils is particularly uncertain, as erosion rates vary widely even within a single field. It is also because few nations have comprehensive, periodic inventories of their soil erosion.

The phosphorus loss from croplands can be roughly estimated based on the amount of topsoil erosion and average phosphorus content. A crop takes up the majority of the nutrients it requires from topsoil. The topsoil is often identified as the 'plow layer,' that is, the 20–30 cm depth of soil, which is turned over before seedbed preparation. The volume of topsoil in the plow layer is around 2500 m^3 $ha^{-1}$and weighs approximately 2000 t (Johnston and Steen, 2000). A ton of fertile topsoil can contain 0.6–3.0 kg of phosphorus, based mainly on US and European agricultural practices.

At a global scale, 20–30 MMT P $year^{-1}$ is lost via erosion, and this would be equivalent to an annual loss of 15–20 kg P ha^{-1}, assuming that erosion from land other than arable land is negligible. Estimates of the amount of soil lost via erosion range from 5×10^3 to 40×10^3 kg ha^{-1} $year^{-1}$ for an average European arable soil to 10×10^3 kg ha^{-1} $year^{-1}$ at most for the major part of Europe. As the phosphorus concentration in an average European soil range between 0.05% and 0.2%, erosion of 10×10^3 kg ha^{-1} $year^{-1}$ of soil represents an annual loss of 5–10 kg P ha^{-1}. Annual soil erosion from agricultural systems of the United States, China, and India was estimated to be 3.0, 5.5, and 6.6 Gt $year^{-1}$, respectively. Some of the most serious soil erosion takes place in the agricultural systems of Southeast Asia, Africa, and South America. Hence, the real global soil erosion loss could be even higher, perhaps as much as 75 Gt $year^{-1}$.

The erosion intensity from croplands varies a lot among countries, ranging from 0.5 to 400 t ha^{-1} $year^{-1}$. Worldwide, soil erosion is highest in Asia, Africa, and South America, averaging 30–40 t ha^{-1} $year^{-1}$ of soil loss (Pimentel, 2006). It was suggested that the global average erosion rate is at least 20 t ha^{-1} $year^{-1}$. The lowest erosion rates occur in the United States and Europe where they average about 10 t ha^{-1} each year. It is evident that soil erosion in the United States has been reduced by soil conservation policies; a national survey showed that the total soil erosion between 1982 and 1992 decreased by 32%. The annual sheet and rill erosion rate in the United States fell from an average of 10 t ha^{-1} in 1982 to 7.7 t ha^{-1} in 1992, and the wind erosion rate fell from an average of 8.1–5.9 t ha^{-1} $year^{-1}$ over the same period. Assuming global erosion rate averaging 25 t ha^{-1}, the soil loss from crop land was estimated to be 38.5 Gt $year^{-1}$ from cropland (cf. **Table 1**). Furthermore, most of the loss is permanent and may not be replenished by weathering. For instance, the excessive soil loss, a rate that would impair long-term crop productivity, is estimated at about 25.4 Gt $year^{-1}$ in around 1980.

Table 2 Global soil erosion and phosphorus losses from agricultural land (2003)

	Permanent pasture		
	Cropland	*Overgrazed*	*Ordinary*
Total area (million ha)	1541	1720	1720
Soil erosion			
Erosion rate (t ha^{-1} $year^{-1}$)	25	15	5
Erosion quantity (Gt $year^{-1}$)	38.5	25.8	8.6
Phosphorus loss			
P content in topsoil (kg P ha^{-1})	0.5	0.5	0.5
P loss (MMT P $year^{-1}$)	19.3	12.9	4.3

Erosion from pastures is commonly less intensive than that from plowed fields. However, soil losses have been greatly increased by overgrazing, which now affects more than half (i.e., at least 1720×10^6 ha) of the world's permanent pastures with a high erosion rate of 15 t ha^{-1} each year. This leads to 25.8 Gt $year^{-1}$ of the soil loss from overgrazed pastures. Together with the amount of soil loss from cultivated grassland, the world's permanent pastures lose their topsoil at an annual rate of 34.4 Gt $year^{-1}$. Adding the losses from cropland and pastures, the world soil erosion from agricultural areas amounts to 72.9 Gt $year^{-1}$ in total, or 15 t ha^{-1} $year^{-1}$ on average. This is similar to previous estimates as discussed earlier. Allowing for the poor condition of topsoil in developing countries, it might be appropriate to assume that the global phosphorus content in topsoil averages about 0.5 kg P t^{-1}, or 1.0 t P ha^{-1}. This gives the world phosphorus losses at 19.3 and 17.2 MMT P $year^{-1}$ from cropland and pastures, respectively, as shown in Table 2.

The surface runoff loss of applied inorganic phosphate fertilizer varies significantly with a number of agronomic factors. Typical runoff rates of phosphorus in European countries range from 0.2% to 6.7%, an average of 3.5% (Hart et al., 2004). Worldwide, the maximum rate can reach 10% under certain soil characteristics and climatic condition. Roughly, the world total phosphate fertilizer application can lead to a loss of 0.5 MMT P $year^{-1}$ in surface runoff.

Phosphate Balance in Cropland

The national phosphorus balance varies significantly from one country to another, due to differences in the use of mineral fertilizers and manure and differences in animal husbandry practices. Broadly speaking, in developing countries, soils tend to be deficient in phosphorus, while in developed countries, the phosphorus content of the soils is adequate or even excessive. Taking into account applications of mineral fertilizers and manure, the balance for some West European countries is positive, particularly in the Netherlands where it exceeds 39 kg P ha^{-1} each year. For the majority of Western European countries, the phosphorus balance ranges from 8.7 to 17.5 kg P ha^{-1} annually. China, one of the largest agricultural systems in transition, also achieved a positive balance around 1980 at the national level, in parallel with increasing application of synthetic fertilizers. In 2004, the national balances of phosphorus in Chinese soils for arable land and grassland were estimated at an average of 59 kg P ha^{-1} (surplus) and −5 kg P ha^{-1} (deficit), respectively (Chen et al., 2008).

The world phosphorus budget for cropland is summarized in Table 3. To balance the phosphorus budget for the world's cropland, two natural inflows of phosphorus to croplands should be taken into account. Based on the ratio of cropland area to world total land areas, weathering and atmospheric deposition contribute 2.0 MMT P $year^{-1}$ as inputs to world croplands. Although the magnitudes of recycling of animal wastes and soil erosion need further verification, the budget provides a comprehensive overview on the global phosphorus flows associated with the farming sector, which is the most intensive and complicated subsystem of the anthropogenic phosphorus cycle.

Although there is a global phosphorus deficit for cropland, in regions with developed agriculture, residual soil phosphorus is very high, and soil phosphorus status has been improved over the past decades by applying fertilizer and manure. Cumulative inputs of phosphorus fertilizer and manure in Western Europe, Asia, North America, and Oceania for the period 1965–2007 amounted to 1115, 700, 500, and 560 kg P ha^{-1}, respectively. Since the 1980s, phosphorus application rates have declined in many European countries, but uptake continued to increase. This finding is possibly due to the continued supply of plant-available phosphorus from the residual soil phosphorus pool.

Ecological Impacts of Phosphorus Use

The phosphorus-related ecological issues fall into a broad range. Some of them are caused by inappropriate use of the material, some are not. Eutrophication, being regarded as the most immediate environmental consequences of extensive phosphorus usage in contemporary societies, has received wide attention. However, it is not the whole story, and other issues deserve to be taken into consideration.

Table 3 Phosphorus budget for the world's cropland in recent year (2004)

Flows	*Annual fluxes (MMT P)*
Inputs	29.2
Weathering	1.6
Atmospheric deposition	0.4
Synthetic fertilizers	19.8
Organic recycling	7.4
Crop residues	2.4
Animal wastes	2.8
Human wastes	2.2
Removals	13.9
Crops	9.0
Crop residues	4.9
Losses	19.8
Erosion	19.3
Runoff	0.5
Balance	−4.5
Input shares	
Fertilizer application	68%
Organic recycling	25%
Uptake efficiency	48%

Mineral Conservation

Estimate of world phosphorus reserves varies from 15 to 1200×10^3 MMT. But the most credible data come from the US Geological Survey, which gave estimates of 19.1×10^3 for reserve and 71×10^3 for reserve base in 2010. Regardless, it is widely accepted that phosphorus is nonrenewable within the timescale of human society, and it is becoming increasingly scarce and expensive. Peak phosphorus was estimated to occur by 2035, after which demand would outstrip supply (Cordell et al., 2009; Filippelli, 2008, 2011). Already in 1972, the Institute of Ecology reported that phosphorus could be depleted before the end of the twenty-first century. Present estimates concluded that world-known phosphorus would be depleted in the next 50–150 years; otherwise, additional resource could be found. Moreover, it has been projected that the utilization trend is unlikely to decline in next 20 years. It will instead probably increase at the rate of 0.7–1.3% annually (van Vuuren et al., 2010). This strongly suggests that phosphate rock, as a finite nonrenewable resource, may be exhausted in a much shorter time. It has been shown that the global average phosphorus content in raw ores dropped to 29.5% in 1996 from 32.7% in 1980 and that global reserves can sustain the current mining intensity for only another 80 years. Some phosphorus-rich deposits around the world can be exploited much sooner. China's phosphorus reserves, for instance, constitute 26% of the world's total reserve base, second only to Morocco and the Western Sahara. With a highly intensive extraction activity as well as losses incurred during mining, the basic reserve of the nation's phosphorus resources, that is, 4054 million tons with average P_2O_5 content of 17–22%, could be exhausted in 50–70 years. Certainly, the larger reserve base and probably more reserves to be discovered in the future guarantee a longer life span of the extraction. Even so, the deposits of phosphorus in the lithosphere will inevitably be depleted before new igneous or sedimentary rocks can be formed via the biogeochemical process at the timescale of millions of years.

Soil Erosion

One of the most important results derived from the phosphorus budget (cf. **Table 3**) is that the world cropland has lost phosphorus at a surprising rate of 10.5 MMT P $year^{-1}$. This massive loss from croplands is mainly caused by wind and water erosion of topsoil. Soil erosion has been recognized as one of the most serious environmental crisis the world is suffering from. It is estimated that 10 million ha of cropland is abandoned each year worldwide due to lack of productivity caused by the soil erosion (Pimentel, 2006). Nearly 60% of present soil erosion is induced by human activity, increasing by 17% since the early 1900s.

In contrast to the erosion loss, a huge amount of phosphorus has been mobilized in cultivated soils. Contemporary scientific knowledge cannot fully explain the complex transportation of phosphorus between plant roots, soil waters, and soil particulates. More complete understanding of these processes might suggest a possibility of controllable remobilization of soil phosphorus that would benefit the environment via reducing both the input of fertilizers and the loss of phosphorus from soils.

Animal Wastes

Livestock husbandry, in particular large intensive feedlots, has become a major problem both for recycling of organic phosphorus and for emission of phosphorus pollutants. Worldwide, the structure of animal agriculture has changed as livestock are concentrated in fewer but larger operations. In the United States, in spite of losing nearly a fourth of the livestock operations between 1982 and 1997,

the total number of animal units (an equivalent that converts various kinds of animals into cattle based on individual nutrient excretion) has remained fairly constant at *c.* 91–95 million. In China, a large number of intensive feedlots appeared in suburbs and rural areas during the last decade. According to a national investigation, the output of hogs, meat chicken (broilers), and egg chicken (layers) produced by intensive feedlots and farms accounted for 23%, 48%, and 44% of the national total in 1999, respectively.

As livestock operations have become fewer, larger, and more spatially concentrated in specific areas, animal wastes have also become more concentrated in those regions. This leads to a considerable phosphorus surplus in manure, as the amount of manure nutrients relative to the assimilative capacity of land available on farms for application has grown, especially in specific high-production areas. Consequently, off-farm manure export requirements are increasing.

But because of its bulk, uneven distribution, and prohibitive cost of transport beyond a limited radius, a large proportion of manure phosphorus is now subject to disposal instead of recycling. If construction of necessary infrastructures for appropriate disposal of manure lags behind, animal wastes become a major source of phosphorus loads in surface waters. Uncontrolled phosphorus emission from intensive feedlots and farms in China has escalated in parallel with the gradual growth in total animal feeding operations and the rapid shift in breeding structure. The emission of China's livestock was estimated at 39% of its national phosphorus load to aquatic environments in 2004. Thus, livestock husbandry is the most significant source of phosphorus flux to surface waters in China, similar to the situation in European countries in the early 1990s.

Sewage Treatment

In the 1960s, many developed countries began to alleviate the pollution in surface water by constructing municipal sewage infrastructures and implementing phosphorus discharge restrictions on production sectors. The giant infrastructure of centralized wastewater treatment has drastically reshaped the phosphorus cycle within modern cities. Despite high economic costs, its environmental benefits with regard to removal of phosphorus from wastewater are far less than satisfactory worldwide. However, some progress has been achieved in European countries and the United States (Litke, 1999). As the centralized control strategy just removes 'pollutants' into sewage sludge rather than promotes a recovery and recycling of resources, including phosphorus, it does not really solve the long-term ecological problem. The costly and rigid infrastructures have significantly reduced agricultural reuse of urban human excreta and contributed to a disconnect of nutrient cycles between urban areas and croplands. Unfortunately, no available technologies for stable recovery and recycling of phosphorus are likely to be successfully commercialized in the near future. Hence, most of the phosphorus in urban human wastes is not subject to efficient recycling and is permanently lost from the land.

Proposals for recovery of phosphorus via decentralized source-separated strategies have received increasing attention since the mid-1990s. This decentralized and downsized sanitation concept, focused on ecologically sustainable and economically feasible closed-loop systems rather than on expensive end-of-pipe technologies, advances a new philosophy. It departs from the one-way flow of excreta from terrestrial to aquatic environments, as introduced by the conventional flush-and-discharge sewage system. The new alternative separates nutrients and domestic used water at source and handles both components individually based on material flows approaches. Thus, it avoids the disadvantages of conventional wastewater solutions and enables and facilitates nutrient recycling. Although the reinvention and transition of urban wastewater systems poses a major challenge, it does provide a promising prospect for future phosphorus recovery and recycling in an ecological and economic efficient way. (Detailed studies are essential as a first step, inter alia, of technological, organizational, economic, and social aspects. In addition, the involvement of multistakeholders, such as residents, building owners, farmers, politicians, officials, and other interested parties, from the start seems essential. All these problems cannot be solved overnight, as it requires nothing less than a paradigmatic change of a large sociotechnical system.)

Detergent Use

The use of sodium tripolyphosphate ($Na_5P_3O_{10}$, STPP), the most widely used detergent additive, has been identified as a significant contributor to eutrophication. STPP was first introduced in the United States in 1946 (Emsley, 2000). After reaching a peak in the 1960s, global production has finally fallen down to one-half of the peak level, *c.* 1.0 MMT P $year^{-1}$, mainly due to bans on phosphorus-containing detergents in developed countries. The total quantity of STPP production was estimated at 0.865 MMT P in 2004. In the late 1990s, phosphorus-free detergents accounted for 45%, 97%, and 100%, respectively, in the United States, Japan, and the European countries (Litke, 1999).

There has been a controversy on the environmental impacts of STPP since the mid-1980s. Today, it is acknowledged that limiting or banning household consumption of phosphorus-containing detergents would not lead to a significant or a perceivable improvement of eutrophication. It would have little impact on water and human health compared to other substitute chemicals (sodium carbonates, sodium silicates or zeolites A, and sodium nitrilotriacetate), from both an ecological and an economic perspective. In parallel with these discoveries, some Nordic countries ecolabeled STPP as an environmentally friendly component of detergents in 1997 and have repromoted the production and consumption of STPP since then.

Eutrophication

Eutrophication is an unwanted explosion of living aquatic-based organisms in lakes and estuaries that results in oxygen depletion that can destroy an aquatic ecosystem. It has been regarded as the most important environmental problem caused by phosphorus

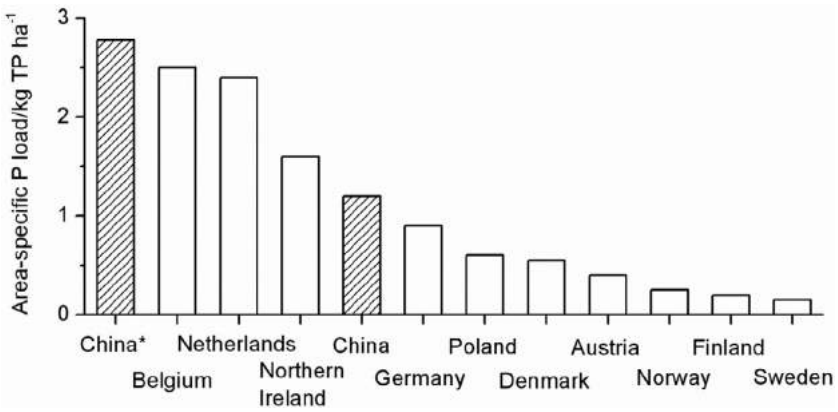

Figure 4 Comparison of phosphorus loads to aquatic environments by country (unit: kg P ha^{-1}). Reproduced from EEA (2005). *Source apportionment of nitrogen and phosphorus inputs into the aquatic environment*, No.7/2005. Copenhagen: European Environment Agency; Chen, M., Chen, J., Sun, F. (2008). Agricultural phosphorus flow and its environmental impacts in China. *Science of the Total Environment* **405**(1), 140–152.

losses. Significant eutrophication took place in the 1950s in the Great Lakes of North America and has been prevalent in many lakes and estuaries around the world. Phosphorus is often the limiting factor responsible for eutrophication, since nitrogen fluxes to water bodies are relative large.

Phosphorus losses from industries, croplands, animal farms, and households constitute the main sources. Figure 4 illustrates a cross-country comparison of the phosphorus loads in European countries and in China to their domestic aquatic environments.

The results show that the phosphorus loads range from 0.2 kg P ha^{-1} in Sweden to 2.5 kg P ha^{-1} in Belgium at the national level. China lies between Germany and Northern Ireland in turns of the load per unit land area. At the basin level, the comparison of phosphorus loads shows a similar figure. These results suggest that the Chinese economy is in general processing phosphorus 'wastes' less efficiently than developed countries. However, regarding phosphorus control strategy, it is nearly impossible to determine a common benchmark (of a desired phosphorus load) to prevent eutrophication in water bodies. This is because the complex interrelations between the amount of aquatic biomass and the phosphorus load are affected by a number of hydrological, meteorological, and biochemical factors that remain unclear under current knowledge. Further improvement of our current understanding of phosphorus movement and transformation within aquatic and territorial ecology, across socioeconomic and ecological boundaries, is desired.

Regulating the Societal Phosphorus Flows

Phosphorus (P), intensively extracted from the natural sink in the lithosphere and processed through various production–consumption cycles, ultimately deposits in soil or reaches the water body by different pathways. The anthropogenic P flows are characterized by complicated physical interconnections in high intensities among a number of production and consumption sectors. Hence, it is vitally important to connect the P flows with environmental regulations introduced to intervene in social practices and human behaviors.

Instead of continuously trying to limit the growth of P (like the bans of detergent P), there is a great need to reconstruct the physical structure of P flows, in particular by redirecting the crucial P flows with highly negative environmental impacts. The ecological restructuring of the current one-through mode of societal P metabolism is thus desired, leading to a structural shift in the societal production and consumption of P flows. The ecologically rational switch can contribute to a substantial decline of P outflows by minimizing P input and maximizing P recycling. Since ecologizing the P flows only succeeds when measures are institutionalized into the economy and society as a whole, this process will most likely be a gradual one rather than a radical revolution.

Sulfur Cycle

PA Loka Bharathi, National Institute of Oceanography, Panaji, India

Sulfur Cycle

Most elemental cycles are operative in both oxidative and reductive mode, each fueling the other, either in a dynamic instantaneous manner in space or sequentially over time. Sulfur and its species are important geochemical agents. While the element sulfur is the fourteenth most abundant element on Earth, sulfate ion is the second most abundant ion next only to chloride in seawater and carbonate in freshwater. Elemental sulfur is produced hydrothermally and also by oxidation of sulfide by weathering. The element is also formed as an intermediate of sulfide oxidation or sulfate reduction. Sulfides exist in a variety of forms, most of which are solids. However, dissolved sulfide can occur as bisulfide (HS^-) at neutral pH, sulfide ions (S^{2-}) at alkaline pH, and H_2S at acidic pH, which is volatile and has a rotten egg smell.

Sulfur transformations govern the compositions of the oceans, and the redox balance on the Earth's surface. It is complex due to a variety of oxidation states. Besides, some transformations occur at significant rates both bacteriologically as well as chemically.

The sulfur cycle involves eight electron oxidation/reduction reactions between the most reduced H_2S (-2) to the most oxidized SO_4^{2-} ($+6$). It acts as either electron donor or acceptor in many bacterially mediated reactions. The oxidation states of key sulfur compounds are given in the following table:

Organic	S (R–SH)	−2
Sulfide	(H_2S)	−2
Elemental S	(S^0)	0
Thiosulfate	($S_2O_3^{2-}$)	+2 (av./S)
Tetrathionate	($S_4O_6^{2-}$)	+2 (av./S)
Sulfur dioxide	(SO_2)	+4
Sulfite	(SO_3^{2-})	+4
Sulfur trioxide	(SO_3)	+6
Sulfate	(SO_4^{2-})	+8

Bacteria can mediate these oxidations. While bacterial oxidation of sulfur at the expense of oxygen or nitrate generally leads to chemosynthetic carbon fixation, the reductive S cycle is respiratory.

Sulfur Oxidation

Although a variety of oxidation states exist, only three forms are important, namely the sulfhydryl and elemental form besides the sulfate radical.

Reduced sulfur compounds can be used either by colorless sulfur bacteria or the colored photosynthetic bacteria. These bacteria notably belong to β purple bacteria group, namely the colored *Chromatium* sp. or the colorless *Thiobacillus* sp. The others include *Thiosphaera*, *Thiomicrospira*, *Thermothrix*, *Beggiatoa*, and the archaean *Sulfolobulus*. The final product sulfate and different amounts of energy are available depending on the oxidation state of sulfur used as the electron donor:

$$H_2S + 2O_2 \rightarrow SO_4^{2-} + 2H^+ \quad -798.2\ \text{kJ}$$

$$HS^- + 1/2O_2 + H^+ \rightarrow S^0 + H_2O \quad -209.4\ \text{kJ}$$

$$S^0 + H_2O + 11/2O_2 \rightarrow SO_4^{2-} + 2H^+ \quad -587.1\ \text{kJ}$$

$$S_2O_3^{2-} + H_2O + 2O_2 \rightarrow SO_4^{2-} + 2H^+ \quad -822.6\ \text{kJ}$$

Those forms that can oxidize sulfur under acid conditions are also able to oxidize iron. Yet others grow at neutral pH.

$$S_2O_3^{2-} \rightarrow S_4O_6^{2-} + 2e^-$$

The oxidation of sulfur involves the reaction of sulfhydryl groups of the cell, like glutathione, with the formation of sulfide–sulfhydryl complex. The enzyme sulfide oxidase oxidizes the sulfide to sulfite.

Chemosynthetic Sulfur Oxidation

The chemotrophic pathways are involved in the oxidation of reduced sulfur compounds, H_2S, S, and $S_2O_3^{2-}$. The oxidation of $S_2O_3^{2-}$ to tetrathionates $S_4O_6^{2-}$, trithionate $S_3O_6^{2-}$, pentathionate $S_5O_6^{2-}$, and elemental S^0 depends on environmental factors like

 doi:10.1016/B978-0-444-63768-0.00761-7

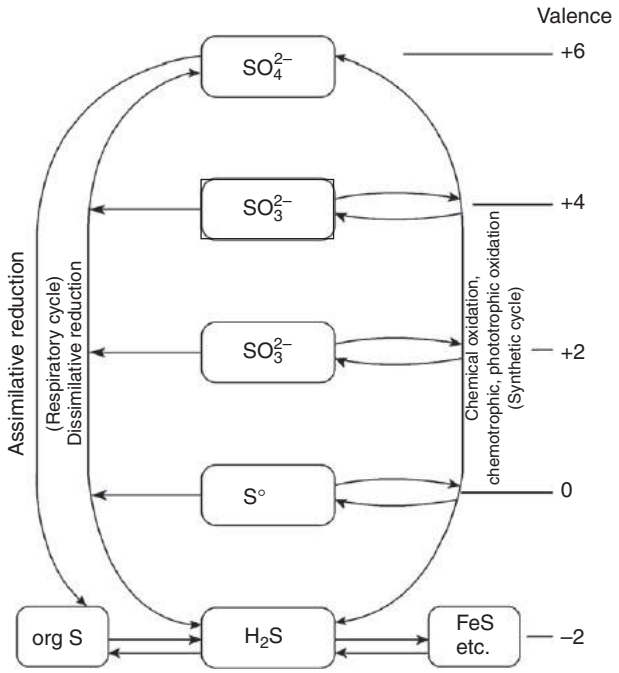

Fig. 1 The microbial sulfur cycle. Modified from Fenchel T and Blackburn TH (1979) *Bacteria and Mineral Cycling*. London: Academic Press.

oxygen and pH. The trithionate and pentathionate are formed from tetrathionate with sulfite and thiosulfite, respectively:

$$S_4O_6^{2-} + SO_3^{2-} \leftrightarrow S_3O_6^{2-} + S_2O_3^{2-}$$

$$S_4O_6^{2-} + S_2O_3^{2-} \leftrightarrow S_5O_6^{2-} + SO_3^{2-}$$

The chemotrophic bacteria have to compete with the spontaneous oxidation of sulfide. However, this chemical oxidation rates are speeded up by bacterial intervention – for example, bacterial oxidation of sulfide ores by thiobacilli. Thiobacilli-like bacteria play an important role in thiosulfate oxidation and sulfide oxidation, sometimes at the expense of nitrate as in *Thiobacillus denitrificans*:

$$5S_2O_3^{2-} + 8NO_3^- + H_2O \leftrightarrow 10SO_4^{2-} + 4N_2 + 2H^+$$

Sulfide oxidation coupled to nitrate reduction could be an important process in some coastal ecosystems where sediment-produced sulfide encounters nitrate-rich overlying waters that have been depleted in oxygen.

In other ecosystems like deep-sea hydrothermal vents, sulfur/sulfide oxidation is one of the main processes that bacteria utilize for chemosynthetic production of organic matter. Gigantic tubeworms in and around the vent fields harbor symbiotic sulfide-oxidizing bacteria. Special hemoglobins that bind H_2S as well as O_2 transport both substrates to the trophosome where they are released to the bacterial symbiont, thus preventing sulfide poisoning of the host.

Sulfide concentration in some vents measured as the sum of H_2S, HS^-, and S_2 can be related to prevailing temperature, but where biological uptake is rapid, the relationship can become nonlinear. The proportion of these species is strictly determined by pH of the surrounding. At the near-neutral pH from 7 to 7.9 of low-temperature fluids, HS^- is the prevailing species. Sulfide exposed to oxygen could be inorganically oxidized with a half-life of *c.* 380 h at 2 °C, and pH 7.8 and 110μm O_2 and 10μm H_2S. Biological oxidation of sulfide by macroorganisms and microorganisms at Galapagos vents could be 4–5 orders of magnitude greater than spontaneous sulfide oxidation in the laboratory. Generally in nature, the transition zones where the anaerobic zone meet the aerobic, the sulfide-oxidizing bacteria can form a sumptuous source of food to protozoans, microzooplanktons, and other higher forms of life. The oxidation of reduced sulfur compounds generates organic compounds (CH_2O) from inorganic substrates and is akin to primary production. In the marine microbial sulfur cycle, there is no net gain of organic material (Fig. 1). This is because organic material must be oxidized to generate the sulfide that is required for chemosynthetic production of organic carbon. However, at geothermal vents sulfide is released from the geochemical interaction of seawater and hot rock deep within the Earth crust. Under these conditions there is a net gain of organic material through the oxidation of sulfide and production of new biomass. The actual biochemical transformations are complex with light or chemical energy used to generate reducing power like NADH that is coupled to CO_2 fixation generally through Calvin–Benson cycle. Though chemosynthesis was described more than a century ago by Winogradsky, it was only with the discovery of hydrothermal vents that its significant quantitative role got established.

Geochemical Implications of Sulfur Oxidation

The sulfur-oxidizing microbes act as competitors and sinks for inorganic sulfur along with other reduced compounds as producers of organic biomass as food for zooplankton and a variety of benthic organisms.

Just as dissolved sulfides support chemosynthetic production, particulate sulfides too can support autotrophic growth. Metal sulfides, including pyrite, FeS_2, pyrrhotite, Fe_5S_6-$Fe_{16}S_{17}$, chalcopyrite, $CuFeS_2$, and sphalerite, ZnS, form widespread active and relict hydrothermal sites. Though sulfide oxidation of metal sulfides generally takes place at low pH, nonacidophiles from vent's sulfides are capable of autotrophic growth. Thus massive sulfide deposits on the seafloor may serve as potential source of electrons for autotrophic growth even when the vents are extinct. Such systems are also known to support high biomass of invertebrates.

Chemosynthetic systems in extreme environments like hydrothermal vents are likened to extreme environment systems on other planets or other extraterrestrial bodies. The search is on for chemoautotrophic forms on Mars. Such systems are also suspected to occur on Europa, a moon of Jupiter. They could represent the type of nonequilibrium systems which are thought to have been important in the origin of life on our planet.

Applications

These microbes evoke deep scientific interest because of their metabolic diversity and their adaptability to extreme environments. These characteristics can be gainfully harnessed by biotechnological firms for their enzymes or other metabolic products.

Sulfur-oxidizing bacteria could be judiciously used to contain `crude oil souring' due to excess sulfide production in oil wells.

Sulfur Bacteria in Symbiosis

The association of thioautotrophic (autotrophic at the expense of reduced sulfur compounds) symbiotic bacteria could be very specific. Most of them are related to subdivision of Gamma proteobacteria. Mariculture of symbiont-bearing invertebrate bivalves has also been suggested as a means of treating industrial sulfur waste.

Photosynthetic Sulfur Oxidation

Anoxygenic photosynthesis is also responsible for converting reduced sulfur to sulfate, thus forming habitats called `sulfureta'. The purple sulfur bacteria like *Chromatium* can oxidize sulfide internally through elemental sulfur to sulfate. The green sulfur bacteria do so externally. Consequently, the former are less tolerant to sulfide (-0.8 to 4 M) as compared to the latter (4–8 mM). The purple nonsulfur bacteria are least tolerant (0.4–2 mM).

When an anoxygenic bacteria grows on CO_2 as sole source of carbon, besides the formation of ATP, reducing-power NADPH must also be made available so that CO_2 can be reduced to form cell material. The source of reducing power is not water as in photosynthetic plants but reduced sulfur compounds like H_2S, S°, or thiosulfate. Hydrogen or organic compounds, such as lactate, succinate, butyrate, and malate, can also donate electrons for the activity:

$$6CO_2 + 12H_2S \rightarrow C_6H_{12}O_6 + 6H_2O + 12S^\circ$$

Habitats in which oxygenic photosynthesis is important is relatively limited in distribution and is therefore restricted to shallow coastal sediments or coral lagoon or sediments on beaches. These bacteria are at the end of anaerobic food chain that operates within microbial level. Heterotrophs feed sulfate-reducing bacteria (SRBs) and SRBs in turn feed photosynthetic bacteria, which can act as food sources for protozoans or microzooplankton.

Mixotrophy

Sulfur oxidation is carried out not only by chemolithotrophs but also by other groups like (1) mixotrophs (capable of autotrophic and heterotrophic growth); (2) chemolithotrophic heterotrophs; (3) heterotrophs which do not gain energy but derive benefits; (4) heterotrophs which gain nothing from the oxidation. Most pseudomonads are capable of growing mixotrophically on organic compound and reduced inorganic sulfur. Both marine and freshwater pseudomonads are capable of growing on thiosulfate and oxidizing it to tetrathionate.

The metabolic capabilities of a microbe sometimes cannot be too specific. It is argued that many microbes could be facultative, autotrophic at times, and heterotrophic at other, assimilating simple organic substrates that are available. Thus microbes like *Pseudomonas* sp. and *Alcaligenes* sp. have also been implicated in the heterotrophic sulfide oxidation. They could also behave like *Thiobacillus denitrificans*-like organisms (TDLOs) oxidizing reduced sulfide at the expense of nitrate and fixing carbon dioxide in the process. Such metabolic flexibility increases their competitive edge.

Sulfate Reduction

Assimilatory Sulfate Reduction

Sulfate-reducing activity (SRA) that takes place for the incorporation of sulfide radical for biosynthetic cycle is referred to as assimilatory sulfate reduction (ASR). Sulfate is reduced to sulfide in the assimilatory cycle which combines with serine to form cysteine. This in turn can be converted to methionine. These two amino acids are the main constituents of sulfur-containing molecules in the cells. Sulfur content can vary from 0.3% in eel grass to 3.3% in marine algae. As the N:S ratio in land plants is only 30:1, the reductive assimilation of sulfate is less important than nitrate. Assimilatory reduction is common among organisms and does not lead to the production of sulfide.

The eight-electron reduction of sulfate to sulfide proceeds in different stages. As the ion is stable it needs to be activated with ATP. The enzyme ATP sulfurylase catalyzes the attachment of sulfate ion to phosphate of ATP to form adenosine phosphosulfate (APS). Another P is added to APS to form phosphoadenosine phosphosulfate (PAPS) before it gets reduced to form sulfite.

Dissimilatory Reduction

The SRA that takes place in anaerobic respiration is termed as dissimilatory sulfate reduction (DSR). Here sulfate is used as terminal electron acceptor leading to the production of sulfide. Here too the sulfate ion is activated by ATP to form APS. However, in this case, the sulfate moiety of APS is reduced directly to form sulfite with the release of AMP. Thus the first product of ASR and DSR is sulfite.

Dissimilatory SRBs act as agents of synergy in sulfur cycle and bring about syntrophic associations. The end products from organic substrate oxidation and sulfate reduction lead to the formation of sulfide and carbon dioxide. SRA can account for nearly 80% of organic carbon mineralization in marine environment, especially in coastal regimes where nearly 5×10^{12} kg yr^{-1} of sulfate gets reduced.

SRA follows zero-order kinetics in marine sediments with respect to sulfate up to a concentration of *c*. 2 mM . The rate of SRA depends on both quantity and type of organic matter and the sulfate ion available which is generally not limiting in the marine environment. There is in general 2:1 molar relationship between the labile carbon utilized and the sulfate reduced. Sulfate-reducing rates (SRRs) can span several orders of magnitude: 50–500 nm cm^{-3} day^{-1} in coastal zones; 2785 nm g^{-1} day^{-1} in salt pans; 4000 nm ml^{-1} day^{-1} in salt marshes; and up to 14 000 nm ml^{-1} day^{-1} in microbial mats.

The other environmental parameter that affects SRA is temperature. Though the rates of activity can vary by factors ranging from <5 in winter to >0.30 in summer in the temperate region, in the tropics it is not very marked.

SRA predominates in marine sediments but the accumulation of the end products of sulfate respiration is pH dependent. Both metal sulfide formation and rapid biological oxidation are responsible for controlling the amount of sulfide that eventually escapes any system. Sediments harboring vegetation tend to emit less sulfide due to rapid oxidation by oxygen emitted from roots.

Though SRA is largely anaerobic there have been observations of its occurrence in the surficial oxic layers of microbial mats. Sometimes the rate measured in these oxic layers can equal or exceed the SRA of the deeper anoxic layers.

Abundance, Physiological Groups, and Taxonomic Diversity

Though SRBs are high in activity, they are low in abundance contributing to a maximum of 5–6% of total counts of bacteria. While culturable forms retrieved as colony-forming units (CFUs) range from 10^2 to 10^4 l^{-1} in agar shake tubes, most probable numbers (MPNs) methods yield 10^6–10^8 ml^{-1} and fluorescent *in situ* hybridization method (FISH) up to 10^7 ml^{-1}.

SRBs form two main groups based on their ability to utilize carbon sources completely or incompletely. In incomplete organic carbon oxidation, SRBs utilize a variety of organic substrates and oxidize it to acetate:

$$2(\text{lactate}) + SO_4^{2-} \rightarrow 2(\text{acetate}) + CO_2$$

In complete organic carbon oxidation, the organic substrate is totally oxidized to carbon dioxide, water, and sulfide:

$$\text{Acetate} + SO_4^{2-} \rightarrow 2CO_2 + S^{2-} + H_2O$$

Though the above two groups of SRBs are physiologically distinct they can coexist with the latter using the metabolic end products of the former.

SRBs also fall in the following major groups, namely Gram-negative mesophilic, Gram-positive spore-forming thermophilic bacteria belonging to δ subgroup of Proteobacteria and Archaea. The former includes two main families Desulfovibrionaceae and Desulfobacteriaceae. Desulfovibrionaceae includes the genera Desulfovibrio and Desulfomicrobium. Desulfobacteriaceae includes at least 20 genera, most of which are complete oxidizers of organic acids. The Gram-positive group comprises of *Desulfotomaculum*.

Desulfobacteriaceae are metabolically more versatile and are highly adapted to environments that undergo drastic redox changes as in salt marsh sediments or intertidal regions. Rhizosphere habitats are replete with *Desulfobulbus* species which are capable of sulfur disproportionation.

Sulfur-reducing activity

Bacteria like *Desulfuromonas acetoxidans* are capable of reducing sulfur at the expense of acetate. Some SRBs and iron-reducing bacteria are also capable of reducing sulfur. Many of these bacteria are able to generate ATP during sulfur reduction. These groups can also use organic disulfide molecules like cysteine or glutathione. Though sulfur and sulfate reducers can coexist, the latter can produce more sulfide. Most of these bacteria belong to Archaea. Methanogenic thermophilic Archaea reduce sulfur to sulfide while methane generation gets retarded. The process of sulfur reduction is an ancient process, as is suggestive from their presence in the deep branches of the phylogenetic tree. Though some sulfur reducers phylogenetically belong to δ subclass of Proteobacteria, they show affinity to other unrelated classes as well. Metabolic flexibility assures ecological competitiveness.

Sulfur disproportionation

Inorganic fermentation or disproportionation of sulfur and sulfur compounds, thiosulfate, and sulfite has been frequently encountered in SRB:

$$S_2O_3^{2-} + H_2O \rightarrow SO_4^{2-} + HS^- + H^+$$

$$4S^\circ + 4H_2O \rightarrow SO_4^{2-} + 3HS^- + 5H^+$$

$$4SO_3^{2-} + H^+ \rightarrow 3SO_4^{2-} + HS^-$$

Disproportionation seems to be very important and therefore widespread. Thiosulfate is an important intermediate as it can act as an electron acceptor or donor and thus mediate both oxidative and reductive cycle. Thus the thiosulfate shunt provides for complete anaerobic sulfur cycling. Though this is not energetically very viable, the bacteria are able to grow in the presence of metal oxides which can scavenge sulfide.

Use of Heavy Isotopes in Ecology

Sulfur exists primarily as two stable forms of isotopes: ^{32}S and to a certain extent as ^{34}S. Heavier isotopes are discriminated against; that is, most biochemical reactions prefer the lighter isotope and this preference is useful in elucidating microbial interactions. Thus sulfide production by bacterial reduction is much lighter than sulfide of strictly chemical or geothermal origin. Also the biological oxidation of sulfide to sulfur or sulfate either aerobically or anaerobically shows a preference for the lighter isotope. However, this fraction is not as great as that occurring through sulfate reduction as respiratory rates are faster and higher than synthetic ones.

Geochemical Implications of SRBs and SRA

Though the abundance of SRBs is generally low, their high respiratory activity mediates many other activities. Sulfate reduction sets other geochemical reactions in pace. The sulfide formed is responsible for the precipitation of metal sulfides which are available for autotrophic sulfide-oxidizing bacteria. It has been argued that about 90% of the sulfide produced by SRA is recycled back to sulfate to complete the cycle. The rest gets buried to form FeS_2. However, the energy gain from dissimilatory SRA is relatively low: at an energy yield $\Delta G'$ of -128 kJ with lactate and -48 kJ with acetate. Nevertheless, the sulfide produced by these bacteria can act as an energy source for other autotrophic bacteria.

The SRBs are also capable of using a variety of inorganic sulfur compounds as electron acceptors. These include dithionite, tetrathionite, thiosulfate, sulfite, bisulfite, metabisulfite, sulfur, sulfur dioxide, and dimethyl sulfoxide.

Sulfate reducers can use other electron acceptors like nitrate; group 4 oxyanions like molybdate and selenate; and even metals like uranium, chromium, technetium, gold, iron, and manganese(IV).

SRA Implications on Climate

SRBs can not only mediate synergistic reactions locally but also impact the climate on a wider scale. They are known to participate not only in the degradation of dimethylsulfoniopropionate (DMSP) but also in the flux of degradation product, dimethyl sulfide (DMS).

The SRBs are involved in the demethylation of DMSP to yield methylmercaptopropionate (MMPA), carbonate, and sulfide or oxidation of DMS to yield bicarbonate and sulfide.

DMSP demethylation

$$3/4SO_4^{2-} + DMSP \rightarrow MMPA + HCO_3^- + 3/4HS^- + 5/4H^+$$

DMS oxidation

$$3/4SO_4^{2-} + DMS \rightarrow HCO_3^- + 5/2HS^- + 3/2H^+$$

Intertidal sediments harbor algal osmolyte DMSP. DMSP could release DMS by the intervention of SRB. This could have countereffect on global warming. This reaction also decreases the effect of the potent greenhouse gas methane.

Fig. 2 Fluxes of the global biogeochemical sulfur cycle. Modified from Ivanov MV (1981) Global biogeochemical sulfur cycle. In: G E Likens (ed.) *Some Perspectives of the Major Biogeochemical Cycles*, ch. 4. Chichester, UK: Wiley.

DMS emissions form an important bulk of sulfur that enters the atmosphere and affects the climate. It accounts for 90% of the biogenic sulfur emissions from the marine ecosystem. DMS produced from DMSP breakdown which reaches the atmosphere serves to decrease warming by radiative backscatter from aerosols. It also reflects radiation from increased cloud cover. Both methanogens and SRBs compete for DMS but methanogens outcompete SRBs when DMS concentrations are high.

Similarly, the breakdown of the osmoregulant glycine betaine in marine sediments releases acetate and trimethylamine. The former is a preferred substrate for SRBs and the latter for methanogens. Other sulfur compounds like carbonyl sulfide (OCS) and carbon disulfide (CS_2) species could be formed photochemically or biologically for bacterial consumption.

Thus, the gaseous products of sulfur cycle interlink land, water, and atmosphere. These include hydrogen sulfide, DMS, methane thiol, carbonyl sulfide, and carbon disulfide. These volatile sulfur compounds get photochemically oxidized to produce acid rain or aerosol sulfate particles that decrease the incoming solar radiation and lead to cloud condensation nuclei. These processes influence the global radiative balance and consequently the climate.

Applications

The activity of SRB could be deleterious to all underground constructions because of their involvement in corrosion. The sulfide they produce is responsible for anodic corrosion, and their propensity to scavenge hydrogen generated in underwater metal structures could cause cathodic corrosion. However, some of these activities could be used in metal recovery from wastewater treatment as metal sulfides. The synergy existing between SRB and other microbes could be effectively used in bioremediation and ecosystem management. This trait could be exploited to contain mercury and other heavy metal contamination in water bodies.

Fluxes of the Global Biogeochemical Sulfur Cycle

The sulfur fluxes, both natural and anthropogenic, have been derived from various studies. A summary diagram of the global sulfur cycle with quantitative estimates of the sulfur fluxes is given in Fig. 2. The numbers near the arrows designate the total sulfur flux in Tg S yr^{-1} for all compounds. The contributions from anthropogenic activities are indicated by numbers in parentheses. About 120 Tg S are extracted annually by man from the lithosphere in fossil fuels and sulfur-containing raw materials for the chemical industry of which about 58% (70 TgS) gets emitted to the atmosphere. About half of the remaining 50 Tg S directly enters rivers through sewage and residual waters, and another part from fertilizers to agricultural land. Simultaneously, volcanic gases contribute markedly to the atmospheric sulfur cycle over continents amounting to 29 Tg yr^{-1}. The major transfer of sulfur from continents to the ocean by river runoff amounts to 224 Tg of which anthropogenic contribution is about 109 Tg. The total flux of various sulfur forms, that is, organic, sulfate, and pyrite from oceanic water to sediments and further to the lithosphere, amounts to 130 Tg yr^{-1}. Thus the estimates suggest that the anthropogenic sulfur fluxes to the atmosphere and hydrosphere have reached a level comparable with that of natural fluxes. The natural sulfur flux from the lithosphere, its main reservoir, is compensated by the reverse flux of sulfur compounds to the lithospheric sediments of the ocean. Further, there is also indication that by the end of this century the anthropogenic sulfur fluxes could notably increase all over the world.

All of the main reactions of the sulfur cycle involving living organisms are closely related to the carbon cycle. The amount of carbon involved in the fluxes of the sulfur cycle through biogenic processes varies depending on the type of organisms undertaking the metabolism of the sulfur compounds. In the processes of bacterial chemosynthesis, which are characterized by low amounts of energy utilized for the CO_2 assimilation, only relatively small amounts of carbon are transformed into organic matter. In anaerobic bacterial photoassimilation of CO_2 where sulfur compounds are used as electron donors, the amounts of oxidized sulfur and assimilated carbon are comparable. In anaerobic sulfate reduction, 24 g of organic carbon is mineralized for each 32 g of reduced sulfate sulfur. Thus, in ecosystems with an advanced development of photoauotrophic bacteria and SRBs, both groups of microorganisms transform significant amounts of carbon compounds and, consequently, these organisms should be considered not only as participants in the sulfur cycle but also as active biogeochemical agents of the carbon cycle.

Summary

Microbes, especially bacteria, play an important role in oxidative and reductive cycle of sulfur. The oxidative part of the cycle is mediated by photosynthetic bacteria in the presence of light energy and chemosynthetic forms in the absence of light energy. At the end of the anaerobic food chain in bacteria they serve to purify the system of sulfide and other metabolic end products. In the process sulfur is returned to the system as sulfate. In transition zones from anaerobic to aerobic, photosynthetic bacteria can form a food source to protozoans and microzooplankton. Chemosynthetic sulfur-oxidizing bacteria are the dominant bacterial forms that support thriving ecosystems in hydrothermal vents. Scientists are seeking evidences from such extreme environment for similar life on other planetary bodies.

The reductive cycle on the other hand is mostly driven by the sulfate/sulfur-reducing bacteria which use sulfate as the electron acceptor in anaerobic respiration to produce sulfide. Their close association with other microbes can have profound geochemical influence. Their metabolic activity dictates the availability of trace metals to other forms of life. While sulfide gets precipitated, phosphate gets released into the systems. Nitrogen fixation by these anaerobes also adds to the nitrogen economy of the environment they inhabit. In sediments of continental shelves that hold the reserve of gas hydrates, these microbes can modulate the concentration of methane in such ecosystems. Most importantly, the interaction with DMSP, an osmolyte from phytoplankton, can have wide-ranging climatic implications.

The main reactions of the sulfur cycle involving living organisms are closely related to the carbon cycle. The amount of carbon involved in the fluxes of the sulfur cycle through biogenic processes varies depending on the type of organisms undertaking the metabolism of the sulfur compounds. The estimates suggest that the anthropogenic sulfur fluxes to the atmosphere and hydrosphere have reached a level comparable with that of natural fluxes. The natural sulfur flux from the lithosphere, its main reservoir, is compensated by the reverse flux of sulfur compounds to the lithospheric sediments of the ocean. Further, there is also indication that by the end of this century the anthropogenic sulfur fluxes could notably increase all over the world.

Introduction

As the world population has grown so has the portion of surface land area of the globe that is used for crop systems to produce food for humanity (11% of 13.6 billion ha, according to FAO). Also, the productivity of food production per unit of land area has increased so that land required for food production per capita has declined from 0.45 to 0.25 ha since 1965, thanks to a compliment of diverse technologies in the fields of genetics, engineering, chemistry, ecology and others. Genetics has provided more productive and hardy crop plants, engineering has provided more efficient and more rapid tools and machines, chemistry has provided more effective fertilizers and pesticides, and ecology has helped famers better understand how to manage their fields and landscapes sustainably (e.g., effective crop rotations and pest management). Most of the world's food is produced on the richest soils with the most favorable climate (temperatures and precipitation) although in some regions supplementary irrigation is required during dry spells. Everywhere, crops have displaced natural vegetation; in moist areas crops have displaced forests and in dry areas grasslands and shrubs. Original plant communities, like tall grass prairie, have almost completely disappeared due to crop production in some countries.

Crops typically need at least 100 days of favorable weather, free of frost, and for a typical wheat crop about 1 mm of rain per 5–22 kg of grain per ha (or 0.7–3 kg of protein per ha). Besides providing most of the carbohydrates, proteins and fats in our diets, crops also give us essential nutrients like minerals and vitamins, health promoters like flavonoids, and amenities like flavors, medications and even recreation. And a substantial proportion of all crops produced are fed to livestock that provide a more varied plate but also help to balance dietary fats, proteins and supplement certain minerals (e.g., iron and selenium) obtained directly from plants.

The study of crops and their relationship to other plants (weeds and invasive plants), macro- and micro-fauna, microbes, and the soil substrate is called crop ecology. This is a field of study gaining worldwide interest, as can be seen by increasing university positions and publications, because crop ecology is expected to help sustain crop production and ecosystem services like biodiversity and soil carbon sequestration, while also helping to protect surface water from phosphorous eutrophication, ground water from nitrate contamination, air from fine particles and trace gases pollution, and climate from emissions of greenhouse gases. This article will describe three contrasting cropping ecosystems that are typical of major crop growing regions around the globe. The article will also discuss the long term sustainability of these three diverse crop ecosystems.

Semi-Arid Small Grain Cropping Systems

Semi-arid small grain cropping systems refer to rain-fed agriculture in areas where precipitation ranges between 250 and 500 mm per year (Fig. 1). These dryland cropping systems are prevalent in the Great Plains region of North America, as well as in areas of Australia, Africa, and Asia. By definition water availability is restricted in semi-arid cropping systems and is generally the most limiting environmental production factor, particularly in warmer regions where evaporative losses are high. Cropping choices and productivity are also restricted by the length of growing season which is constrained by temperature and/or water seasonality. Crop productivity is also affected by nutrient limitations, particularly nitrogen deficiency, and by crop losses from weed competition, insects and diseases.

Management practices in semi-arid cropping systems are designed to optimize crop yield potential and long-term sustainability. Crop yield is optimized by using incoming moisture as efficiently as possible, utilizing as much of the growing season as possibly, supplying the nutrients needed to support the crop yield potential and removing the weeds, diseases and insects that compete with the crop for resources such as light, water, and nutrients. Environmental sustainability requires that the soil, air, water and biological resources in the ecosystem are not degraded. Soil erosion and degradation from salinization, organic matter loss and nutrient depletion are of major concern in semi-arid regions. Nutrient movement from field areas to the air and water may affect environmental quality. Introduction of foreign pests and diseases and development of genetic resistance by pests to commonly used control practices present ongoing challenges to effective pest management and economic sustainability of production.

Efficient semi-arid cropping systems rely on the capture, conservation, and utilization of the limited available precipitation. In the past, use of a fallow year between one or two crop years was common to capture water and lower production risk. Tillage during the fallow phase was used to control weeds and release nutrients through organic matter decomposition. The moisture and nutrients conserved during the fallow period increased the productivity of the following crop. However, availability of improved equipment, herbicides, crop genetics and fertilizers has allowed a reduction in tillage. Reduced tillage and increased crop residue cover lead to greater moisture retention, lower water run-off, reduced evaporative losses and higher available moisture for crop growth, allowing for intensification of crop production and the reduction or elimination of fallow.

 doi:10.1016/B978-0-12-409548-9.10580-9

Fig. 1 Small-grain (wheat in foreground) based cropping systems in the semi-arid Northern Great Plains.

A key principle in sustainability of semi-arid cropping systems is intensification of crop production to balance crop water extraction with available moisture. Optimizing crop production per unit available moisture will normally optimize economics of production. Environmentally, it is also important that incoming moisture is used by the crop, rather than being lost from the soil–crop system through infiltration below the rooting depth, run-off or evaporation. Water moving through the soil by infiltration can lead to leaching of nutrients, while run-off can cause soil erosion and nutrient movement to surface waters. Evaporative loss of water from soil rather than transpiration through plants enhances the movement of salts towards the soil surface through capillary action, increasing the risk of salinization. Intensified crop rotations effectively use the available water for crop production, reducing the risk of leaching, salinization and surface run-off. In addition, intensified rotations increase the amount of crop biomass produced and returned to the soil, potentially increasing soil organic matter content and contributing to a healthy soil biological community. Diversification of semi-arid cropping systems will also contribute to economic and environmental sustainability. Including crop species with different rooting and water use patterns can improve water use efficiency. For example, a deep-rooted crop can be used to capture water that may have moved below the rooting zone of a more shallow-rooted crop. Keeping an actively growing crop in the field for as long as possible will help to increase organic matter input and reduce the risk of soil erosion, run-off, and leaching. Inclusion of perennial crops in a rotation where possible, is therefore of particular value.

As with moisture, crop nutrient supply and demand must be balanced to ensure crop yield and water uptake and avoid environmental problems. Intensification of crop production increases nutrient removal. For long-term sustainability, nutrients removed from the soil in the harvested crop must be replaced to maintain crop yields and avoid soil nutrient depletion and degradation. However, excess or poorly managed fertilizer inputs, whether from organic or inorganic sources can harm ecosystem and human health by contributing to nitrate accumulation in groundwater, eutrophication of surface water, soil and water acidification, greenhouse gas production, formation of ground-level ozone and particulate matter, and loss of biodiversity. Phosphorus movement to surface waters can lead to eutrophication while potentially toxic trace elements such as cadmium present in phosphorus fertilizers can accumulate in the soil over time. Carbon dioxide emissions from the large amount of fossil fuel used in fertilizer production and transport can also contribute to climate change. Rate, source, timing and placement of nutrient application must be carefully selected to match supply to the crop uptake in order to improve nutrient use efficiency and reduce potential environmental impacts. Crop nutrient use efficiency can be increased by including crops with different nutrient requirements, for example following a nitrogen-fixing legume, such as pulse crops or alfalfa (*Medicago sativa* L.), by a crop with a high nitrogen demand to utilize nitrogen left behind in the soil or mineralized from high nitrogen crop residues.

Efficient crop production in semi-arid systems requires that pests are controlled to optimize crop vigor and reduce competition for water, light, and nutrients. Integrated pest management using a variety of tools is commonly practiced. Effective tillage management and seed-bed preparation allows for establishment of a vigorous crop that can compete with pests. A diversified crop rotation that includes cereals, legumes and oilseed crops can reduce the build-up of insects and diseases specific to certain plant species. Integrated disease management uses a range of practices to reduce disease pressure including residue management, balanced crop nutrition, disease-resistant cultivars, crop rotation, field sanitation, and chemical application if necessary. Insect management also utilizes crop rotation, cultivar selection, and chemical application where insect populations warrant. Weed control is a major challenge in semi-arid agriculture and the majority of semi-arid cropping systems rely on judicious use of herbicides to control weeds, which would otherwise drastically reduce crop yield and quality. Use of herbicide-resistant crop cultivars that allow the application of relatively non-selective herbicides has been widely adopted, particularly in North America, closely tied to the expansion of reduced tillage systems. Overuse of a limited range of herbicides has led to selection of some weeds that are no longer controlled by certain herbicide families. Diversified cropping systems allow for use of herbicides with varying modes of action, slowing the development of herbicide resistant weeds.

Organic systems make up a small but significant portion of semi-arid small grain production systems. Organic systems attempt to improve environmental sustainability by minimizing external inputs that may be disruptive to the agroecosystem. Organic farmers normally manage crop nutrient supply through the use of diversified crop rotations, including legume crops for nitrogen fixation, production of green manures, and addition of manures or composts. Weed populations are managed by non-chemical means such as crop rotation and production of perennial crops, use of competitive cultivars, high seeding rates, field sanitation, and tillage. Just as with conventional production systems, crop yields in organic systems can vary widely, but are normally lower than in conventional systems. Profitability of organic systems can be increased because of reduced input costs and availability of price premiums associated with organic products.

Environmental benefits attributed to organic systems include enhanced biodiversity, higher energy use efficiency, and reduced risk of nutrient loss to air and water. Organic systems that include addition of livestock manure or compost as a nutrient source may increase organic carbon levels in the soil thus improving soil quality. Manure and compost inputs in organic systems must be managed carefully, just as chemical fertilizers must be, in order to limit the risk of off-site nutrient movement. However, systems that do not include replacement of exported nutrients can deplete the soil, resulting in lower crop productivity, lower long-term inputs of organic carbon, and reduced sustainability. While nitrogen can be provided internally to the system through production of nitrogen-fixing legume crops, exported nutrients such as phosphorus cannot be generated internally and their depletion may be problematic for long-term sustainability. Another concern related to organic production systems is the reliance on tillage for pest control. Excessive tillage can increase the risk of soil erosion and lead to depletion of soil organic matter. Development of management practices that maintain residue cover and restrict the amount of tillage are helping to improve sustainability of organic systems in semi-arid regions.

Mesic Corn (*Zea mays* L.) and Soybean (*Glycine* max (L.) Merr.) Cropping Systems

A large part of former deciduous forest in North Central United States and Ontario is now in cropping systems planted to predominantly corn which has been dubbed the Northern Corn Belt (Fig. 2). The corn, which is often grown from hybrids, is used for livestock feed, ethanol production, and a variety of food uses. The national average corn grain yield (per land area) in this region has steadily increased since the 1940s and is now nearly five times greater than 70 years earlier. Yield increases resulted from the adoption of hybrid corn, improved genetics, availability of nitrogen fertilizer and chemical pesticides, improved agronomy, and mechanization. Soybean expansion into the Northern Corn Belt began in the 1920s. Soybeans are produced for their oil and protein, which compliment carbohydrate-rich corn in livestock feed rations. A smaller percentage of soybean is processed for human consumption or other non-food (industrial) products. Like corn, soybean yield per land area has steadily increased due to improved genetics, availability of chemical pesticides, improved agronomy, and mechanization.

As corn and soybean production expanded from about 1860 to 1970, the Northern Corn Belt was transformed from a mixed crop-and-livestock farming system that included rotations with perennial forages to a highly specialized and simplified cash-grain farming system dominated by corn/soybean crop rotation (Fig. 3). Whereas in the past, farmers relied upon crop rotation (and manures) to provide weed and pest control, fertility, and labor distribution, various technologies now available provide farmers an alternative to crop rotation. For example, farmers do not require crop rotation to manage weeds and pests as they can achieve this with herbicides, insecticides, fungicides and improved crop varieties with resistance to pests.

Fig. 2 Coarse grain cropping systems (corn in mid-frame) in the mesic (deciduous forest) Northern Corn Belt region.

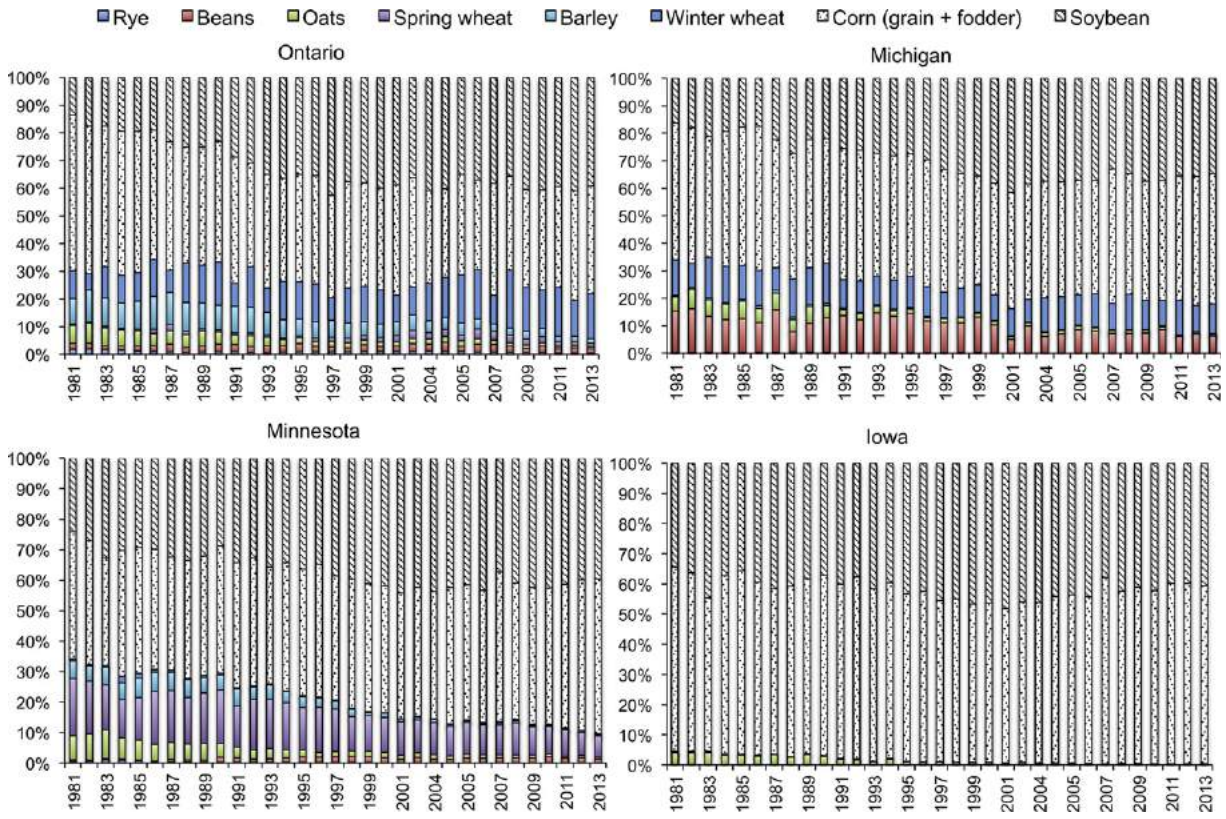

Fig. 3 Harvested areas (as % of total harvested area) of 8 major field crops in four states/provinces of the Northern Corn Belt from 1981–2013. Areas of canola and hay were not included for clarity. Sources OMAFRA, 2014, USDA-NASS, 2014; Reproduced from Gaudin, A. C. M., Janovicek, K., Deen, B. and Hooker, D.C. (2015). Wheat improves nitrogen use efficiency of maize and soybean-based cropping systems. *Agriculture, Ecosystems and Environment* **210**, 1–10. https://doi.org/10.1016/j.agee.2015.04.034.

The decline in bio-diversity of the Northern Corn Belt has been manifested not only through the dominance of the simple 2-crop corn/soybean rotation system but also through (1) an increase in field size which facilitates use of larger equipment, and (2) a decline of diversity at the sub-field scale. As field size has increased there has been a corresponding decline in fence rows, grass waterways, and buffer zones to environmentally sensitive areas such as streams. Also, over the past three decades, homogeneity of within-field management has increased; whereas formerly many farmers made agronomic decisions at the subfield scale, the increase in size of farms and equipment, and improved herbicides has encouraged farmers to apply agronomic management practices at a much larger scale. It should be noted that this particular trend is currently being challenged by the introduction of precision agriculture techniques (Berry *et al.*, 2003). These techniques involve collecting data at the subfield scale in order to inform decision tools that interact with agricultural equipment to vary management spatially in real time.

There is growing concern that there is a loss of biodiversity in the Northern Corn Belt agroecosystem, particularly due to less diverse crop rotations. It is well established that highly diverse cropping systems that more closely mimic the diversity of natural ecosystems are more resilient and environmentally sustainable due to their biological diversity. The decline in rotation diversity has been shown to be associated with reduction in soil quality parameters such as organic matter and aggregate stability (or tilth), increased soil erosion, increased greenhouse gas emissions, and ultimately decreased yield potential and yield stability. These agronomic and environmental consequences have also negatively influenced crop response to nitrogen and soil nitrogen processes leading to nitrogen losses from fields. In fact, it was shown removal of either a legume, such as alfalfa, red clover (*Trifolium pratense* L.) or soybean, or a non-legume such as winter wheat (*Triticum aestivum* L.), from a corn based rotation increased corn requirement for nitrogen fertilizer. This demonstrates that simple rotation systems have a greater reliance on inputs such as nitrogen fertilizer to achieve maximum yields. Also, crop yields respond more poorly to no-till (direct planting without any soil disturbance) under simple than under diverse crop rotation. This is a significant concern since no-till systems are associated with benefits such as reduced soil erosion and reduced energy consumption. Hence, under a simple crop rotation, farmers are more likely to forego the benefits of no-till which may lead to reduced soil health and poor nutrient use efficiency, and increased contamination of water sources by sediment and nutrients. Finally, since low biodiversity systems have reduced water use efficiency, simple crop rotations are associated with reduced resilience to extreme weather events, particularly drought.

The trend towards crop rotation simplification in the Northern Corn Belt indicates that farmers and society have been willing to accept the negative consequences of these practices. There is, however, growing evidence that costs associated with maintaining simple rotations are increasing and that there may be increasing incentives for farmers and society to reintroduce diversity into the system. (1) The direct

costs of yield loss and yield variability are expected to increase under simple rotations due to warmer temperatures, more variable precipitation patterns, and greater frequency of drought anticipated under a changing climate. This effect will be exacerbated by increased yield potential of new corn and soybean varieties, which will place further strains on an increasingly limiting water supply. (2) The indirect benefits of increasing soil organic matter associated with complex rotations are becoming increasingly valuable to farmers in a changing climate. Increasing soil organic matter represents sequestered carbon which can meaningfully mitigate increasing greenhouse gas levels. Soil organic matter is also correlated with improved soil structure rendering soil more fertile and less vulnerable to soil erosion resulting from expected extreme weather events. (3) Reductions in soil erosion will help reduce water quality concerns resulting from deposition of nitrogen, phosphorus, and soil sediment from farmland into waterways. Complex rotation also mitigates greenhouse gases by reducing nitrogen fertilizer requirements and improving nitrogen fertilizer use efficiency. (4) Weed management may re-emerge as an incentive for farmers to diversify crop rotation. Simple rotations have been facilitated by herbicides and the emergence of crops that have resistance to herbicides that are effective across a range of weed species, soil types, and timings. However, simple rotations are also associated with larger weed seedbanks, increased weed pressure and increased rapidity of herbicide resistance. Many herbicides that have been commonly used in corn and soybean are now less useful due to widespread weed resistance in the Northern Corn Belt. By necessity, farmers are again looking to complex crop rotations to enable more integrated weed management strategies with less reliance of herbicides for controlling weeds.

The fact that many farmers in the Northern Corn Belt have already begun reintroducing diversity is encouraging for sustainability of cropping systems in the Northern Corn Belt. The following are some modern examples of farmer efforts to reintroduce diversity. (1) As mentioned, new precision agriculture techniques are being employed to enable agronomic decisions at a smaller scale. (2) To overcome the poor results from no-till systems, particularly in a simple corn/soybean rotation, farmers are increasingly using strip tillage or other innovative reduced tillage systems. These systems provide some of the soil protection under extreme weather events that no-till provides, but minimize the yield lag associated with no-till. (3) Farmers are increasingly using cover crops to protect the soil over winter, to capture excess nutrients and to add diversity to their cropping system. In a corn/soybean rotation, cover crops are typically inter-seeded into juvenile corn plants or planted following soybean harvest. Biomass production of cover crops in a corn soybean rotation is limited by the fact that both corn and soybean are full season crops (i.e., high yielding long-season crops); however, even the small amounts of organic matter added to the soil helps to reduce soil erosion risks. (4) Finally, farmers are increasingly adding crops to their rotations. In Ontario, for example, winter wheat is again gaining in popularity as farmers are increasingly recognizing the extensive benefits of adding a third crop to their corn soybean rotation. Since winter wheat is planted after soybean in late summer, it also functions as a cover crop protecting the soil over winter. Moreover, since winter wheat is harvested in July–August, it provides an ample 2-month window to establish a cover crop with sufficient biomass to contribute significantly to soil organic matter. While these changes are incremental, over time they will provide substantial improvements in the sustainability of production in the Northern Corn Belt. This ability of farmers in the Northern Corn Belt to respond to shifting realities underpins the resiliency and sustainability of both human and biological systems.

Intensive Forage Cropping Systems in a Humid Region

Cattle and other ruminants comprise a major source of meat, milk, fiber, crop nutrients (manure), fuel (manure and tallow), and draft power. Ruminants have a nutritional requirement for forage crops that are high in cellulosic fiber that cannot be digested by monogastric animals (including humans). The public observes dryland forage landscapes with beef cattle in western "cowboy" films and moist forage systems with dairy cows in the bucolic images of the English and Swiss country-sides (**Fig. 4**). The former are expansive water-limited grasslands that are given few inputs and often comprise largely of native flora (i.e., native grasslands). The latter are planted by farmers, typically replacing forests, and often receiving more nutrients and pest control measures than the dry grasslands but less than arable crops as described above. For society, production of animal products is often seen as inefficient since the yield of protein per land area is much lower than arable crops. However, forage crops are usually perennial and are often much better suited than arable crops to difficult soils and landscapes that may be steep, stony, flooded, or with extremely fine or coarse soil texture that have, respectively, poor drainage and poor water holding capacity. Production of cattle and other ruminant

Fig. 4 Forage and ruminant pastoral cropping systems in a moist region.

species can make use of substandard soils or inedible crops so forage-livestock systems are contribute value to society. Also, when properly managed, perennial crops may be benign and even beneficial to the environment, relative to arable crops, by preventing erosion, sequestering C and improving fertility.

Feeding cattle for production of milk has, over recent decades, become a very exacting practice with very high milk production resulting when well managed cows are provided a high-quality, balanced ration. Most often on dairy farms there are at least two crops with complimentary nutritional attributes that are grown and fed whole (stems, leaves and grain) to the cows. There is typically an annual crop with high grain content (over 40%) that is highly digestible and energy-rich like corn or barley (*Hordeum vulgare* L.). There is also a fiber and protein rich forage, typically a perennial grass like timothy (*Phleum pretense* L.) or perennial ryegrass (*Lolium perenne* L.) or a legume like alfalfa or red clover, or a mix of one to many grasses and legumes. Both crop types need to be managed precisely, especially in terms of timing of harvest, to ensure that large amounts of very high quality feeds are produced and not spoiled during preservation.

Corn is a remarkable crop with tremendous capacity for producing large amounts of highly digestible feed. However, corn has a tropical origin and grows only in warm weather. In temperate regions, this means that for the cooler part of the year the field may be bare and therefore, as stated above, subject to soil loss by erosion, and nutrient loss into water bodies by runoff and leaching. Furthermore, nutrient uptake ends in August, 1–2 months before harvest, so nutrients released in late summer from applied manure, from crop residues, and from the soil itself, may accumulate in the soils and eventually leach even when the crop is still standing in the field. However, corn is often coupled with a winter cover crop which provides for some fall nutrient capture and soil protection over winter. Due to its relatively shallow root system and the distance between rows, corn is also subject to nutrient loss during its early growth period. An innovative cropping technique is to plant the cover crop into the young corn crop so that it captures the sunlight that falls wastefully between corn rows until the canopy closes, and resumes growth rapidly after the corn is harvested (**Fig. 5**). This technique provides more fall growth, more nutrient capture, and better overwinter soil cover than on conventional fall cover crops. And more high quality feed is produced in spring before the corn is replanted. For the somewhat staggered growth periods of the winter and summer crop, including the time of overlap, this progressive cropping system has been dubbed "relay cropping". Relay cropping is widely used by dairy farmers in northwest Washington State and nearby areas.

In contrast to corn, widely grown temperate perennial forages such as alfalfa and tall fescue (*Festuca arundinacea* L.) are better adapted to temperate conditions and hence have a long growing period, which may start even before the snow is gone and continue after initial frosts. To harden before winter, temperate perennial crops have a tendency towards becoming dormant in fall, triggered by the short days, then break dormancy when the days start to get longer, even in sub-zero temperatures. Crops that have broken dormancy especially in spring are subject to injury from a late freeze. Depending on the region and the amount of land available, cattle producers may grow grass, alfalfa or a mixture to complement their corn (or in cooler regions a small grain like barley).

Nutrient Management Using Cow Manure

The challenge for all sustainable livestock-crop farms is to use manure as the primary or, ideally, the only nutrient source for crops. Most dairy farms in industrialized countries handle manure as a liquid or slurry. Slurry has a very high water content (90%–95%) and low nutrient concentrations (0.3% nitrogen and 0.05% phosphorous) and is thus heavy and laborious to haul to fields and spreading can cause soil compaction and rutting in fields. The ratio of nitrogen to phosphorous in dairy slurry is about 5:1 but half the nitrogen is bound in organic molecules, such as proteins, that resist mineralization so that the ratio of available nitrogen to phosphorous is about 3:1. This contrasts with plant requirement which is about 10:1. Furthermore, most of the available (mineral) nitrogen in manure in the ammonia form (NH_3 or NH_4^+ depending on pH) which is subject to loss by volatilization especially if the slurry is broadcast on the soil or crop surface, which is the cheapest and most convenient method for farmers. Volatilization of

Fig. 5 Cover crop planted into a juvenile corn crop as it looks in the following spring in coastal British Columbia.

ammonia from land applied manure is one of the main nitrogen loss pathways from cropping systems to the environment; in the environment reactive forms of nitrogen (i.e., all chemical forms except dinitrogen, N_2) can acidify soil and water, create greenhouse gas emissions, reduce biodiversity and form fine particulates with significant human toxicity.

Many farmers abate ammonia loss by applying slurry to grass with a low emission method such as surface banding or by injecting into shallow (5-cm deep) trenches; both methods reduce emissions by maximizing contact of the manure, hence ammonia, with the soil. This approach also improves recovery of manure N by crops which improves yield and protein content of the herbage. However, even with reduced emissions, application of slurry for optimum crop production inevitably results in excessive loading of phosphorus which will accumulate in soils and be at risk for loss to waterways by runoff and leaching.

To help address the problems of low efficiency of both nitrogen and phosphorous in manure, a strategy has been developed which involves separating the dairy slurry into two products, one with low solids and high proportion of mineral nitrogen and the other with high solids and high ratio of phosphorus. This is done by first allowing the phosphorous-rich particles to passively settle to the bottom of the storage tank. The next step is to decant the thin nitrogen-rich supernatant and apply it with a low emission applicator to grass, to meet its high nitrogen requirement. Due to its low viscosity, this fraction rapidly infiltrates into the soil, thereby limiting ammonia volatilization and the saved nitrogen increases crop and protein production. And, importantly, there is little buildup of phosphorous in the soil as uptake by the grass is nearly equal to the amount applied. The final step is to use the phosphorous-rich sludge for corn by placing the sludge in furrows which were precisely 10 cm or less from the corn seed furrows. In practice, the corn is precision seeded near the sludge a few days after the sludge is injected. The precision injected sludge obviates the need for any fertilizer phosphorous and also reduces volatilization and the need for nitrogen.

Is it Sustainable?

There are no biological systems, natural or anthropogenic, that are hermitically sealed and even some natural systems are structured to benefit from the leakage of other systems. **Fig. 6** shows a field of alfalfa in Wisconsin where rising smoke illustrates worm channels and other macro-pores that are potential pathways for rapid nutrient loss especially in un-tilled crops.

For cropping system managers there is always concern that measures to reduce environmental impact may have unexpected side-effects or unintended consequences. As an example, **Fig. 7** shows that a sharp spike in emissions of a potent greenhouse gas, nitrous oxide (N_2O), followed the precision injection of slurry as described above. The emission spike is due to the moist and anaerobic conditions in the manure furrow which favors microbial denitrification of soil nitrate which often contributes to nitrous oxide emissions. This spike is obviously an unintended consequence. However the emission spike was controlled by adding a commercially available product which inhibits oxidation of ammonia to nitrate (NO_3) thereby curtailing N_2O formation. While the inhibitor was very effective in controlling emissions, unfortunately it did not result in more corn yield, so for now there is little economic incentive for farmers to purchase this product. However, where the technical tools exist there is always the option that policy makers will intervene to help make cropping systems more sustainable.

Is Yield Sustainable?

There are many factors that affect crop productivity so long term yield trends need to be carefully considered. **Fig. 8** shows yields from 23 years of corn hybrid testing on a dairy farm in the Lower Fraser Valley of British Columbia. The corn was grown under actual farm

Fig. 6 Rising smoke in this alfalfa field illustrates the presence of macropores that may be channels for nutrient loss from un-tilled fields. Photo courtesy of Michael Russelle.

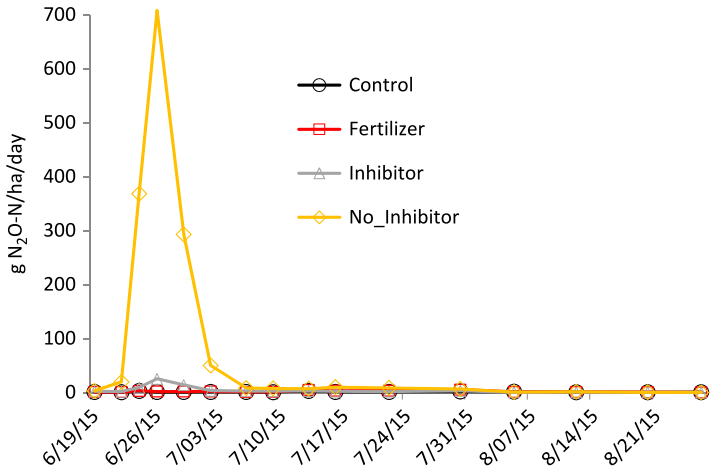

Fig. 7 Emissions of nitrous oxide from the soil surface following application of dairy slurry by two methods, broadcasting and injection. The spike in emissions after injection was controlled by adding a chemical which hinders the conversion of ammonium to nitrate (called nitrification).

conditions including rotation with grass, and received typical inputs of manure, fertilizer, and weed control measures. The unmistakable gradual rise in yield (mean of the top ten hybrids tested each year) is a reflection of a combination of many natural and manmade factors which cannot be teased out: crop genetics, farm equipment, soil quality, nutrient inputs, weed control practices, and climate. Also, often forgotten is the important aspect of farmer's crop husbandry skills. While we cannot know if yield will continue to rise, there is certainly no evidence of a threat to corn production on dairy farms in this region. The rise in crop yield and crop quality has supported consistently increasing milk production per land area over the past few decades in this region.

Conclusion: Cropping Systems and the Environment

Cropping ecosystems are intended to produce food efficiently and economically, and by their nature are more simple and homogeneous than most natural systems. However, this is mitigated by a number of factors. Diversity is added by tree-belts along field edges which provide habitat for wildlife including pollinators and help to sequester carbon along the field edges. There are now more often strips of natural or natural-like vegetation along riparian (streambank) areas that help prevent nutrient loss and protect fish habitat in streams. In some topographies, such as the prairie potholes, there are frequently ponds or "sloughs" which are important breeding grounds for migratory waterfowl. There is growing appreciation and adoption of crop rotations and even fairly complex multi species rotations with winter crops which have both agronomic benefits like break in disease cycles and cycling of nutrients, and ecosystem benefits such as soil biodiversity and health. Diverse crops may also support more varied wildlife. A study in coastal British Columbia showed that overwintering shorebirds (Dunlin, *Calidris alpine* L.) which are typically seen on the mudflats outside the dikes move to farm fields at night especially during high tide and stormy weather, and for the juvenile birds, the fields provide almost half their feed. The shorebirds clearly preferred bare fields due to supply of invertebrates and facility for detecting predators. In the same landscape it was determined that waterfowl preferred fields with grass or winter cereals while raptors preferred perennial shrubs and grass set-asides where they would find an abundance of rodents and roosting areas. Thus a diversity of crops, not within fields, supported a diversity of wildlife in this landscape. The open landscape, compared to the native cottonwood (*Populus trichocarpa* L.) forests, was also favorable for observing wildlife, a valuable ecosystem service to add to that of food security.

Epilogue: Cropping Systems in the Context of Society

While it is true that almost all our nutrition is derived from crop production, the corollary that all crop production is consumed for nutrients is not true at all. Currently topical is the use of scarce land resources to produce bioenergy crops ranging from corn grain for ethanol, to rapeseed (canola) for biodiesel, to whole corn for biogas, to *Miscanthus x giganteus* or switchgrass (*Panicum virgatum* L.) for direct combustion. No less controversial is the amount of cropland and resources (especially nitrogen and water) and the magnitude of environmental impact associated with crops used to feed farm animals, from the grain used to feed mainly chickens and pigs (and cattle) to non-edible forages used mainly for cattle and other ruminants. There is little doubt that these lands can be returned to more natural ecosystems. Since meat and energy consumption are largely discretionary, it must follow that large amounts of crops are not used to mitigate hunger or malnutrition. The situation is even more complex when we take into account the many crops we produce, often with high inputs, for amenities like wine, sugar and chocolate, but even vegetables like onions and coriander which we use mostly to flavor our food, and colored fruits to meet uncertain requirements for anti-oxidants. Even production of

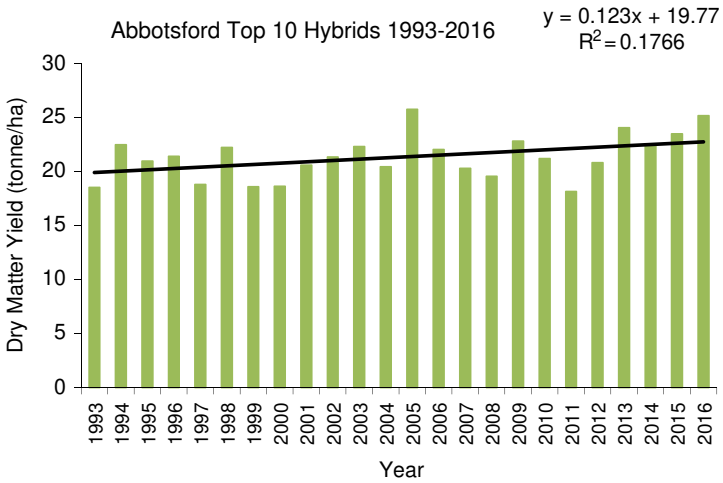

Fig. 8 Trend in yield of corn on a dairy farm between 1993 and 2016. Yield trend is due to crop genetics, management and climate.

vegetables in glasshouses is often more for their value as amenities than nutrients, and concentrations of glasshouses (and other protected cropping systems agriculture) are changing the land-cover in some regions to the possible detriment of natural species like migratory birds. The debate is over allocation of land, depleting inputs like phosphorous and natural gas, and environmental impact from pollution of air, fresh and marine waters, and even the soil itself (especially by salinization).

But, at the center of the discussion is water. Water is the ultimate paradox of a limitless renewable resource that is clearly depleting due to overuse, contamination and most of all, due to irregular climate (affecting both recharge and consumption). Water more than any other aspect of cropping systems is subject to society competition because of its many uses. It can be vital for food production, although the foods may not be vital themselves, but it is also needed for many of our other economic activities and comforts. In many parts of the world there is a direct competition for water and hence also growing pressure to clean it up. It is the worry about shortages that has led some countries to adopt new water recycling technologies in, for example, urban waste water treatment plants.

Mankind has probably always suffered during periods of drought, which have been tied to famines and migrations, and still are a force in our modern world. But one may ask why, during the Millennium Drought in Australia and the persistent multi-year drought in California, there was barely a ripple in the food supply, the almond wars in Fresno notwithstanding. This is an important question for society. To some extent this is thanks to globalization and the ability to move food around cheaply via marine waters. It is also due to very clever agronomic practices that have dampened the effect of water shortages. Water use is greatly improved with nitrogen inputs, and yields are enhanced if the crop can be planted rapidly to take advantage of more favorable spring water balances. Even crop rotations favor better exploitation of water from different soil depths. Plant breeders have improved yields with better plant architecture and pest resistance to take better advantage of agronomic strategies and inputs. Building organic matter helps soils hold water against powerful physical forces like evaporation and drainage. It is noteworthy that less successful have been the efforts to directly improve the physiology of drought tolerance and water use efficiency in plants. There have only recently been drought adapted corn hybrids licensed and they are only modestly better than standard cultivars. So, perhaps the message here is that we are not likely to have great breakthroughs in plant water use, either directly or indirectly. The future of our food security lies in a climate of changing weather patterns and changing human expectations. Hunger has become internationalized and solutions will likely be increasingly dependent on public policy which includes placing crop production systems within the panoply of human endeavors.

Urbanization as a Biospheric Process: Carbon, Nitrogen, and Energy Fluxes☆

Anastasia Svirejeva-Hopkins, Potsdam Institute for Climate Impact Research, Potsdam, Germany

Glossary

Anthropogenic Heat Flux The heat flux resulting from human activities such as traffic, heating and cooling of buildings, industrial processes and the metabolic heat release by people.

Exergy Exergy is the potential of a system to cause a change as it achieves equilibrium with its environment, i.e. is the energy that is available to be used.

Urban density The degree of people's concentration $D = P/S$, where P is population size and S is the area it occupies.

Urbanization dynamics The change of urban population and or area.

Urbanization (*Encyclopaedia Britannica)* This is the process by which large numbers of people become permanently concentrated in relatively small areas, forming cities and their suburbs.

Introduction

While the global population growth process has come to the stagnation, urban population continues growing and in some regions exponentially. The article will consider the ongoing process of urbanization and the interaction of urban areas with other compartments of the Vernadsky's biosphere. Hence, we must study the material and energy fluxes that take place. Cities are looked at as some entities that change the characteristics of land cover and the direction of matter and energy flows, not only on the territories they occupy but on much larger areas. As one can see from the above definition of urbanization, there are two aspects of it: the population and area, interconnected by the notion or urban population density. Population, P, and territory, S, of these formations are changing in time, so that urbanization is a dynamic process controlled by these main variables. The degree of people concentration is determined by the "population density," $D = P/S$, where P is population size and S is the area it occupies.

Different national statistics operate with different definitions and meanings of the terms "urban," "urban area," or "urbanized territory." For instance, the United Nations defines all places with $>20{,}000$ inhabitants living close together as urban, while the US Census Bureau uses "urban area" as a densely populated area (built-up area) with $D > 1000$ inhabitants per square mile and $P > 50{,}000$. Thus, the minimal urban area is equal to 50 square miles. At the same time, settlements with more than 2500 inhabitants are considered to be urban areas in the United States; while 2000 inhabitants living in contiguous housing form an urban area in France, and in the Netherlands it is municipalities with 2000 or more inhabitants. The highest urban density of 45,700 km^{-2} was registered in Dhaka (Bangladesh) (Demographia, 2009, 2017). Settlement densities can be orders of magnitude higher than agricultural rates, although residential densities in some urban areas are only marginally higher than the farmland densities in the most intensively cultivated agricultural areas (compare 2500 people per square kilometer in Los Angeles suburbs with 2000 peasants per square kilometer of arable land in Sichuan, China). However, maximum residential densities, *c*. 90,000 people per square kilometer (downtown of Hong Kong), translate into an anthropomass of 36 MJ m^2. This is roughly 200 times higher than the density of large herbivorous ungulates in Africa's richest ecosystem.

The definition of urban area in some other regions differs significantly from the above-mentioned one, with the concept of urban area somewhat based on the ancient structure of a city. All this shows a significant uncertainty in the term "urban(ized) area" and which is necessary to take into account in any quantitative estimations.

Past, Present, and Future of Urbanization

Two thousand years ago, there were about a quarter of a billion people living on our planet. The global population doubled to about half a billion by the 16th to 17th centuries. The next doubling required two centuries (from the middle of the 17 century to 1850, when the size of two European cities, Paris and London, exceeded 1 million inhabitants); the following doubling occurred just over the next 100 years, while the last one took only 39 years. The year 1650 is named as the start of "the urban explosion." Generally speaking, beginning from this date, the enormous population growth started.

☆*Change History:* March 2018. Anastasia Svirejeva-Hopkins slightly changed the title, hence added nitrogen flux description as well as exergy and index to make up for the "biospheric content." Introduction has been altered and Figure 1 has been updated with the latest data (2014). New sections Nitrogen Balance in Urbanized Territories, Cities: Sources or Sinks of Nitrogen?, Food-Print, Nitrogen Budget for the Paris Metropolitan Area, and Cities From the Thermodynamic Point of View: Sustainability of Cities and Exergy Maps are added. New Figures 5 and 6 and references are added.

This is an update of A. Svirejeva–Hopkins, Urbanization as a Global Ecological Process, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 3672–3678.

Nevertheless, it is a common practice to perceive the beginning of urbanization to coincide with the start of the agricultural revolution (7000–5000 BCE). It was at this time that nomadic hunters settled down and began to grow their food. A food surplus was created, and the division of labor made it possible to evolve gradually into the complex, interrelated social structures we know now as cities. The first cities were located along the Tigris and Euphrates Rivers (4000–3000 BCE) in contemporary Iraq, with urbanization then occurring also in Egypt, North Africa, India, China, Japan, and Europe—the Americas being the regions of most recent urbanization. Environmental factors were the major driving forces in the development of earlier cities. Fertile soils and easy access to water bodies, as well as adequate water supply, were essential. The first environmental disaster was triggered by the deforestation of the Middle East that led to soil degradation in the area, followed by a collapse of irrigations systems, and, as a consequence, to famine. Ancient cities were extremely dependent on the surrounding ecosystems, in particular, on agricultural lands. In Europe, since the 11th century, there has been a historical continuing flow of people from the countryside to the cities, although the "Black Death" in the 14th century impaired the process of urbanization. Europe recovered from the effect of this pandemic only by the middle of the 17th century, when the "urban explosion" occurred. Urbanization had also been occurring worldwide for at least two centuries. During the 18th century we have seen modern urbanization due to technological development, while earlier the process was driven by the migration of people from rural areas, since they were not needed in farming anymore.

However, in the last decades of the last century, we observed the unprecedented global population growth and the accompanying process of urbanization (Fig. 1).

Generally speaking, this enormous population growth was accompanied by other significant changes:

1. the rise of each person's ability to affect the natural environment through energy sources' exploitation;
2. the rise of the unevenness of the spatial distribution of people through development of "cities";
3. migration and travels' increase, while contacts between cultures also rise.

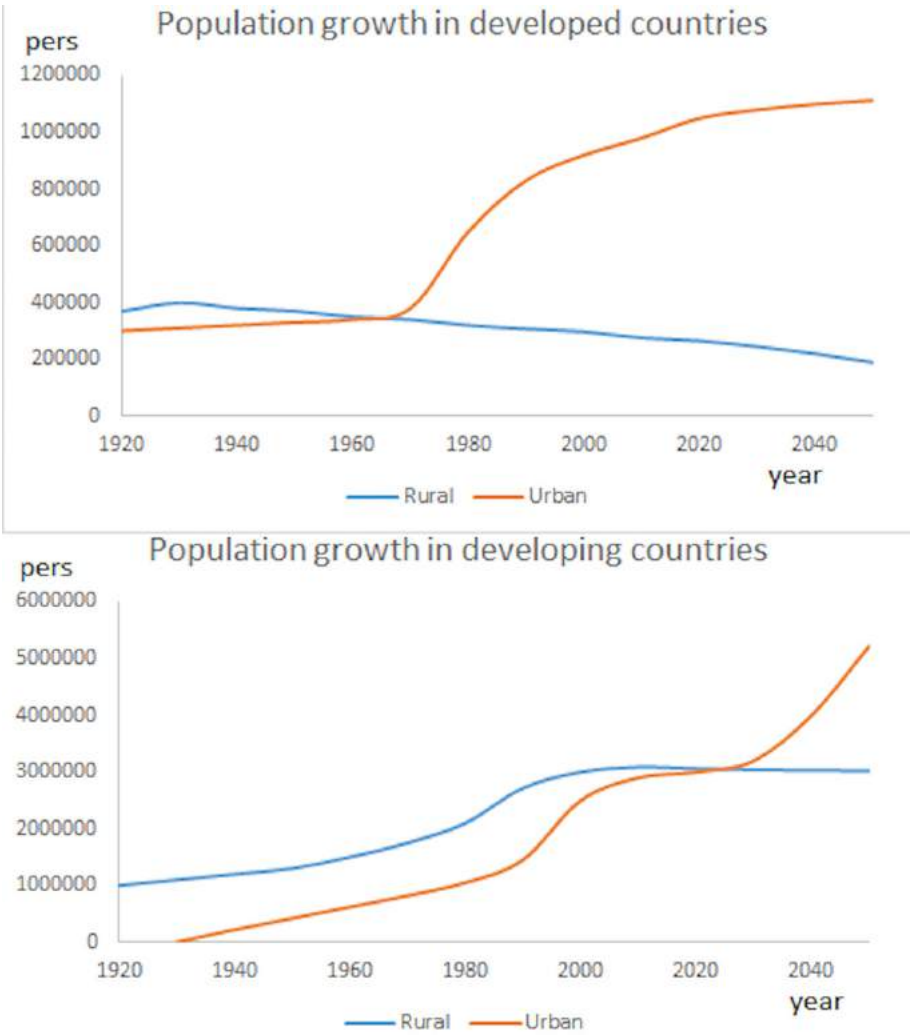

Fig. 1 Comparison of urban and rural population growth in developed and in developing countries (urban is defined as settlements of 20,000 people and above). Source: UN, World Urbanization Prospects, 1990, 1991 and 2014 revision.

Although only 12% of the world's population lived in urban centers in 1940, this percentage had risen to 33% by 1980. After World War II, a 2% urbanization rate was observed in the developed world, while it was almost 4% in the developing countries.

However, urban growth rates doubled that of the total population. And while the total population growth rate in the developed world has been decreasing, the urban population's proportion has increased from 55% to 70% of the total population. The major reason is the decline in rural population, as well as the arrival of new immigrants to the cities of some countries.

Since the middle of the last century, the following trend is observed in the percentages of urban population: 1950, 29%; 1960, 34%; 1970, 37%; 1980, 40%; 1990, 43.5%, and in 1995, 45%. However, the definition of what is urban varies greatly, which is why the estimations differ as well. For example, another source estimates 20% in 1950.

Urbanization growth rate has significantly left total population growth behind. From the year 1800 to 1990, the absolute number of city dwellers increased from 18 million to 2.3 billion, a 128-fold increase, while the total population has increased by only 6 times (from 0.9 to 5.3 billion). Furthermore, more than 1.4 billion city dwellers live in the less-developed world. If we look at the rates of urban area growth and compare them with urban population growth, we find that the first grows faster than the population, which in turn grows at a faster rate than the total country population, and this is a common phenomenon.

In 1990–95, the world's urban population grew by 2%–4% per year, while rural population only grew by 0.7% per year. Urban population increased by 2.1% during the 1995–2000 period, while rural population only by 0.7%. Today, 75% of the world's population lives in the less-developed countries, and 58% in Asia. In 1999, 19 urban settlements had 10 million or more inhabitants, and 47% of all people lived in cities. The number of "mega-cities," that is, giant urban agglomerations with a densely settled urban core of the original city, is increasing. Around this core, the satellite cities have grown, either planned or unplanned, linked to the central core by transport, communication, economic interdependence, and political-administrative structures. This tendency is confirmed by the following statistics: from 1950 until 1975, many cities with population of 5 million people have doubled in total urban population, while at the same time, cities with $<100{,}000$ people declined in their relative importance. In 1992, there were 23 M-cities with populations >8 million: 6 in the developed world (Tokyo, New York, Los Angeles, Osaka, Paris, and Moscow), and 17 in the developing world (from which 11 were in Asia). For most Asian cities, the shortage of water will be the most critical issue and is the limiting factor for the further growth of Beijing, Manila, Bangkok, Jakarta, and other cities. Also, while during the 19th century water and air pollution were associated with only a few larger cities, they are now becoming a global problem due to the rapid industrialization and the simultaneous concentration of people in cities.

While the past and current demographic situations are estimated more or less accurately, future dynamics are forecast with a very high level of uncertainty. The UN vividly illustrates that if current exponential and hyperbolic growth continues in each major region and at the current rates, then the population will increase by >130-fold in 160 years, from 5.3 billion in 1990 to 694 billion in 2150. However, eventually, the problem will be how to feed these people, since food and water limitations will certainly arise. The UN also shows that future global population size is very sensitive to the future level of average fertility.

Projections of global population dynamics are also uncertain, because external factors such as climate may change unexpectedly. Furthermore, even if external factors change as expected, the relationship between those factors and demographic rates may change.

We have the following hypothetical picture for the next half of the century. The global population will grow by 2–4 billion people, mostly in poor, but not rich, countries. It will also increase less rapidly than before and will become more urban than now. Hence, "from here on it is an urban world." Most of all, the additional people will be living in cities in poor countries, which can become an epidemiological danger. Population of the more developed countries will decline slightly, but increase substantially in less-developed countries.

In this century, global urban population will increase 1.8 times by 2020 (relative to 1990), while the total population will grow by only 1.4 times, and almost all population growth will be associated with cities in the developing countries. By the year 2030, the world urban population will reach 4.9 billion (1 billion in developed countries and 3.9 billion in developing countries). The global rural population will remain constant at 3.2 or 3.3 billion, although in the developed countries the rural population will decline. The trend in the developing countries is that rural population will slowly rise through the next couple of decades, reaching 3.1 billion, and then will slowly decline.

Present and Future Dynamics of Urban Areas

In 1985, 43% of the world population lived in cities while urban settlements covered just over 1% of the Earth's surface. In 1990, 50% of the global population of *Homo sapiens* inhabited $<3\%$ of the Earth's ice-free land area. However in the near future we may expect a further growth of the urban territories' area. World dynamics of this process is shown in **Fig. 2**. All these prognoses are based on two models: the first is a regression model, connecting urban population and urban area, and giving a minimal estimation, and the second, uses the spatial distribution of population density and gives a maximal estimation.

Note that the dynamics of urban areas are significantly different in the major world regions (**Fig. 3**). For instance, the fast growth in African region differs from almost constant dynamics in the highly industrialized countries.

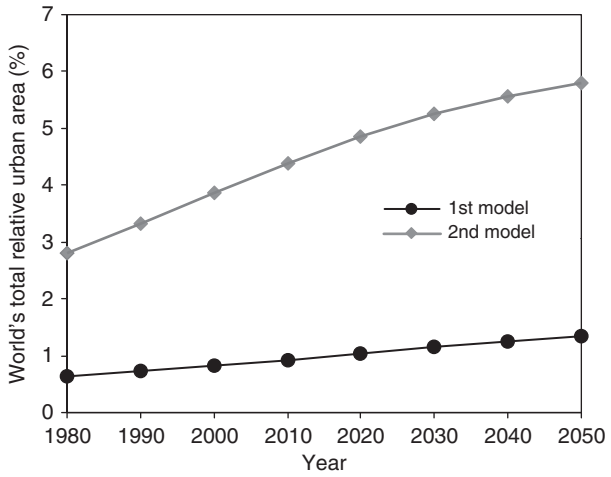

Fig. 2 Dynamics of the relative world urban area (in percentage of the total world area) between 1980 and 2050.

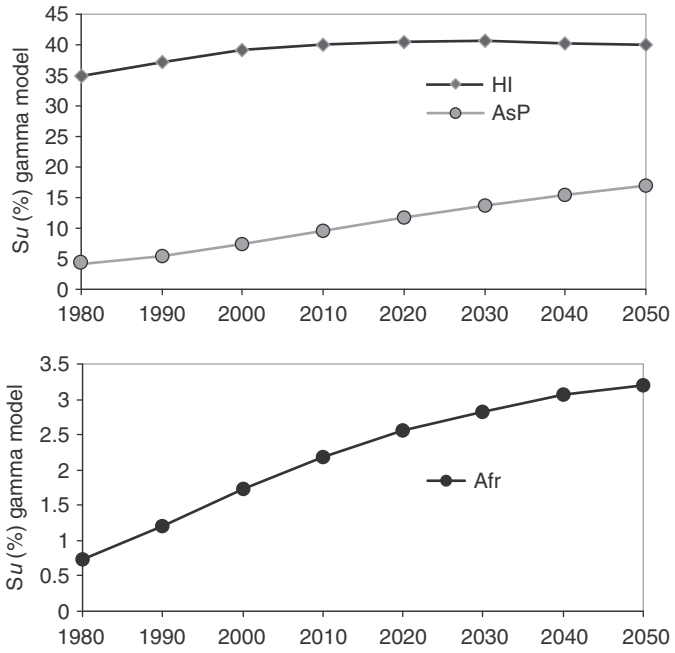

Fig. 3 Dynamics of the relative urban areas (% of the total regional area) for the three world regions: HI, highly industrialized European; AsP, Asia and Pacific; and Afr, African.

The City as a Specific Heterotrophic Ecosystem

From an ecological point of view, any city is a heterotrophic system maintained by external inflows of energy, food, water, and other substances. Thermodynamically, any city (and generally, any urbanized territory) is an open system that is far from thermodynamic equilibrium. All matter and energy needed for a city's functioning are collected from external territories that are significantly larger than the area of the city itself and very often are located quite far away.

The heterotrophic ecosystem "city" differs very much from a natural heterotrophic ecosystem. In fact, a city has a more intensive metabolism per area unit, requiring a significant inflow of artificial energy. Its consumption per urban area unit may be 3–4 orders of magnitude higher than the same for rural area. For instance, the annual subsidies in fuel, fertilizers, labor, etc., required to maintain a lawn in the Madison metropolitan area (Wisconsin, USA) is equal to 22 GJ ha^{-1}, which is approximately equal to the artificial energy input for a maize field. During the process of its own metabolism, a city consumes large amounts of various materials: food, water, wood, metals, etc., all that we call "gray energy." Products of city's metabolism have larger volumes of, and more toxic, substances than the same of natural ecosystems.

If we compare cities and natural forests in Wisconsin, USA, we can see that the number of species in a city forest (75 tree and 74 bush species) is more than in natural one (10 tree and 20 bush species). The annual net production and the amount of living biomass (in

carbon units) in city's forests are equal to 500 t C $km^{-2}year^{-1}$ and 7000 t C km^{-2}; while in a natural forest the corresponding values are 400 t C km^{-2} $year^{-1}$ and 13,000 t C km^{-2}. The greater values of species diversity and production are provided in city's forests at the expense of additional inflow of "gray energy." For instance, the annual import of fertilizers is about 140 t km^{-2}.

While natural forest is almost a closed system, a city forest is a typical through-flow system with "gray energy" input and output in the form of dead organic matter: about half of the annual accretion is exported from the city to waste treatment plants. This is one possible explanation why the amount of biomass in the city forest is lesser than in the natural ecosystem. The carbon storage in urban forests with their relatively low tree cover (25.1 t C ha^{-1} in average for United States) is less than in natural forest stands (53.5 t C ha^{-1}). The gross sequestration rate, that is, the fraction of the gross annual production accumulated in wood, in urban forests is equal to 0.8 t C ha^{-1} $year^{-1}$, which is also less than in natural ones (for instance, 1.0 t C ha $year^{-1}$ for a 25-year-old natural regeneration spruce–fir forest with 0.1 kg C m^{-2} cover), although the difference is insignificant. However, on a per-unit tree cover basis, carbon storage by urban tree and gross sequestration may be greater than in natural forests, 92.5 t C ha^{-1} and 3.0 t C ha^{-1} $year^{-1}$, due to a larger proportion of large trees and the more open structure (that leads to the weakness of competition) in urban forests.

Environmental Effect of Urbanization and Ecological Footprint

Retrospectively, most humans have lived in small settlements dispersed within larger biomes (Fig. 4). We see there is a certain correlation between the type of biomes and the degree of urbanization, some biomes being more preferable for cities.

The growth of cities in these "patches," absorbing and transforming nearby natural ecosystems and agricultural lands, modifying energy and matter flows, typical for these ecosystems, negatively influences the local and regional biodiversity, increasing fragmentation of large rural areas and natural zones. This process (and contamination of the atmosphere) leads to the changing of the nature of land surfaces and near-surface atmospheric layer, and therefore its reflection and absorption of solar radiation and aerodynamic properties. This in turn leads to raising urban temperatures and the changing of the local climate, creating so-called "urban heat islands," which is warmer by 1–2°C than surrounding territories. The "urban heat island" effect occurs mainly at night, when the buildings, etc., release heat absorbed during day.

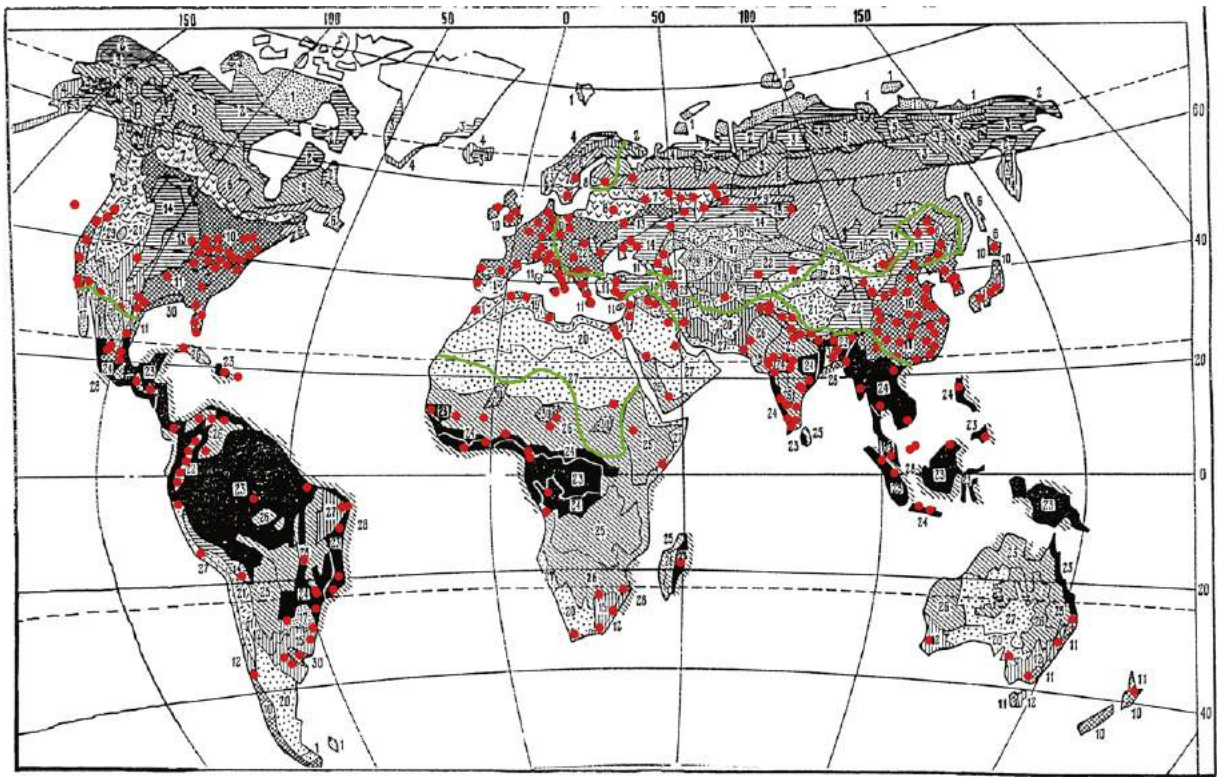

Fig. 4 Different types of global vegetation (biomes). Red dots represent the concentration of cities; the green line is the border of the regions. 1, Polar desert, polar tundra; 2, tundra; 3, mountainous tundra; 4, forest tundra; 5, north taiga; 6, middle taiga; 7, south taiga; 8, temperate mixed forest; 9, aspen–birch lower taiga; 10, deciduous forest; 11, subtropical deciduous and coniferous forest; 12, xerophyte woods and shrubs; 13, forest steppe; 14, temperate dry steppe (including mountainous); 15, savanna; 16, dry steppe; 17, sub-boreal desert; 18, sub-boreal saline "desert"; 19, subtropical semidesert; 20, subtropical desert; 21, mountainous desert; 22, alpine and subalpine meadows; 23, evergreen tropical rainforest; 24, deciduous tropical forest; 25, tropical xerophyte woodland; 26, tropical savanna; 27, tropical desert; 28, mangrove forest; 29, saline land; 30, subtropical and tropical woodland and Tugay shrubs.

In addition, metropolitan agglomerations influence the local and global environment through their consumption of nonnative resources and their concentrated production of waste and consumables.

The footprint is the quantitative conversion of the material and energy flows required to support human population in cities into the land area required to produce these flows. Although cities occupy a relatively small area on the planet, they are the dominant human ecosystem and the ecological space taken up by humans as a species is much higher. Every city depends (for its existence and growth) on a globally diffuse productive hinterland up to 200 times the size of a city itself. To illustrate this, let us examine the following case studies.

For instance, one person of the US urban population consumes daily (1) food produced by 0.75 ha of agriculture land, (2) paper and wood by 0.4 ha of forest, (3) water by about 7.5 m^3. So, a 1 million-populated city with the population density of 4000 persons per kilometer (city area is 250 km^2 correspondingly) needs a significantly larger area for its support: 7500 km^2 of agriculture land and 4000 km^2 of forest. A rather large river watershed (presuming abundant precipitation) can provide inflow of 7.5 million m^3 of water daily. If we take into account that the area of such watershed is about 15,000 km^2 then the total footprint area will be about 26,500 km^2, that is, 106 times the city area.

The city of Vancouver (Canada) had in the year 1991 a population of 47,2000 living in an area of 11,400 ha. If we assume that the per capita land consumption rate is 4.3 ha, then the people in this city would require 2.03 Mha of land. Hence, the inhabitants would require a land area 180 times larger than their habitat. Furthermore, adding a marine footprint of 0.7 ha per person, the total area needed to support the city becomes 2.36 Mha, or 200 times larger than the geographic area of the city. For London, the equivalent footprint is 120 times the area of the city itself. The New York metropolitan area annually consumes the equivalent of 800,000 ha of wheat, or approximately the total amount of wheat grown yearly in the state of Nebraska.

So, if we presume that the world urban area constitutes 1% of the total land area, and the footprint is 100 times this area (note that these are minimal estimations), even in this case the urban footprint exceeds all the world land area.

Carbon Balance in Urbanized Territories

Therefore, we can say that although the total area of urbanized territories is relatively small (1%–2% in 1990s), they play an ever-increasing role in global change in general and in the global carbon cycle, the main biogeochemical cycle of the biosphere, in particular.

Urban areas emit (in accordance with different estimations) 78%–97% of the total anthropogenic carbon emission. Up to 60% of this emission comes from the transportation and building sectors, while the rest are from industry. Of course, all of these emissions are "spread" and mixed in the entire atmosphere over 3–4 months period, but they are generated in particular by urban point sources.

Cities transform the natural territories they occupy, partially obliterating vegetation and soil, partially modifying them. Similarly, urbanization changes the structure and function of the local carbon flows within these territories. Note that the process often involves considerably larger territories than the exact city areas.

Cities consume a lot of organic carbon in the form of food and other agricultural products, as well as wood, etc., produced, as a rule, far from the urban territories, transforming them into other forms of carbon (feces, exhaled CO_2, residues of food processing, dead organics of "green zones," etc.) in the process of urban and purely physiological human metabolism. In other words, cities destroy the spatial entity of the processes of production and decomposition of living matter that is typical for natural ecosystems. Note that this entity provides the closure of any local carbon cycle.

Urban territories have more carbon stored per unit area than natural ecosystems. Organic carbon is stored in soils and vegetation of urban territories, but also in people and pets; nonorganic carbon includes carbon transported into the cities and stored in buildings, etc., but most of this carbon is transformed into waste. Processes similar to those in peatlands accompany carbon fluxes from mineralization, incineration (rapid oxidation of carbon), and landfilling of solid waste. For instance, the global input of carbon into solid waste (sludge and industrial waste) is estimated to be 0.16 Gt year $^{-1}$ (1 Gt 1/4 $\times$ 10^9 t).

Long-term organic carbon in urban territories is accumulated in

1. *Biomass in humans and animals*: For the world population of 6 billion, the total amount of carbon is equal to 45 million tons of carbon that constitutes about 10% of the total biomass of land animals. A biological metabolism of 6 billion people is accompanied by exhalation of 0.34 Gt C $year^{-1}$ and secretion of 0.18 Gt $year^{-1}$ with feces and other discharges that, respectively, give a total 0.52 Gt C $year^{-1}$. The value is entirely comparable with components of the global carbon cycle. For instance, soil erosion releases 0.98 Gt C $year^{-1}$.
2. *Biomass in trees and other plants*: The mean global value of living plant biomass in cities is 3500 t C km^{-2}, and the mean net primary production is 500 t C km^{-2} $year^{-1}$. By taking the global urban area in 1980 as 2 $\times$ 10^6 km^2 and assuming that 50% of it is covered by city vegetation, we find that urban territories contain 3.5 Gt C in living vegetation biomass, while a global figure for net plant assimilation of carbon in urban territories is approximately 0.5 Gt C $year^{-1}$.
3. *Carbon in construction material, furniture, books*: Extensive amounts of carbon are accumulated for long time period in building constructions, furniture, books, and other articles made of organic materials. For instance, *c.* 3 Gt C is fixed in houses in the whole of Europe, North America, Japan, and Australia, and about 0.4 Gt C in other regions.
4. *Carbon in solid waste*: Most products of forestry and agriculture are turned eventually into waste. Solid waste is either deposited in sanitary landfills or incinerated. Carbon stored in landfills experiences slow decomposition rates and is gradually released due to microbiological activity. The annual world solid-waste production is equal to 170–180 million tons of carbon.

Approximately 60–70 million tons is released into the atmosphere by burning, while about 110–120 million tons is deposited in landfills followed by slow release into the atmosphere.

Landfills are often regarded as long-term accumulators of carbon and in this respect can be compared with natural peatland ecosystems (even after 30 years one-third of the organic carbon remains nonmineralized). This carbon is bound in long-lived humus and has not been mineralized for a very long time.

Nitrogen Balance in Urbanized Territories

Let us have a look at another important element in the biosphere, nitrogen, and study how "urban compartment" changes its fluxes. It is important to mention that we consider the so-called reactive Nitrogen (Nr) and that in its case, and as compared to carbon, there is downscaling to the level of landscapes. Cities import and concentrate Nr in the form of food and fuel, and then disperse it as air and water pollution to other ecosystems covering much larger areas. Certainly, they also dramatically change the global nitrogen cycle, but it is difficult to quantify these changes at that level. In detail, firstly, urban lands fix substantial amounts of atmospheric N_2 to Nr as NO_x through the high temperature combustion of fossil fuels. Secondly, they drive the industrial fixation of Nr to fertilizers, importing the Nr produced in food for burgeoning urban populations, subsequently dispersing it in air and water to other ecosystems over much larger areas than the cities themselves.

In other words, cities act as concentrators, transformers and dispersers of nitrogen, therefore acting as new entities of the Earth System, or compartments of the biosphere.

Cities: Sources or Sinks of Nitrogen?

What are the important issues concerning N management in a certain city, or cities of a certain region? Cities can be characterized either as a source of Nr (i.e., emitting large amounts as liquid or solid household waste, automobile exhaust, air pollution from power plants) or a sink of Nr (either through importing more food, fossil fuels, etc., and/or having fewer emissions to the air and water). Let's have a look at Paris Metropolitan Area for a more in-depth quantification of terrestrial and atmospheric fluxes, and input and output to the system-city. Besides, by constructing mass balances at scales from the household to the city, human choice can be linked directly to biogeochemical cycling.

Paris Metropolitan Area changed from being a sink in the 18th and 19th centuries to a source of Nr today. Major changes in the city functioning occurred before 1950, but especially recent decades have been characterized by an unprecedented amplification of those changes.

1. The major part of Nr output is attributed to the combustion of fossil fuels for transport and energy, which converts both atmospheric N_2 and fossil Nr to reactive NO_x. The second largest Nr contribution comes from incineration of solid waste, and third highest emissions come from sewage water treatment plants.
2. Urban wastewater discharge into rivers largely contributes to N contamination of the aquatic environment, although sophisticated and expensive tertiary treatment techniques are now available to drastically reduce Nr emissions.
3. Denitrification in urban landscapes is controlled by the presence of water bodies and green areas. These areas have lower biomass and decomposition rates than natural ecosystems.
4. To achieve sustainability of urban systems in relation to the N cycle, road transport of goods and passengers has to be reduced, household waste generation minimized, and wastewater treatment improved.
5. More attention should be given to future sewage processing systems that process Nr (and other nutrients) for reuse as a fertilizer rather than losing the Nr resource by denitrifying it back to N_2.
6. Such measures could eventually turn urban areas from sources of Nr to N-neutral or even N-sink areas. Regional adaptation measures should be specifically tailored to the individual urban ecosystems of Europe.

Food-Print

Apart from ecological footprint, there is so-called "food-print" indicator that takes into account the area required for producing agricultural goods, being expressed in terms of the effective surface of the surrounding territory needed to support the food requirements of a city. It was found, for example, that despite a 50-fold increase in the population of Paris since the 15th century, the food-print of the city barely increased twofold. In contrast, the further doubling of the population in the 20th century was paradoxically accompanied by a fivefold decrease in the food-print, because of the intensification of agricultural production. However, "food-print" is only a partial indicator of the impact of a city. For example, it does not include a comprehensive account of all resources required, such as energy, fertilizers and waste disposal.

Nitrogen Budget for the Paris Metropolitan Area

The urban nitrogen budget (balance) can be considered as a subset of national and regional N budgets. It incorporates imports of Nr-containing products into the city, their conversion within the city boundaries and exports outside of the urban

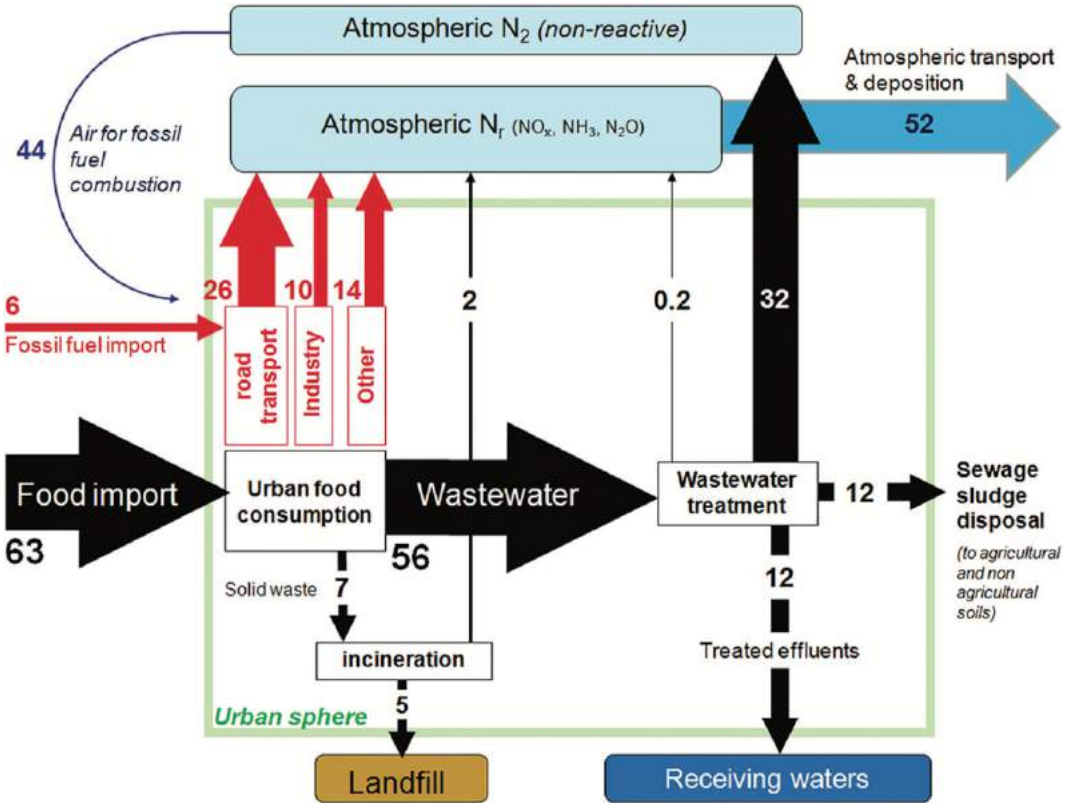

Fig. 5 Nitrogen flows quantified for the Paris Metropolitan Area for the year 2006 (PAM, numbers in Gg N $year^{-1}$). The quantified fluxes displayed reflect major N flows through the PAM originating from food import and fossil fuel use, as well as N_2 out-flux from wastewater treatment. From Svirejeva-Hopkins, A., Reis, S., Magid, J., Nardoto, G. B., Barles, S., Bouwman, A. F., et al. (2012). Nitrogen flows and fate in urban landscapes. In: M. A. Sutton, et al. (eds.), *The European nitrogen assessment: Sources, effects and policy perspectives*. Cambridge: Cambridge University Press.

sphere. The urban sphere incorporates the three dimensional space surrounding the urban habitat and spans all environmental media, water, air, and soil.

We made the first step by creating a detailed Nr mass balance for Paris and its urbanized surroundings in order to estimate the magnitude of major fluxes across the urban landscape and to see how N cycling varies among urban system components. It will help to determine which budget terms are most open to management in order to reduce N pollution to recipient systems. The budget is shown in Fig. 5.

The Paris Metropolitan Area is a source of Nr, emitting in total the amount of 50 Gg $year^{-1}$ to the atmosphere, the major part being attributed to the emissions from transport and energy. Although much smaller, emissions of Nr to air from the incineration of solid waste are also substantial, contributing 2 Gg $year^{-1}$. The amount emitted to the aquatic environment, at about 12 Gg N $year^{-1}$, greatly depends on the type of wastewater treatment adopted. Disposal of solid wastes and incineration residues in landfills or of sewage sludge on agricultural and nonagricultural soils (potentially leaking to the ground water over time), together amount to 17 Gg N $year^{-1}$.

Regarding the transformations between N_2 and Nr, the largest of these occurs outside this budget, in the production of fertilizer Nr to provide food. Overall, the food Nr import of 63 Gg $year^{-1}$ is of a similar order of magnitude to the inadvertent fixation of N_2 to Nr through combustion processes.

In the case of Nr from combustion processes, all of this is exported from Paris as Nr. Thus four times as much Nr is released to the environment of Paris from combustion processes than from the Nr originating in food imported to Paris. If this highlights the problem of Nr emissions from combustion sources for this city, it should not be forgotten that the Nr, denitrified in wastewater treatment, represents the loss of a valuable resource. Without commenting here on the economic viability of recycling wastewater Nr, it may simply be noted that, at an indicative value of €1 per kg fertilizer Nr, the denitrification of wastewater Nr in Paris represents an annual resource loss of €32 million per year.

Urban Areas From the Thermodynamic Point of View: Sustainability of Cities and Exergy Maps

Urban areas "modify" the surrounding landscape by changing the fluxes of matter and energy. The urban area is viewed as an open thermodynamic system, maintaining its structure through the conversion of energy. During its evolutionary process including

growth (increase in size) and structural development (increase in the system's organization), the system-city fluctuates from one state to another and its exergy grows and becomes the highest when the system is farthest from an equilibrium state that has local maximum of entropy.

We estimate numerically this state (and the degree of nonequilibrium) by recalculating standard satellite data, deriving and combining global maps of entropy, information gain and exergy, as well as proposing a new approach for the study of urban sustainability questions. Human decisions are also affected by various ecological factors, so that urban structural organization then determines the parameters of the thermodynamic system and its many specialized sub systems and forms of energy transfer. Spatially, cities constitute a mosaic of open, built-up and vegetated spaces, which creates high internal gradients of entropy, exergy and heat flux. Urban areas are also known as the biggest producers of the anthropogenic heat flux (AHF, or thermal pollution). The certain Index (anthropogenic heat flux/exergy) is chosen to serve as the measure of the degree of disturbance in urban areas at certain geographical locations, which, recalculated per capita, reflects the level of urban infrastructure in cities of different regions.

Fig. 6 shows the global map of annual average exergy in the year 2002 overlaid by the 23 largest urban areas. The highest values of exergy are attributed to the tropical forest zones with the highest biomass density.

AHF/Ex shows the degree of urban system disturbance, calculated "per million inhabitants", since that better reflects the level of a city's infrastructure/energy efficiency. The lower the index, the less disturbed is the system.

We then overlay this map with the map of Anthropogenic Heat Flux (*AHF*) for 2005, or thermal pollution (http://www. cgd. ucar.edu/tss/ahf/). Preliminary analysis shows that New York is quite energy efficient, especially when the *AHF/Ex* index value is compared to Seoul, considering that their populations are the same. Osaka-Kobe urban area is also similar to Seoul in terms of index value, while Mumbai's value is the lowest. We notice that there is no relationship between population size, energy and thermodynamic characteristics of cities and attribute the thermodynamic characteristics to the structural characteristics of urban areas. Exergy of cities mainly depends on their geographical location. Tropical cities have larger values of exergy in comparison with temperate and subtropical cities, as they are situated in more unstable and environmentally sensitive zones. The largest heat flux is produced by cities of developed countries, particularly those that are concentrated in the temperate zone (with the exception of New York), while the smallest values naturally exist in the least developed cities (e.g., Kinshasa, Lima, Lagos). Similarly, when we recalculate the index of disturbance per million inhabitants, we see that the least disturbance is found in undeveloped countries and the greatest levels of disturbance are in cities of developed countries (Paris, London, Osaka), most likely due to the long history of human impacts. Only one city from of the developed countries, New York, is in the least disturbed state, while BRIC countries (Brazil, Russia, India, and China) have medium values. However, this method cannot answer the question about the actual ways of degradation, that is, it only shows the possibility of degradation and estimates the value of the entropy over-production (energy of disorder) that can eventually destroy the system—but it cannot show the pathways along which this destruction will really occur.

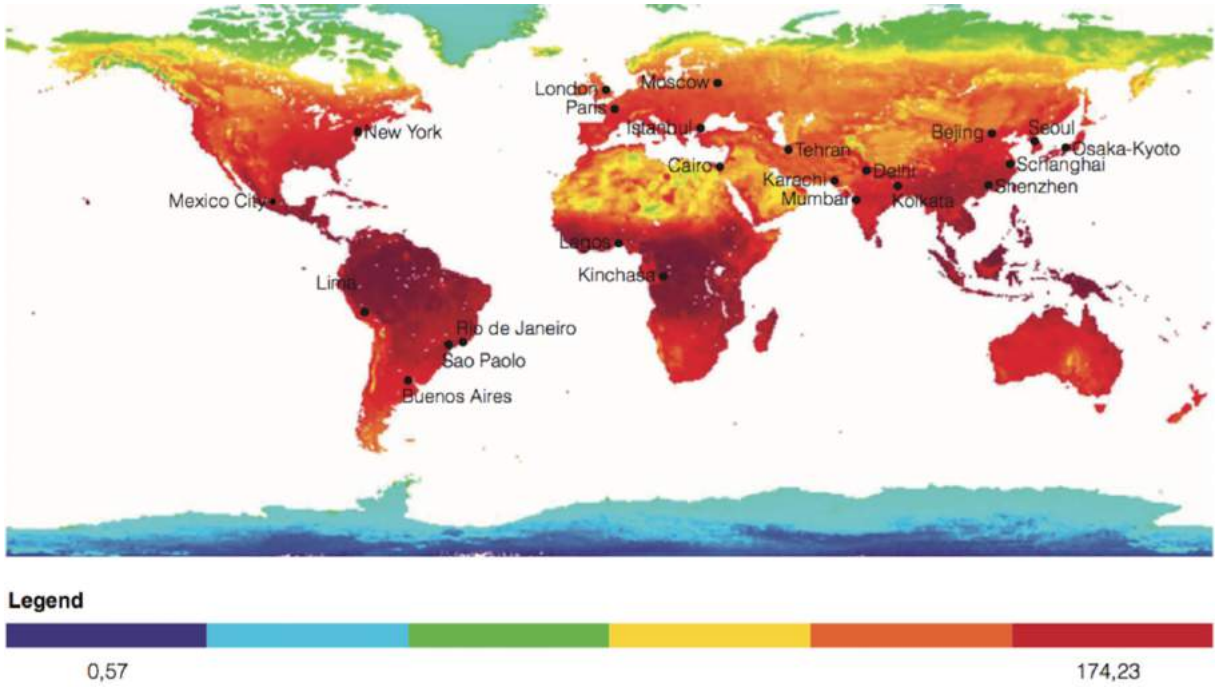

Fig. 6 Annual average exergy W/km^2 and 23 largest UA locations (Demographia, 2009, 2017). Svirejeva-Hopkins, A., et al. (2011). City systems, their growth and sustainability: An urban biogeochemistry approach. UGEC Viewpoints No. 5, April 2011, www.ugec.org.

Conclusions

Urbanized territories dominate the surrounding environment in a number of ways—the growth of cities, and absorbing and transforming nearby natural ecosystems and agricultural lands. This process leads to the changing of the nature of land surfaces. Therefore, we can say that although the total area of urbanized territories is relatively small (1%–3%), they play an ever-increasing role.

We can summarize this influence as the following:

- Cities transform the natural territories they occupy, partially obliterating vegetation and soil, partially modifying them. By the same token, urbanization changes the structure and function of the local carbon flows within these territories. Note that the process often involves considerably larger territories than the exact city areas.
- Cities consume a lot of organic carbon in the form of food and other agricultural products, as well as wood, etc., produced, as a rule, far from the urban territories, transforming it into other forms of carbon (feces, exalted CO_2, residues of food processing, dead organics of "green zones," etc.) in the process of urban and purely human metabolism. In other words, cities destroy the spatial entity of the processes of production and decomposition of living matter that is typical for natural ecosystems. Note that this entity provides the closure of any local carbon cycle.

Water Cycle☆

Zbigniew W Kundzewicz, Polish Academy of Sciences, Poznan, Poland

Introduction

Water resources of our planet take part in an infinitely recurrent water cycle. It is the largest movement of matter in the Earth's system. The Earth is indeed a blue planet, since the oceans cover nearly 71% of its surface, that is, over 361 million km^2, while the continents and islands—the solid surface of the Earth—make up only 29% of the total Earth area. The hydrosphere includes all water on the planet and is interconnected with all the other "spheres" in the Earth system, that is, the geosphere (lithosphere and atmosphere), biosphere, and human-related anthroposphere.

Water is the most widespread substance in the natural environment of our planet. It is available everywhere on Earth, albeit its abundance largely differs in space and time. Water molecules take one of three states—liquid, solid, and gaseous (vapor), with liquid state being most commonly occurring in the Earth's conditions. Water undergoes phase changes: from liquid to gaseous phase—by evaporation (evapotranspiration); from gaseous to liquid phase—by condensation; from liquid to solid state—by freezing; and from solid to liquid state—by thawing. Direct phase change between the solid and the gaseous phase is also possible, in the process of sublimation.

Water is the basic element of the life-support system of the planet. It is a constituent in plant and animal tissues. Water transfer plays an essential physiological role in human organisms—for example, physical workers in warm climate lose water and drink water in the same time. Due to the thermoregulation mechanism of the human body, they are sweating and, simultaneously, feeling thirst.

Water cannot be substituted by any other substance. By its capacity to dissolve substances, water plays an essential role in the chemistry of life. Water is an excellent solvent, able to dissolve many chemical compounds, for example, mineral salts. It also plays a substantial role in biogeochemical cycles of carbon, phosphorus, nitrogen, as solvent and carrier. Water interacts with both the atmosphere and the lithosphere, acquiring solutes from each. Water cycle contains natural purification mechanisms. Evaporation purifies (distills) salty oceanic water. Evaporate is freshwater, but salt remains in the oceans as water evaporates. Moreover, water self-purification takes place in rivers and wetlands.

Movement of Water Between Stores

There is water in the hydrosphere (oceans and seas, polar ice, lakes, rivers and streams, wetlands and marshes, snow pack and glaciers; containing liquid and solid water) and in the lithosphere (solid Earth), under the Earth's surface (in the rocks and soil, including permafrost, and deeper in the ground, down to the Earth crust—in liquid, solid, and gaseous phases), in the atmosphere and in the biosphere (living organisms, flora, and fauna).

The total global water resources constitute approximately 1.385 billion km^3 (0.17% of Earth's volume) but only 2.5% of global water resources are fresh. Water is the most abundant substance at the Earth's surface, with 96.5% of its volume (1.338 billion km^3) contained in salty oceans. Oceans, the largest water store, play an essential role in the water cycle as the main source of water for the atmosphere. Other water stores on Earth contain much smaller volumes. Glaciers and permanent snow cover contain 24.3 million km^3 of water, that is over 50 times less than the ocean volume (c. 1.72% of global water resources). However, this solid water store (whose prevailing part is ice and permanent snow cover in the Antarctic, the Arctic, and mountainous regions) contains freshwater, making up most (69.6%) of the total freshwater resources. The third largest global water store is groundwater (23.4 million km^3), but more than half of it is not fresh. Even if frozen hydrosphere (cryosphere) is the largest reservoir of freshwater, groundwater is the largest available source of freshwater. All the lakes on Earth contain 176,400 km^3 of water, with freshwater constituting more than half of the total volume. Approximately 16,500 km^3 of water is stored in the soil (0.05% of total freshwater), while all the rivers of the world carry, on average, in any time instant about 2120 km^3 of water, being only 0.006% of total freshwater. The atmosphere itself stores approximately 13,000 km^3 (0.001% of total water, 0.04% of total freshwater) and

☆*Change History:* March 2018. Z W Kundzewicz updated all the sections in this chapter, as well as Fig. 1.

wetlands about 11,500 km^3 of water. Biological water has a global volume of 1120 km^3 that is 0.0001% of total water and 0.003% of freshwater. Total freshwater resources are estimated to be in excess of 35 million km^3.

The water is on a perpetual move, converting from liquid to solid or gaseous phase, or back. It partakes in processes of exchange of mass and energy between the various spheres of the Earth system. The main, in volumetric terms, water transfer takes place between the hydrosphere and the atmosphere in processes of evaporation and precipitation. The evaporation process purifies (distills) salty oceanic water into freshwater. Annual precipitation total largely depends on the latitude. Globally averaged latitudinal precipitation is highest near the equator and relatively high at the latitude around 60 degree (where upward lift of air masses is dominating). It is lower at the latitude around 30 degree and near the poles (where downward movement of air masses dominates). Also the altitude above the sea level is an important control of the amount of precipitation. Among further factors of importance are distance from source of water, exposition to prevailing wind, and large-scale landscape structure. Water moves not only in the processes of evaporation, precipitation, and infiltration, or flow in rivers and streams, plants and animals, but also in oceans, seas, and lakes, in snow pack, and in even seemingly immobile glaciers.

The most essential, and universal, law guiding the water cycle is the rule of balance (expressed by the continuity equation, also called equation of conservation of mass). It reads, for any fixed control volume:

$$\text{Inflow} - \text{Outflow} = \text{Change of storage}$$

Considering only the most essential hydrological processes, that is, the total precipitation on the basin, evaporation from the basin, runoff (river flow in a cross section terminating the basin), and change of storage in the basin (manifesting itself via surface waters—rivers, lakes, ponds, wetlands; soil moisture, groundwater, and intercepted water), one can formulate the continuity equation for a river basin as:

$$\text{Precipitation} - \text{Evaporation} - \text{Runoff} = \text{Change of storage}$$

The total volume of water in the hydrosphere has been nearly constant over a longer timescale. Hydrosphere is a closed system and water takes part in recycling rather than loss and replenishment processes.

The major water fluxes are evaporation and precipitation. Every year, solar energy lifts about 500,000 km^3 of water, 86% of which (i.e., 430,000 km^3) evaporates from the oceanic surface and 14% (i.e., 70,000 km^3) from land. About 90% of the volume of water evaporating from oceans precipitates back onto oceans, while 10% is transported to areas over land, where it precipitates. About two-thirds of the latter evaporate again and one-third runs off to the ocean. By virtue of the continuity equation for stationary conditions, the global volume of precipitation is equal to that of evaporation, that is, 500,000 km^3 of water falls as atmospheric precipitation (on the ocean 390,000 km^3 and on land 110,000 km^3). The resulting imbalance—difference between precipitation on and evaporation from land surface (110000–70,000 = 40,000 km^3 $year^{-1}$)—represents the water vapor movement from oceans to terrestrial atmosphere over continents and islands, being equal to the total runoff of Earth's rivers and direct groundwater runoff to the ocean. Fig. 1 illustrates the principle of the global water cycle, as explained above. Solid arrows represent movement of water in liquid and solid phases, while broken-line arrows represent movement of water vapor.

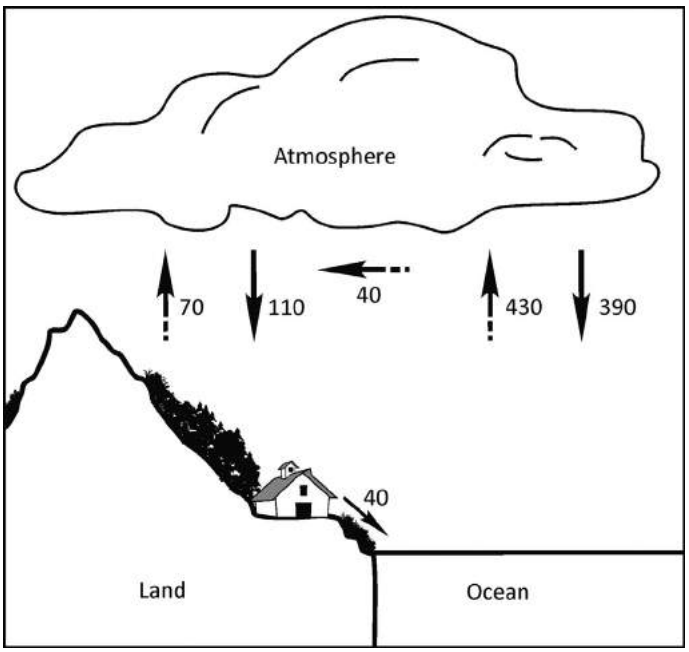

Fig. 1 Principle of the global water cycle. Numbers refer to annual fluxes in thousands of cubic kilometers. The processes of vertical movement of water are precipitation and evaporation, and processes of nearly lateral movement are runoff and advection of atmospheric moisture from ocean areas to the land areas.

Since the large volumes in hundreds of thousands of cubic kilometers are not easy to interpret, the fluxes in the global water cycle can be expressed in units of length (thickness of water layer). On average, a layer of 140 cm of water evaporates from the oceans, and 127 cm of water precipitates onto the oceans. The difference of 13 cm is very important, as it drives the continental phase of the water cycle. Since more water evaporates from the ocean than precipitates on it, there is a surplus of moisture, which moves over land and precipitates there. In result, precipitation on the land (80 cm) is much higher than evaporation from land (48 cm).

The mean sojourn time of a water particle in different stores varies from hours to millennia. Slow turnover is typical in ocean bodies, large lakes, and deep groundwater, where mean residence time of a water particle depends on the depth, and in ice sheet and glaciers, due to their frozen, immobile nature in cold (low-energy) climates. A water particle spends, on average, about 10,000 years in underground ice in the permafrost area or the eternal snows and polar ice, 2500 years in the ocean, 1600 years in mountain glaciers, and 1400 years in groundwater. In lakes, wetlands, and the soil, the mean residence times of a water particle read 15–17, 5, and 1 year, respectively. Much faster is the turnover of stored water in rivers (16 days), atmospheric water (8–10 days), and biological water (a few hours). Since water in the atmosphere is completely replaced once every 8–10 days, one can state that the atmosphere recycles its contents about 40 times per year.

For millennia, people have not properly interpreted the hydrological cycle, even if they understood water as an indispensable condition of life and carried out advanced water management. In the ancient times, water was treated as one of four elements (beyond fire, air, and Earth). It was easy to comprehend that the gravity force dominates in the atmospheric precipitation, overland (surface) flow, river runoff, and infiltration. It was followed in the water supply technology (aqueducts). However, it was not clear how the water got up to the source areas located in higher altitudes, against the force of gravity. It was difficult to understand how the loop of the water cycle was closed—what was the force lifting water to the atmosphere, so that it could precipitate onto the ground. It was also not clear why the sea level does not grow despite the perpetual inflow of gigantic rivers. In short, many thinkers falsely interpreted the closing of the water cycle, expecting an underground connection. A concept of the water cycle, similar to the present interpretation, was known in ancient Rome over 2000 years ago, but possibly earlier in China and Greece.

Hydrological Processes

Water cycle can be interpreted as a set of hydrological processes that transfer water between different stores (reservoirs).

The water cycle is powered by solar energy, mainly through direct vaporization. Water evaporates from the Earth's surface, vapor is lifted into the atmosphere to form clouds, and transported in the atmosphere. The heating is spatially uneven, as most of the solar energy warms tropical seas and drives evaporation there. Water vapor, which has risen to the atmosphere, is carried by winds away from the tropics, where it condenses, releasing latent heat and precipitates over oceans and land. Vertical processes of evaporation and precipitation are the (two) major fluxes in the water cycle.

Precipitation water falling down on land is the main source of the formation of land waters: rivers, lakes, groundwater, and glaciers. Precipitated water may be intercepted by vegetation, infiltrate into the ground, be stored in ponds, lakes, and depressions at the Earth's surface, or run off. A portion of atmospheric precipitation evaporates, a part infiltrates and contributes to groundwater, and the rest gets as river flow to the ocean, then evaporates, so that the process repeats again and again. A portion of global river

Table 1 Major hydrological processes

Process	*Description*
Evaporation	Transformation of liquid water from the Earth's surface into the vapor state
Transpiration	Transformation of liquid water into the vapor state and transfer of water vapor to the atmosphere via plant metabolism
Evapotranspiration	Joint category embracing evaporation and transpiration. Potential evapotranspiration is the upper limit to evaporation and transpiration, assuming unlimited supply of water and full opening of the stomata (daylight hour)
Condensation	Transformation of water from vapor into (denser) liquid form in the air, producing clouds or fog
Advection	Transport of water by horizontal movement of mass of air
Precipitation	Transfer of water from the atmosphere to the Earth's surface in liquid (rainfall, fog drip) or solid (snow, graupel, hail, and sleet) state
Runoff	Transfer of water across the land. This category includes surface runoff (overland flow), subsurface flow, groundwater runoff, and river flow
Sublimation	Change of water state directly from solid (snow or ice) to gaseous
Infiltration	Flow of water from the ground surface (also bottom of water body) into the ground, under the combined forces of gravity, viscosity, and capillarity. Infiltrating water contributes to soil moisture (within the vadose or aeration zone), or percolates deeper to become groundwater (in the aquifer, that is, saturated zone)
Snowmelt	Transfer of water from snow cover (solid state) to liquid state, by melting process
Interception	Storage of precipitated water (in liquid or solid state) by plant foliage. Intercepted water may evaporate back to the atmosphere or fall onto the ground. The amount of intercepted water depends on the duration of the storm, wind speed, temperature, and the density of foliage. A dense forest can intercept nearly all water from a low intensity rainfall
Subsurface flow	Flow of water under the ground surface, in the vadose (aeration) zone or saturation zone (aquifer)
Capillary rise/ exfiltration	Movement of infiltrated water back toward the Earth surface, driven by an upward capillary potential gradient (caused by evaporation)

discharge, in the drainless areas of endorheic runoff, does not reach the ocean. Water moves also in the biosphere, in oceans, seas, and lakes, in snow pack, and even in seemingly immobile glaciers.

A list of major hydrological processes partaking in the water cycle, and their short characteristics, are compiled in Table 1.

One can conceptually divide precipitated water into "green" water and "blue" water. The former is a part of precipitation that evaporates and sustains plant growth, while the latter is liquid water in surface and subsurface water bodies, which can be withdrawn for human use (e.g., for irrigation). Blue water turns to green water in the ecosystems (including agriculture).

There is a considerable movement of water within the ocean bodies. Mixing between two stratified layers (upper—warmer; deeper—colder), separated by the thermocline, is very slow. Motions (currents) of ocean's waters result from the density differences, dependent on temperature and salinity. The thermohaline circulation is intense—the Gulf Stream is a conveyor belt of heat responsible for the relatively mild climate of Europe.

Extremes

At times, volumes of water in stores and fluxes of water between stores, at various spatial scales, take extremely high or extremely low values. For over a century, highest precipitation values have been recorded in meteorological stations worldwide, for various time intervals. The list of global records range in different time intervals include 38 mm of precipitation in 1 min, through 1825 mm in 1 day (24 h), to 9.3 m in 1 month, 22.45 m in 6 months, 26.46 m in 1 year, and 40.76 m in 2 years.

Too much rainfall can cause excess runoff and inundation (flooding) of terrain, while too little rainfall leads to drought, decrease in water level, or even drying out of surface-water bodies, drop of groundwater level and soil moisture, often accompanied by failure of crops, and adverse effects, for example, related to water supply, navigation, hydropower, and wild fire.

Amounts of precipitation may considerably vary from year to year. The same areas may experience a drought in 1 year and a flood in next year (or sometimes—even drought and flood in the same season). For instance, the River Elbe flooded Dresden (Germany) in summer 2002 with a record high level and featured extremely low flow in summer 2003. In 1988, an intense drought disrupted agriculture in the Midwestern United States (too little water), while in 1993 the same area was subjected to severe inundations, greatly reducing the annual harvest (too much water).

Human Impacts

The Earth's freshwater resources remain constant, but man is capable of altering the water cycle and the water resource itself, in both quantity and quality context.

Humans have always interacted with the water cycle, drinking freshwater and using it for various purposes. They have influenced hydrological processes, in order to accelerate the water movement (e.g., improving conveyance in open channels), or to slow it down (by damming a river and catching water in a reservoir rather than letting it flow promptly to the sea). Man has benefited from the kinetic or dynamic energy of water and the value of water itself.

The water resources have always been distributed unevenly in space and time and man has tried to reduce this unevenness and smoothen the spatial–temporal variability. Regulating flow in space can be achieved via water transfer, while regulating flow in time to suit human needs can be achieved by storage reservoirs (capturing water when abundant and using it when it is scarce).

Water transfer is an old idea. Man-made water conduits (aqueducts) date back to the ancient world. Already 6000 years ago, river water was diverted for irrigation agriculture in Mesopotamia. In Mesopotamia and Egypt, *qanats*—underground lateral canals—were used, through which water was conveyed without losses by evaporation.

The rationale for a large-scale water transfer is backed by the following observations:

- The aggregate renewable freshwater resources on the Earth (total river discharge) are sufficient to meet the human water demands for many decades ahead;
- Freshwater resources on the Earth are spatially distributed in a very uneven way; and;
- Man's economic activities additionally exacerbate natural unevenness in spatial distribution of water resources.

It is therefore tempting to transfer water from the regions where it is abundant to water-scarce regions. However, effects of large-scale water transfers on the natural environment have to be thoroughly analyzed, because adverse side effects may prove to be serious.

Today, water storage reservoirs serve multiple purposes—water supply for agriculture, households, industry, hydropower, navigation, and recreation. Irrigated agriculture is indispensable to feed the increasing population of the globe. Hydropower developments have been enhanced by increasing fossil fuel cost and the advent of climate mitigation policy via renewable energy sources. However, beneficial impacts of reservoirs are not for free. Among adverse effects of dams and reservoirs are disturbances to ecosystems, barrier to fish, inundation of fertile land, and relocation of people. Moreover, enhanced evaporation from a large water surface reduces available water resources of the region. Hence, reservoirs should be taken into account, while estimating water consumption. Dams have been built for millennia, but most large dams have been constructed since the mid-20th century. At present, the total design volume of world reservoirs exceeds 6000 km^3, and their total water surface area reaches 500,000 km^2.

Beyond water storage and water transfer schemes, the water cycle is exposed to many other human impacts: changes in land use and land cover, deforestation or afforestation, modification of soil layers, urbanization, and agricultural activities. Water withdrawals and uptake from rivers, lakes and wells for irrigation, as well as municipal and industrial water usages modify water cycle significantly in both quantitative and qualitative aspects. Impacts of population growth, economic activities, and consumptive lifestyle on hydrological cycle and water withdrawals result in rising water stress. Water withdrawals increase directly with the growth of population and water usage per capita, and indirectly through the increase in food production.

Particularly important are easily accessible freshwater resources, such as surface waters and shallow groundwater, part of which is accessible to plant roots. At present, about 600–700 km^3 of annual water withdrawal stem from groundwater. A large part of this groundwater is used for irrigation and municipal needs. For areas with almost no river runoff (e.g., Arabian Peninsula, Libya), groundwater and desalinated seawater are the main water sources, but much of the groundwater is nonrenewable. The recharge took place in past climates, and after withdrawal, the groundwater resources will not be replenished.

The ongoing globalization has increased the transport and trade of "virtual water" worldwide. The virtual water content of goods is equal to the amount of water required if the transferred goods are produced in the importing and consuming area. Hence, in destinations of virtual water trade, water encapsulated in products (e.g., food) is imported from source regions.

Access to freshwater is now being regarded as a universal human right and extending access to safe potable water is one of the Millennium Development Goals—to halve, between 1990 and 2015, the proportion of people without sustainable access to safe drinking water. However, there are still more than 880 million people that have no access to safe freshwater. Human population of 7.5 billion people drink more than 7 km^3 of water per year.

Until a century ago, the number of people on Earth was not high, and human impact on water resources was generally insignificant and local rather than global. Thanks to the renewal process of the water cycle and its self-purification properties, on average, the quantity and quality of fresh waters had not changed much (except for climate-driven natural variability). The process of evaporation and surface water systems (rivers, lakes, and, in particular, wetlands) remove a large portion of pollutants from the water, in liquid or gaseous state. There had been an illusion that water resources are infinite, inexhaustible, and perfectly renewable, free goods. The situation has dramatically changed over the last century, when water withdrawals strongly increased due to the dynamic population growth and socioeconomic development driving the increase of human living standards. There has been a dramatic expansion of irrigated agricultural areas, growth of industrial water use (including the power sector), and intensive construction of storage reservoirs worldwide.

Indeed, water is not a free goods any more. A future-oriented water resources management should emphasize shaping demands rather than supply extension. It is a must to improve the efficiency of water use, trying to "do more with less" ("more crop per drop"). Financial instruments, such as the water pricing not only granting full cost recovery but also accounting the cost of the resource, in the sense of foregone opportunities, can generally improve the efficiency of water use.

Global water consumption has increased more than sixfold since the beginning of the 20th century, being twice stronger than the population growth. Facing the increasing pressures, the business-as-usual approach to water development and management cannot be globally sustainable.

The problems of water shortage are likely to be aggravated in the 21st century, which was baptized "the age of water scarcity." Population growth, economic development, and increasingly consumptive lifestyle impact on the hydrological cycle, boosting water withdrawals and increasing the hazard of water stress and water scarcity.

Irrigated agriculture consumes, globally, 70% of the world water withdrawals. More and more water is needed to produce food for the ever-increasing population of the globe. Since projections for the future foresee further growth of population, the consequences to food and fiber production are clear and the global demand for water will grow further. Faster growth is expected in less developed countries: in the whole of Africa and much of Asia.

Man has changed the quality of the world's water, creating acute problems in densely populated regions of the Earth, where no efficient wastewater purification takes place. It is estimated that only 5% of the world's wastewater is treated. The structure of human-caused water pollution problems has changed in time, with fecal coliform bacteria and organic pollution being the oldest.

Today, important water pollution problems are caused by bacteriological and organic contamination, salinization of freshwater (groundwater, rivers, lakes), driven by irrigation, groundwater overexploitation or saltwater intrusion, water withdrawals, pollution by nutrients (nitrogen, phosphorus), whose abundance leads to eutrophication and toxic algae blooms, remains of agricultural chemistry products, metals, and radioactive material, organic micropollutants, and acidification. Remains of agricultural chemistry products, artificial fertilizers, pesticides, and herbicides, are particularly difficult to eliminate, due to the distributed nature of the source. Some synthetic chemicals, for example, organochlorines (organohalides) have a long half-life time: 8 years in the case of DDT.

Even when perennial surface water source is available in a given location, water consumption in untreated state may present a risk to human health because of contamination by pathogens or waste. The number of people dying each year of water-related diseases is of the order of millions. Particularly burning water supply problems occur in informal human settlements, for example, slums around mega-cities in developing countries, where the poor have no access to public, safe, tap water. They have to buy lower-quality water from vendors and pay much more than the price charged to more wealthy citizens who have access to the public supply of safe water.

The need for protection of the aquatic ecosystems is being increasingly recognized. Despite the rising human demand for water, it is necessary to allocate a share of water to maintain the functioning of freshwater-dependent ecosystems, thus meeting conditions of environmental flow and environmental water requirements. This would allow (if flows are regulated) to maintain the water

regime within a river or a wetland, that suits aquatic and riparian ecosystems. However, earmarking water for environmental requirements is very difficult in some areas. At times, river flow may not reach the sea due to excessive human water withdrawal.

In order to improve the quality of water in the countries of the European Union (EU), the Water Framework Directive entered into force in December 2000, setting out a framework for actions in the field of water policy in the European Union. The key objective of the Directive, which imposes legal obligations on the authorities in EU member states, is to achieve a "good water status" for all waters of the European Union.

Climate Change Impact on Water Resources

Climatic and freshwater systems are interconnected in a complex way, so that any change in one of these systems induces a change in the other. Climate and water on the planet Earth are closely linked. Climate change exerts considerable impact on the water cycle and all the hydrological processes partaking in it.

Water takes part in a large-scale exchange of mass and heat between the atmosphere, the ocean, and the land surface, thus influencing the climate, and also being influenced by the climate. Water plays a pivotal role in the redistribution of heat in the Earth's atmosphere, and in the Earth's thermal system. Due to its high specific and latent heat, water moderates the Earth's climate, acting as air-conditioner in the Earth system. Large hidden energy is released in the atmosphere when water vapor condenses and latent heat (water vapor) transport is a major component of the Earth's heat balance. Some 23% of the solar radiation that reaches the Earth is used for evaporating water. Most of the Earth's waters is contained in the oceans and the very high heat capacity of this large volume of water buffers the Earth surface from strong temperature changes such as those occurring on the waterless Moon. Ocean acts as the principal heat storage component in the Earth system, a regulating flywheel in the Earth's heat engine.

The water cycle affects the energy budget of the Earth. Clouds alter Earth's radiation balance. Atmospheric water vapor (along with carbon dioxide and methane) is a powerful greenhouse gas, playing a significant role in the greenhouse effect. This effect, which can be described as absorbing the long-wavelength infrared radiation emitted by the Earth's surface, is responsible for maintaining the mean surface temperature about 33°C higher than would be the case in the absence of the atmosphere.

In the history of Earth's climate, there were time periods when much of the hydrosphere on the surface of the planet was in the solid form of glacial ice. Possibly, during the Cryogenian period, the range of sea ice extended nearly to the equator. There have been several ice ages in the history of the Earth, and the most recent retreat of glaciation is dated at some 10,000 years ago. Range and extent of ice sheets, glacier, and permanent snow areas remain a sensitive indicator of changes in the Earth's climate. After expansion during the Little Ice Age, they have been shrinking recently in response to the ongoing global warming.

Earth's climate has always been changing, reflecting regular shifts in Earth's orbit and solar activity and radiation, and irregular volcanic eruptions. However, a large part of the ongoing climate change is due to human activity. Man has been carrying out a planetary-scale experiment, disturbing the natural composition of the atmosphere by increasing the contents of greenhouse gases, by unprecedented level of burning of fossil carbon (coal) and hydrocarbons (oil and natural gas), and large-scale deforestation (reduction of carbon sink). In consequence, the greenhouse effect becomes more intense, leading to global warming.

The globally averaged Earth (land and ocean) surface temperature data as calculated by a linear trend, show a warming of 0.85°C [0.65–1.06°C], over the period 1880–2012. Further temperature increase is projected, depending on the socioeconomic (hence, greenhouse gas emission) scenarios. If effective global climate change mitigation will not take place (development pathway, RCP8.5), the global mean temperature may grow in 2081–100 to 2.6–4.8°C relative to 1986–2005. The mean warming over land will be larger than over the ocean and the Arctic region will warm more rapidly than the global mean.

Apart from the warming, there are several further manifestations of climate change and its impacts on freshwater resources, many of which have already been observed, and further (and more pronounced) impacts have been projected. Observational evidence indicates an ongoing intensification of the water cycle, with increasing rates of evaporation and precipitation. There is more water vapor in the warmer atmosphere, and this creates potential for enhanced intense precipitation. There is a poleward shift of the belt of higher precipitation. Increase in midsummer dryness in continental interiors has been observed and further increase is projected.

Changes in streamflow volume, both increases and decreases, have been recorded in many regions, but often these trends cannot be definitively attributed to changes in climate, due to existence of several other factors. The effect of climate change on streamflow, lake levels, and groundwater recharge, which varies regionally, largely follows changes in precipitation. A robust finding is that warming leads to changes in the timing of river flows where much of the winter precipitation currently falls as snow. The effect is greatest at lower elevations (where snowfall is more marginal). Winter flows increase and summer flows decrease.

Carbon dioxide enrichment improves efficiency of plant water use, reducing stomatal conductance and leaf-scale evaporation, but this is partly offset by increased plant growth. Warmer temperatures generate increased glacier melt; hence, widespread glacier retreat has been already observed, and many rivers draining glaciated regions have increasing flows, due to increase of melt. Many small glaciers disappear.

Water quality is likely generally to be degraded by higher water temperature, but this may be offset regionally by the dilution effect of increased flows. Warming-enhanced sea-level rise can lead to saltwater intrusion into fresh groundwater bodies. Thus, freshwater availability in coastal areas is likely to decrease in the warmer climate.

Effects of future climate change on average annual river runoff across the world indicate some generally consistent patterns of change—increases in high latitudes and the wet tropics, and decreases in mid-latitudes and some parts of the dry tropics. High reductions in the mass of Northern Hemisphere glaciers are expected in the warming climate. As these glaciers retreat, rivers, which

are sustained by glacier melt during the summer season, feature flow increase, but the contribution of glacier melt will gradually fall over the next few decades.

Xenobiotic (Pesticides, PCB, Dioxins) Cycles

VN Bashkin, VNIIGAZ/Gazprom, Moscow, Russia

Introduction

Persistent organic pollutants, POPs, are a wide class of chemical species with different physicochemical properties and toxicology. Here we will consider the following priority list of POPs: 1,1,1-trichloro-2,2-bis (4-chlorophenyl) ethane, DDT; hexachlorocyclohexanes, HCHs; hexachlorobenzene, HCBs; polychlorinated dibenzo-*p*-dioxins and dibenzofurans, PCDD/Fs; polychlorinated biphenyls, PCBs; polycyclic aromatic hydrocarbons, PAHs. Environmental pollution by POPs is one of the global problems that is drawing attention at national and international levels. The transboundary aspects of POP transport and pollution of various environmental media require study of the relevant effects on human health and the environment, including quantification of those effects. In accordance to Protocol on POPs to the UN ECE Convention on Long-Range Trans-Boundary Air Pollution that entered into force in October 2003, the parties to the protocol shall encourage research, development, monitoring, and cooperation related, in particular, to an effects-based approach which integrates appropriate information on measured or modeled environmental levels, pathways, and risk to human health and the environment.

Evaluation of POP Deposition

Calculated fields of depositions and concentrations give the opportunity to assess the changes in atmospheric contamination and deposition of POPs and to select `hot spots´ of contamination. As an example, the spatial distribution of PCDD/Fs depositions to the EMEP region, calculated for the beginning and the end of the considered period, is given in **Fig. 1**. `Hot spots´ are particular cells of the EMEP grid characterized by the highest values of PCDD/Fs deposition fluxes in both years (marked by arrows). As seen from the data presented, deposition fluxes over the European countries decreased substantially. PCDD/F deposition at one `hot spot´ near Prague (the Czech Republic) decreased more than 2 times. Such calculated fields of depositions for other considered POPs are also available on the Internet (http://www.msceast.org).

Spatial Pattern of PCDD/Fs Contents in Various Environmental Compartments

For PCDD/Fs the spatial distribution of concentrations in air in comparison with that for soil concentrations in 2001 is shown in **Fig. 2**. Note that significant differences in the spatial distribution of air and soil concentrations in most European countries are observed. This fact can be explained by the long-term accumulation of PCDD/Fs in soil and relatively low degradation rates in this medium in combination with changes in the emissions during a long time period.

To take into account the effect of accumulation of POPs in different environmental compartments (soil, seawater, and vegetation) the modeling of their long-range transport was performed for a more prolonged period of time (1970–2001). In general, the trends of PCDD/F content in air and seawater followed the emission variation. The trend of PCDD/F accumulation in soil was strongly different from that of emissions. Emissions began to reduce in 1980, whereas the decrease in soil contamination started in 1990. The rate of the soil content decrease is much lower. This causes substantial PCDD/F re-emission flux from soil, which slows down the tendency for a decrease in PCDD/F content in the atmosphere.

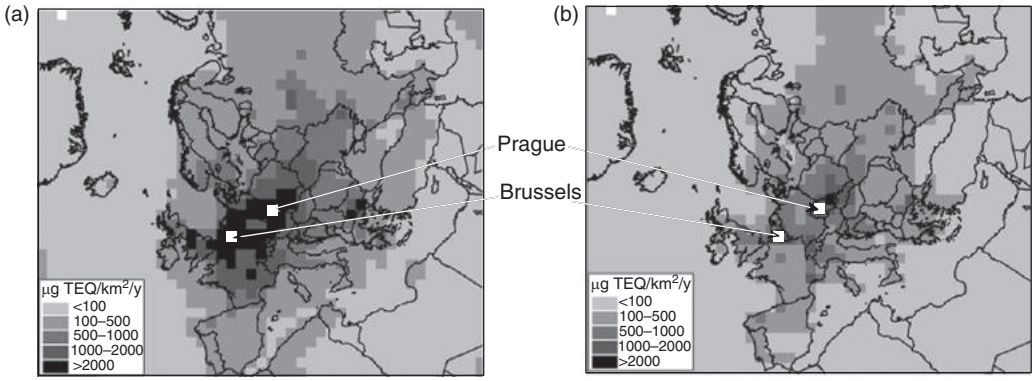

Fig. 1 Spatial distribution of PCDD/Fs depositions, (a) 1990 and (b) 2001 (the arrows show `hot spots').

 doi:10.1016/B978-0-444-63768-0.00767-8

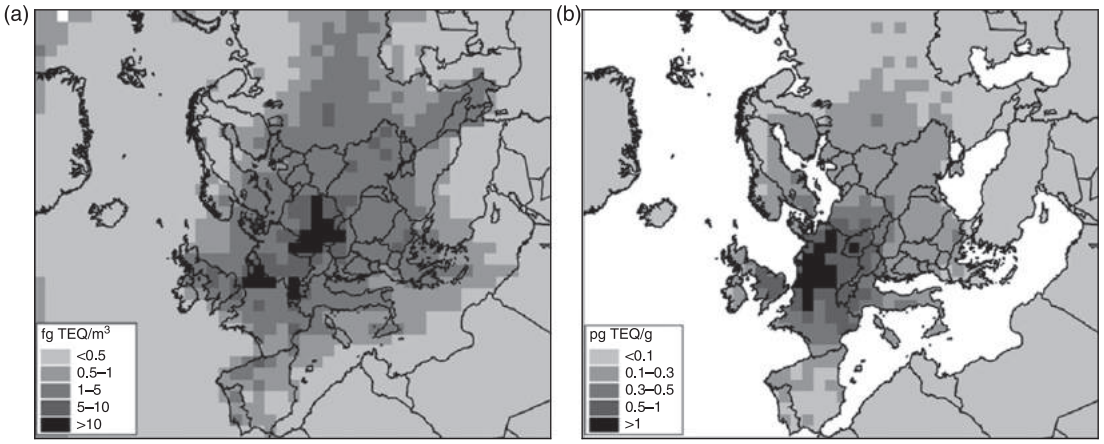

Fig. 2 Spatial distribution of PCDD/F concentrations in the (a) air and (b) soils of Europe in 2001.

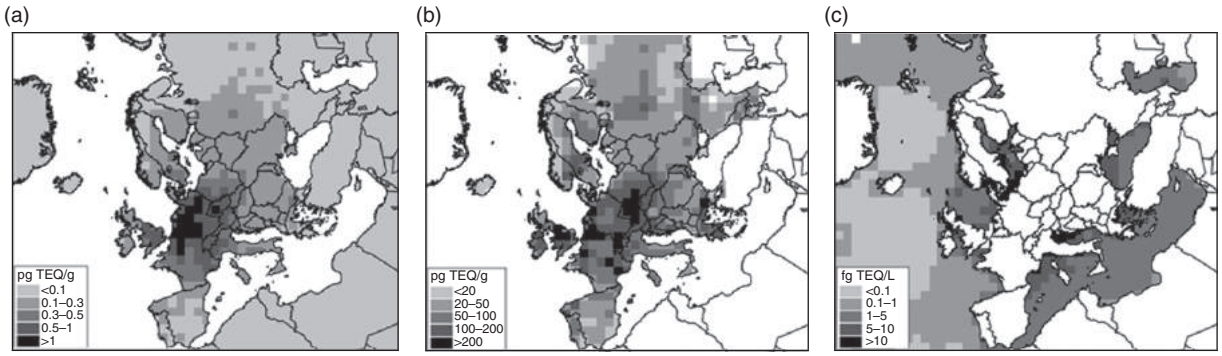

Fig. 3 Spatial distribution of PCDD/F concentrations in (a) soil, (b) vegetation, and (c) seawater in 2001.

Such pollutants as PAHs and PCBs also tend to be accumulated in the terrestrial environment but HCB and γ-HCH in the marine ones. Thus, this information gives us an idea of the POP exposure pathways to human beings.

To identify the areas and regions which were the most polluted by the considered POPs, the preliminary model results on the spatial distribution of their concentrations in different environmental media of the EMEP region were obtained. As an example, the spatial distributions of PCDD/F concentrations in soil, vegetation, and seawater with a spatial resolution of 50×50 are presented in **Fig. 3**.

POP Transport in the Northern Hemisphere

To evaluate the long-range transport ability of the considered POPs, the amount of each of these pollutants emitted in Europe and transported outside the EMEP region (outflow) was estimated. For the considered POPs, the percentage ratio of outflow to annual emissions ranged from 20% to 80%. For pollutants with the highest long-range transport potential, such as PCBs, HCHs, and HCB, calculations on the hemispheric scale were made. To evaluate the importance of intercontinental transport for these pollutants, calculations of their transport from different groups of sources such as European, American, and so on were carried out. To make these calculations tentative, hemispheric emission data for these pollutants were used.

On the basis of calculations made, contributions of different groups of emission sources located in the Northern Hemisphere, for instance, to HCB depositions over Europe and the Arctic were evaluated (**Figs. 4a** and **4b**). The contributions of remote source groups in the contamination of these regions are essential. Contributions of Russian emission sources to the European and Arctic contamination amount to about 19% and 31%, respectively. The relevant sum values of Canada and USA are 7% for the European domain and 17% for the Arctic.

At present evaluation of POP depositions to various types of the underlying surface are under investigations. The spatial distribution of PCB-153 depositions to areas covered with forests, soil, and seawater in 2000 is demonstrated in **Fig. 5**. Depositions of this pollutant to forests, soil, and seawater were estimated using different parametrizations of dry deposition velocities for different types of underlying surfaces. This resulted in considerable differences in depositions to the considered areas. As seen from the maps, the highest levels of PCB-153 depositions were characteristic of forested areas.

Exposure Pathways of Dioxins and Dioxin-Like PCBs to Human

General Description of Dioxins

In this section, we consider the exposure pathways of POPs to human beings on the example of PCDD/Fs, often called just `dioxins'. These species consist of two groups of tricyclic aromatic compounds with similar chemical and physical properties. The number of chlorine atoms in each molecule can vary from one to eight. The number of chlorine atoms and their positions are of utmost importance for the toxicological potency of each congener. PCDD/Fs have never been produced intentionally, except for pure substances used as references in analytical and toxicological research, and have never served any useful purpose, unlike many other POPs such as PCBs and DDT. PCDD/Fs are formed as unwanted by-products in many industrial and combustion processes. They have also been shown to be formed in the environment by forest fires and volcanoes, and also via enzymatically catalyzed processes.

Primary sources of environmental contamination with PCDD/Fs in the past were the production and use of organic chemicals containing chlorine. PCDFs were formed as inadvertent by-products in the production and use of PCBs and, in combination with PCDDs, in such high-temperature processes as waste incineration, the metal industry, home heating, and other energy production processes.

PCDFs are also found in residual waste from the production of vinyl chloride and the chlor-alkali process for chlorine production. Factors favorable for the formation of PCDD/Fs are high temperatures, alkaline media, the presence of ultraviolet light, and the presence of radicals in the reaction mixture/chemical process.

Previous production of pentachlorophenol, as well as the bleaching process in pulp and paper mills, has been shown to be a major source. Changes in industrial processes have resulted in a reduction of PCDD/Fs concentration in products. Whereas in the past the chemical industry and, to a lesser extent, the pulp and paper industry were considered to be the main sources of PCDD/Fs (and also the cause of many of today's contaminated sites in several industrialized countries), today's dioxin input is mainly due to thermal processes. There is still a considerable focus on waste incineration but, owing to requirements for dioxin reduction in stack gases set by several national authorities, the importance of this category has declined during the last years. Examples can be seen especially in the European emission inventories. An overview of combustion sources known to generate and emit PCDD/Fs is presented in **Table 1**.

PCDD/PCDFs are found not only in stack gases but also in solid residues from any combustion process such as bottom ash, slag, and fly ash. With advanced technology and better burnout of the ashes and slag (characterized by a low content of organic carbon), PCDD/F concentrations have declined.

Secondary sources of PCDD/Fs, their reservoirs, are those matrices where they are already present, either in the environment or as products. Product reservoirs include PCP-treated wood, PCB-containing transformers and sewage sludge, compost and liquid

Table 1 Sources of emission of PCDD/Fs

Stationary sources	
Waste incineration	Municipal solid waste, clinical waste, hazardous waste, sewage sludge
Steel industry	Steel mills, sintering plants, hot-strip mills
Recycling plants	Nonferrous metals (melting, foundry: Al, Cu, Pb, Zn, Sn)
Energy production	Fossil fuel power plants, wood combustion, landfill gas
Diffuse sources	
Traffic	Cars
Home heating	Coal, oil, gas, wood
Accidents	PCB fires, fires in building, forest fires, volcanic eruptions

From Fielder H (1999) Sources of PCDD/PCDF and impact on the environment. *Chemosphere* 32: 55–64.

manure, which can be used as fertilizers in agriculture and gardens. Reservoirs in the environment are, for example, landfills and waste dumps, contaminated soils (mainly from former chemical production or handling sites), and contaminated sediments (especially in harbors and rivers with industries discharging directly to the waterways).

Although these reservoirs may be highly contaminated with PCDD/Fs, the chemical and physical properties of these compounds imply that dioxins and furans will stay adsorbed to organic carbon in soils or other particles. On the other hand, mobilization can occur in the presence of lipophilic solvents (leaching into deeper layers of soils and/or groundwater) or in cases of erosion or runoff from topsoil (translocation into the neighborhood). Experience has shown that transport of PCDD/Fs due to soil erosion and runoff does not play a major role in environmental contamination and human exposure.

PCBs have been used commercially since 1929 as dielectric and heat exchange fluids and in a variety of other applications. The presence of PCBs in human and wildlife tissues was first recognized in 1966. Investigations in many parts of the world have since revealed widespread distribution of PCBs in the environment, including remote areas with no PCB production or use. There is evidence that the major source of PCB exposure in the general environment is the redistribution of PCBs previously introduced into the environment. It is believed that large bodies of water, such as the Baltic Sea and the Canadian Great Lakes, may release significant amounts of PCB residues from previous uses into the atmosphere. The fact that PCB levels seem to decline in a similar way at different latitudes indicates that primary sources may still play an important role. The amount of dioxin-like PCBs might vary in the environment but the sources, transport, and distribution, as well as persistence, show similarities with the general properties of PCBs.

Potential for Long-Range Transboundary Air Pollution

PCDD/Fs are very persistent compounds; as their Kow and Koc are very high, they will intensively adsorb on to particles in air, soil, and sediment and accumulate in fat-containing tissues. The strong adsorption of PCDD/Fs and related compounds to soil and sediment particles means that their mobility in these environmental compartments is negligible. Their mobility may be increased by the simultaneous presence of organic solvents such as mineral oil. The air compartment is probably the most significant compartment for the environmental distribution and fate of these compounds.

Some of the PCDD/Fs emitted into air will be bound to particles while the rest will be in the gaseous phase, which can be subject to long-range transport (up to thousands of kilometers). In the gaseous phase, removal processes include chemical and photochemical degradation. In the particulate phase, these processes are of minor importance and the transport range of the particulate phase will primarily depend on the particle size. PCDD/Fs are extremely resistant to chemical oxidation and hydrolysis, and hence these processes are not expected to be significant in the aquatic environment. Photodegradation and microbial transformation are probably the most important degradation routes in surface water and sediment.

The number of chlorine atoms in each molecule can vary from one to eight. Among the possible 210 compounds, 17 congeners have chlorine atoms at least in the positions 2, 3, 7, and 8 of the parent molecule and these are the most toxic, bioaccumulative, and persistent ones compared to congeners lacking this configuration. All the 2,3,7,8-substituted PCDDs and PCDFs plus coplanar PCBs (with no chlorine substitution at the *ortho*-positions) show the same type of biological and toxic response.

PCDD/Fs are characterized by their lipophilicity, semivolatility, and resistance to degradation. The photodegradation of particle-bound PCCD/Fs in air was found to be negligible. These characteristics predispose these substances to long environmental persistence and to long-range transport. They are also known for their ability to bioconcentrate and biomagnify under typical environmental conditions, thereby potentially achieving toxicologically relevant concentrations. The tetra–octa PCCD/PCDFs have lower vapor pressures than PCBs and are therefore not expected to undergo long-range transport to the same extent; nevertheless, there is evidence for deposition in Arctic soils and sediments.

Persistence in water, soil, and sediment

Owing to their chemical, physical, and biological stability, PCDD/Fs are able to remain in the environment for a long time. As a consequence, dioxins from so-called `primary sources' (formed in industrial or combustion processes) are transferred to other matrices and enter the environment. Such secondary sources are sewage sludge, compost, landfills, and other contaminated areas. PCBs and PCDD/Fs are lipophilic (lipophilicity increases with increasing chlorination) and have very low water solubility. Because of their persistent nature and lipophilicity, once PCDD/Fs enter the environment and living organisms, they will remain for a very long time, like many other halogenated aromatic compounds. As log Kow (typically 6–8) or log Koc are very high for all these compounds, they will intensively adsorb on to particles in air, soil, and sediment. The strong adsorption of PCDD/Fs and related compounds to soil and sediment particles causes their mobility in these environmental compartments to be negligible.

Their mobility may be increased by the simultaneous presence of organic solvents such as mineral oil. The half-life of TCDD in soil has been reported as 10–12 years, whereas photochemical degradation seems to be considerably faster but with a large variation that might be explained by experimental differences (solvents used, etc.). Highly chlorinated PCDD/Fs seem to be more resistant to degradation than those with just a few chlorine atoms.

Bioaccumulation

The physicochemical properties of PCBs and their metabolites enable these compounds to be absorbed readily by organisms. The high lipid solubility and the low water solubility lead to the retention of PCCD/Fs, PCBs, and their metabolites in fatty tissues. Protein binding may also contribute to their tissue retention. The rates of accumulation into organisms vary with the species, the duration and concentration of exposure, and the environmental conditions. The high retention of PCDD/Fs and PCBs, including their metabolites, implies that toxic effects can occur in organisms spatially and temporally remote from the original release.

Gastrointestinal absorption of tetrachlorodibenzo-*p*-dioxin (TCDD) in rodents has been reported to be in the range of 50–85% of the dose given. The half-life in rodents ranges from 12 to 31 days except for guinea pigs, which show slower elimination ranging from 22 to 94 days. The half-life in larger animals is much longer, being around 1 year in rhesus monkeys and 7–10 years in humans.

Monitoring

PCCD/Fs have been found to be present in Arctic air samples, for example, during the winter of 2000/2001 in weekly filter samples (particulate phase) collected at Alert in Canada. PCDD/PCDFs have been monitored since 1969 in fish and fish-eating birds from the Baltic. The levels of PCDD/Fs in guillemot eggs, expressed as TEQ, decreased from 3.3 ng/g lipids to around 1 ng/g between 1969 and 1990. Since 1990, this reduction seems to have leveled off and today it is uncertain whether there is a decrease or not. Fish (herring) show a similar picture.

Thus both physical characteristics and environmental findings support the long-range transport of PCCD/Fs and PCBs. There are differences, however, both between and within the groups regarding ability to undergo LRTAP.

Pathways of LRTAP-Derived Human Exposure

For decades, many countries and intergovernmental organizations have taken measures to prevent the formation and release of PCDD/Fs, and have also banned or severely restricted the production, use, handling, transport, and disposal of PCBs. As a consequence, release of these substances into the environment has decreased in many developed countries. Nevertheless, analysis of food and breast milk show that they are still present, although in levels lower than those measured in the 1960s and 1970s. At present, the major source of PCB exposure in the general environment appears to be the redistribution of previously introduced PCBs.

Significant sources and magnitude of human exposure

PCDD/Fs are today found in almost all compartments of the global ecosystem in at least trace amounts. They are ubiquitous in soil, sediments, and air. Excluding occupational or accidental exposures, most human background exposure to dioxins and PCBs occurs through the diet, with food of animal origin being the major source, as they are persistent in the environment and accumulate in animal fat.

Importantly, past and present human exposure to PCDD/Fs and PCBs results primarily from their transfer along the pathway: atmospheric emissions → air → deposition → terrestrial/aquatic food chains → human diet. Information from food surveys in industrialized countries indicates a daily intake of PCDD/Fs on the order of 50–200 pg I-TEQ/person per day for a 60 kg adult, or 1–3 pg I-TEQ/kg bw per day. If dioxin-like PCBs are also included, the daily total TEQ intake can be higher by a factor of 2–3. Recent studies from countries that started to implement measures to reduce dioxin emissions in the late 1980s clearly show decreasing PCDD/F and PCB levels in food and, consequently, a lower dietary intake of these compounds by almost a factor of 2 within the past 7 years.

Biota from the Baltic have, however, not shown any clear trend for dioxins or PCBs since 1990. Occupational exposures to both PCDDs and PCDFs at higher levels have occurred since the 1940s as a result of the production and use of chlorophenols and chlorophenoxy herbicides and to PCDFs in metal production and recycling. Even higher exposures to PCDDs have occurred sporadically in relation to accidents in these industries. High exposures to PCDFs have occurred in relation to accidents such as the Yusho (Japan) and Yucheng (Taiwan) incidents, involving contamination of rice oil and accidents involving electrical equipment containing PCBs.

Exposure levels in adults

PCDD/Fs accumulate in human adipose tissue, and the level reflects the history of intake by the individual. Several factors have been shown to affect adipose tissue concentrations/body burdens, notably age, the number of children and period of breast-feeding, and dietary habits. Breast milk represents the most useful matrix for evaluating time trends of dioxins and many other POPs. Several factors affect the PCDD/PCDF content of human breast milk, most notably the mother's age, the duration of breastfeeding, and the fat content of the milk. Studies should therefore ideally be performed on samples from a large number of mothers, taking these variables into account.

The WHO Regional Office for Europe carried out a series of exposure studies aimed at detecting PCBs, PCDDs, and PCDFs in human milk. The first round took place in 1987–88 and the second in 1992. In 2001–02, a third round was organized in collaboration with the WHO Global Environmental Monitoring System/Food Contamination Monitoring and Assessment Programme (GEMS Food) and the International Programme on Chemical Safety (IPCS). Results are currently available from 21 countries. **Fig. 6** presents the temporal trends of levels of PCDDs and PCDFs expressed in WHO–TEQ for those countries participating in all three rounds or in the last two rounds of the WHO study. A clear decline can be seen, with the largest decline for countries originally having the highest level of dioxin-like compounds in human milk.

The general population is mainly exposed to PCBs through common food items. Fatty food of animal origin, such as meat, certain fish, and dairy products, is the major source of human exposure. Owing to considerable differences in the kinetic behavior of individual PCB congeners, human exposure to PCB from food items differs markedly in composition compared to the composition of commercial PCB mixtures.

PCB levels in fish have been decreasing in many areas since the 1970s, but the decrease has leveled off during the last couple of years. Today, the daily PCB intake is estimated to be around 10 ng/kg bw for an adult.

Exposure levels in children (including prenatal exposure)

Once in the body, PCBs and PCDD/Fs accumulate in fatty tissues and are slowly released. Lactation or significant weight loss increases the release of the substances into the blood. PCBs can cross the placenta from mother to fetus, and are also excreted into the breast milk. PCB and PCDD/F concentrations in human milk are usually higher than in cow's milk or other infant foods. As a

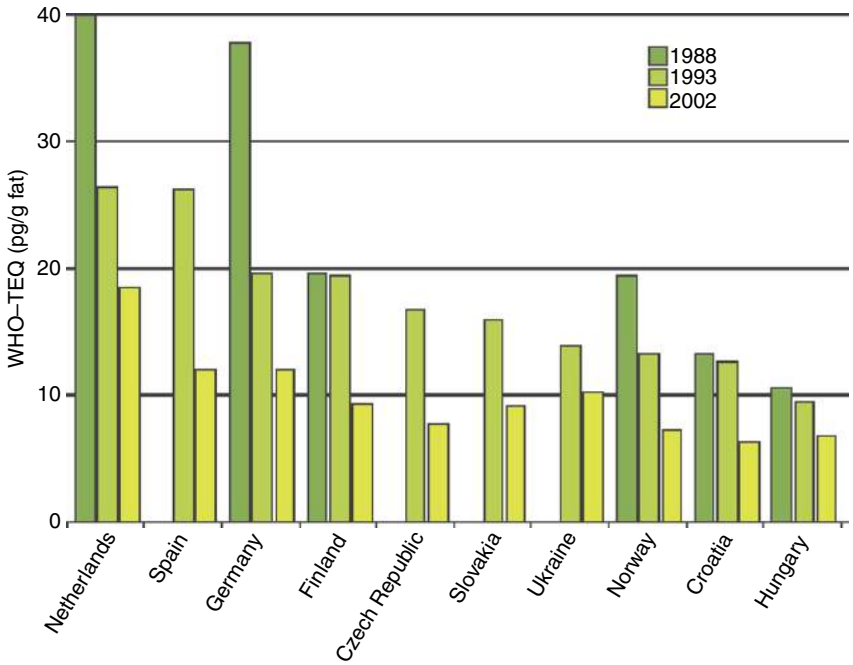

Fig. 6 Temporal trends in the levels of dioxins and furans in human milk in various countries participating in consecutive rounds of the WHO exposure study. From van Leeuwen FXR and Malisch R (2002) Results of the third round of the WHO-coordinated exposure study on the levels of PCBs, PCDDs and PCDFs in human milk. *Organohalogen Compounds* 56: 311–316.

result, breastfed infants undergo higher dietary exposure than those who are not breastfed. This concerns particularly breastfed infants of women exposed to high levels of PCBs, including Inuit and women whose diet is mainly based on fish from highly contaminated rivers and lakes, such as the Great Lakes and the Baltic Sea. Time-trend information suggests that PCDD/F and PCB concentrations in human milk have decreased significantly since the 1970s in countries that have taken measures against these substances. However, the decrease has leveled off during the last couple of years. Therefore, current fetal and neonatal exposures continue to raise serious concerns regarding potential health effects on developing infants.

Compared to adults, the daily intake of PCDD/Fs and PCBs by breastfed babies is 1–2 orders of magnitude higher. A recent field study showed higher mean levels of PCDD/Fs and PCBs in human milk in industrialized areas (10–35 pg I-TEQ/g milk fat) and lower levels in developing countries (<10 pg I-TEQ/g milk fat). Very few studies have been performed on Arctic populations with respect to the exposure of children to these substances. It is likely, however, that the differences in exposure between children and adults demonstrated in many industrialized regions also exist in Arctic regions.

Potential for high-exposure situations

It has been shown that these substances, and especially PCBs, can occur in elevated concentration in Arctic fauna. As the diet of many Arctic populations relies to a vast extent on marine mammals that represent high trophic levels, human exposure has been shown to be considerably high compared to industrialized areas.

Health effects in humans

There are many studies on the carcinogenicity of 2,3,7,8-TCDD in accidentally exposed workers. Epidemiological studies on people exposed in connection with the accident in Seveso have generated valuable information. Excess risks were observed for ovarian and thyroid cancers and for some neoplasia of the haematopoietic tissue; these results were, however, based on small numbers. Epidemiological studies on the cohorts most highly exposed to 2,3,7,8-TCDD produced the strongest evidence of increased risks for all cancers combined, along with less strong evidence of increased risks for cancers of particular sites. The relative risk for all cancers combined in the most highly exposed and longer-latency subcohorts is 1.4.

Studies of noncancer effects in children have indicated neurodevelopmental delays and neurobehavioral effects, including neonatal hypotonia. In children in Seveso who were highly exposed to TCDD, small, transient increases in hepatic enzymes, total lymphocyte counts and subsets, complement activity, and nonpermanent chloracne were observed. Also, an alteration of the sex ratio (excess female to male) was observed in children born to parents highly exposed to TCDD.

Critical outcomes and existing reference values

During the last two decades, a number of different risk assessments of dioxins and related compounds have been performed. Since the mid-1990s, coplanar PCBs have often been included in the assessments. In 1997, WHO established an expert group on dioxins and related compounds. It proposed, based on the toxic equivalency Factor (TEF) scheme shown in **Table 2**, a TDI for dioxins and

OCDF	0.0001		

related compounds. The proposal was based on kinetic calculations of doses to body burden and vice versa. The body burden approach resulted in a reduced need for a safety factor for extrapolation between species. The WHO expert group calculated that a reliable LOAEL probably could be found in the range of 14–37 pg/kg bw per day. By applying a safety factor of 10 to this range, it proposed a TDI of 1–4 pg/kg bw. The group emphasized that the TDI represents a tolerable daily intake for lifetime exposure, and that occasional short-term excursions above the TDI would have no health consequences provided that the averaged intake over long periods was not exceeded. In addition, it recognized that certain subtle effects may be occurring in some sections of the general populations of industrialized countries at current intake levels (2–6 TEQ /kg bw per day), but found it tolerable on a provisional basis since these reported subtle effects were not considered overtly adverse and there were questions as to the contribution of non-dioxin-like compounds to the observed effects. The group therefore stressed that the upper range of the TDI of 4 pg TEQ /kg bw should be considered a maximum tolerable intake on a provisional basis, and that the ultimate goal was to reduce human intake levels to below 1 pg TEQ /kg bw per day. In 2001, the European Commission and the Scientific Committee for Food proposed a temporary TWI of 14 pg/kg bw for 2,3,7,8-PCDD/Fs and dioxin-like PCBs.

Summary

It has been demonstrated that dioxins and many PCBs resist degradation, bioaccumulate, are transported through air, water, and migratory species across international boundaries, and are finally deposited far from the place of release where they can accumulate in terrestrial and aquatic ecosystems. The clearest evidence for this long-range transport derives from the levels of PCDD/Fs and PCBs measured in the Arctic. Owing to long-range transboundary transport, these substances are nowadays ubiquitous contaminants of the ecosystem and are also present in the food chain. Therefore, most of the human population is exposed to PCDD/Fs and PCBs. Moreover, since dioxins and PCBs pass from mother to fetus through the placenta, and from mother to newborn through breastfeeding, infants are at risk of harmful effects in the most critical period of their development. There are just a few reports of dioxins in humans from Arctic regions, but there are plenty of animal samples analyzed for dioxins and PCBs that give information on human exposure through food. As many people living in the Arctic still practice hunting and fishing for an important part of their diet, their exposure to dioxins, PCBs, and other contaminants could be elevated compared to people living in industrialized parts of the world.

Adaptive Management and Integrative Assessments

L Gunderson, Emory University, Atlanta, GA, USA

Adaptive management is an approach for planning and managing natural resource systems. It is based on a perception of ecosystems as complex, dynamic systems that have a large degree of unpredictability. Hence, it was proposed as a learning-based approach that confronts inherent uncertainties and complexities of resource systems. As originally described, adaptive management is not a trial and error approach to management. That is, it utilizes scientific approaches to design actions that generate learning and understanding. Nor is it an approach that updates management action as new information becomes available. While it has these elements, it is an approach that is structured to learn while doing, and to attempt to make that learning efficient in order to winnow key resource uncertainties.

Background

A sequence of works has outlined, tested, and expanded the theory and practice of adaptive environmental assessment and management since the late 1960s. The first exercise in adaptive management was the Gulf Island Recreational Land Simulation study in 1968, where the participants attempted to explore ways to bridge gaps among scientific disciplines, technical experts, and policy designers. C. S. Holling and his colleagues introduced the concepts of adaptive management and results of various early attempts at implementation in the 1978 compendium *Adaptive Environmental Assessment and Management*. In 1982, the Canadian government commissioned a review and evaluation of the approach. Carl Walters presented theory and methods for dealing with the uncertainties of managing resources in the classic book *Adaptive Management of Renewable Resources*, which was published in 1986. In 1993, Kai Lee related the experience in the Columbia River basin of using adaptive management concepts to guide decision making in a social and political arena in his book, *Compass and Gyroscope*. Continuing the series in 1995 is the volume *Barriers and Bridges to the Renewal of Ecosystems and Institutions*, which presents a series of case studies on resource management histories and comments by social scientists in order to test ideas about the coevolution of ecosystems and management institutions. Recent ideas of adaptive management appeared in 2002 in *Panarchy*; *Understanding Transformations in Systems of Humans and Nature* which focuses on developing theoretical frameworks for why systems are so surprising based upon cross-scale dynamics (in space and time), and *Navigating Social–Ecological Systems*: *Building Resilience for Complexity and Change* which focused on approaches to management in social–ecological systems.

Adaptive management was proposed to fill three perceived gaps in extant management approaches. The first is to bridge diverging assumptions (mental models or paradigms) of resource dynamics; the second is to integrate differing perspectives among scientific disciplines; and third is to fill the breach between knowledge and action. Adaptive management was originally treated as adaptive environmental assessment and management (AEAM) to describe separate but linked processes of integrated assessment and active management. The main process during the integrative assessment aims to articulate assumptions of resource dynamics and integrate disciplinary perspectives and assess what is known and not known about resource issues. The most common approach at integration is to construct a computer model in a series of workshops that attempts to summarize and synthesize existing information and understanding in order to propose a set of policy options. Those options then generate a set of plausible management actions that help test the uncertainties of managing with incomplete knowledge and information, while confronting complexities of resource systems.

Confronting Complexity

Managed resource systems are inherently complex. One source of complexity is the number of dimensions in resource systems, including ecological, economic, social, political, organizational, among others. Indeed, even each of these dimensions are complex themselves, which leads to difficulties in tractability. The high dimensionality of these issues as well as the lack of common methods and institutions to manage these multiple dimensions has led some authors to apply the phrase `wicked problems' to natural resource issues. Practitioners of adaptive management acknowledge these multiple dimensions and attempt to separate resource issues into scientific (primarily ecological) and social (political) components. Although not always separable, these two categories provide a useful way of discussing the application of adaptive management to resource issues.

One source of complexity arises from differences in paradigms, theories, methods, and practices among academic disciplines that underlie resource issues. Even though many would argue the pragmatic and applied aspects of their work, all applied disciplines have a corollary academic field. For example, conservationists' ideas are rooted in understanding of ecology or biology; engineers in mathematics and physics; planners in geography or architecture. Some ecologists may be very good at understanding and evaluating ecological impacts and yet they often make myopic or inadequate suggestions for action because they are unaware

 doi:10.1016/B978-0-444-63768-0.00635-1

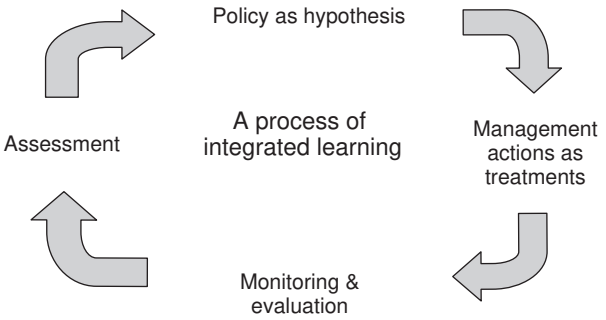

Fig. 1 Flowchart of adaptive environmental assessment and management. The assessment phase integrates existing knowledge to develop policies that are structured for learning about system uncertainties. The policies are tested by management actions and evaluated through monitoring and research.

or dismissive of the realities of human behavior, organizational structures, and institutional arrangements. Another such example is when engineers or managers assume that the uncertainty of nature can be replaced by human attempts to control and stabilize ecological systems. It is not that these approaches are wrong, but that they are partial and require more disciplinary integration. Overcoming disciplinary differences and bridging the gap between theory and praxis has been one of the central purposes of adaptive environmental assessment and management.

Complexity in resource systems leads to difficulties in prediction. All phases of environmental management, assessment, and planning activities involve some estimation about `what will happen'. However, these activities are problematic because of difficulties relating to our abilities to forecast. Certainly, many things are known, especially the broad and the general. However, there are many reasons why our predictive abilities of ecological systems are limited. These include sheer complexities of ecological systems, the wide range of scales of ecological structures and processes, competing ideas about how ecological systems are structured and function, and lack of data/information to test ideas about ecosystems across scales. These same arguments could be applied to the social dimensions of assessment and planning, but include problems of shifting and multiple values that society places on different aspects of ecosystems.

The wide range of spatial and temporal scales over which ecological systems are structured and operate provides another source of complexity. Ecosystems operate over spatial scales from millimeters to thousands of kilometers, and temporal scales of milliseconds to millennia. The cross-scale interaction of processes and structures in ecosystems can lead to surprising behavior. The concept of ecological resilience suggests that ecosystem shifts among alternate states are linked to cross-scale interactions. Examples of such ecological shifts include the transition from grass to shrub dominance in semiarid rangelands, population outbreaks of forest pests, shifts from clear water to turbid water in shallow lakes and similar structural shifts in inland sea systems, as well as shifts between coral and algae dominance in coral reefs. In all of these cases, the transition is mediated by the interaction between slower and faster components in ecosystems. Nonlinearities, alternative ecological states, and the inherent unpredictability of ecosystems suggested by resilience theory are all ecological concepts that underpin adaptive management.

The original works of adaptive management introduced the idea that it is equally important to address uncertainties of resource issues and management actions as it is to state what is known. A number of other approaches have been developed to address and winnow uncertainties. These include processes such as qualitative assessments by knowledgeable persons, judgment of experts, the development of narratives or scenarios, strategic gaming, statistical analyses of empirical or historical data, and causal modeling. Expert opinions are often used in legal situations or where causal understanding or data are lacking. The development of narratives or scenarios has been used successfully to highlight emerging issues or to roughly define feasible alternative futures that contain great uncertainty (such as Rachel Carson's 1962 book *Silent Spring*). Scenario-based planning has been used in business, to address issues of climate change, to explore sustainable futures, or in resource issues fraught with a large number of unknowns (such as the recent Millennium Ecosystem Assessment). While a growing number of theories, methods, and approaches have been developed to confront the ecological and technical components of resource systems, they are but part of the overall complexity of resource issues. As mentioned above, the social dimensions of these problems are as vexing and problematic, as discussed in the next section.

Other sources of complexity in managed resource systems arise from conflicting worldviews and interests of stakeholders. Resource issues most often engage governmental agencies, resources users, and other stakeholder groups, all with competing views and expectations of how ecosystems are valued and should be managed. In the United States, for example, federal agencies such as the Fish and Wildlife Service have responsibilities under the Endangered Species Act, while the Environmental Protection Agency and Army Corps of Engineers each have specific mandates that are not overlapping and can come into conflict with other governmental goals and claims. Nongovernmental organizations (NGOs) and even sovereign entities (First Nations) have taken larger roles in the lobbying, planning, design, and management of resources. Yet difficulties persist and protract the planning and design process due to the number and types of agencies and stakeholders that are engaged. In addition to the complexities due to the number and types of competing interests, another obstacle to integration is in the ways in which these groups interact and resolve differences so that actions can be taken.

The set of laws and bureaucratic structures developed to implement laws appear to generate partial solutions to the myriad problems faced in integrating ecology into all elements of resource management. Moreover, the legal and bureaucratic frameworks are set up in a way that defaults first to administrative processes and second to legal institutions to resolve conflicts or fill in missing pieces. In these frameworks, integration of ecological concerns into other social objectives is rarely achieved. Rather, these partial solutions shortchange ecological concerns. Often this is due to a lack of understanding about the natural systems, or unrealistic expectations about how these systems behave. Sometimes, these partial solutions generate greater ecological problems.

In order to manage these different forms of complexity, adaptive assessment and management was developed to simplify the complex and manage different forms of uncertainty. That is, processes were developed to make the issues tractable, and embrace the recognized uncertainties of managing complex systems. Two separable but related processes were developed and refined over the past three decades (**Fig. 1**). The first process is an integrative assessment that is usually followed by a management or implementation phase. The assessment process identifies uncertainties, points of intervention, and alternative explanations around resource issues. The management phase designs actions that can sort among competing hypotheses while achieving social objectives. Each of these phases is described in the following sections.

Integrative Assessments

Developers of adaptive environmental assessment suggest that an assessment must deal with three questions: (1) how to decompose usually complex resource issues so that they are tractable; (2) how to bring dispersed expertise and information to the problem; and (3) how to effectively communicate results to decision makers and the public. The questions are addressed by a number of techniques all of which have been designed and refined to process information developed in a series of workshops. In the workshops, constructing a computer model is the primary focus of information processing and compilation. The building of the model forces the group to bound the assessment, by defining what components go into a computer model. The model addresses the second question also, by consolidating disparate views of the issue. A number of techniques, including visualization and storytelling, are important and effective in transferring and communicating the results of the integrated understanding.

The objective in building computer models during adaptive assessments is to synthesize and reflect on current modes of understanding, rather than to predict ecosystem behavior. This is because uncertainties arise that are not amenable to uncovering by existing scientific approaches and techniques. Developers of this approach outline three steps in the assessment process: (1) determine resource issues and generate alternative hypotheses of system behavior; (2) develop quantitative approaches to evaluate how uncertainties relate to management options and actions; and (3) use a combination of approaches involving gaming and formal optimization to winnow these options.

The integrative assessment of resource issues begins with identifying management objectives and constraints. Often an explicit set of management objectives such as sustainable or maximum sustainable yield are stated. Implicit objectives arise from people with different backgrounds, training, and without a clear model. Constraints are identified in a larger social or political setting, and hence determine whether policy development is possible or not. These policy and management objectives and constraints are incorporated into a simple computer model.

The construction of computer models is used to integrate disciplinary understanding of ecological dynamics with management objectives. The construction of the model itself is fraught with uncertainty. At least three levels of uncertainty can be dealt with by this technique. Background noise or variation can be dealt with by including feedbacks on variables in a model. Statistical or parametric uncertainty about forms and values of relationships can be assessed by evaluating alternative sets of equations or by estimating ranges or variations of parameters used in the equation sets. Finally, structural uncertainty in models, or what variables to consider in the model, is a matter of judgment, because situations in nature, such as surprises, cannot easily be dealt with even in the most sophisticated models. The body of literature on adaptive management describes how models should be developed with respect to the tradeoffs between model complexity and utility. These models help clarify uncertainties, but usually cannot resolve them by decomposition or research. Some uncertainty can be highlighted by the use of alternative statistical models that assign probabilities or odds on the possible outcomes.

The models are viewed as hypotheses, and as such cannot be validated; they can only be invalidated in the Popperian view of science. The models are caricatures of reality, only including what is essential. Therefore, what is important is model credibility, not validity. It is only after resisting attempts at invalidation that a model becomes credible. One way of attempting invalidation is to compare the model output with historical data (verified data, not interpreted). Another way is that correlation between the model and historical data does not imply causation. Other means of invalidation include trial and error approaches, that is, compare the model predictions with what happens in the real world. There may be natural trials where model output can be compared to natural experiments. One can also compare the behavior of alternative models. Once the models (or sets of models) have resisted invalidation, they can be used to evaluate alternative actions. Proponents of adaptive management suggest that the adaptive assessment phase utilizes models to highlight uncertainties and foster communication but they cannot and should not be used to prescribe specific management actions. Most management decisions are gambles because of the inherent uncertainty of outcomes of a management action. In essence, the development of credible or plausible models helps determine what is not feasible, rather than specify a particular set of actions. Indeed, the most important outcome from the assessment phase is to identify a set of alternative policies that can be discussed in the social–political arena.

Once a set of alternative policies has been developed, it is important to communicate these results to policy makers. A number of techniques have been developed, including audiovisual presentations (slide shows, story boards, and computer animations) that attempt to simplify the complexities of both the analysis and results. Communication of alternative potential policies to social and political entities of the resource system should start early in the assessment process. Decision makers and the public should be actively involved from the beginning, rather than passively informed at the end. There are three arguments made for doing this: (1) that it is a fairer way of making social decisions; (2) that participation of stakeholders in a decision process increases the likelihood that they will accept the outcome; and (3) that people bring important knowledge to assessment process that will improve its quality.

Adaptive assessments have been applied to hundreds of resource issues around the world over the past three decades. Some of the assessments resulted in no future activity. Some have led to the development of new monitoring programs, especially in the cases where insufficient data were available for sorting among competing explanations, whereas other assessments led to dramatic transformations in understanding and new management efforts. Unless the assessment can generate an agreed-upon set of actions for testing the uncertainties of the system, it is unlikely that the system will move into the adaptive or active management phase.

Adaptive Management

Once a policy is chosen, then two implementation activities are launched: management actions and monitoring. The implementation phase is the experimental phase, in which hypotheses are challenged, that is, the policy is subject to invalidation.

The design of management actions covers a wide range of options, in terms of the scientific rigor. In an experiment, all sources of variation are identified, and used in the design. In the adaptive sense, some of the variations can be accounted for, but unforeseen dynamics are likely to appear. Two types of adaptive management have been identified, active and passive. Actively adaptive actions probe the sources of variation; hence, actions cover a wide range of possible treatments in order to uncover a wide range of system response. The passively adaptive approach lets natural processes provide the sources of variation.

Monitoring should be the means by which policies are tested and evaluated, rather than collecting data for the sake of gathering information. Monitoring is the way in which policies are put at risk of invalidation. It should involve key variables in the system and choice of these key variables is critical. Variables to be monitored are critical ecosystem processes identified in the modeling exercises. The information developed from monitoring should be useful for future learning. The usual limitations on fiscal and human resources should not decide what variables to monitor, but be used as way of forcing the important variables into monitoring.

Summary

Prior experience indicates that adaptive environmental assessment and management has been successful at identifying key points of intervention and developing lurches of understanding. That is, they have led to new management actions and improved understanding of resource dynamics. These include situations of adaptive waterfowl harvest in North America, harvest of fisheries in the reefs of Australia, and sediment transport in the Grand Canyon. Many other cases, however, point to a failure of adaptive management due to institutional rigidity, bureaucratic inertia, lack of ecological resilience, and lack of social capital in the form of trust and cooperation. Adaptive assessment and management is one approach that can help bridge the gap between science and resource management, but its implementation requires a small set of agreed-upon hypotheses, sufficient resources to conduct and evaluate experiments, and a social willingness to accept failure at appropriate scales.

Adaptive management proposes that ecological management be viewed as a series of experiments rather than the application of a solution. Adaptive management is an ongoing process that combines assessment with management actions that are structured in a way to learn about the complexities of system dynamics as well as to achieve social objectives. Assessing a system requires synthesizing available data to generate a set of competing alternative hypotheses about particular sets of resource problems and social objectives. Management actions are designed to sort among alternative hypotheses, prior to implementation. These actions are evaluated by monitoring key system indicators. While these activities are described linearly, adaptive management usually is designed to be an iterative process that develops a social dialog about a system. Modifying and creating ecological management institutions is difficult. Consequently, one of the main challenges of adaptive management is to develop new ways to enable social learning and experimentation.

The Anthropocene

Clive Hamilton, Charles Sturt University, Canberra, Australia

Origin of the Term

At a workshop in Mexico in 2000, the atmospheric chemist Paul Crutzen became frustrated at the repeated references to the Holocene. "Stop using the word Holocene", he interrupted. "We're not in the Holocene any more. We're in the . . . the . . . the . . . (searching for the right word) . . . the Anthropocene" (Steffen, 2013: 486). Those assembled immediately concurred that the Earth had entered into a new geological epoch to succeed the Holocene. The rapid increase in the concentration of carbon dioxide in the atmosphere due to the burning of fossil carbon and its cascading effects throughout the Earth System is the principal reason for agreeing that the planet had shifted out of the previous epoch.

The new idea quickly caught on and spread, initially though two short articles by Crutzen (one coauthored) (Crutzen and Stoermer, 2000; Crutzen, 2002). The work of Earth System scientists around the world soon became organized around this powerful, new concept.

At one level, the definition of the Anthropocene is straightforward. It refers to the very recent rupture in the functioning of the Earth System as a whole arising from the impact of human activity (Hamilton, 2016a: 251). This definition is conceptually rich and requires explanation. In particular, the concept of "the Earth System" is very new and often misunderstood. The kinds of human activity capable of disrupting the Earth System have to be separated from those that merely alter the landscape or interfere in an ecosystem. And (as we will see) the claim that the rupture is "very recent" has been a matter of intense scientific debate (although it is now largely settled).

Before beginning to explore these ideas it's important to remind ourselves that the Anthropocene is put forward as a new epoch to be added to the Geological Time Scale (GTS). The Scale divides the Earth's 4.5 billion-year history into ages, epochs, periods, eras and eons in ascending order of significance. The Earth entered the Holocene epoch around 11,700 years ago when the planet began to warm rapidly from an ice-age freeze. It is a division of the Quaternary period (of the Cenozoic era) that began some 2.58 million years ago. Around 10,000 years ago the Earth's mean temperature stabilized at a level close to the one that prevailed until the start of the industrial revolution some two centuries ago.

The International Commission on Stratigraphy (ICS) is the body formally charged with responsibility for deciding on the divisions of the Geological Time Scale (GTS). Stratigraphy is the branch of geology specializing in the study of rock layering and what it can tell us. In 2009 it created the Anthropocene Working Group (AWG), chaired by geologist Jan Zalasiewicz, to prepare a report on the case for adding the Anthropocene as a new epoch to the GTS to succeed the Holocene. The AWG now faces an intellectual challenge because the new division has been proposed not by geologists digging down into the rock layers but by Earth System scientists observing changes in the Earth System "above ground." The coming together of stratigraphy and Earth System science is provoking creative tension leading to new scientific insights. At the time of publication, a formal decision about the Anthropocene had not been made, but there is no doubt that work on this rich and potent idea will continue to grow.

Earth System Science

The idea of the Anthropocene cannot be properly understood except in the context of the emergence of Earth System science. Thomas Kuhn's language of "paradigm shift" and "scientific revolution" (Kuhn, 1962) has often been applied too freely, yet it seems to be justified in this case. (This section and the next draw heavily from Hamilton (2016b) and Hamilton and Grinevald (2015). I owe a large debt to Jacques Grinevald for helping develop much of the analysis in this section, including the intellectual history of the concept.) If a paradigm is a distinct set of assumptions and patterns of thought then there can be no doubt that Earth System science represents a strikingly new way of thinking about the Earth as an object.

The emergence of Earth System science can be traced in the following terms (Hamilton and Grinevald, 2015). The foundations were laid in the 1950s, during the Cold War, when oceanographic and atmospheric sciences were transformed and globalized with the emergence of early computers (Edwards, 2010: 129ff). Numerical weather prediction for large regions became routine only in the 1960s, but it is worth noting that the notion of a *global* climate (one of the components of the Earth System) became widely accepted by scientists only after the Second World War. Except for a few speculative commentaries, "the climate" had previously been considered a local or regional phenomenon. A popular handbook still being published in 1961 argued that "the notion of a global climate made little sense" because the weather is too changeable between the poles and the tropics (Edwards, 2010: 67–9).

Systems ecology was developed in the 1960s, notably within the Radiation Ecology Section of Oak Ridge National Laboratory, itself an outgrowth of the Manhattan Project that developed the atom bomb (Coleman, 2010). The Laboratory became an important center for understanding the CO_2-energy-climate problem, leading to the creation of the Carbon Dioxide Information Analysis Center in 1982. Biophysical modeling of the biosphere (building on legacy of the great Russian geologist and geochemist Vladimir Vernadsky) was developed in the 1980s by Russian scientists in collaboration with Western colleagues at the International Institute for Applied Systems Analysis and later at the Potsdam Institute for Climate (Jørgensen, 2010).

Within these increasingly global ways of thinking, scientists began to understand the Earth as a total functioning entity composed of a number of interacting "spheres"—the atmosphere, the hydrosphere, the cryosphere, the biosphere and the lithosphere. In particular, climatologists built a deeper conception of the climate as a global phenomenon, and not one confined to the atmosphere, with expanding understanding of the ocean-atmosphere circulation.

This emerging notion of the Earth as a total functioning entity would be married to the new conceptual approach known as system dynamics. The computer-based methodology of system dynamics was developed by Jay W. Forrester at Massachusetts Institute of Technology in the 1950s. Initially it was applied to social systems. An invitation from the Club of Rome to apply it to the functioning of Earth as a complex "world ecosystem" led to the influential and controversial book *The Limits to Growth*, published in 1972 (Meadows et al., 1972). System dynamics brought to Earth science essential concepts for thinking about the Earth as an entity that behaves as a *complex system* rather than as a set of cause-and-effect processes.

The complexity of a complex system goes beyond the idea that relationships between variables are complicated. It means the system is more than the sum of its parts because it has certain properties that are inherently difficult to represent in mathematical models. They include: nonlinearity, so that a tiny change somewhere can bring about a very large change somewhere else; feedback loops, which dampen or amplify a change leading either to system stability or run-away change; self-organization, so that the system spontaneously creates order out of chaos; and, most puzzlingly, emergent properties, that is, properties that belong to the system but cannot be found in any individual element of it, so that something new can emerge with no apparent cause.

It was into this flux of emerging ideas that in 1974 James Lovelock and Lynn Margulis introduced the Gaia hypothesis, the idea that life and the Earth's nonliving environment form "a self-regulating system that maintains the Earth's climate and the composition of the atmosphere in a habitable state" (Lenton 2016: 4–5). The Gaia concept was a forerunner of the Earth System; both reject the idea that the Earth is a fixed, static ball of rock on which the other components develop and move. The scientific establishment (with rare exceptions) rejected the Gaia hypothesis, often vehemently, not least because it challenged the basis of the theory of evolution, according to which all causation runs one way, from the natural environment to the development of living entities (Lovelock, 1988: xiv–xv). The hypothesis has undergone substantial modification since then, but its foundational idea of the Earth as a system whose components evolve together is close to that of the conception of the Earth being developed by Earth System science.

Meanwhile, scientists had been developing instruments to measure changes in global processes. Sometimes in science, new instruments give rise to new thinking and occasionally to great conceptual breakthroughs (Shapin and Schaffer, 2011). Three measurement projects should be noted: the launch from the 1970s of artificial satellites to monitor, inter alia, global change in air pollution, land cover and solar radiation fluxes; the recording of variations in atmospheric CO_2 at the Mauna Loa Observatory in Hawaii by Charles David Keeling from the late 1950s (Keeling, 1970); and, the revelations of ice core drilling in Antarctica which began in the early 1980s (Jouzel et al., 2013). Insights from these measurement projects nudged scientists toward a firmer grasp of the globality, complexity and systemic nature of the Earth.

In addition, worldwide programs on measuring biogeochemical cycles had begun in the 1970s. The first reports on the global carbon (and other biogeochemical) cycles, the greenhouse effect and climatic change (Bolin et al., 1986) played a vital role leading into the first report of the Intergovernmental Panel on Climate Change in 1990. As climate scientists have explored the global climate system more deeply they have come to realize that climate change is not only (or even predominantly) a phenomenon of the atmosphere but is tightly connected with changes in the hydrosphere, the cryosphere and the biosphere, and even the lithosphere in the form of earthquakes, volcanism and new kinds of sedimentation (McGuire, 2012).

In the 1980s, scientists became increasingly concerned about the impact of human activity on the planet as a whole, beyond the damage being done to local or regional environments. Evidence of the dangers to life from the expanding hole in the stratosphere's ozone layer and from global warming due to burning fossil fuels led them to build global monitoring networks and to explore the interactions of the various components of planetary processes through elaborate models that attempted to capture the connections between the major processes governing the Earth. As Zalasiewicz et al. (2017: 208) would observe: "it was long the case that most of the geological community thought of the human impact on the Earth's geology as trivial and fleeting by comparison with large-scale geological processes acting over millions of years. That general opinion began to change in the second half of the 20th century . . .". The emerging paradigm of Earth System science led in 1986 to the launch of the International Geosphere-Biosphere Programme (IGBP), which would become the institutional heart of global ecology and Earth System thinking (Grinevald, 1990; Steffen and Tyson, 2001).

The Earth System and the Anthropocene

In their textbook, Charles Langmuir and Wally Broecker provide a concise definition of the Earth System.

> The various parts of the Earth system – rock, water, atmosphere – are all involved in interrelated cycles where matter is continually in motion and is used and reused in the various planetary processes. Without interlocked cycles and recycling, Earth could not function as a system. . . . In the last fifty years or so we have come to recognize the movements in all Earth's layers, including the plates at the surface, the mantle and the core as well as the atmosphere and ocean (Langmuir and Broecker, 2012: 20, 22).

Earth System thinking, which emerged fully in the 1990s, is the integrative metascience of the whole planet as a unified, complex, evolving system beyond the sum of its parts. It is a transdisciplinary and holistic approach integrating earth sciences and life sciences, as well as the "industrial metabolism" of humankind, all within a systems way of thinking, with special focus on the nonlinear dynamics of a system. (With thanks to Jacques Grinevald for helping formulate this definition.) By contrast, ecological thinking, which emerged fully in the 1960s and 1970s, is the biological science of the relationship between communities of organisms and their local environments. While ecological thinking may or may not draw on systems concepts (much practical ecology deploys cause-and-effect thinking), Earth System science could not exist without systems thinking. The gulf between the two remains even when local environments are aggregated up to the "global environment." The global environment thought this way is not the Earth System, understood as the Earth taken as a whole in a constant state of movement driven by interconnected cycles and forces, from the planet's core to the atmosphere and out to the Moon, and powered by the flow of energy from the Sun. It is a single, dynamic, integrated system, rather than a collection of ecosystems.

Now that we are clear about what the Earth System is (and when the idea emerged), we can gain a proper understand of the Anthropocene. In what might be regarded as the canonical statement on the Anthropocene, the new epoch is defined by the fact that the "human imprint on the global environment has now become so large and active that it rivals some of the great forces of Nature in its impact on the functioning of the Earth system" (Steffen et al., 2011: 843). Some authors have claimed to have found "precursors" of the concept in the work of natural scientists going back as far as the late 19th century. It is claimed that, among others, Antonio Stoppani (in 1873), G.P. Marsh (in 1874), Vladimir Vernadsky (in 1929), Pierre Teilhard de Chardin (in 1925) and Edmund Le Roy (in 1927) developed the idea of humankind as a significant geological or morphological force and thereby discovered the essential idea of the Anthropocene.

However, Hamilton and Grinevald (2015) argue that none of these earlier scientists could have grasped the Anthropocene as a disruption to the functioning of the Earth System because the concept of the Earth System did not emerge until the 1980s and 1990s. Instead, they were referring to spreading human impact across the Earth's surface, a phenomenon of the landscape or ecosystems or in some cases the local or regional climate. And instead of being a rupture, the change they identified was understood as a continuous one. None had a conception of disturbance to global biogeochemical cycles; as we saw, even the climate was understood as a regional phenomenon rather than a globally integrated system until the 1950s.

The effect of finding precursors is to gradualize the new epoch so that it is no longer a break in the functioning of the Earth System due primarily to the burning of fossil fuels. Finding these alleged precursor concepts actually "undermines the radical novelty of the concept and the actuality of the proposed new geological epoch" and thereby "misconstrues the suddenness, severity, duration and irreversibility of the Anthropocene . . ." (Hamilton and Grinevald 2015: 3, 8–9).

Not long after Crutzen conceived the concept of the Anthropocene, others began to appropriate the concept of the Anthropocene into their own ways of understanding, at times distorting its meaning. The pioneers of the Anthropocene—mainly Paul Crutzen, Will Steffen, John McNeill, Colin Waters and Jan Zalasiewicz—have repeatedly reminded us that the concept holds water only if it can be shown that humans have had a *detectable* impact on the *functioning of the Earth System*. It's worth belaboring this point: the fundamental test of the Anthropocene is whether human activity disturbs the functioning of the Earth System as a whole, does so discernibly, and is outside the range of natural variability (Steffen et al., 2007).

Much of the debate has centered on the question of when the Anthropocene can be said to have begun. Initially, Crutzen and his coauthors identified its beginning at the end of the 18th century with the onset of large-scale coal burning to power the Industrial Revolution in England. More recently, the Anthropocene Working Group has argued that the new epoch is better dated from the years after the Second World War when the impact of humans on the Earth System as a whole was unmistakable (Zalasiewicz et al., 2015a). The decades after the War have been dubbed "the Great Acceleration," years in which there was "a sharp step change in the nature, magnitude, and rate of human pressures on the Earth System, driving impacts that push the system beyond the Holocene basin of attraction" (Steffen et al., 2016: 336). Within that basin of attraction negative feedbacks keep the system in a state that is recognizably Holocene.

In 2003, palaeoclimatologist William Ruddiman published a paper arguing that the Holocene-Anthropocene shift occurred not at the end of the 18th century with the Industrial Revolution but 5000–8000 years ago with the onset of forest clearing and farming, which led to enhanced levels of CO_2 and CH_4 in the atmosphere (Ruddiman, 2003). However, Ruddiman's interpretation of the data turned out to be unpersuasive. Crutzen and Steffen (2003) pointed out that human impact on the Earth System 5000 to 8000 years ago is not discernible in the data, and certainly was not large enough to upset permanently the stability of the Holocene Earth. The data do show a shift occurring in the late 18th century, the beginning of the Industrial Revolution. And the charts also show an incontrovertible leap after World War Two.

> The mid-twentieth century was a pivotal point of change in the relationship between humans and their life support systems. The period of the Anthropocene since 1950 stands out as the one in which human activities rapidly changed from merely influencing the global environment in some ways to dominating it in many ways (Crutzen and Steffen, 2003).

A number of other analyses have rejected the evidence for Ruddiman's early Anthropocene hypothesis, leading the Intergovernmental Panel on Climate Change to conclude that it is not clear that the small and very slow changes in CO_2 and CH_4 from around 8000 years ago were due to human activity, let alone were sufficient to change the course of the Earth System (Ciais et al. 2013, 483–5 & Fig. 6.6).

A number of analysts have interpreted the Anthropocene as no more than the continuation of human impacts on the landscape or ecosystems. If true, then it is not a disruption to the functioning of the Earth System. This has been taken to its furthest point by Ellis who claims that humans

> have been reshaping the terrestrial biosphere, and perhaps even the global climate, for millennia. The entire past 11,000 years of the Holocene might simply be renamed the Anthropocene (Ellis, 2013: 32).

In this view the Anthropocene is just another name for the Holocene. How is such a conclusion possible? The words to notice in the quoted passage are "the terrestrial biosphere," human changes to which are enough, in Ellis's view, to define a new geological epoch. This misinterpretation of the Anthropocene arises from a misunderstanding of Earth System science. Ellis believes earlier work on biomes and anthromes—where anthromes are global ecological patterns influenced by human activity—can be simply scaled up to get to the Earth System, a reading that misses the significance of the Earth System.

Elsewhere, Ellis and Ruddiman have asked: "Does it really make sense to define the start of a human-dominated era millennia after most forests in arable regions had been cut for agriculture . . .?" (Ruddiman et al., 2015). The answer is "yes," if those human activities did not change the functioning of the Earth System. The pioneers of the Anthropocene concept have always written of the new epoch *in contrast to* the Holocene as a geological epoch, never in terms of landscapes or ecosystems modified in the Holocene. None of the leading exponents of Earth System science believes that changes in the terrestrial biosphere alone can bring about a new epoch, and even less so if we are thinking of vegetation and landscape ecology (Lenton and Williams, 2013: 382).

The writing of the new geological epoch into established ways of thinking is an instance of what Kuhn called "drastically restricted vision" (Kuhn, 1962). A similarly restricted vision has come from a contribution from archeology. Again, the issue is the starting date of the new epoch. In a paper titled "The onset of the Anthropocene", the abstract begins:

> A number of different starting dates for the Anthropocene epoch have been proposed, reflecting different disciplinary perspectives and criteria regarding when human societies first began to play a significant role in shaping the earth's ecosystems (Smith and Zeder, 2013).

One need not read past this sentence to know that the authors have misconstrued the new epoch, and that their conclusions about the onset of the new epoch must be mistaken. It's the very last letter, the "s" in ecosystems, that gives it away. The Anthropocene does not begin when humans first play "a significant role in shaping the earth's ecosystems"; it begins when humans first play a significant role in shaping the *Earth*, that is, the Earth that evolves as a totality, as a unified, complex system comprised of the tightly linked atmosphere, hydrosphere, cryosphere, biosphere and lithosphere. It is not about changes to ecosystems except insofar as ecosystems are affected by changes in the functioning of the Earth System.

It is also possible to misread the nature and significance of the Anthropocene by viewing it through the lens of geography. Reprising the "pre-Columbian Anthropocene hypothesis" of Dull et al. (2010), Lewis and Maslin (2015) locate the start of the new epoch in 1610. They put forward a complex narrative covering the colonization of South America, introduced diseases, depopulation, forest regrowth, trans-continental trade, species exchange and pollen counts, all of which are said to be associated with a small dip of 10 ppm in the atmospheric concentration of CO_2 in 1610. However, the analysis failed to show numerically that the dip in CO_2 changed the functioning of the Earth System or was caused by human activity (Hamilton 2015), and a number of Earth System scientists pointed out that in the pre-industrial Holocene there were many comparable dips in atmospheric CO_2 concentration and that a change of 10 ppm is well within the range of natural variability in the Holocene (Zalasiewicz et al., 2015a, b).

A common feature of these misreadings of the Anthropocene through lenses other than that of Earth System science is that, by treating the new epoch as a continuation of landscape or ecosystem change going back centuries or millennia, they divorce it from modern industrialization and the burning of fossil fuels. In this way they miss the central fact that the Anthropocene represents a rupture in Earth history (and so deprive it of its dangerous quality).

An interesting attempt to bridge the gap between Earth System science and other disciplines has been put forward in the form of the concept of the Palaeoanthropocene," "the period from the beginning of human effects on the environment to the beginning of the Anthropocene" (Foley et al., 2013). The beginning of the Palaeoanthropocene would then be diffuse (including all of the Holocene and much of the Pleistocene), associated with local rather than global events, and not be linked to geological boundaries or changes in the functioning of the Earth System. All of the erroneous concepts of the Anthropocene discussed above would fall into this pre-Anthropocene zone, with the Anthropocene reserved for describing the era of disruption in Earth System processes.

Reconciling Earth System Science With Stratigraphy

One of the prime objectives of ongoing research on the Anthropocene is to identify a suitable stratigraphic signature in rock or soil sediments or in ice layers that can be used to meet the criterion for the declaration of a new geological epoch (Waters et al., 2016). There are plenty of deposits that might suit, including "technofossils" like concrete and plastics, black carbon and spherical carbonaceous particles showing up in sediments worldwide from around 1950, and geochemical signatures like pesticide residues and polyaromatic hydrocarbons. Along with elevated CO_2 and CH_4 concentrations in the atmosphere, these "novel signatures" signal the impact of humankind on the functioning of the Earth System and provide indicators of the persistence of that impact.

There have, however, been some important criticisms of the proposal to add the Anthropocene to the GTS. A full review is not possible here, but they have been detailed and replied to by Zalasiewicz et al. (2017). One consequence of these critiques is that the AWG has been more explicit about its determination to make the case for a new epoch using strictly stratigraphic criteria and to eschew "above ground" indicators of Earth System change.

One of the more telling criticisms of the Anthropocene concept is that, unlike all previous divisions in the GTS, the proposed new epoch emerged not out of stratigraphy (digging down through rock layers) but by observation of human impact on the Earth System (Finney and Edwards, 2016). It therefore represents a kind of "geology of the future", which is highly uncertain. Zalasiewicz et al. (2017) acknowledge this break with established methods, and concede that formal acceptance of the proposed epoch must hinge on stratigraphic evidence. But they note that the Anthropocene concept arises from the entirely unexpected overlap of geological time with (human) historical time. This suggests two important observations.

First, the Anthropocene proposal poses the new question of whether and how the established boundaries in the GTS—which are often defined by a major change in the Earth's biota captured in the fossil record—demarcate shifts in the functioning of the Earth System. The relationship between them is described by Zalasiewicz et al. (2015a) as follows:

> An effective geochronological and chronostratigraphical boundary often reflects a substantial change in the Earth system, so that the physical and chemical nature of the deposits, and their fossil contents, are recognizably different above and below the boundary.

The association between the boundaries and shifts is prompting new thinking about what happened in the Earth System at some of those major boundaries.

Second, the mixing of geological time and historical time gave rise to a seminal observation that has had a profound impact among social scientists and humanities scholars thinking about the Anthropocene. The observation was made by the historian Dipesh Chakrabarty who noted that the arrival of the Anthropocene represents the "the collapse of the age-old humanist distinction between natural history and human history," two kinds of history that had always existed in entirely separate realms (Chakrabarty, 2009: 201).

Social Science and the Anthropocene

Kinds of Critique

No more than a quick overview is possible here, but the idea of the Anthropocene has attracted intense interest from social scientists and humanities scholars. It has attracted very little interest from philosophers, although Danowski and Viveiros de Castro (2017) is a notable exception. For social scientists, the new epoch's arrival is telling us something novel and profound about humankind's relationship with the Earth. In addition, the idea itself is lobbed like a hand grenade into a deep epistemological divide among social scientists, that is, a disagreement over the nature and scope of kinds of knowledge. While some have fruitfully analyzed the scientific and para-scientific discourses around the concept (Bonneuil and Fressoz, 2016), among the interpretations and developments of the new concept two broad epistemological approaches are evident.

One, which I will call humanist, takes as given the facts presented by Earth System science and asks about the social and philosophical meaning of the changed physical relationship between humans and the Earth, and how to respond to it. In this view, the advent of the Anthropocene shows up the disastrous consequences of the contradiction between human separation and domination of nature and our unavoidable dependence on it. In the light of our deeper understanding of our ecological entanglement in ecological processes, the modern philosophical distinction between nature and society remains valid, although the collision of natural history and human history in the Anthropocene, arising from the fact that humans have become a force of nature (Chakrabarty 2009), complicates and weakens the distinction. However, Hornborg argues that the "physical mixing" of nature and society does not invalidate the analytical distinction between them (2015: 58).

For the other approach, which I will call posthumanist (also known as new materialist), the distinction between the human and the natural, known as Cartesian dualism or the subject-object split, has never been valid, and the arrival of the Anthropocene is seen as a vindication (Latour 2017: 3). (Posthumanists writing in this domain are often influenced by the work of Bruno Latour (1993, 2014).) Unlike the humanists, the posthumanists challenge the epistemological priority given to the Earth System science underlying the Anthropocene, arguing that since the Anthropocene is a human-dominated epoch "the facts" are as much in the domain of the social sciences as the physical sciences (although to make this claim they must draw first on evidence generated by Earth System science.)

The difference between the two approaches reflects the split in philosophy and the social sciences that opened up in the 1970s with the emergence of what is sometimes named postmodernism, that is (in the present context), a rejection of the notion of objective truth and the assertion that all claims to knowledge are socially constructed and therefore the products of social and historical conditions. In this view, the scientists' Anthropocene—both the idea of it and even the epoch itself—is subject to interpretation by understanding the social conditions that gave rise to it.

Humanist Analysis

Scholars in both camps have taken exception to Paul Crutzen's term for the new epoch. To name the new epoch "the Anthropocene" seems to attribute the shift in the Earth System to the actions of humankind as such, *anthropos*, whereas in fact it was brought on by the actions of a rich, white minority. Malm and Hornborg (2014) write that if we talk of "the geology of mankind in general" then the new epoch "must have its roots in the properties of that being." Yet it is *divisions* between humans rather than any homogeneity that we must look to for the origins of "sociogenic" climate change. This argument has led to a proliferation of alternative names, such as the Capitalocene, the Technocene and the Econocene.

Scholars working in the broad Marxist tradition have integrated the new science of the Anthropocene into their critique of capitalism. Foster et al. (2010) write that the Anthropocene highlights the disastrous "ecological rift" between humanity and nature that is embedded in modern capitalist society. In that society, humanity is alienated both from itself and from nature, and this alienation is so entrenched that humans are on the verge of destroying the conditions of life. In a way that is structurally inescapable, the system places its survival first, and solutions to the ecological crisis must be made to work around it. They identify traditional social science as part of the problem.

Angus (2016) analyzes the contradictions of "fossil capitalism," in which fossil fuels in the hands of powerful corporations have permitted enormous improvements of human health and wealth yet which now threatens to destroy it all. The Anthropocene is properly understood as a biophysical phenomenon, but it is also a socio-ecological one representing a shift in the relationship between human society and the rest of the natural world. Only by understanding the social origins of the Anthropocene in capitalism can we find an answer to the looming crisis, and that is the replacement of capitalism with societies that are radically egalitarian and fully democratic, operating on the best ecological principles.

Humanists accept that our embeddedness in networks of biophysical relationships constrains and complicates what humans can do; but, in contrast with the posthumanists, they do not accept that this embeddedness redefines and deflates human *agency*. Traditionally in sociology, "agency" refers to the capacity of free beings to act independently, and is posed in opposition to the power of social structures (like social classes) and institutions (like governments) to guide and constrain individual behavior. While posthumanists (as we will see) take agency away from humans and discount political action to effect social change, humanists reject what they see as an essentially conservative political philosophy that denies political agency and therefore the capacity to bring about the radical social changes needed to respond to the climate crisis and the Anthropocene.

Posthumanist Critique

Many social scientists have interpreted the arrival of the Anthropocene as proving the danger of anthropocentrism—the predisposition of modernity to which they are most strongly opposed. Anthropocentrism is the assignment to humankind a moral and practical right to exploit nature in its own interests. *Anthropos* is "central" in the sense that the rest of nature is understood through human experience and values. For moderns, this standpoint gives humans the right to dominate and exploit other creatures and natural systems for their own benefit. Although the critique of anthropocentrism had been made by eco-philosophers for some decades, it has been taken up by posthumanist philosophers. For them, the idea of the Anthropocene can be critiqued by extending the catalogue of "essentialist" assumptions embedded in European colonialism, that is, Eurocentrism, androcentrism and racism. Moore puts it bluntly: "Just as we have been learning to move beyond the dualisms of race, gender, sexuality, and Eurocentrism over the past four decades, it is now time to deal with the source of them all: the Nature/Society binary" (Moore 2015: 4).

Humanists, by contrast, do not identify a generalized belief in anthropocentrism as the source of our predicament. They locate the problem in a social structure that treats the natural environment as an endless, exploitable resource in the pursuit of profits and growth.

For posthumanists, anthropocentrism is possible because of the modern Cartesian split between subject (the human agent) and object (the world of things it acts on), a division now shown as impossible by the evidence of humankind's deep entanglements with the natural world (Bennett, 2009). So, for example, primates are more like us than we realize; natural systems and resources have shaped our cultures deeply; our gut fauna influences how our brains work. Morton (2015) writes that "simply allowing nonhumans to be what they are, namely entangled with us in all kinds of strange ways, neither absolutely reducible to human access nor completely divorced from it". Haraway (2015) tries to overcome dualism by arguing that both "nature" and "human" are cultural categories.

Drawing on ecological science, the posthumanists extend the postmodernist argument that ideas have no objective truth, because they are products of social conditions and structures, to argue that our *physical selves* have no independence because we are deeply embedded in the natural world, just as other creatures are. They use this fact to criticize all beliefs in anthropocentrism. (Curiously, they reject the central role of humans precisely at the time, in the Anthropocene, of humankind's greatest power.)

Determined to prick the bubble of human hubris and deny any view that humans have the right to dominate nature, posthumanists draw on the entanglement of humans in nature to diminish or "redistribute" agency through the natural world. Other creatures and even natural processes and objects are attributed agency. For critics of posthumanism, it makes no sense to attribute agency to a mollusk except by changing the meaning of agency. Hornborg (2017) helpfully draws a distinction between nonliving objects that have *consequences*, living entities other than humans that have *purposes* (due to their sentience and communication), and humans who have *intentions* (because they can reflect on their purposes). When agency is stripped of all element of choice it becomes mere influence.

And, argues Hamilton (2017), posthumanists make an epistemological mistake in regarding human domination of nature as a form of oppression equivalent to racism or androcentrism. The other targets of postmodern critique were forms of discrimination characteristic of relations between people (among human subjects), while anthropocentrism applied to the relationship between humans and the natural world (blithely crossing the boundaries between subjects and objects or nonhuman subjects). The arrival of the Anthropocene is a resounding affirmation of the extraordinary power of humans, yet at this very moment posthumanist theorists are attempting to cut humans down to size and deflate their power and significance to the planet.

In the Anthropocene, it is necessary to recognize *both* the ecological truth that humans are embedded in nature in a thousand ways, but also that we have unprecedented power in nature. We therefore need to draw a distinction between, on the one hand, anthropocentrism as a description of the uniqueness of humans as a species and our actual power on Earth, and, on the other, the attitude of arrogance and mastery over nature that has led to the new epoch, and which manifests in ecomodernists' calls for geoengineering schemes that aim to regulate the planet's functioning. A "new anthropocentrism" has been proposed (Hamilton 2017) as a way of acknowledging humankind's exceptional, real power on Earth and an attitude of caution and modesty in the face of the Earth System's essentially uncontrollable and unpredictable power.

Acknowledgments

I am grateful to Alf Hornborg for helpful comments on a draft.

Biophilia

SR Kellert, Yale University, New Haven, CT, USA

Biophilia is defined here as the inherent human inclination to affiliate with natural systems and processes, most particularly life and life-like (e.g., ecosystems) features of the nonhuman environment. The notion of biophilia advances the idea that people's physical and mental well-being remains reliant on contact with natural systems and processes. This dependency reflects the fact that humans evolved in adaptive response to the fitness and survival requirements of a largely natural and not artificial or human-constructed world. In other words, the evolutionary context for the development of the human mind and body largely was a sensory challenging and diverse natural environment with critical elements being light, sound, odor, wind, vegetation, landscape, water, animals, and more that provided much of the basis for human learning and maturation.

The emergence during the past 5000 years of small- and large-scale agriculture, technology, industry, and the city represents but a small fraction of human evolutionary history. It is unreasonable to assume, thus, that human physical and mental well-being may have escaped the dictates of a largely natural environmental evolutionary context. Yet, many people in modern society assume that human distinctiveness, progress, and civilization reflect our species' capacity to separate from, if not transcend, our biological roots. This entry views this assumption as an illusion, and instead advances the idea that contact with natural systems and processes remains an anvil on which human fitness, health, and productivity continue to be forged, even in an increasingly fabricated urban world.

Biophilia is manifest in a range of genetically encoded tendencies to attach meaning to and derive benefit from, in effect value, the natural world. Nine biological inclinations to value nature have been identified, each reflecting a range of adaptive benefits instrumental in human physical, emotional, and intellectual fitness and well-being. This view of ``the human mind…in evolutionary perspective,'' presumes when these values are adaptively expressed they enhance human performance and development. In other words, these values are regarded as not vestigial in the sense of having evolved in an environmental context no longer relevant to modern life. Collectively, the nine values continue to reflect the richness of the human reliance on natural systems for fitness and security, a web of relational dependency so pronounced an ethic of concern for nature can emerge from a broad understanding of human self-interest from continuing contact with natural systems and processes. **Table 1** provides brief definitions of each of the nine values of biophilia and associated adaptive benefits.

Biophilia is, however, a `weak' biological tendency greatly dependent on learning, experience, and sociocultural support to become functionally manifest. The biophilic values are not `hard-wired' instincts, but rather genetically programmed tendencies that rely on sufficient stimulation and reinforcement to functionally occur, although as `genetically prepared learning rules' they can be easily triggered and learned relatively quickly. Like so much of what makes humans unique, biophilia is subject to people's choice and free will as they respond to their weak biological urges. We may be born with the inclination to affiliate with natural systems and processes, but this tendency remains nascent and atrophied in absence of stimulation and reinforcement. The `genius' of humanity is its extraordinary capacity for learning, creativity, and cultural construction in response to weak inherent tendencies. This ability to affirm or deny much of our biology has fostered considerable human invention and the ability to change and progress. Yet, this adaptability and innovative capacity is ultimately subject to the dictates of biology. Not all individual and cultural creations are functional over time, and some eventually prove damaging and destructive. Human creativity and free will is, thus, a two-edged sword, carrying both the potential for positive innovation and negative self-destruction.

As noted, biophilia is highly dependent on learning, experience, and social support to become functionally manifest. Biophilia can, therefore, be classified as a `biocultural' phenomena, where each biophilic value is the product of both genetics and cultural construction. Considerable diversity consequently occurs in the content and intensity of each value in response to the influences of learning, history, and geography. Yet, this variability is bound over time by the requirements of biological fitness. Each value hypothetically occurs along a continuum where considerable `normal and functional' variation is encountered, but where

Table 1 Typology of values of biophilia

	Definition	*Adaptive benefits*
Esthetic	Physical appeal and beauty of nature	Inspiration, harmony, security
Dominionistic	Mastery and physical control	Physical prowess, self-confidence, mastery skills
Humanistic	Emotional attachment to aspects of nature	Bonding, cooperation, companionship
Moralistic	Spiritual reverence and ethical concern	Order, meaning, kinship
Naturalistic	Direct experience and exploration	Curiosity, discovery
Negativistic	Fear and aversion	Security, protection, awe
Scientific	Systematic and empirical study	Knowledge, understanding, critical thinking skills
Symbolic	Nature in language and expressive thought	Communication, mental development
Utilitarian	Practical and material exploitation	Physical sustenance and security

dysfunction also takes place at the extremes – atrophied development at one end and excessive expression at the other, both resulting in emotional and intellectual deficits and maladaptive behavior.

The biophilia hypothesis that contact with natural systems and processes fosters human health, productivity, and well-being will be briefly reviewed, drawing largely on evidence from recent conducted scientific studies. Following this review, the article will conclude with a limited discussion of how modern, especially urban, society has increasingly diminished biophilic contact with the natural environment, and how this situation can be improved through a different design approach to the human built environment. The brief review of data bearing on the benefits of contact with nature will focus on studies of outdoor experience, healthcare, work, and community relationships.

Evidence Relating Contact with Nature to Human Health and Well-Being

Exposure to parks and gardens has long been associated with restorative and healing affects. Presumed benefits include rest, relaxation, physical restoration, even spiritual renewal. This assumption is reflected in such ancient practices as establishing `sacred' groves, mountains, water bodies, and other prominent natural features. These natural areas were frequently viewed as places where benign deities and guardian spirits resided. In more secular societies, parks and gardens, in both wilderness and more densely populated areas, have also been rationalized by their presumed physical, psychological, and even moral benefits.

The association of protected areas and open spaces with human physical and mental well-being has been more systematically studied in recent years, although the data remain sparse. Several investigations have documented various benefits of human contact with the nonhuman environment in such settings including stress relief, peace of mind, enhanced coping capacity, physical health, illness recovery, and improved critical thinking and problem-solving abilities. Even passive viewing of nature has been correlated with stress reduction, `emotional balance', and improved cognitive functioning. Most of the data have been derived from social surveys, but some investigations have employed more reliable and valid physiological indicators including measures of blood pressure and muscle tension. Overall, these studies have consistently demonstrated largely positive affects on people exposed to park-like settings, gardens, and landscapes. In addition, the natural areas studied have often been characterized by savanna-like meadows, large and mature canopy trees, forest edges, brightly colored flowers and shrubs, the presence of water, and other natural features that have largely proven instrumental in human evolution and survival.

An illustrative study examined the physical, emotional, and intellectual effects of park-like settings in urban areas. Randomly chosen college students were subjected to a series of intellectually demanding and mentally fatiguing tasks and assigned to three groups: one who took a 40 min walk in an urban park, another who walked for an equivalent period in an attractive urban area dominated by buildings and human activity, and a third who remained indoors in a comfortable chair listening to music and reading. After 40 min, each group completed a demanding proofreading assignment. Significantly higher scores on measures of emotional restoration (`levels of positive and negative affect') and cognitive functioning (attentiveness and concentration) occurred among students who walked in the park.

A number of studies have also examined the effects on participants of diverse outdoor recreational activities. Both anecdotal evidence and research results found immersion in relatively undisturbed natural settings often exerted significant and sometimes life-changing impacts, especially on late adolescents in the company of peers. Among the documented effects included: significant improvements in physical fitness, stamina, endurance, coordination, self-esteem, self-confidence, independence, initiative, personal responsibility, coping abilities, seeing tasks to completion, critical thinking, problem solving, curiosity, inventiveness, school and work performance, cooperation, teamwork, conflict avoidance, respect for others, peace of mind, and spiritual well-being.

Another body of research has focused on the effects of domesticated nature on people, particularly gardens and companion animals (pets). The presence of flowers and appealing vegetation has often been correlated in these studies with healing and calming affects, especially among the physically and mentally impaired. Plants and flowers were also found to be nearly universal in modern hospitals, their presence often among the most widely stated healthcare preferences of patients, and generally assumed to exert stress- and symptom-relieving benefits.

Several studies reported simply viewing nature reduced stress, relieved tension, and enhanced recovery among patients suffering from clinically diagnosed disorders. One investigation of patients recovering from gall bladder surgery randomly assigned patients to two types of hospital rooms – one with window views of trees and vegetation, the other of a brick wall. The investigators reported patients with the view of vegetation had significantly faster recovery rates, more positive treatment responses, and required less pain medication than the patients who only looked at the brick wall. Another study of patients recovering from heart surgery involved their being randomly assigned to three types of recovery rooms – one with pictures of water and trees, the second with pictures of abstract art, and the third with only blank walls. Significantly less anxiety and fewer demands for strong pain medication occurred among patients with the pictures of water and trees. Still, a third study of persons facing dental surgery examined three groups of patients – one, exposed to `serene' pictures of nature, a second, who viewed pictures of highly active outdoor scenes (ocean surfing), and a third who saw no pictures at all. Significantly lower blood pressure levels were observed among patients exposed to the serene nature scenes. Finally, another study focused on patients facing dental surgery who were randomly assigned to three treatments: one group exposed to a live fish tank, a second who observed pleasant pictures of nature, and a third who viewed only a blank wall. Nearly all patients showed signs of distress, but significantly lower levels of physical discomfort and `treatment-aversive behaviors' occurred among patients exposed to the fish tank.

A different body of research focused on the effects of companion animals. These studies generally revealed that the presence of companion animals enhanced calm and peace of mind, fostered physical and mental restoration, and relieved loneliness. Various studies of the physically and mentally disturbed reported major improvements in symptoms, more rapid healing, and faster recovery times among persons who had contact with companion animals. One illustrative study examined the effect of companion animals on persons recovering from heart attacks. Patients were matched demographically and symptomatically and randomly assigned to two groups: one who received conventional treatment and the other who were carefully exposed to companion animals. Researchers reported the presence of companion animals resulted in a one-third decrease in mortality rates and corresponding increases in survival and recovery. Another mental health study focused on boys suffering from attention-deficit hyperactive disorder who were randomly assigned to two nature-related activities – an outdoor challenge program that included canoeing and rock climbing, and an animal interaction activity focusing on care for companion animals, with the two groups switched to the other activity midway through the study. Therapeutic gains were reported for both activities, although significantly more positive and lasting benefits were observed among the animal care activity. Caring for companion animals resulted in significant symptomatic improvements, greater learning, improved school performance, speech gains, better attentiveness, and control over impulsive behavior. Moreover, differences were evident 6 months following the program, prompting the researchers to conclude a caring relationship for companion animals can relieve stress, improve social interaction, increase empathy, and contribute to task performance.

Benefits from contact with nature have been further studied in the modern workplace. Most environmental contact was limited to exposure to plants, outside views, natural lighting, natural ventilation, and pictures of nature and decorative art. Yet, the data have been consistent and generally supporting the contention that even restricted contact with nature in the modern work place can enhance health, productivity, and well-being. Most of the initial research focused on work settings with problems resulting from air-tight construction, artificial lighting, and widespread use of toxic chemicals in paints, coverings, furnishings, and other products and materials. The presence of these conditions often correlated with higher levels of respiratory and skin disorders, increased fatigue and absenteeism, diverse physical and psychological ailments, poor morale, and lower productivity. These conditions also prompted the identification of `building-related illness' and `sick building syndrome'.

More recent studies have begun to focus on the positive affects of exposure to nature in the work place, particularly from improvements in natural lighting, natural ventilation, the use of natural materials, and increased direct and representational contact with nature. These studies have revealed these positive environmental conditions can result in significant improvements in employee comfort, satisfaction, morale, health, well being, and productivity. For example, studies of European office and factory workers found viewing nature or the presence of plants could reduce job-related stress, allergies, and improve emotional well-being. Studies in the US also found window views and plants reduced job-related frustration and improved physical and mental well-being. Productivity studies of workers who had contact with plants and views of nature demonstrated fewer errors, more efficient work performance, lower blood pressure, and better attentiveness. Several studies reported workers with improved natural lighting and natural ventilation had significantly better cognitive performance. One particularly ambitious study examined office and manufacturing workers at a furniture company immediately before, immediately following, and 9 months after workers moved from facilities with minimal environmental amenities to new facilities with extensive natural lighting, natural ventilation, natural materials, improved energy efficiency, restored natural areas, greater open space, and walking trails. These changes were correlated with a 20% gain in productivity 9 months after the move to new facilities, as well as significant improvements in job satisfaction, physical health, relaxation, peace of mind, and contentment at work.

A limited number of community-based studies have also been conducted. One ambitious large-scale investigation focused on 18 rural, suburban, and urban neighborhoods within a single overall watershed. This study found a strong correlation between environmental quality, environmental values, and people's physical and mental well-being in the communities studied. Neighborhoods characterized by better environmental quality tended to express more positive values of nature and had a higher quality of life, whereas lower environmental quality communities generally demonstrated less environmental interest and typically had a lower quality of life. Moreover, the relationship of environmental quality, environmental values, and quality of life occurred in both urban and nonurban communities, as well as independent of income and education level.

Regarding the latter finding, it is sometimes assumed that the positive effects of contact with nature is mainly relevant to socioeconomically secure or privileged persons, and that conversely nature is of limited significance for individuals and groups characterized by poverty and social oppression who must cope with more basic needs. This assumption is not only unsupported by the previously cited finding, but also by important studies of Chicago public housing projects home to mainly poor African-Americans. Residents of architecturally identical buildings in these projects were compared, the only difference being that some buildings were surrounded by limited grass and a few trees, while other buildings had no vegetation and were surrounded instead by asphalt and concrete. Residents were randomly assigned to the buildings and had no control over landscaping. Yet, the study found residents of the vegetated buildings had significantly higher levels of physical and emotional well-being, better coping and conflict management skills, and superior cognitive functioning. Moreover, residents of the buildings surrounded by trees and grass revealed better social ties, superior interpersonal relationships with neighbors and strangers, lower violence and crime rates, greater safety and security, and a stronger sense of community than residents of the buildings surrounded by concrete and asphalt.

The final briefly reviewed area of research focuses on the role of contact with nature in childhood development. As noted, the biophilic notion that people have an inherent need to affiliate with nature implies that even for a human species capable of

lifelong learning the most important period for the development of a biological tendency will be childhood. Limited research supports this contention, or as the psychiatrist Harold Searles concluded: ``The non-human environment, far from being of little or no account to human personality development, constitutes one of the most basically important ingredients of human psychological existence.'' Studies of adults reflecting on childhood have found that the outdoors was almost universally cited by them as their most important environment during childhood, although the outdoor areas were often modest and located in backyards and nearby open spaces. Several features of the natural environment were identified in these studies as especially powerful maturational influences on children including: the stimulation of diverse senses, variability of conditions, dynamic and changing circumstances, and the presence of animate and life-like features. These and other characteristics of the natural environment appeared to foster coping and problem solving, creativity and challenge, change and adaptation, and other critical elements of learning and development. Additional research has suggested the most important period for children's contact with nature is middle childhood, roughly between the ages of 6 and 10.

In the most general sense, the inherent tendency to affiliate with nature or biophilia is viewed as the primary causative agent for the association revealed in the various cited studies of contact with nature and human health and well-being. In other words, the assumption is that various genetically encoded tendencies to affiliate with nature developed during the course of human evolution – for example, responses to sunlight, landscape, habitat, weather, color, plant and animal associations, etc. These tendencies fostered varying states of comfort, satisfaction, relaxation, alertness, curiosity, imagination, and more that proved instrumental in human fitness and survival. The actual causal mechanisms or linkages involved in this relationship require far more explanation and, at this point, our understanding must be considered largely speculative.

Decline in Contact with Nature in Modern Urban Society

Despite the evidence presented of the benefits of contact with nature on human health, productivity, and maturation, various modern trends suggest a significant decline in the `direct' experience of the natural environment, especially among urban youth. It is important to note, however, people experience nature in direct, indirect, and vicarious or symbolic ways. Direct experience involves relatively unstructured contact with largely self-sustaining natural features and processes. Indirect experience involves highly structured and organized contact with natural features requiring extensive human input and management (e.g., zoological parks, gardens). Vicarious or symbolic experience involves no actual contact with real or living nature, but rather with the image or representational expression of nature through, for example, the media of books, film, and computers. The apparent decline in human contact with natural systems and processes is principally a decline in direct and spontaneous contact. By contrast, the indirect and vicarious experience of nature appears to have increased in modern times.

As intimated earlier, functional and adaptive behavior is highly reliant, however, on direct environmental experience, especially during childhood. A decline in direct contact with nature, especially among modern youth, has led some to refer to the related phenomena of `nature-deficit disorder' and an `extinction of experience' to describe this condition. Factors associated with a significant decline in adult and children's direct experiences of nature include major biodiversity loss, degradation of natural systems, declining open space, and chemical pollution and contamination. Most of these trends have been linked to rapid urban growth and sprawl, at least as urban development has occurred until now. It is sobering to recognize that nearly three-quarters of the industrially developed world now resides in an urban area, and the majority of the world's population was recently identified as living in or near a city for the first time in human history.

Unfortunately, the prevailing paradigm of design and development of the modern urban environment has relied on massive consumption of energy and natural resources, enormous generation of wastes and pollutants, extensive degradation of natural habitats and loss of biological diversity, and increasing separation if not alienation of people from contact with natural systems and processes. This urban development paradigm is viewed as a design flaw rather than an inevitable and intrinsic failure of modern life. Fundamentally altering this design paradigm will necessitate a radically different development strategy, one sometimes referred to as sustainable but which has been called here `restorative environmental design'.

Sustainable design to date has largely focused on minimizing and avoiding adverse impacts of the human built environment on natural systems and human health. Important elements of this `low environmental impact' approach have included: energy and resource efficiency, waste minimization, avoidance of toxic products and materials, and protecting and restoring natural systems. This approach is vital and necessary but not sufficient for mending the current `nature deficit'. In addition, we also require design strategies that foster beneficial contact between people and nature in places of ecological and cultural familiarity and significance. This latter approach can be called `positive environmental impact' or, for reasons apparent by now, `biophilic design'. Some specific elements of biophilic design in the built environment include: environmental features (e.g., natural materials, natural ventilation); natural shapes and forms (e.g., botanical and animal motifs); natural patterns and processes (sensory variability, aging, and change); light and space (natural light, spaciousness); place-based relationships (historic and ecologic connection to locality); and evolved humans relations to nature (e.g., prospect and refuge, organized complexity). Restorative environmental design is the integrated and complementary combination of both low environmental and biophilic design approaches, a necessary basis for a true and lasting sustainability. Hopefully, this new design paradigm will render more compatible if not harmonious the relationship between the natural and human built environments in even our modern cities, resulting in the protection and restoration of necessary ecosystem services, as well as enhancing people's biophilic needs for positive contact with nature.

Carbon Footprint

Dario Caro, Aarhus University, Roskilde, Denmark

Introduction

Climate change represents one of the most relevant challenges for human being. It evolves into a full range of issues such as economy, technology, society and ecology. Limiting the effects of climate change is necessary to achieve sustainable development and equity. Countries' future contributions to the accumulation of greenhouse gas (GHG) emissions in the atmosphere will play a key role in keeping warming below 2°C relative to preindustrial level (UNFCCC, 2015). In a globalized era, countries have different impact on climate change as well as different vulnerability to the effects of the resulting climate change. They also have different capacities to address mitigation and adaptation. Monitoring GHG emissions at different level of analysis (national, city, organization, product) constitutes an important reference point upon which environmental policies and strategies able to drive the GHG emission mitigation can be based. Indeed, emission drivers need to be considered at different scales for making possible to set goals for GHG emissions mitigation, develop a management plan and implement new policies aimed to reduce the impact of climate change.

In the last decades there has been a growing interest in estimating and revealing GHG emission drivers via analyses based on carbon footprint at different scales. The carbon footprint originates from the concept of ecological footprint which is a measure of the impact on the environment expressed as the amount of land required to sustain natural resources. However, the carbon footprint of a functional unit, when it is not associated with ecological footprint, is the climate impact under a specified metric that considers all relevant emission sources, sinks and storage in both consumption and production within the specified spatial and temporal system boundary (Peters, 2010). Although a specific definition of carbon footprint has been not stated, according to Wiedmann and Minx (2008) carbon footprint is the measure of the total amount of carbon dioxide emissions directly and indirectly caused by an activity or accumulated over the life stages of a product. Specifically, the carbon footprint is the overall amount of GHG emissions associated with a country, city or product, along its supply chain including end-of-life recovery and disposal. The carbon footprint is an environmental indicator and as such it needs to be used in appropriate contexts thus providing right information. When properly used, it is essential for making decisions and performance evaluations and for allowing policy-makers to have a solid basis upon which climate policies can be established and implemented.

Accounting Systems: Metrics and Standard

Carbon footprint analysis has provided important findings that have helped to shape climate policy at the global and national level. The carbon footprint approach gives consumers the responsibility for their environmental impacts in terms of GHG emissions, regardless of where those impacts occur. Two different sources of emissions are considered on the basis of the system analyzed: (a) direct emissions; occurring inside the boundary of the system, (b) indirect emissions; occurring outside the boundary of the system for satisfying the demand. In general, three scopes regarding three categories of emissions are considered. Scope 1 or direct emissions are defined as emissions from sources that are owned or controlled by the system. Scope 2 or energy indirect GHG emissions are defined as emissions from the consumption of purchased electricity, steam, or other sources of energy (e.g., chilled water) generated upstream from the system. Scope 3 or other indirect emissions are defined as emissions derived from upstream and downstream system activities occurring outside the boundary of the system analyzed. Indeed, the ideal accounting framework of the carbon footprint should reveal the emission source (type and location), the destination and the belonging scope.

In general, the accounting systems used to determine the carbon footprint should meet the requirements of the definition. As such, a carbon footprint can be developed for various different functional units at different scales and using different methods. Concerning the country scale, the way of taking into account GHG emissions is still largely discussed. In particular the IPCC-based accounting and the consumption-based accounting provide two different perspectives on how assign the responsibility of GHG emissions embodied in trade. Although presently, the IPCC inventories represent the official reference point to estimate GHG emission at the national level for countries within the UNFCCC, consumption-based accountings by using environmentally extended input–output (EEIO) analyses are largely developed by researchers worldwide. The IPCC inventories as well as EEIO analyses may be also performed at city scale. However, for several different reasons, their utilization at the city level may be insufficient in providing a complete overview of the system. In recent years, academic researchers proposed a combination of different methods to overcome their respective drawbacks. Such hybrid models aim to merge the strength of different methods becoming more complete with respect to the primary models. For example the combination of the EEIO with LCA represents an innovative hybrid model which is mainly used for estimating the carbon footprint at the city level. Carbon footprint also represents an important tool for estimating direct and indirect GHG emissions generated within the range defined by the organizations (industries or companies) themselves. Although, organizations, companies or industries substantially contribute to the economic growth, they also consume a lot of energy and produce a large amount of waste which also release GHG emissions in the atmosphere. Developing a carbon footprint analysis at organizational scale is therefore an important step for identifying the sources of GHG emissions occurring within the organizational boundaries and provide solutions for reducing them. It may be also aimed specifically at the product level and nowadays, a great consensus on the carbon footprint at the product level has been build up. The carbon footprint is applied by many companies for specific products in all sector worldwide and it represents a solid advanced tool for knowledge-based decision making in the context of sustainable consumption and production. It stimulates companies to achieve the best environmental performances in their production by suggesting actions aimed to reduce GHG emissions of their products and thus promoting the development of the sustainable innovation and technology.

The carbon footprint has not a standardized accounting system to be developed. Although the development of the carbon footprint follows basilar concepts to be performed, the method strictly depends on the different level of analysis. Following, the accounting systems for estimating carbon footprint at different scales are presented and discussed.

Country Scale

In general, GHG emissions accounting at the national level should reflect how national policies contribute to the reduction of the climate change. It means that actions that mitigate GHG emissions should be incentivized whereas action that increase GHG emissions should be discouraged. In this context, carbon footprint plays a key role, being an effective reference point for climate policies. Multiregional input–output (MRIO) models are one of the current instrument for estimating the carbon footprint at the national level. Multiregional input–output models have been developed to study the economic and production networks, and associated environmental impacts, that lie upstream of a given purchase. The use of MRIO models in environmental accounting is constantly increasing. Numerous improvements have been achieved in recent years for the assessment of the carbon footprint at the national level. In a MRIO model, national input–output tables, representing financial transactions between economic sectors within a country, and trade flow tables, showing the value of exports and imports by country and economic sector, are linked together in one coherent accounting framework (Lutter et al., 2016). This core of a combined, multinational interindustry transaction matrix is furthermore linked to primary inputs on one hand and final demand on the other hand. Multiregional input–output models allow analyses at a multiregional level, thus avoiding the double counting of emissions. It should be noted that carbon footprint at the national level represents an alternative GHG accounting with respect to the traditional approach based on the IPCC guidelines. Although the IPCC guidelines are widely used and provide punctual measures of GHG emissions at the national level, their geographical approach implies that the countries where the finished products are actually consumed take no responsibility for the environmental impacts generated by the producer countries, thus neglecting the international trade effect. A MRIO analysis complements the geographical approach by including all driving forces for GHG emissions associated with consumption and focusing on the localization of emissions, especially those embodied in international trade (Jakob and Marschinski, 2013). In short, the carbon footprint is capable to capture the environmental impact of a national economy in terms of GHG emissions. In a globalized era, estimating the trade effect in terms of GHG emissions is relevant as a large amount of goods are internationally traded. In this context, policy relevant issues connected with the trade such as carbon leakage, allocation of emissions embodied in trade and border-tax adjustments are a basic part of carbon footprint analysis. Although there are several advantages to develop a carbon footprint analysis at the national level, some questions arise concerning the feasibility of the actual implementation of the MRIO models. While the MRIO models have been widely approved within the scientific community their adoption when dealing with national emissions accounting has so far been limited by a number of implementation issues. In particular MRIO models are labor-intensive and not always available as a long, continuous time series. Moreover, currently MRIO databases provide results, without accompanying estimates of reliability and uncertainty. In this context, the recently developed multiregional, environmentally-extended database called “Exiobase” proves to be cutting-edge in the reduction of data uncertainty (Tukker and Dietzenbacher, 2013). Anyway, all the GHG accounting systems have their limitations especially when they deal with macro-scale analyses. A complementation of different methods, when properly developed may also be an important alternative approach. For instance, complementing carbon footprint with traditional IPCC-based accounting may reveal both the effects of policies aimed to

encourage the development of low carbon technologies within the national boundaries and the effects of policies addressed to the final consumption of goods, thus also including the trade effect in the computation.

City Scale

The carbon footprint evaluating the environmental impact of cities or subnational regions represents an important assessment to provide a valuable tool for local policy decision makers. An important aspect when a carbon footprint is applied to cities is where the city emissions occur which means the spatial boundary considered. In this context, the accounting system should be properly selected also considering the limited amount of data available at the city level. Once the accounting system has been selected it is necessary to apply a model to assess the carbon footprint of the city. Although there exist standardized methods used to calculate and report GHG emissions at different level of analysis (national, regional, city), hybrid models which combine the strength of different methods are presently an active area of research and are increasingly being used for estimating the carbon footprint at the city level.

IPCC guidelines

The Intergovernmental Panel on Climate Change (IPCC) has defined a complete method to standardize the computation of GHG emissions at national level. Currently, the monitoring of GHG emissions within a territorial system (country, region, etc.) uses IPCC guidelines to realize annual inventories assessing the amount of six main gases (CO_2; CH_4; N_2O; HFCs; PFCs; SF_6), outlined in the Kyoto Protocol (IPCC, 2006). Although the IPCC method has been performed for countries, it has been also adapted at the subnational level such as regions and cities. The estimation of GHG emissions by using the IPCC method cannot be considered a carbon footprint measure because it only reports direct emissions from sectors and subsectors within city boundaries regardless of where output of the production is consumed. It means that the IPCC method only takes in account the Scope 1 and some parts of the Scope 2, thus neglecting parts of the Scope 2 and the entire Scope 3. However some studies showed that a GHG inventory developed by using the IPCC method is able to suggest suitable plans to mitigate GHG emissions and provide important information to public authorities interested in reducing GHG emissions at the subnational level (Bastianoni et al., 2014).

Input–output analysis

The input–output analysis is a top down model able to take in account transactions between activities measured in monetary units and extend them at the environmental level in terms of GHG emissions (environmental extended input–output analysis, EEIO). It has long been recognized as a useful and consistent technique to estimate carbon footprint at different level of analysis. So, monetary flows are converted into GHG emissions thus considering the associated emissions embodied in trade. Indeed, some input–output based studies have revealed that substantial GHG emissions can be embodied in goods and services that are traded and, therefore, not typically included in the IPCC based accounting. On the basis of the data availability the input–output analysis can be used at each level of scale. In particular input–output matrixes are necessary to fulfill the analysis and they are not always available at the city level. However the use of input–output analysis in GHG accounting is increasing and numerous improvements have been achieved in recent years, such as specific advanced databases for the assessment of the carbon footprint at the city level (Dong et al., 2016).

Life cycle assessment

Life cycle assessment (LCA) is a very popular analysis for reporting potential environmental loads and resources consumed in each step of a product or service supply chain. Although its use is mainly associated with the estimation of the environmental impact of products, some studies have also used a LCA for cities. Since in LCA data are collected for all processes that have been identified as relevant to include within the chosen system boundary, its application at the city level imply a time-consuming process requiring a large amount of input data. Therefore, estimating the carbon footprint at the city level by LCA is not recommended due to its complexity. However, LCA has a great level of accuracy and is able to provide responses to actions as well as important information for policy makers interested in improving the environmental performances and understanding the potential of GHG mitigation art the city level.

Hybrid models

The use of LCA datasets in EEIO modeling is a practice to improve the EEIO analysis, as the detail, accuracy, representativeness and technological specificity of the life cycle processes are notably higher in the LCA than the environmental satellite accounts associated with IO tables. EEIO models are capable of tracing back all the intermediate steps of the supply chain and identifying the sources of impact. Service and capital goods expenses data are provided by EEIO whereas the process-based data are added by LCA. The complementation of EEIO with LCA can provide benefits, as LCA, unlike EEIO, is a standardized and continuously improved tool for environmental accounting. Although some still-existing methodological challenges (Caro et al., 2015) EEIO/LCA is one of the most promising models for estimating the carbon footprint at the city/region level. Additional hybrid models have been presented and performed complementing LCA and EEIO. For instance, a combination of material flow accounting with EEIO (Ramaswami et al., 2012) or emergy and LCA (Pincetl et al., 2012). Such models aim to overcome specific drawbacks in taking into account environmental impacts that mass and energy flow analyses neglect. Alternative dynamic methods for estimating the carbon footprint at city scale have been recently such as City Carbon Map and City Carbon Network, respectively introduced by Wiedmann

et al. (2016) and Chen et al. (2016). City Carbon Map was applied to Melbourne. It is a consistent method based on EEIO to report the carbon footprint, showing the origin (physical source) and the destination (allocation of supply chain to final products) of the emissions in a carbon map. Basically, Carbon Map is a two dimensional decomposition of the carbon footprint of a city's final demand. The City Carbon Network, starting from the Carbon Map approach, focuses on the intercity embodied emission flows across countries, giving more information about trade partners and thus providing important insights for local policy makers. Although an improvements in data and methodology is still required these two dynamic carbon footprint's accountings are capable to assess the total impact of the commitments that city made at the Paris Climate Conference thus being two promising methods for the next years.

Organizational Scale

Over the last years the application of carbon footprint at the organizational level has constantly increased with so many companies interested in improving their environmental performances. In the next two paragraphs the two assessment standards for developing a carbon footprint analysis at organizational scale are presented.

GHG protocol

The GHG Protocol Corporate Accounting and Reporting Standard, which has been the first standard for estimating carbon footprint at organizational scale, helps organizations to identify, calculate, and report GHG emissions, providing specific guidelines for performing a GHG emission inventory at organizational scale (WRI, 2011). The GHG protocol website provides freely available electronic GHG calculators able to estimate carbon footprint associated with specific sources or sectors of the organization. In connection with the United Nations Framework Convention on Climate Change, the GHG Protocol covers the accounting of seven GHGs such as carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), hydrofluorocarbons (HFCs), perfluorocarbons (PCFs), sulfur hexafluoride (SF_6) and nitrogen trifluoride (NF_3). The GHG Protocol not only focuses on results, but also includes a deepened analysis to identify the most effective reduction opportunities.

The key steps in calculating an organizational carbon footprint are (i) defining organizational boundaries; (ii) defining operational boundaries; (iii) estimating carbon footprint and (iv) reporting the final achievement. The definition of the organizational boundaries depends on the characteristic of the organization and several aspects should be considered such as the organizational structure, geographic location and purpose of information. The choice of the operational boundaries is also relevant because it determines which emission sources will be quantified such as Scope 1 and 2 (it should be included) and Scope 3 (not always included). The carbon footprint is generally estimated multiplying activity data by standard emissions factors. In some cases organizations may need to track emissions over time in order to identify their temporal advancements and a specific base year is selected. Finally, organizations develop reports to inform internal and external partners thus promoting actions addressed to mitigate GHG emissions at the organizational level.

ISO 14064

In 2006, ISO released the ISO 14064 standard, which is an international standard for the determination of boundaries, quantification, mitigation and removal, used to guide the companies to measure and control the GHG emissions (ISO 14064, 2006). ISO 14064 has been prepared in three parts. Part 1 provides the principles and requirements for designing, developing, managing and reporting organization level GHG inventories. It includes requirements for determining boundaries, quantifying emissions and removals, and identifying specific company actions or activities aimed at improving GHG management. Part 2 provides the requirements for determining scenarios and provides the basis for GHG analysis to be validated and verified. Part 3 provides principles, requirements and guidance for validation and verification of the analysis. Three key steps are required for developing carbon footprint at the organizational level: setting GHG inventory, quantifying GHG emissions, and finally verifying and reporting the final achievement. ISO 14064 provides the steps to develop an inventory that is not only able to be easily verified but can be compared to the inventories of other organizations.

Most cases, the methodology used for estimating GHG emissions is based on the general equation: emission = activity data × emission factor. Activity data is recommended to be collected at site level and data collection should be described in detail when reporting the final outcome. Emission factors relative to each activity data are generally obtained from literature such as IPCC guidelines or more specific national handbooks. It should be noted that if the analysis does not include the Scope 3, carbon footprint is not properly estimated because the total amount of GHG emissions indirectly caused by the organization is not captured. However, specific assumptions may be explicated to make the analysis valuable and representative as well.

Implementing the ISO 14064 allows organizations to promote credibility in GHG quantification, facilitate the trade of GHG credits, support the development of strategies and plans for reducing GHG emissions and finally disseminate their ability in achieving environmental targets. The application of standard measurement methodologies such as the GHG protocol and ISO 14064 have increased in the last decades and by now they are important reference points for estimating carbon footprint at the organizational level. The need to generate a common language and platform to address GHG reduction is more and more important and the public and the public and private body's efforts may play a key role in mitigating GHG emissions worldwide.

Product Scale

Life cycle assessment aims at estimating the magnitude and significance of the potential environmental impacts of a product or a service throughout its entire life cycle. The impact categories of a LCA represent environmental issues of concern to which LCA results may be assigned. One of the key impact categories considered in an LCA is climate change for the estimation of the GHG emissions released along the life cycle of products that is from the extraction of raw materials, the manufacture of goods, and their use by final consumers including recycling, energy recovery and ultimate disposal. The carbon footprint at the product level is a LCA focused on the climate change category. As a consequence, when the carbon footprint of a product is estimated, other important environmental impacts are not considered. This is mainly due to the relevance that climate change has with respect to other environmental impacts, especially in terms of imminence and magnitude of the issue. However, it should be highlighted that achieving sustainable consumption also requires the evaluation of all environmental impacts.

Data sources for estimating the carbon footprint of a products are therefore obtained from LCA databases with so many sources of data, software tools and handbooks on LCA available. The key steps in calculating the carbon footprint of a product are: (i) identifying all materials, activities and processes that contribute to the life cycle of the product; (ii) defining the system boundary; (iii) estimating the carbon footprint; (iv) reporting results obtained by specific report or declaration.

A typical problem with LCA has mainly concerned the comparability of different studies. For instance, assumptions are an important component of the LCA process and they may have effect on final results. In this context, a standardization of the process has been required and the LCA community has widely worked on the fulfillment of specific standard for calculating the carbon footprint of products. Currently the international standards ISO 14067 provide robust and practice-proven requirements for performing transparent and accepted carbon footprint calculations. It specifies principles, requirements and guidelines for the quantification and communication of the carbon footprint of a product which are based on International Standards on LCA (ISO 14040 and ISO 14044) for quantification and on environmental labels and declarations (ISO 14020, ISO 14024 and ISO 14025) for communication.

Conclusions

The decision by national and international governments to take measures to limit GHG emission calls for suitable tools for objectively monitoring and quantifying emission, as well as checking mitigation/reduction programs. As a consequence of potential exposure to carbon pricing, also companies are increasingly interested in understanding their carbon footprint. The carbon footprint represents a crucial tool for developing an environmental plan on the GHG emission assessment and their reduction. It acts as bridge between the scientific community and decision makers, suggesting the best environmental actions to policy makers and guiding future management choices. It plays a key role when used as tool for labeling products in order to incentivize consumers toward a more sustainable consumption and so improve their environmental lifestyle. It can also be a tool for generating a positive competition between companies in terms of environmental impact. In this context, the carbon footprint is capable to capture the trade effect, thus including companies outside the consuming country.

The recent standardization of carbon footprint at the city and product level is an important evidence of how companies and local institutions place the carbon footprint as tool in their decision making (Afionis et al., 2017). Instead, at the international level the utilization of carbon footprint and its potential ability in addressing issues such as carbon leakage and emissions embodied in trade have still been not given sufficient consideration. In facts, while carbon footprint has become an important indicator for supply chain improvements at micro level, its application as tool for evaluating strategies and taking decisions at macro scale has still not been sufficiently approved from the international community. However, the adoption of carbon footprint at the national level might have deep consequences on the global trading system as well as on the international environmental policies aimed at mitigating GHG emissions at country scale. Indeed, with respect to the traditional IPCC-based accounting, the carbon footprint would assign GHG responsibility to consumer countries in international trade, thus inducing all the subjects involved in commercial dynamics to improve their environmental performances. Anyway, there is a large potential for carbon footprint to be used in policy at a variety of scales and so far, the application of carbon footprint also at country scale has been so much useful for identifying important issues to a wide audience. While its utilization is expected to increase over the next years, further advancements in the development of the carbon footprint analysis are still needed. For instance, most of the studies have neglected emissions from land-use change and the proposed methodologies for including such substantial emissions source still suffer from different shortcomings. The lack of a standardized uncertainty analysis associated with the carbon footprint at different scales is also required. While in so many carbon footprint related studies the uncertainty analysis is not considered, it may add valuable information thus strengthening the case studies analyzed. Future standardization actions for an acceptable level of uncertainty are therefore needed at each level of analysis.

Ecological Economics 1☆

Robert Costanza, Australian National University, Canberra, ACT, Australia

Basic Worldview and Goals

Ecological economics starts with the observation that the human economy is a subsystem of society and the larger ecological life support system. It recognizes that humans are a part of this larger ecological system and not apart from it. Humans have shaped and modified their supporting ecosystems since the time of their appearance as a species, sometimes sustainably, sometimes not. In the past, this human presence (the economic subsystem) was relatively small in scale compared to the size of the rest of the supporting ecosystem. In the last century, due largely to the utilization of fossil fuels, the human subsystem has expanded so dramatically that it is now a major component of the overall system. Unlike the situation in the majority of human history, we now live in a relatively "full" world and have entered a new geologic epoch called the "anthropocene." This changes everything. In a full world context, the goal of the economic subsystem can no longer be simply expansion and growth with little regard to the rest of the system. We must now consider the whole system and the goal must shift from economic growth to sustainable development. Growth implies increasing in quantity or size, while development implies improvement in quality without necessarily increasing in size. In a full world context, the goal must shift from creating "more" to creating "better"—to create a sustainable and desirable future.

This shift in primary goals and vision for the future has profound implications for analysis and policy, across the full range of academic disciplines and human activities. For example, if one's goals include ecological sustainability then one cannot rely on the principle of "consumer sovereignty" on which most conventional economic solutions are based, but must allow for coevolving preferences, technology, and ecosystems. One of the basic organizing principles of ecological economics is thus a focus on this complex interrelationship between ecological sustainability (including system carrying capacity and resilience), social sustainability (including distribution of wealth and rights, social capital, and coevolving preferences), and economic sustainability (including allocative efficiency in the presence of highly incomplete and imperfect markets). The complexity of the many interacting systems that make up the biosphere means that this involves a very high level of uncertainty. Indeed, uncertainty is a fundamental characteristic of all complex systems involving irreversible processes, and ecological economics is particularly concerned with problems of uncertainty. More particularly, it is concerned with the problem of assuring sustainability under uncertainty. Instead of locking ourselves into development paths that may ultimately lead to ecological collapse, ecological economics seeks to maintain the resilience of the highly interconnected socioecological system by conserving and investing in natural and social capital assets in a balanced way with investments in human and built capital.

History

Ecology and economics share the same Greek root, *oikos*, meaning "house." Ecology is, literally, the "study of the house," while economics is the "management of the house," where the house is taken to be the world or any part of it. Thus ecological economics implies studying and managing the world in an integrated way, taking full advantage of our accumulated knowledge and understanding of both the natural and the social parts of the system.

Ecological economics has historical roots as long and deep as any field in economics or the natural sciences, going back to at least the 17th century. Nevertheless, its immediate roots lie in work done in the 1960s and the 1970s. Kenneth Boulding's classic *The Economics of the Coming Spaceship Earth* set the stage for ecological economics with its description of the transition from the "frontier economics" of the past, where growth in human welfare implied growth in material consumption, to the "spaceship economics" of the future, where growth in welfare can no longer be fueled by growth in material consumption. This fundamental difference in vision and worldview was elaborated further by Herman Daly, who in 1968 recast economics as a life science, akin to biology and especially ecology, rather than a physical science like chemistry or physics. The importance of this shift in "preanalytic vision" cannot be overemphasized. It implies a fundamental change in the perception of the problems of resource allocation and how such problems should be addressed. More particularly, it implies that the focus of analysis should be shifted from marketed resources in the economic system to the biophysical basis of interdependent ecological and economic systems and their coevolution over time.

Ecological economics is not, however, a single new paradigm based on shared assumptions and theory. It is instead a "metaparadigm." Rather than espousing and defending a single discipline or paradigm, it seeks to allow a broad, pluralistic range of viewpoints and models to be represented, compared, and ultimately synthesized into a richer understanding of the inherently complex systems it deals with. It represents a commitment among economists, ecologists, and other academics and practitioners to

☆*Change History:* February 2018. R. Costanza made changes to the text and references.

This is an update of R. Costanza, Ecological Economics 1, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 999–1006.

learn from each other, to explore new patterns of thinking together, and to facilitate the derivation and implementation of effective economic and environmental policies. Ecological economics is deliberately and consciously pluralistic in its conceptual underpinnings. Within this pluralistic metaparadigm, traditional disciplinary perspectives are perfectly valid "as part of the mix." Ecological economics therefore includes some aspects of neoclassical environmental economics, traditional ecology, and ecological impact studies, and several other disciplinary perspectives as components, but it also encourages completely new, more integrated ways to think about the linkages between ecological and economic systems.

Ecological economics has also developed a solid institutional base. After numerous experiments with joint meetings between economists and ecologists, the International Society for Ecological Economics (ISEE) was formed in 1988 and currently has over 3000 members worldwide. The journal of the society, *Ecological Economics*, published its first issue in February 1989 and is currently publishing 12 issues per year, with an impact factor taking it to the top one-fifth of all economics and all environmental journals. Major international conferences have been held since 1990, with attendance reaching as high as 1500. Several ecological economic institutes have been formed around the world, a significant number of books have appeared with the term ecological economics in their titles, and a fair number of university courses, certificate programs, and graduate degree programs have also developed.

Links With Natural Sciences

Ecological economics' explicit links with the natural sciences result in a more scientific approach, which is inherently more pluralistic and empirically grounded. It places humans and human behavior in a broader historical, evolutionary, and ecological context. Humans are seen as a part of the natural world, not abstractions in isolation from nature and each other. It is problem-based, not tool-based, and its methods include any that are applicable to the problems at hand. These include everything from participatory processes to envisioning alternative futures to complex systems simulation modeling. It recognizes the importance of envisioning and the limits of the positive-normative dichotomy. It goes well beyond interdisciplinary dialog. It aspires to be a truly transdisciplinary science.

The broad spectrum of relationships between ecosystems and economic systems is the locus of many of our most pressing current problems (i.e., sustainability, climate disruption, species extinction, income and wealth distribution) but it is not covered adequately by any existing discipline. Environmental and resource economics, as they are usually practiced, are subdisciplines of neoclassical economics focused on the efficient allocation of scarce environmental resources but generally ignoring ecosystem dynamics and scale issues, and paying only scant attention to wealth distribution issues. Ecology, as it has historically been practiced, sometimes dealt with human impacts on ecosystems, but the more common tendency was to stick to "natural" systems and exclude humans.

Ecological economics also focuses on a broader set of questions and goals than the traditional disciplines. Here, again, the differences are not so much the newness of the questions or goals, but rather the attempt to integrate them. They can be stated as both questions and goals, since they represent both complex questions requiring further research to fully understand and goals that most people would agree are worthy of the title:

1. Assessing and insuring that the scale of human activities within the biosphere are ecologically sustainable; how do we stay within the biophysical planetary boundaries?
2. Distributing resources and property rights fairly, both within the current generation of humans and between this and future generations, and also between humans and other species; and
3. Efficiently allocating resources as constrained and defined by (1) and (2) above, including both marketed and non-marketed resources, especially social and natural capital and ecosystem services.

These questions/goals are interdependent and yet need to be addressed hierarchically. The problem of ecological sustainability needs to be solved at the level of preferences or technology, not at the level of optimal prices. Only if the preferences and production possibility sets informing economic behavior are ecologically sustainable can the corresponding set of optimal and intertemporally efficient prices be ecologically sustainable. Thus the principle of "consumer sovereignty" on which most conventional economic solutions are based is only acceptable to the extent that consumer interests do not threaten the overall system, and through this the welfare of future generations. This implies that if one's goals include ecological and social sustainability then one cannot rely on consumer sovereignty, and must allow for coevolving preferences, technology, and ecosystems.

Material and Energy Flows

One focus of the work on joint ecological economic systems has been material and energy flows. A dominant theme in this body of work has been the grounding of conventional economic models in the biophysical realities of the economic process. This emphasis shifts the focus from exchange to the production of wealth itself. Cleveland traces the early roots of this work dating back to the physiocrats. The energy and environmental events of the 1960s and the 1970s pushed work in this area to new levels. Energy and material flow analysis in recent times is rooted in the work of a number of economists, ecologists, and physicists. Economists such as Boulding and Geogescu-Roegen demonstrated the environmental and economic implications of the mass and energy

balance principle. Ecologists such as Lotka and H. T. Odum pointed out the importance of energy in the structure and evolutionary dynamics of ecological and economic systems. And physicists such as Prigogine worked out the far-from-equilibrium thermodynamics of living systems.

The principle of the conservation of mass and energy has formed the basis for a number of important contributions. The assumption was first made explicit in the context of a general equilibrium model by Ayres and Kneese and subsequently by Mäler, but it also is a feature of the series of linear models developed after 1966. All reflect the assumption that a closed physical system must satisfy the conservation of mass condition, and hence that economic growth necessarily increases both the extraction of environmental resources and the volume of waste deposited in the environment.

Perrings developed a variant of the Neumann–Leontief–Sraffa general equilibrium model in the context of a jointly determined economy–environment system subject to a conservation of mass constraint. The model demonstrates that the conservation of mass contradicts the free disposal, free gifts, and noninnovation assumptions of such models. An expanding economy causes continuous disequilibrating change in the environment. Since market prices in an interdependent economy–environment system often do not accurately reflect environmental change, such transformations of the environment often will go unanticipated.

Ayres described some of the important implications of the laws of thermodynamics for the production process, including the limits they place on the substitution of human capital for natural capital and the ability of technical change to offset the depletion or degradation of natural capital. Although they may be substitutes in individual processes in the short run, natural capital and human-made capital ultimately are complements, because both manufactured and human capital require materials and energy for their own production and maintenance. The interpretation of traditional production functions such as the Cobb–Douglas or constant elasticity of substitution (CES) must be modified to avoid the erroneous conclusion that "self-generating technological change" can maintain a constant output with ever-decreasing amounts of energy and materials as long as ever-increasing amounts of human capital are available.

Furthermore, there are irreducible thermodynamic minimum amounts of energy and materials required to produce a unit of output that technical change cannot alter. In sectors that are largely concerned with processing and/or fabricating materials, technical change is subject to diminishing returns as it approaches these thermodynamic minimums. Ruth uses equilibrium and nonequilibrium thermodynamics to describe the materials–energy–information relationship in the biosphere and in economic systems. In addition to illuminating the boundaries for material and energy conversions in economic systems, thermodynamic assessments of material and energy flows, particularly in the case of effluents, can provide information about depletion and degradation that are not reflected in market price.

There is also the effect of the time rate of thermodynamic processes on their efficiency, and, more importantly, their power or rate of doing useful work. H. T. Odum and Pinkerton pointed out that to achieve the thermodynamic minimum energy requirements for a process implied running the process infinitely slowly. This means at a rate of production of useful work (power) of zero. Both ecological and economic systems must do useful work in order to compete and survive, and H. T. Odum and Pinkerton showed that for maximum power production an efficiency significantly worse than the thermodynamic minimum was required.

These biophysical foundations have been incorporated into models of natural resource supply and of the relationship between energy use and economic performance. Cleveland and Kaufmann developed econometric models that explicitly represent and integrate the geologic, economic, and political forces that determine the supply of oil in the United States. Those models are superior in explaining the historical record than those from any single discipline. Larsson et al. also use energy and material flows to demonstrate the dependence of a renewable resource such as commercial shrimp farming on the services generated by marine and agricultural ecosystems.

One important advance generated by this work is the economic importance of energy quality, namely, that a kilocalorie of primary electricity can produce more output than a kilocalorie of oil, a kilocalorie of oil can produce more output than a kilocalorie of coal, and so on. H. T. Odum describes how energy use in ecological and economic hierarchies tends to increase the quality of energy, and that significant amounts of energy are dissipated to produce higher-quality forms that perform critical control and feedback functions which enhance the survival of the system. Cleveland et al. and Kaufmann show that much of the decline in the energy/real GDP ratio in industrial nations is due to the shift from coal to petroleum and primary electricity. Their results show that autonomous energy-saving technical change has had little, if any, effect on the energy/real GDP ratio. Stern finds that accounting for fuel quality produces an unambiguous causal connection between energy use and economic growth in the United States, confirming the unique, critical role that energy plays in the production of material wealth.

The analysis of energy flows has also been used to illuminate the structure of ecosystems. Hannon applied input–output analysis (originally developed to study interdependence in economies) to the analysis of energy flow in ecosystems. This approach quantifies the direct plus indirect energy that connects an ecosystem component to the remainder of the ecosystem. Hannon demonstrates this methodology using energy flow data from the classic study of the Silver Springs (Florida) food web. These approaches hold the possibility of treating ecological and economic systems in the same conceptual framework, one of the primary goals of ecological economics.

Accounting for Natural Capital, Ecological Limits, and Sustainable Scale

Most current economic policies are largely based on the underlying assumption of continuing and unlimited material economic growth. Although this assumption is slowly beginning to change as the full implications of a commitment to sustainability sink in,

it is still deeply embedded in economic thinking as evidenced by the frequent (but mistaken) equation of "sustainable development" with "sustainable growth." The growth assumption allows problems of intergenerational, intragenerational, and interspecies equity and sustainability to be ignored (or at least postponed), since they are seen to be most easily solved by additional material growth. Indeed, most conventional economists define "health" in an economy as a stable and high "rate of growth." Energy and resource depletion, pollution, and other planetary boundaries and limits to growth, according to this view, will be eliminated as they arise by clever development and deployment of new technology. The assumption is that we can completely "decouple" the economy from environmental impacts. This line of thinking often is called "technological optimism."

An opposing line of thought (often called "technological skepticism") assumes that technology will not be able to circumvent fundamental energy, resource, or pollution constraints and that eventually material economic growth will need to stop. It has usually been ecologists or other life scientists that take this point of view (notable exceptions among economists are Boulding and Daly), largely because they study natural systems that invariably do stop growing when they reach fundamental resource constraints. A healthy ecosystem is one that maintains a relatively stable level. Unlimited growth is cancerous, not healthy, under this view.

Technological optimists argue that human systems are fundamentally different from other natural systems because of human intelligence and that history has shown that resource constraints can be circumvented by new ideas. They claim that Malthus' dire predictions about population pressures have not come to pass and the "energy crisis" of the late 1970s is behind us. Technological skeptics, on the other hand, argue that many natural systems also have "intelligence" in that they can evolve new behaviors and organisms (including humans themselves). Humans are therefore a part of nature, not apart from it. Just because we have circumvented local and artificial resource constraints in the past does not mean we can circumvent the fundamental ones that we will eventually face. Malthus' predictions have not come to pass yet for the entire world, the skeptics would argue, but many parts of the world are in a Malthusian trap now, and other parts may well fall into it. This is particularly important because many industrial nations have increased their numbers and standard of living by importing carrying capacity and exporting ecological degradation to other regions.

The debate has gone on for several decades now. It began with Barnett and Morse's *Scarcity and Growth* in 1963, but really got into high gear only with the publication of *The Limits to Growth* by Meadows et al. in 1972 and the Arab oil embargo in 1973. Several thousand studies over the last 45 years have considered aspects of our energy and resource future, and different points of view have waxed and waned. But the bottom line is that there is still considerable uncertainty about the impacts of energy and resource constraints. We have already hit real fossil fuel limits, not so much because of supply constraints but because of their impacts on climate. Will fusion energy or solar energy or conservation or some as yet unthought of energy source step in to save the day and keep economies growing? The technological optimists say "yes" and the technological skeptics say "maybe." Certainly we can "decarbonize" the economy by shifting to solar and wind energy to deal with climate impacts. The price of these sources have dropped dramatically in recent years. They could certainly sustain a steady state economy with vastly improved quality of life and wellbeing, but whether they could sustain a materially growing economy on a finite planet is another question.

The more specific issues of concern all revolve around the question of limits: the ability of technology to circumvent them, and the long-run costs of the technological "cures." Do we adapt to limits with technologies that have potentially large but uncertain future environmental costs or do we limit population and per capita consumption to levels sustainable with technologies which are known to be more environmentally benign? Must we always increase supply or can we also reduce demand? Is there an optimal mix of the two?

Issues of sustainability are ultimately issues about limits. If material economic growth is sustainable indefinitely by technology then all environmental problems can (in theory at least) be fixed technologically. Issues of fairness, equity, and distribution (between subgroups and generations of our species and between our species and others) are also issues of limits. We do not have to worry so much about how an expanding pie is divided, but a constant or shrinking pie presents real problems. Finally, dealing with uncertainty about limits is the fundamental issue. If we are unsure about future limits the prudent course is to assume they exist. One does not run blindly through a dark landscape that may contain crevasses. One assumes they are there and goes gingerly and with eyes wide open, at least until one can see a little better.

Vitousek et al., in an oft-cited paper, calculated the percent of the Earth's Net Primary Production (NPP) which is being appropriated by humans. This was the first attempt to estimate the "scale" or relative size of human economic activity compared to the ecological life-support system. They estimated that 25% of total NPP (including the oceans) and 40% of terrestrial NPP was currently being appropriated by humans. It left open the question of how much of NPP could be appropriated by humans without damaging the life-support functions of the biosphere, but it is clear that 100% is not sustainable and even the 40% of terrestrial NPP currently used may not be sustainable.

A related idea is that ecosystems represent a form of capital—defined as a stock yielding a flow of services—and that this stock of "natural capital" needs to be maintained intact independently in order to assure ecological sustainability. The question of whether natural capital needs to be maintained independently ("strong sustainability") or whether only the total of all capital stocks need to be maintained ("weak sustainability") has been the subject of some debate. It hinges on the degree to which human-made capital can substitute for natural capital, and, indeed, on how one defines capital generally. In general, conventional economists have argued that there is almost perfect substitutability between natural and human-made capital, while ecological economists generally argue on both theoretical and empirical grounds that the possibilities for substitution are severely limited. They therefore generally favor the strong sustainability position.

Another critical set of issues revolve around the way we define economic income, economic welfare, and total human welfare or wellbeing. Daly and Cobb clearly distinguish these concepts, and point out that conventional GDP is a poor measure even of

economic income. Yet GDP continues to be used in most policy discussions as the definitive measure of economic health and performance, and will continue to be until viable alternatives are available. According to Hicks, economic income is defined as the quantity we can consume without damaging our future consumption possibilities. This definition of income automatically embodies the idea of sustainability. GDP is a poor measure of income on a number of grounds, including the fact that it fails to account for the depletion of natural capital and thus is not "sustainable" income in the Hickian sense. GDP is an even poorer measure of economic welfare, since many components of welfare are not directly related to income and consumption. The Index of Sustainable Economic Welfare (ISEW) devised by Daly and Cobb (and its renamed, but almost identical successor, the Genuine Progress Indicator (GPI)) is one approach to estimating economic welfare (as distinct from income). GPI starts with Personal Consumption Expenditures (a major component of GDP) but adjusts them using 24 different components, including income distribution, environmental costs, and negative activities like crime and pollution, among others. GPI also adds positive components left out of GDP, including the benefits of volunteering and household work. By separating activities that diminish welfare from those that enhance it, GPI better approximates sustainable economic welfare. However GPI is not the perfect indicator of societal wellbeing and needs to be viewed alongside biophysical and other indicators.

Past national GPI studies have indicated that in many countries, beyond a certain point, GDP growth no longer correlates with increased economic welfare. An important function of GPI is to send up a red flag at that point. Since it is made up of many benefit and cost components, it also allows for the identification of which factors increase or decrease economic welfare. Other indicators are better guides of specific aspects.

For example, Life Satisfaction is a better measure of overall self-reported wellbeing. By observing the change in individual benefit and cost components, GPI reveals which factors cause economic welfare to rise or fall even if it does not always indicate what the driving forces are behind this. It can account for the underlying patterns of resource consumption, for example, but may not pick up the self-reinforcing evolution of markets or political power that drives change.

Valuation of Ecological Services

All decisions concerning the allocation of environmental resources imply the valuation of those resources. Ecological economics does not eschew valuation. It is recognized that the decisions we make, as a society, about ecosystems imply a valuation of those systems. We can choose to make these valuations explicit or not; we can undertake them using the best available ecological science and understanding or not; we can do them with an explicit acknowledgment of the huge uncertainties involved or not; but as long as we are forced to make choices about the use of resources we are valuing those resources. These values will reflect differences in the underlying worldview and culture of which we are a part, just as they will reflect differences in preferences, technology, assets, and income. An ecological economics approach to valuation implies an assessment of the spatial and temporal dynamics of ecosystem services, and their role in satisfying both individual and social preferences and their broader contribution to wellbeing that may not be perceived by most people. It also implies explicit treatment of the uncertainties associated with tracking these dynamics.

Ecological economics is different from environmental economics in terms of the latitude of approaches to the ecosystem valuation problem it allows. They include more conventional Willingness To Pay (WTP)-based approaches, but they also include other more novel methods, including deliberative and participatory approaches and approaches based on explicitly modeling the linkages between ecosystems and economic systems.

Preference formation is influenced by limited information in estimating WTP-based values for biodiversity preservation. Empirical studies show that a significant portion of individuals exhibit "lexicographic" preferences, that is, they refuse to make tradeoffs that require the substitution of biodiversity for other goods. This places significant constraints on the use of stated preferences, as used in contingent valuation studies, for valuation of ecosystem services and decision-making. It places more emphasis on the need to develop more direct methods to assess the value of these resources as a supplement to conventional WTP-based methods.

The valuation of ecological resources requires a deeper understanding of the ways in which economic activity depends on biogeophysical processes than is usually recognized. However, the issue of ecosystem valuation is far from solved. In fact, it is probably only in the early stages of development. Conventional WTP-based approaches have severe limitations. Key directions for the future include integrated ecological economic modeling, as elaborated in the next section.

Integrated Ecological Economic Modeling and Assessment

The emphasis on both (1) issues of scale and limits to the carrying and assimilative capacity of ecological systems and (2) underlying dynamics of those systems imply the need for a new approach to the modeling of joint systems. It is not surprising that this is an active area of research in ecological economics. Indeed, combining (sometimes implicit) models of ecological processes and economic decision models in a new that makes the feedbacks between the two sets of processes transparent is where we most expect new advances to be made as a result of the ongoing dialog between economists and ecologists.

Ecology and economics have long diverged both methodologically and conceptually. One reason for the difficulty in bridging the modeling gap is that economics, as a discipline, has developed almost no tools or concepts to handle spatial differentiation beyond the notions of transport cost and international trade. The spatial analysis of human activity has been seen as the domain of geographers, and has had remarkably little impact on the way economists have analyzed the allocation

of resources. This makes collaboration between economists and disciplines based more directly on spatial analysis difficult. Since the development of spatially explicit integrated models is one of the areas in which ecological economics is expected to develop most rapidly, it would seem that geographers are likely to become an increasingly important part of the research agenda in ecological economics.

A second characteristic of ecological–economic models concerns the way in which the valuation of ecological functions and processes is reflected in the model structure. The point was made in the previous section that valuation by stated preference methods (estimation of willingness to pay or accept using contingent valuation or contingent ranking) may capture the strength of people's perceptions and their level of income and endowments (their ability to pay), but it generally fails to capture the impact of a change in ecosystem functions and processes on the output of economically valued goods and services. Unless the role of non-marketed ecological functions and processes in the production of economically valued goods and services is explicitly modeled, it is hard to see how they can be properly accounted for in economic decision making.

A third characteristic concerns the role of integrated modeling in strategic decision making. One of the challenges to ecological economics has been to devise methods to address strategic "what if" questions in a way that reflects the dynamics of the jointly determined system. The general problem confronting anyone attempting to model long-run dynamics explicitly is that ecological–economic systems are complex nonlinear systems. The dynamics of economic systems are not independent of the dynamics of the ecological systems which constitute their environment, and that as economies grow relative to their environment, the dynamics of the jointly determined system can become increasingly complex. Indeed, the development of ecological economics can be thought of as part of a widespread reappraisal of such systems.

In ecology, this reappraisal has influenced recent research on scale, complexity, stability, and resilience, and is beginning to influence the theoretical treatment of the coevolution of species and systems. The results that are most important to the development of ecological economics concern the link between the spatial and temporal structure of coevolutionary hierarchical systems. Landscapes are conceptualized as hierarchies, each level of which involves a specific temporal and spatial scale. The dynamics of each level of the structure are predictable so long as the biotic potential of the level is consistent with bounds imposed by the remaining levels in the hierarchy. Change in either the structure of environmental constraints or the biotic potential of the level may induce threshold effects that lead to complete alteration in the state of the system.

In economics there is now considerable interest in the dynamics of complex nonlinear systems. Economists have paid less attention to spatial scale and its significance at or near system thresholds, but there is now a growing body of literature with roots in geography which seeks to inject a spatial dimension into nonlinear economic models. There is also an economic analog to the biologist's interest in evolution and the significance of co-dependence between gene landscapes. The steady accumulation of evidence that economic development is not a stationary process, that human understanding, preferences, and technology all change with development, and that such change is generally nonlinear and discontinuous, has prompted economists to seek to endogenize technological change. Although the adaptation of this work by environmental economists has been rather disappointing, the treatment of technology and consumption preferences as endogenous to the economic process is a fundamental change that brings economics much closer to ecology.

The challenge to ecological economics in the future is to develop models that capture these features well enough to incorporate at least the major risks in economic decisions that increase the level of stress on ecological systems.

Summary and Conclusions

This is a sample of the range of transdisciplinary thinking that can be put under the heading of ecological economics. While it is difficult to categorize ecological economics in the same way one would a normal academic discipline, some general characteristics can be enumerated.

- The core problem is the "sustainability" of interactions between economic and ecological systems.
- An explicit attempt is made at "pluralistic dialog" and integration across disciplines, rather than territorial disciplinary differentiation.
- An emphasis is placed on "integration" of the three hierarchical goals of sustainable scale, fair distribution, and efficient allocation.
- There is a deep concern with the "biophysical underpinnings" of the functioning of jointly determined ecological and economic systems.
- There is a deep concern with the relationship between the "scale" of economic activity and the nature of change in ecological systems.
- Since valuation based on stated willingness to pay reflects limitations in the valuer's knowledge of ecosystems functions, there is an emphasis on the "development of valuation techniques" that build on an understanding of the role of ecosystem functions in economic production and wellbeing.
- There is a broad focus on systems and "systems dynamics, scale, and hierarchy" and on "integrated modeling" of ecological economic systems.

These characteristics make ecological economics applicable to some of the major problems facing humanity today, which occur at the interfaces of human and natural systems, and especially to the problem of improving humanity's wellbeing and assuring its

survival within the biosphere into the indefinite future. It is not so much the individual core scientific questions that set ecological economics apart—since these questions are covered independently in other disciplines as well—but rather the treatment of these questions in an integrated, transdisciplinary way, which is essential to their understanding and effective use in policy.

Ecological Economics 2☆

Robert Costanza, Australian National University, Canberra, ACT, Australia

Introduction

Stories about the economy typically focus on gross domestic product (GDP), jobs, stock prices, interest rates, retail sales, consumer confidence, housing starts, taxes, and assorted other indicators. We hear things like "GDP grew at a 3% rate in the fourth quarter, indicating a recovering, healthy economy, but with room for further improvement." Or, "The Fed raised short-term interest rates again to head off inflation."

But do these reports, and the indicators they cite, really tell us how the economy is doing? What is the economy anyway? And what is this economy for?

Conventional reports on these questions are rather narrow. The "economy" we usually hear about refers only to the market economy—the value of those goods and services that are exchanged for money. Its purpose is usually taken to be to maximize the value of these goods and services—with the assumption that the more the activity, the better off we are. Thus, the more the GDP (which measures aggregate activity in the market economy), the better. Likewise the more contributors to GDP (such as retail sales and salaries paid to employees), the better. Predictors of more GDP in the future (such as housing starts and consumer confidence) are also important pieces of information from this perspective. Declining or even stable GDP is seen as a disaster. Growth in GDP is assumed to be a government's primary policy goal and also something that is sustainable indefinitely.

But is this what the economy is all about? Or more accurately, is this "all" that the economy is about? Or, is this what the economy "should be" about? The answer to all of these is an emphatic "no." Here's why.

Let's start with purpose. The purpose of the economy "should be" to provide for the sustainable well-being of people. That goal encompasses material well-being certainly—but also anything else that affects well-being and its sustainability. This seems obvious and noncontroversial. The problem comes in determining what things actually affect well-being and in what ways.

There is substantial new research on this "science of happiness" that shows the limits of conventional economic income and consumption in contributing to well-being. Psychologist Tim Kasser in his 2003 book *The High Price of Materialism* points out, for instance, that people who focus on material consumption as a path to happiness are actually less happy and even suffer higher rates of both physical and mental illnesses than those who do not. Material consumption beyond real need is a form of psychological "junk food" that only satisfies for the moment and ultimately leads to depression, Kasser says.

Economist Richard Easterlin, a noted researcher on the determinants of happiness, has shown that well-being tends to correlate well with health, level of education, and marital status, and with income only up to a fairly low threshold (**Fig. 1**). He concludes in a recent paper in the *Proceedings of the National Academy of Sciences* that,

> People make decisions assuming that more income, comfort, and positional goods will make them happier, failing to recognize that hedonic adaptation and social comparison will come into play, raise their aspirations to about the same extent as their actual gains, and leave them feeling no happier than before. As a result, most individuals spend a disproportionate amount of their lives working to make money, and sacrifice family life and health, domains in which aspirations remain fairly constant as actual circumstances change, and where the attainment of one's goals has a more lasting impact on happiness. Hence, a reallocation of time in favor of family life and health would, on average, increase individual happiness.

British economist Richard Layard's 2005 book *Happiness: Lessons from a New Science* echos many of these ideas and concludes that current economic policies are not improving happiness and that "happiness should become the goal of policy, and the progress of national happiness should be measured and analyzed as closely as the growth of GNP." Several countries are now interested in alternative measures of progress. For example, the country of Bhutan has recently announced that it will make "gross national happiness" its explicit policy goal.

Economist Robert Frank, in his 2000 book *Luxury Fever*, also concludes that the nation would be better off—overall national well-being would be higher, that is—if we actually consumed less and spent more time with family and friends, working for our communities, maintaining our physical and mental health, and enjoying nature.

On this last point, there is substantial and growing evidence that natural systems contribute heavily to human well-being (**Fig. 2**). In a paper published in 1997 in the journal *Nature*, the author with his co-workers estimated that the annual, nonmarket value of the Earth's ecosystem services is $33 trillion globally, substantially larger than global GDP. The just released UN Millennium Ecosystem Assessment is a global update and compendium of ecosystem services and their contributions to human well-being.

So, if we want to assess the "real" economy—all the things which contribute to real, sustainable, human welfare and quality of life—as opposed to only the "market" economy, we have to measure the nonmarketed contributions to human well-being from

☆*Change History:* February 2018. R. Costanza made minor changes to the text, figures and references.

nature, from family, friends, and other social relationships at many scales, and from health and education. One convenient way to summarize these contributions is to group them into four basic types of capital that are necessary to support the real, human-welfare-producing economy: built capital, human capital, social capital, and natural capital (**Fig. 3**).

The market economy covers mainly built capital (factories, offices, and other built infrastructure and their products) and part of human capital (spending on labor), with some limited spillover into the other two types. Human capital includes the health, knowledge, and all the other attributes of individual humans that allow them to function in a complex society. Social capital includes all the formal and informal networks among people: family, friends, and neighbors, as well as social institutions at all

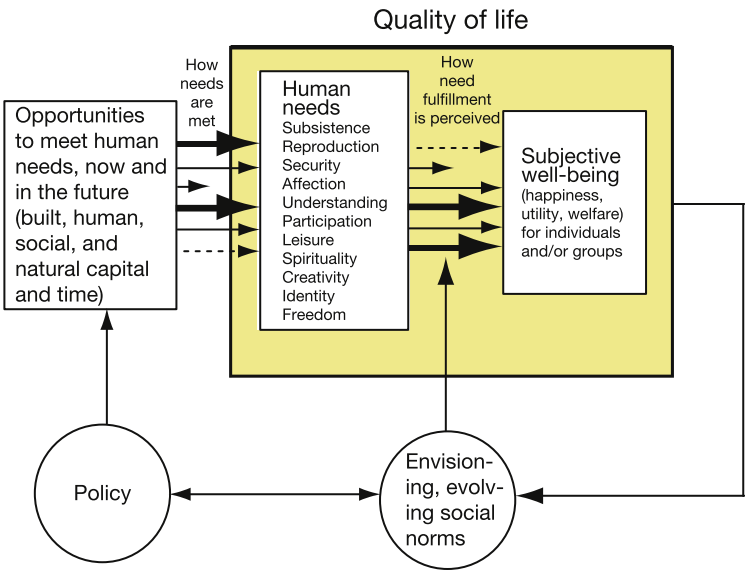

Fig. 3 Quality of life as the interaction of human needs and the subjective perception of their fulfillment, as mediated by the opportunities available to meet the needs. From Costanza, R. J., Fisher, S., Ali, C. et al. (2006) Quality of life: An approach integrating opportunities, human needs, and subjective well-being. *Ecological Economics* **61**, 267–276.

levels, like churches, social clubs, local, state, and national governments, NGOs, international organizations, and the institutions of the market itself. Natural capital includes the world's ecosystems and all the services they provide that support human well-being. Ecosystem services occur at many scales, from climate regulation at the global scale, to flood protection, soil formation, nutrient cycling, recreation, and esthetic services at the local and regional scales.

So, how have the world's real economies been doing recently, compared to their market economies? The short answer is, not so good. How do we know? One way is through surveys of people's life satisfaction, which in the United States has been decreasing slightly since about 1975. A second approach is an aggregate measure of the real economy that has been developed as an alternative to GDP called the genuine progress indicator, or GPI.

Let's first take a quick look at the problems with GDP as a measure of true human well-being. GDP is not only limited—measuring only marketed economic activity or gross income—it also counts all of this activity as positive. It does not separate desirable, well-being-enhancing activity from undesirable well-being-reducing activity. For example, an oil spill increases GDP because someone has to clean it up, but it obviously detracts from society's well-being. From the perspective of GDP, more crime, more sickness, more war, more pollution, more fires, storms, and pestilence are all potentially good things, because they can increase marketed activity in the economy.

GDP also leaves out many things that do enhance well-being but are outside the market. For example, the unpaid work of parents caring for their own children at home does not show up, but if these same parents decide to work outside the home to pay for child care, GDP suddenly increases. The nonmarketed work of natural capital in providing clean air and water, food, natural resources, and other ecosystem services does not adequately show up in GDP, either, but if those services are damaged and we have to pay to fix or replace them, then GDP suddenly increases. Finally, GDP takes no account of the distribution of income among individuals. But it is well-known that an additional $1 worth of income produces more well-being if one is poor rather than rich. It is also clear that a highly skewed income distribution has negative effects on a society's social capital.

The GPI addresses these problems by separating the positive from the negative components of marketed economic activity, adding in estimates of the value of nonmarketed goods and services provided by natural, human, and social capital, and adjusting for income-distribution effects (**Fig. 4** lists the components of the GPI). While it is by no means a perfect representation of the real well-being of a nation, GPI is a much better approximation than GDP. As Amartya Sen and others have noted, it is much better to be approximately right in these measures than precisely wrong.

Comparing GDP and GPI for several countries shows that in many "developed" countries the benefits of growth in the market economy are now being outweighed by the uncounted costs of that growth. For example, **Fig. 5** shows that globally, while GDP has steadily increased since 1950, with the occasional dip or recession, GPI peaked in about 1978 and has been gradually decreasing ever since. From the perspective of the real economy, as opposed to just the market economy, the world has been in recession since 1978. As already mentioned, this picture is also consistent with survey-based research on people's stated life-satisfaction. We are now in a period of what Herman Daly has called "un-economic growth," where further growth in marketed economic activity (GDP) is actually reducing well-being on balance rather than enhancing it. In terms of the four capitals, while built capital has grown, human, social, and natural capital have declined or remained constant and more than canceled out the gains in built capital.

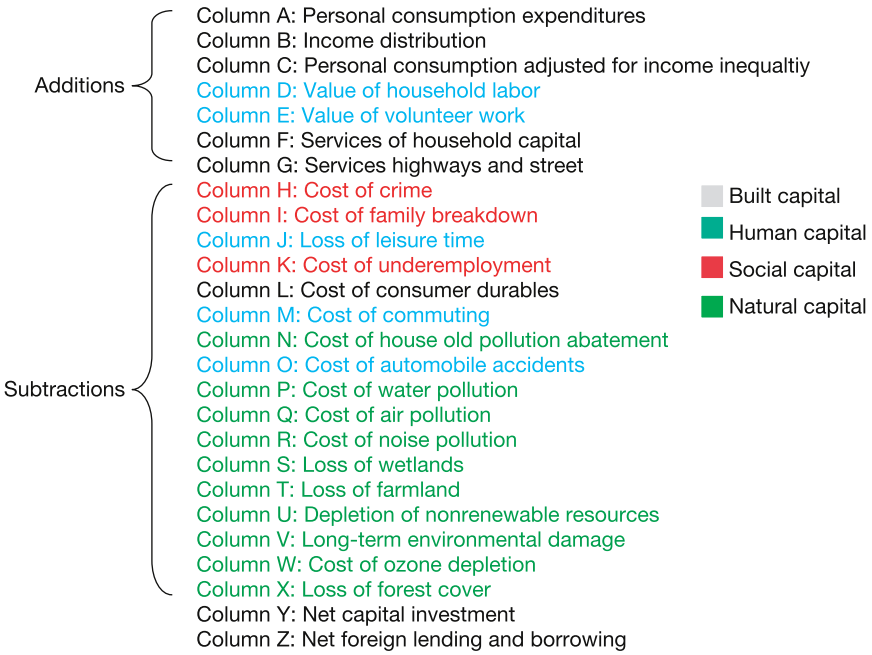

Fig. 4 The genuine progress indicator (GPI) by column.

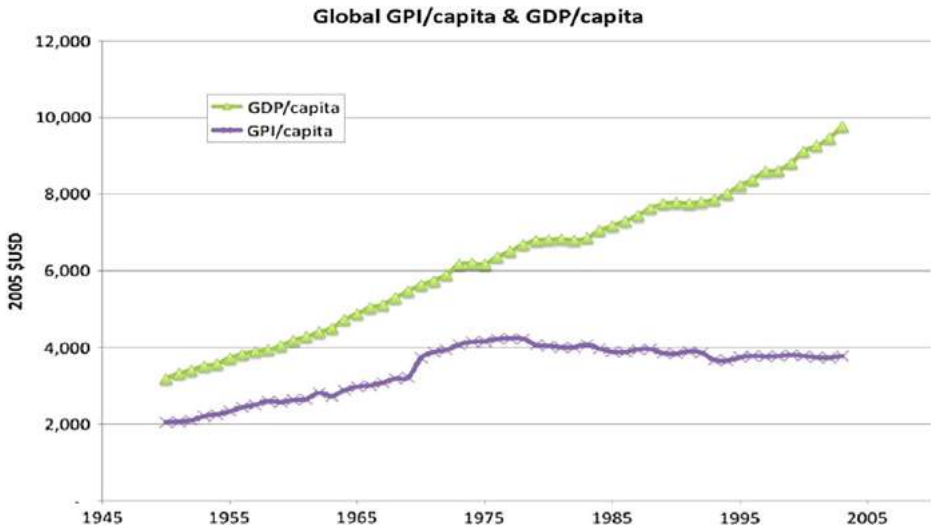

Fig. 5 Global GDP/capita vs. GPI/capita, 1950–2014. Source: Kubiszewski, I., Costanza, R., Franco, C., Lawn, P., Talberth, J., Jackson, T. and Aylmer, C. (2013). Beyond GDP: Measuring and achieving global genuine progress. *Ecological Economics*. **93**, 57–68.

From the perspective of the real economy, things are not improving.

Is the news all bad? No. We estimated the GPI of the State of Vermont and of Burlington, the state's largest city, and found that Vermont's and Burlington's GPI per capita had increased over the entire 1950–2000 period and is now more than double the national average. This was due to Vermont's attention to protecting and enhancing natural, human, and social capital in balance with gains in built capital—accomplished through the application of strong, local democratic principles, and processes still actively at work in Vermont. Recent GPI studies of all US states by M-V Fox and J. Erickson show that the range of variation is quite large.

The lesson is that there is significant variation within and across states and countries in trends in well-being and quality of life, and plenty of good examples we can learn from to improve overall well-being at multiple scales.

How can we apply these lessons to get out of the real recession in human well-being at the national scale that many countries are now in? Several policies have been suggested that would help to turn things around:

- Shifting our primary national policy goal from increasing marketed economic activity (GDP) to maximizing national well-being (GPI or something similar). This would allow us to see the interconnections between built, human, social, and natural capital and build well-being in a balanced and sustainable way.
- Reforming tax systems to send the right incentives by taxing negatives (pollution, depletion of natural capital, over-consumption) rather than positives (labor, savings, investment).
- Reforming international trade to promote well-being over mere GDP growth. This implies protecting natural capital, labor rights, and democratic self-determination first and then allowing trade, rather than promoting the current trade rules that ignore all nonmarket contributions to well-being.
- Implementing strong democracy, as Tom Prugh, Robert Costanza, and Herman Daly have argued in the book *The Local Politics of Global Sustainability*. Strong democracy implies true participation of all in governance and is an essential prerequisite to building a sustainable and desirable future.
- Increasing the size of the "common sector" of the economy (as opposed to the private and public sectors) but creating common property asset trusts to "propertize" natural and social capital assets, as described in Peter Barnes' book *Capitalism 3.0*.

Ultimately, getting out of the recession in well-being we are currently in will require us to look beyond the limited definition of the "economy" we read about in the newspapers, and recognize what the real economy is and what it is for. We must not allow deceptive accounting practices to paint an inaccurate and ultimately destructive picture of how "well" we are doing. Alternatives are available, but they need significant further discussion and research.

With nothing less than our current and future well-being at stake, we can certainly afford to devote greater effort to learning how to adequately understand and measure it. If we want things that really matter to our well-being to count, we must learn how to recognize and count them, use that information to inform policy in a real democracy, and create adaptive institutions that can effectively implement the policy.

Ecological Footprint☆

Mathis Wackernagel, David Lin, Laurel Hanscom, Alessandro Galli, and Katsunori Iha, Global Footprint Network, Oakland, CA, United States

Introduction

Ecosystems provide many critical services to human society, including both the direct provision of goods, such as food and fiber products, as well as less visible services, such as water filtration and climate stabilization. The availability of these ecosystem services depends closely on the functioning of biological capital. Broadly defined, biological capital contains all of the ecosystems and various components of the biosphere that directly or indirectly provide goods and services. Careful management of this capital is central to maintaining not only the health of the natural environment but also human well-being into the future.

Managing biological capital, however, requires tools that are able to track its availability and use. The Ecological Footprint is an accounting tool that calculates human demand on the biosphere, and compares this to the planet's ability to meet these demands. It does this by answering the specific research question, "how much of the Earth's regenerative capacity is occupied by human activities?"

The accounting builds on a simple thermodynamic principle. Since life competes for biologically productive space, every demand that competes for such areas can be added up. Therefore, demand on regenerative capacity can be approximated by adding up these mutually exclusive biologically productive areas occupied for providing the demanded services (the "Ecological Footprint"). This demanded space then can be compared to the space available (the "biocapacity"). Since not every unit of space has equal productivity, both Ecological Footprint and biocapacity are expressed in a productivity adjusted area unit, the global hectare. This is a hectare of biologically productive surface area of the planet with world-average productivity.

Footprint analysis helps governments, businesses, and individuals track economies' dependence on biological capital over time. Similar to financial balance sheets, the resulting ecological accounts can be used as a quantitative input into decision making at all levels.

Metabolism: An Ecological Model of Society

The Ecological Footprint applies principles of ecology and thermodynamics to human society to create a framework for mapping society's material and energy metabolism. As in any ecosystem, primary producers fix energy from sunlight through photosynthesis. This energy is then available for consumers, who use this primary production for powering their activities. All material ingested by consumers eventually returns to the biosphere as waste products. The biological waste products are broken down and recycled back into the raw materials for primary production.

This thermodynamic reality of every input eventually turning into waste, applies to any organism that exists in a natural environment, including human society. The human economy takes high-quality matter and energy as inputs from its environment and returns these in degraded form as material waste and heat. Societies consume resources in order to maintain themselves. Between resource intake and waste discharge, matter accumulates in these systems, leading to increased body mass in the case of animals, or an accumulation of material stocks in societies.

From a human perspective, the ability of the biosphere to absorb wastes and regenerate resources is known as the regenerative capacity of the planet. Although the Earth's regenerative capacity is robust, it can be eroded in a number of ways. The Natural Step framework puts them into three main categories (Robèrt *et al.*, 2002):

1. Harvesting renewably generated resources, such as trees or fish, faster than they can be replenished can overwhelm natural cycles. Direct physical interference, such as the paving over of green surfaces or farming practices that cause soil erosion, can also damage the underlying capital (i.e., loss of soil nutrients or ground water depletion) that creates these resources, further reducing the Earth's total regenerative capacity.
2. Substances produced by society that are persistent and do not readily break down, and which ecosystems have not developed abilities to assimilate, can compromise regenerative capacity as they accumulate in the biosphere. Examples include synthetic chemicals such as DDT and PCBs that persist and bio-accumulate through tropic levels. Many of these man-made substances have no natural analogues, and the biosphere as a whole has not evolved efficient means to break down and reassimilate these products on human time scales.
3. Substances normally buried deep within the Earth's crust can be extracted, refined, and introduced into the biosphere at quantities that ecosystems or the atmosphere are not able to assimilate. Examples include heavy metals, radioactive elements,

☆*Change History:* March 2018. M Wackernagel, D Lin, L Hanscom, A Galli, and K Iha updated all figures and tables.

This is an update of M. Wackernagel, E. Lazarus, D. Lin, K. Iha and J.A. Kitzes, Ecological Footprint, In Reference Module in Earth Systems and Environmental Sciences, Elsevier, 2015.

 doi:10.1016/B978-0-12-409548-9.09567-1

minerals, and mined carbon. Because there are few natural cycles that can return these substances to the crust within human time spans, these substances systematically accumulate in the biosphere and atmosphere.

The fundamental insight emerging from looking at the human economy from the perspective of its metabolism is that, in the long-term, the biosphere must be able to turn wastes back into resources faster than human society turns the resources into waste. If the extraction of resources becomes too large, or if nature's regenerative capacity is compromised, biological capital will be systematically degraded and wastes will accumulate.

While in the past, most "environmental" problems arose from poor management of some local aspects of society's metabolism, such as careless waste disposal, smokestacks, or overuse of a river basin, now the very size of society's global metabolism that has become the overarching concern. While local overuse of the biosphere has a long history (e.g., overfishing, deforestation, soil erosion, etc.), the global human economy has now become so large, relative to the regenerative capacity of planet Earth, that it is now, for the first time in human history, confronting global limits.

Fundamental Assumptions

In order to provide a quantitative answer to the research question of how much regenerative capacity is required to maintain a given resource flow through human society, Ecological Footprint analysis uses a methodology grounded on six basic assumptions:

1. *The annual amounts of resources consumed and wastes generated by countries are tracked by national and international organizations.* Most countries have extensive annual statistics documenting their resource use, particularly in the areas of energy, forest products and agricultural products. United Nations agencies, like the Food and Agriculture Organization (FAO), compile many of these national statistics in a consistent format.
2. *The quantity of biological resources appropriated for human use is directly related to the amount of bioproductive land area necessary for regeneration, accommodation of infrastructure, or the assimilation of waste.* Bioproductive processes are associated with surfaces that capture sunlight for photosynthesis. Even three-dimensional processes that represent layers of such surfaces, as in aquatic ecosystems or rainforests, can be mapped on the two-dimensional area on which they occur.
3. *By weighting each area in proportion to its usable biomass productivity (i.e., its potential annual production of usable biomass), the different areas can be expressed in terms of a standardized average productive hectare*. For this reason, Ecological Footprint accounting uses as its measurement the standardized global hectare with world-average productivity. (In other words, each of the global hectares represents an equal share of the planet's total regenerative capacity).
4. *The overall demand in global hectares can be aggregated by adding all mutually exclusive resource-providing and waste-assimilating areas required to support the demand*.
5. *Aggregate human demand (Ecological Footprint) and nature's supply (biocapacity) can be directly compared to each other*. By using the standardized unit of a global hectare, demand and supply can be compared, as can different components of demand and supply.
6. *Area demanded can exceed area supplied.* A Footprint greater than available biocapacity at any given scale indicates that demand exceeds the regenerative capacity of existing biological capital. This condition, known as "overshoot," is physically possible only in the short-term. For some limited time, resources can be harvested faster than they regenerate (e.g., deforestation) and wastes can accumulate (e.g., carbon dioxide in the atmosphere). In the long-term, however, such overshoot inevitably implies ecological degradation. This will reduce the amount that the overused ecosystems can deliver ever year. Overshoot may also lead to more abrupt change: demand can cross ecological thresholds that trigger nonlinear, large-scale, abrupt environmental change or even collapse (Rockstrom *et al.*, 2009).

Note the similarity and complementarity to the approach named "Planetary Boundaries" (Rockstrom *et al.*, 2009; Steffen *et al.*, 2015). Ecological Footprint accounting summarizes human demand against the planet's level of regeneration. In contrast, Planetary Boundaries investigates nine dimensions of human uses of the biosphere. By mapping overall demand on biocapacity only, Ecological Footprint accounting reveals overall limitations of the biosphere and implies trade-offs between the Planetary Boundaries dimensions.

Planetary Boundaries (Rockstrom *et al.*, 2009; Steffen *et al.*, 2015) identify key physical quantitative conditions that are needed to maintain the integrity of the biosphere. Nine areas have been identified, in which transgressions could lead to shifts in the biosphere's integrity, potentially irreversibly moving the biosphere out of the stable conditions which characterized the Holocene.

Therefore, one could interpret the Planetary Boundaries as the inverse of the ingredients for healthy, productive ecosystems that can maintain their integrity. In other words, staying within the "safe operating zone" for each of the nine ingredients enables the biosphere's productivity, which Ecological Footprint accounting calls the biosphere's biocapacity. These boundaries translate into the following specific ingredients, similar to what economists would call "the production factors" enabling biocapacity:

- Stable climate
- Healthy biodiversity
- Sufficient (yet not excessive amounts of) nutrients
- Protective ozone layer

- Absence of pollutants
- Clean and sufficient fresh water
- Absence of acidification in both water and soils

The Ecological Footprint does not quantify, in contrast to the planetary boundaries' trigger points. Rather it tracks human demand against biological regeneration. If demand exceeds regeneration, the resulting natural capital loss or degradation will eventually trigger irreversible change since one cannot indefinitely take more from ecosystems than they can renew. Ecological Footprint accounts summarize the overall outcome of transgressing planetary boundaries and quantify this transgression in one "biocapacity" number representing the regenerative capacity of the biosphere.

There is strong complementarity between planetary boundaries and Ecological Footprint. Where the planetary boundaries span a broad field of academic inquiry, Footprint assessments can be categorized as a simple biophysical accounting approach based on fundamental thermodynamic laws and biological principles.

The Planetary Boundaries approach mostly applies to the global level, while Ecological Footprint can be tracked at any scale. Planetary Boundaries are richer in describing the impact of the human economy on the biosphere; Ecological Footprint accounting's strength is built on comparing human demand against ecosystem regeneration, but is therefore in return restricted to only one core dimension—biocapacity. This uni-dimensionality makes it easy to apply and interpret Footprint results. Also, Ecological Footprint limits are based on tracking demand against "sustainable yields" or regeneration. Planetary Boundaries tracks human metabolism against trigger points or levels of irreversible change, many of which cannot be predicted, or even defined with accuracy.

Ecological Footprint and Biocapacity Accounting

Ecological Footprint analysis examines the size of society's metabolism with a specific research question: how much of the regenerative capacity of the biosphere is being occupied by human activities (Rees and Wackernagel, 1994; Wackernagel and Rees, 1996; Wackernagel *et al.*, 2014)? To answer this question, Footprint analysis measuring how much biologically productive land and water area an individual, a city, a country, a region, or humanity uses to produce the resources it consumes, accommodate its infrastructure, and to absorb the waste it generates, using prevailing technology and resource management schemes.

This demand can be compared with supply, or biocapacity, which is the total available biologically productive surface of the planet. The common unit used for this analysis, as the term "Footprint" suggests, is area, more specifically productivity adjusted hectares, called global hectares, representing hectares of land or sea with world-average biological productivity.

The most comprehensive Ecological Footprint accounts are the national calculations by Global Footprint Network, called "National Footprint Accounts." The 2017 edition of these accounts tracks Ecological Footprint and biocapacity of all countries accounts from 1961 to 2013. 2013 is the last year for which a complete set of input data is available (United Nations Food and Agriculture Organization, United Nations Comtrade, International Energy Agency, and others). National Footprint Accounts are updated every year—with a 4-year time lag in data. With the use of extrapolation, more recent proxy data (like GDP), or partial data (e.g., greenhouse gases which are reported with less time lag), it is possible to "nowcast" biocapacity and Footprint results to the present.

Calculating Demand: Footprint

At present, human demand on ecosystems, or a population's Footprint, is translated into demands for six major demand types—crops, grazing products, sea food, forest products, built-up land, and carbon Footprint (**Table 1**, Borucke *et al.*, 2013). Carbon Footprint and forest products both compete for productive forest areas. Hence only five area types accommodate the six demand types. The first four demand categories represent food, fiber, and timber products for human consumption. These products may be consumed directly or processed further before final consumption. Regardless of the forms they eventually take within society, however, all products produced from these four categories can be translated, through the use of yields (annual tons per hectare)

Table 1 Major land types in Ecological Footprint and biocapacity accounting

Ecological Footprint (demand types)	*Biocapacity (areas)*
Crops	Cropland
Grazing products	Grazing area
Sea food	Fishing grounds
Carbon Footprint	*Forest*
Forest products	
Built-up land	Built-up land

The forest biocapacity serves two competing uses: absorbing CO_2 for the carbon footprint and providing forest products such as timber and firewood.

and conversion factors (tons of processed product per tons of raw material), back into the amount of world-average bioproductive area required to produce the products. Note that this land and water area can be located anywhere on the planet.

The fifth land type, built-up land, represents the area required for the physical infrastructure associated with human society, such as cities and roads. The sixth demand, carbon Footprint, represents the amount of biologically productive space (forests) required to absorb one of the human economy's currently most significant waste products: carbon dioxide. This Footprint is calculated as the amount of forested area required to sequester a given amount of carbon dioxide, effectively removing it from the atmosphere, after accounting for absorption by the oceans (Mancini *et al.*, 2016). Of course, this sequestration also needs to be accompanied by biological long-term carbon storage (including the preservation of primarily old growth forests and peat bogs).

In earlier calculations, the Footprint of nuclear electricity was included as on par with coal power for lack of better information. But since 2009, only the CO_2 component of nuclear energy is included in Ecological Footprint accounts to make the assessment fully consistent with the research question. Yet, we also recognize and emphasize that the research question driving Ecological Footprint accounts is not the most relevant and critical one for assessing the viability of nuclear power. Other aspects such as costs, operational risks, the military nexus, and waste storage concerns are more relevant issues to be considered. Yet, the use of nuclear power can lead to the loss of significant amounts of biocapacity, as in the case of the Fukushima nuclear accidents with large, productive areas becoming unavailable to human use for decades if not centuries (WWF-Japan and Global Footprint Network, 2012).

The approach of translating fossil fuel use into bioproductive area needed to sequester the emitted carbon dioxide does not suggest that afforestation or other types of biological sequestration are the main solution to reducing atmospheric carbon dioxide concentrations. This measure does show, however, how much larger the biosphere would need to be to stabilize carbon dioxide concentrations in the atmosphere without further human intervention. It also emphasizes that a reduction in emissions is unavoidable if carbon concentration in the atmosphere is to be contained to an acceptable level. The 2017 Edition of the National Footprint Accounts, for example, calculates that in 2013 the release of 1 ton of carbon dioxide per year has a Footprint of approximately 0.34 global hectares. Other human-supported methods exist for sequestering carbon dioxide, and the use of these technologies will be reflected in a decrease in the energy Footprint as they are brought online. Similarly, the introduction of renewable energy technologies with lower carbon-intensities will lead to a reduced carbon Footprint in the future. In addition, land-use changes such as deforestation can add emissions and reduce biocapacity, while land-use changes from erosive to sustainable agriculture can strengthen or even increase biocapacity over the long-term.

Some have questioned the utility of including the carbon Footprint in the Ecological Footprint (e.g., van den Bergh and Verbruggen, 1999 or Blomqvist *et al.*, 2013). However, given the research question, which focuses on the competing demands for biocapacity, CO_2 emission from fossil fuel use is clearly a competing demand for biocapacity and needs to be included. Without the sequestration, natural capital is not being maintained, and ecological debt accumulates in terms of increasing CO_2 concentrations in the atmosphere. This is parallel to overharvesting timber in a forest, where overuse leads to a depletion of natural capital (or a build-up of ecological debt). Trade-offs in biocapacity demands are meaningfully depicted as emissions can be compensated by either allocating more biocapacity to carbon sequestration, or directly reducing emissions.

Therefore, Ecological Footprint accounting complements and strengthens the rationale for climate action in four ways:

1. *Easy, intuitive and transparent*. Ecological Footprint accounts confirm reduction requirements consistent with the Paris Agreement's 2°C or 1.5°C goal, complementing the more complex, dynamic, and less testable climate models. With basic, widely understood and easily testable scientific principles, the accounts can be understood and audited by anyone with basic science education. (Climate models are needed to estimate remaining carbon budget, estimating the links between carbon concentration, radiative forcing and temperature increase; Ecological Footprint accounting complement them by revealing the steady-state availability of renewable capacity through a simple resource balancing approach).

2. *Ecosystem productivity as a core resource*. The focus on ecosystem productivity (or biocapacity, as expressed in Footprint accounting) becomes a primary concern once we acknowledge commit to a societal transition from fossil fuel to renewable energy sources. Economies will therefore rely primarily on what ecosystems can provide for their physical inputs (plus that energy which is not in competition for bioproductive land such as photovoltaics in deserts or windmills off-shore). Without cheap energy, it might be difficult to maintain high agricultural yields, and the demand for fuel wood may go up, both potentially increasing demand on land. If humanity should continue to use fossil fuels beyond the carbon budget, the ensuing climatic changes would most likely reduce the planet's biocapacity, making it even more difficult to run the economy in the future. One main reason why climate change needs to be avoided is to not endanger biocapacity, on which the human economy inevitably depends.
3. *Connecting land and atmosphere*. The National Footprint accounts are consistent with the Paris Agreement's embracing of net-emissions. The focus on net-emissions recognizes the fundamental link between the atmosphere and the biosphere. It is not only about carbon emissions, but also about how much of the carbon can be sequestered, by biological, technical, or other means. This opens up broader opportunities for mitigation. Biocapacity is a safe and natural way to get rid of excess carbon. But biocapacity is also limited in how much excess carbon it can sequester (much less than current emissions from fossil fuel burning). In contrast, there are many geoengineering ideas but no meaningful governance mechanism to keep them under control.

4. *Emphasis on self-interest*. By putting the climate challenge into the context of biocapacity, the resource security perspective (and its link to an economy's self-interest to be resource secure) becomes more obvious, possibly helping to overcome the common misperception that climate change is an inevitable "tragedy of the commons." Rather, addressing resource security and climate change in all investment choices enables the development of successful, resilient economies.

Calculating Supply: Biocapacity

Human demand, or Footprint, can be compared to the total availability of biologically productive land and sea, or biocapacity. Biocapacity is currently measured in five major land types (**Table 1**), analogous to the six demand types of Footprint (where both the carbon Footprint and the forest product Footprint compete for forest land).

Globally, Footprint analysis identifies, for 2013, approximately 12.2 billion hectares of biologically productive land and sea that can provide economically useful concentrations of renewable resources. These 12.2 billion hectares cover just under one quarter of the planet's surface and include 1.6 billion hectares of cropland, 3.4 billion hectares of grazing land, 4 billion hectares of forest, 3 billion hectares of marine and inland fisheries, and 0.2 billion hectares of built-up land. Built-up (or urbanized) land is included because it represents in most cases highly productive areas that are either paved over or fenced in, excluding other uses. The "compromised biocapacity," that is, how much biocapacity was given up for this urbanized area, of paved over areas is accounted for.

These areas concentrate the bulk of the biosphere's regenerative capacity. Global Footprint Network has not yet been able to estimate or identify reliable existing estimates of how much of the total annual biomass generation or net primary production (NPP) is concentrated on these 12.2 billion hectares. But we assume that those productive areas contain the overwhelming majority of the planet's harvestable NPP. While the remaining areas of the planet are also biologically active and support life, such as the deep oceans or deserts, their renewable resources are not concentrated enough to be a significant addition to the overall biocapacity. Also, low concentration of biomass in those areas makes harvesting their products highly resource intensive.

Many materials and pollutants place demands on the biosphere primarily by reducing the ability of ecosystems to provide goods and services, which leads to a loss in biocapacity. Toxins, heavy metals, and other persistent pollutants fall into this category. The amount of bioproductive area required to mine mercury, for example, is insignificant compared to the extent of the ecosystems that this metal affects. Similarly, the area required to absorb this product is an undefined quantity, as ecosystems do not have a well-defined or understood ability to assimilate this metal naturally. As a result, the environmental impacts of mercury, as well as other toxins, do not appear, nor are they specifically tracked by the Ecological Footprint. The physical area occupied by mines is indeed captured as infrastructure or built-up area, while the energy used in production is captured within the carbon Footprint. The primary effect of such materials is represented by the widespread loss of biocapacity that would result if they were released widely into the environment.

The Common Unit: Global Hectares

Given the widely varying scope of human demands, and the wide variety of ecosystems available on the planet, any aggregate analysis or indicator requires a common metric for comparison. Ecological Footprint accounts compare different types of Footprint to each other and to available biocapacity using a global hectare, defined as a hectare with world-average productivity of the 12.2 billion biologically productive hectares on planet Earth.

In the context of global hectares, biological productivity refers to the productivity (or more precisely the maximum sustainable yields) of an area's products and services that the human economy demands. It is an agro-ecological measure of regeneration, which can directly be compared to harvests. In that way it is related to net primary production (NPP) measures for biomass used in ecological sciences. The agro-ecological approach increases the ability to compare harvest with regeneration, a particular weakness of the otherwise highly valuable NPP assessments (Rojstaczer *et al.*, 2001).

The agro-ecological approach inherent in Footprint accounting also helps to compare across various land-uses. For instance, one hectare of highly productive land (e.g., cropland) is worth more global hectares than one hectare of less productive land (e.g., pasture). Global hectares are normalized so that the number of actual hectares of biologically productive land and sea on the planet is equal to the total worldwide budget of global hectares in any given year (therefore, a global hectare is also an average hectare).

Ideally, hectares should be compared against each other in terms of their inherent potential NPP—their unaltered innate ability to regenerate, independent of the human-imposed land-use. But in absence of such data sets, the National Footprint Accounts use relative agricultural productivity as a first approximation of relative biocapacity.

Ecological conservation areas that are not harvested are counted at their full biocapacity in Global Footprint Network's National Footprint Accounts.

Note that comparing amount of biocapacity available to amount of biocapacity is merely one dimension of describing human dependence on ecological services. Using less than can be regenerated is a necessary, but not sufficient condition for sustainability. In addition to getting quantity right, there are a number of additional quality considerations. For instance, in order to meaningfully preserve biodiversity, intact old growth forests are needed, with no fragmentation or other major human intervention. In other words, a global hectare of plantation forest and a global hectare of old growth forest, while representing the same amount of timber productivity or carbon sequestration capacity, do not represent the same biodiversity value. Keeping the human Footprint

within the biocapacity of ecosystems is just one of the many conditions of biodiversity conservation. However, getting quantity right is a precondition for being able to achieve quality at scale. If the quantity of human demand exceeds what biocapacity can regenerate, the quality (and preservation) of biocapacity management of some of the biocapacity will inevitably come at increased pressure on the remainder of the biocapacity.

Methodology

Data Sources

The most robust Ecological Footprint accounts exist at the national scale. Subnational Footprint calculations are possible and increasingly common. They typically build on the national assessments, and the resolution of the assessments depends on the availability and accuracy of data sources at the subnational level. A few examples are available on Global Footprint Network's website at www.footprintnetwork.org/our-work/ecological-footprint/cities. Many other organizations have performed such calculations over the last decade.

The international community of Footprint practitioners developed standards for Footprint applications—the initial standards were launched in 2006 and updated in 2009 (www.footprintstandards.org).

The National Footprint Accounts are currently maintained by Global Footprint Network, a nonprofit organization headquartered in Oakland, California, and its over 65 partner organizations throughout the world. Results are published annually and made available on Global Footprint Network's data platform data.footprintnetwork.org. Other organizations' publications also publish the results, as for example WWF International's bi-annual *Living Planet Report* (The latest one is WWF, Global Footprint Network Zoological Society of London, 2016).

The national analysis relies heavily on data published by the Food and Agriculture Organization of the United Nations (FAO), the United Nations Statistics Division, the Intergovernmental Panel on Climate Change (IPCC) and the International Energy Agency (IEA). Other data sources, including meta-analyses, scientific publications, and thematic collections, are used to fill in the gaps between these international sources. The use of official, typically conservative sources points toward the high probability that biocapacity estimates may be exaggerated, while Footprints may be underreported.

Yield Factors and Equivalence Factors

In the national assessments, two conversion factors, yield factors and equivalence factors, are used in the calculation of Footprint and biocapacity, particularly for translating results into the common unit of global hectares.

Yield factors are calculated as the ratio of national, country-specific yields for a given product to the average world yield for that same product. This ratio describes the extent to which a biologically productive area in a given country is more (or less) productive than the global average of the same land type. Differences in national and global yields can be due to a wide variety of factors, including variation in climate, soil conditions, available technology, and management regimes. Yield factors are specific to individual land types, countries, and years.

Equivalence factors relate the average productivity of a given land type to the world-average productivity of all biologically productive land types. Cropland, for example, has a higher productivity than world-average land. Grazing land is, on average, less productive than the average of all land types. Equivalence factors are currently calculated using Global Agro- Ecological Zones (GAEZ) data, which provides a spatial model of potential agricultural yields. The equivalence factor for a land type depends on its level of potential agricultural productivity relative to other land types.

Calculating Footprint and Biocapacity

The general formula for calculating the Ecological Footprint associated with the consumption of a quantity of product is given as:

$$EF = (M/NY) \times YF \times EQF \quad (1)$$

where EF is the Ecological Footprint of a given product flow (in global hectares), M is the mass of the product flow (in tons per year), NY is the national yield of the country in which that product was produced (in annual tons per hectare), YF is a yield factor calculated as the ratio of national yields to world yields for a given product, and EQF is an equivalence factor reflecting the relative productivity of a given land type compared to world-average productivity.

This formula can be applied directly to all products harvested directly from the first four major productive land types: cropland, grazing land, fishing ground, and forest land. The Footprint of secondary products (e.g., flour) that are created from primary products (e.g., wheat) is calculated by converting them back into primary-product equivalents.

The Footprint of built-up land is calculated by using the physical extent of the area occupied in built area (in hectares) instead of the product of mass (M) and national yield (NY). Yield and equivalence factors for cropland are applied, reflecting the assumption that most built land occupies former cropland, unless more accurate data is available. The carbon Footprint is calculated using the total mass of carbon dioxide emissions released from a given activity and the world-average sequestration rate of forested land (after subtracting the portion absorbed by the oceans). This rate is used in place of the ratio of national yield (NY) and yield factor (YF).

To calculate the Footprint of a nation, the Footprint of all products consumed within that country is calculated using the formula above. All the product Footprints are then summed. The global Ecological Footprint is calculated as the sum of all national Footprints.

The biocapacity associated with a given productive land or sea area is calculated in a similar fashion:

$$BC = A \times YF \times EQF \tag{2}$$

where BC is the biocapacity of a given area (in global hectares), A is physical extent of the area under analysis (in country-specific hectares), YF is a yield factor for that country and land type, and EQF is an equivalence factor for that land type. Note that this formula is identical to that for Ecological Footprint, except here area substitutes for the product of mass and national yield. This formula can be applied equally to all five major productive land types on the planet: crop land, grazing land, fishing grounds, forests, and built-up land. The regenerative capacity of forests is used to meet the demands (i.e., the Ecological Footprint) for both forest products and carbon sequestration.

Key Global and Regional Results

At the largest scales, global Ecological Footprint analysis shows that the total human Footprint, or demand on ecosystems, exceeds the planet's available biocapacity, or its ability to supply resources and waste sinks. Estimates for 2017 (extrapolated from 2013 data) suggest that the Footprint of humanity exceeds biocapacity by 71%. Global overshoot has existed since the early 1970s (Fig. 1). The most significant growth in Ecological Footprint over this time period has been a result of an increase in the productive land area required to meet human demands for carbon sequestration. This carbon Footprint made up 60% of humanity's Ecological Footprint in 2013. The growth in available biocapacity over time largely reflects increases in the productivity of cropland. These increases were at least partially enabled, however, by increases in application of fertilizers and pesticides and use (and overuse) of freshwater, all of which contributed to the rapidly growing Ecological Footprint over this same time period. Also, it indicates that this increase may not be maintained forever: Overuse reduces availability and also reduces future productivity (as in the example of collapsed fisheries, depleted groundwater, overharvested forests, or climate change). When and how this plays out is still an open, significant research question.

These consistently growing global trends, however, mask significant regional variation (Fig. 2). In 2013, the per person Ecological Footprint of North America and in the EU ws 1.7-fold and 2.1-fold the biological capacity available within those regions. If everyone in the world lived with a level of ecological demand equal to the EU or North American average, humanity would require the regeneration of three or five planet Earths, respectively. Asia-Pacific has an average level of ecological demand that would require 1.4 planet Earths if all of humanity lived like them. A free public data package with all the results in a convenient EXCEL sheet can be downloaded from data.footprintnetwork.org.

Levels of demand also vary significantly between high, middle, and low-income countries. These income categories are defined by the World Bank. In 2013, high-income countries had an average Ecological Footprint of 6.4 global hectares per

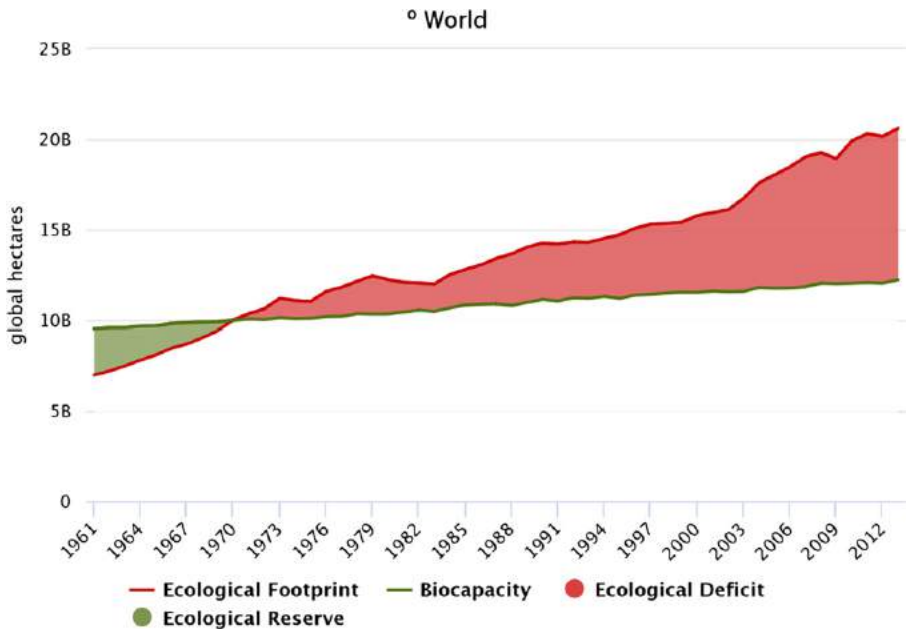

Fig. 1 Humanity's Ecological Footprint and the planet's biocapacity, 1961–2013. Both are measured in global hectares, with hectares representing the area with world-average productivity of the year 2013.

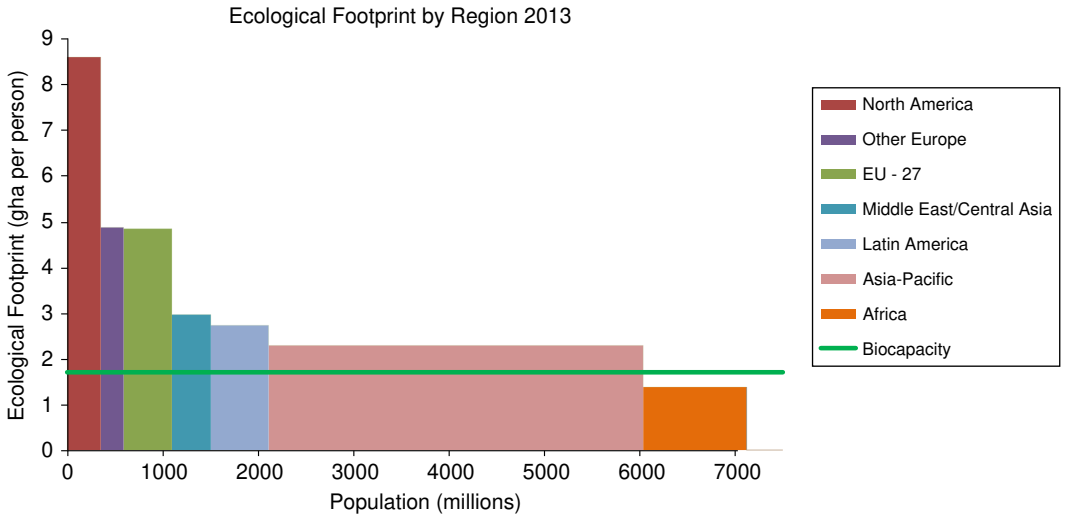

Fig. 2 Regional Ecological Footprint and population, 2013.

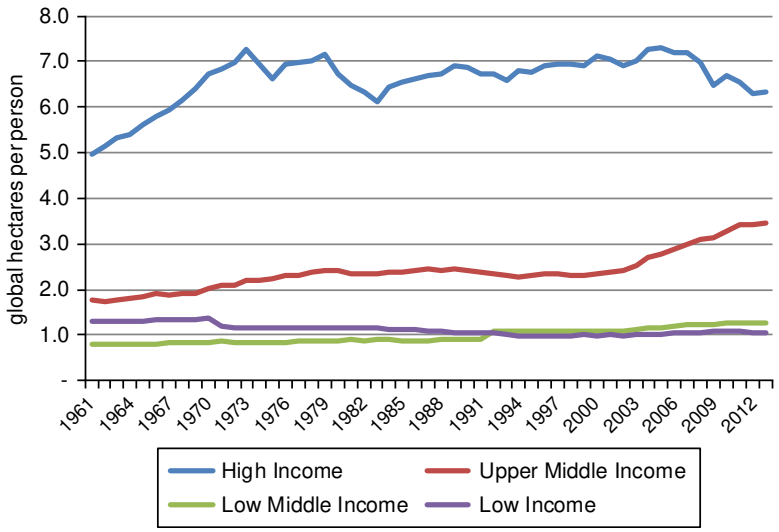

Fig. 3 Ecological Footprint and biocapacity by national income grouping, 1961–2013. Income groupings are defined by the World Bank. The most rapid per person increase took place in upper middle-income countries, mainly driven by the rise of Chinese resource demand (Global Footprint Network, 2017).

person, compared to 1.1 global hectares per person for low-income nations. Over the past 56 years, consumption of ecological resources, per capita, has increased by nearly 30% in high-income countries but fallen by 19% in low-income countries (**Fig. 3**).

More detailed national level Footprint results are published in annual editions by Global Footprint Network. Results for most countries with high enough quality scores are directly available from the open data platform at data.footprintnetwork.org. Further data sets and reports are available on Global Footprint Network's website (www.footprintnetwork.org).

Evaluating the Sustainable Development Performance of Countries

The Ecological Footprint can be applied to evaluate countries' overall performance toward sustainable development. Sustainable development is, as the two words reflect, a commitment to thriving lives for all (development) within the planetary budget (sustainable). Because of these two dimensions, the relationship between the two can be plotted in a graph with two axes (see **Fig. 4**).

The vertical axis (labeled SUSTAINABLE) stands for living within the means of planet Earth. This resource security condition requires an average Ecological Footprint per person of <1.7 global average hectares (the supply of biologically productive

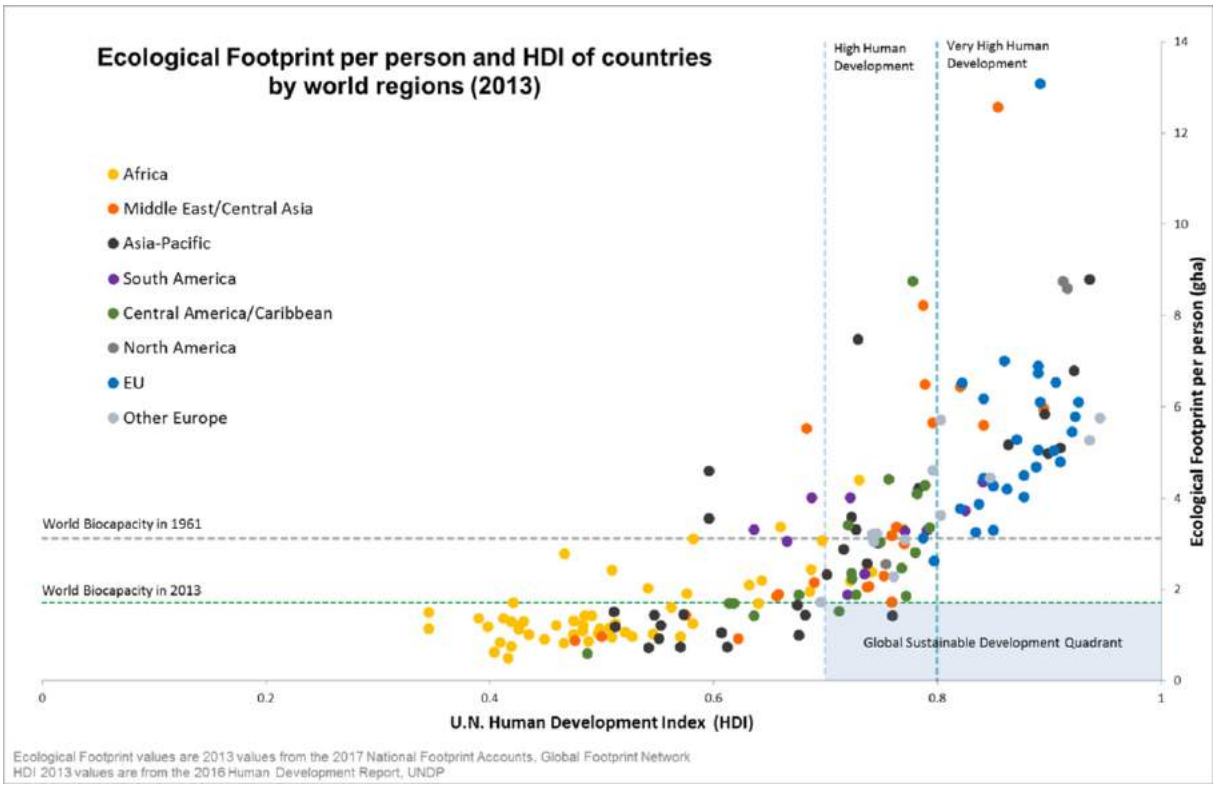

Fig. 4 National Sustainable Development performance can be plotted by comparing countries' per person Ecological Footprint to their HDI achievements (2013 data).

planetary surface area that exists per person in 2013). Note that this amount does not mean that 1.7 is the ultimate goal: the threshold for the Footprint would need to be even lower in order to also support wild species. For instance, if we followed E.O. Wilson's suggestion of leaving half the biocapacity wild there would be 0.85 global hectares per person available at current population levels (Wilson, 2016). In contrast, today's Footprint of humanity is 2.7 global hectares per person.

The horizontal axis represents DEVELOPMENT. Since "development" is not a specific outcome, but rather an issue area, it cannot be measured directly. But indices are available that approximate this concept. The most widely cited is the one conceived and promoted by the United Nations: UNDP's Human Development Index reflects human progress and development outcome through three key components: life expectancy; literacy & education, and per person income of the nation's residents (or more precisely the logarithm of income). On a scale of zero to one, 0.7 is UNDP considered to be the threshold for a high level of development. 0.8 is the threshold for very high.

The sustainability threshold (Ecological Footprint $<$ one Earth) and the development threshold (HDI > 0.7) define two minimum criteria for global sustainable development. The graph with 2013 data shows that few nations have a development model that creates high human development with a resource demand that is globally replicable.

To truly move toward sustainable development, a necessary condition would be to make the world average move toward the identified box of high development within the resource budget of planet earth (Raworth, 2017). Most efforts today do not yet live up to this challenge since on average, humanity's Ecological Footprint is still going up, and biocapacity per person is shrinking (Wackernagel *et al.*, 2017).

The Footprint of Consumption Activities

While the methods and national analysis presented above provide information on the Ecological Footprint and biocapacity of different land types, they do not indicate which types of consumption are responsible for placing these demands. The provision of food products, for example, requires significant quantities of cropland, grazing land, and fishing grounds, and emit significant amount of carbon dioxide. Dividing the Ecological Footprint into its specific consumption components can be valuable for policy applications and communication programs. One way of systematically allocating overall demand to economic activities is ee-MRIO, or environmentally extended Multi Regional Input Output analysis. Global Footprint Network uses a model building on Purdue University's GTAP database. These broken-down results are commonly used in scenario analyses, trade flow analyses, and

by individuals who wish to find ways to reduce their own personal Footprints. Also, while the Footprint does not measure biodiversity loss directly, it tracks global pressures on biodiversity and can be used to complement other measures of ecosystem-specific impacts on biodiversity (Galli *et al.*, 2014).

Various techniques, including input–output analysis and process-based allocation, can be applied to apportion the Ecological Footprint into consumption categories. All of these types of analyses generate a consumption land-use matrix, a table that allocates the total Footprint in each of the major land types across a series of consumption categories. An example for the province of Ontario, Canada, is included below.

By consumption category, personal transportation makes the largest contribution to the average Ontario resident's Ecological Footprint (**Table 2**). The finer level of detail in tables such as this can be used to suggest scenarios for policy making as well as possibilities for individual action.

The Future of Ecological Footprint Applications

Beyond the thousands of existing Footprint applications, much more is still possible. The open data platform, launched in April 2017, has made the results far more easily available, leading to a rapid increase of visits and downloads from the data platform data.footprintnetwork.org. Hopefully, this increased availability will also lead to a new wave of academic publications and fresh ways to analyze the data.

This increased transparency and availability also enables more scrutiny and engagement with the method. Already in the past, various authors have published criticisms about the Footprint and its applications. On the methodological side some of them have been addressed through methodological improvements (Kitzes *et al.*, 2009).

Other critics are uncomfortable with the interpretation of the implications of Ecological Footprint results, even though these may not be specific to the Footprint, but rather a consequence of the planet's finite surface area (Stiglitz *et al.*, 2009, and response by Global Footprint Network (2009). Yet other critics raise issues that are not pertinent to the research question driving Footprint accounting, criticism often inspired by the critics' interpretation of what the name "Footprint" should or could mean according to them. Some of those latter ones are discussed in Lin et al. (2015), Goldfinger et al. (2014), Wackernagel (2014), and Rees and Wackernagel (2014).

To make criticism useful, the first step is to establish whether the criticized method and the criticism both refer to the same research question. Some criticism reads aspects into the name of the methodology without defining or debating the actual research question (examples of such criticism include van den Bergh and Grazi, 2014a, 2014b, 2015, or Blomqvist *et al.*, 2013).

Criticism that actually addresses the pursued research question can legitimately question the method on three grounds:

1. *The method and its results may not be relevant to the identified policy concerns.* Obviously, this would make the method and its results useless. Andrea Collins and Andrew Flynn produced possibly the most comprehensive study to evaluate the utility of the Footprint, particularly in the United Kingdom. They concluded that while the approach shows strength in communicating ecological limits, differences in resource distribution, and interconnectedness of resource issues across scales and geographies, they found that the tool's ability to influence policy outcomes has so far been more limited (Collins and Flynn, 2015). Whether this is a consequence of the challenging sustainability topic per se, or a weakness in the Footprint's relevance still needs to be examined further.
2. *The method and its results, while theoretically relevant may in practice be less accurate than other methods answering the same research question.* van den Bergh and Grazi (2014a) do not question Footprint Accounts on the basis that more accurate methods are available. Rather, they note, "Perhaps it is of consolation to Footprint devotees to know that other efforts to arrive at an aggregate environmental indicator have failed as well." Clearly on specific aspects such as carbon, or particular substances such as nitrogen, other tools can be more accurate. But at the aggregate level of overarching human demand, Global Footprint Network has not been able to identify a method that answers the question with more rigor and robustness.
3. *Even if the method is considered relevant, and critics recognize that there is no better answer to the question available, they may still raise the argument that society would be better off without the results this method generates.* For instance, they may argue that the results are so inaccurate that not having the results is producing less confusion and misdirection than having them. Giampietro and Saltelli (2014) insinuate this even in their title of their 2014 paper "Footprints to Nowhere" in which they set out to make the case that society would be better off without the results this method generates since, according to them answers are so poor that they mislead more than they inform. However, as Global Footprint Network would argue that Footprint results are in line with many other studies addressing humanity's dependence on the Earth's resources and services (Millennium Ecosystems Assessment, 2005; Steffen *et al.*, 2015; IPCC, 2014).

Further, national government agencies of over 12 countries have tested Ecological Footprint accounts. They compared Global Footprint Network results with results they calculated based on their own data sets. For instance, the French statistical office of their environment ministry, on their own, reproduced the French Footprint time series within 1%–3% deviation from the Global Footprint Network numbers. Reports from national and international reviews are collected at www.footprintnetwork.org/reviews. Also international agencies such as UNDP or international organizations such as WWF or WBCSD have used Ecological Footprint results in their publications.

The results are grouped by short-term direct demands in Food, Housing, Personal Mobility, Goods, and Services. Demands paid for by government, and investments in capital assets (such as houses, roads and infrastructure) are shown in separate categories. (Global Footprint Network (2015). The Footprint and Biocapacity of Ontario, Canada: Comparing Results for 2005 and 2010. California: Global Footprint Network. Produced for the Ontario Ministry of Natural Resources and Forestry. http://sobr.ca/_biosite/wp-content/uploads/Zokai-et-al.-2015_Ontario-Ecological-Footprint-and-Biocpacity-Technical-Report-2015-03-23-final.pdf.)

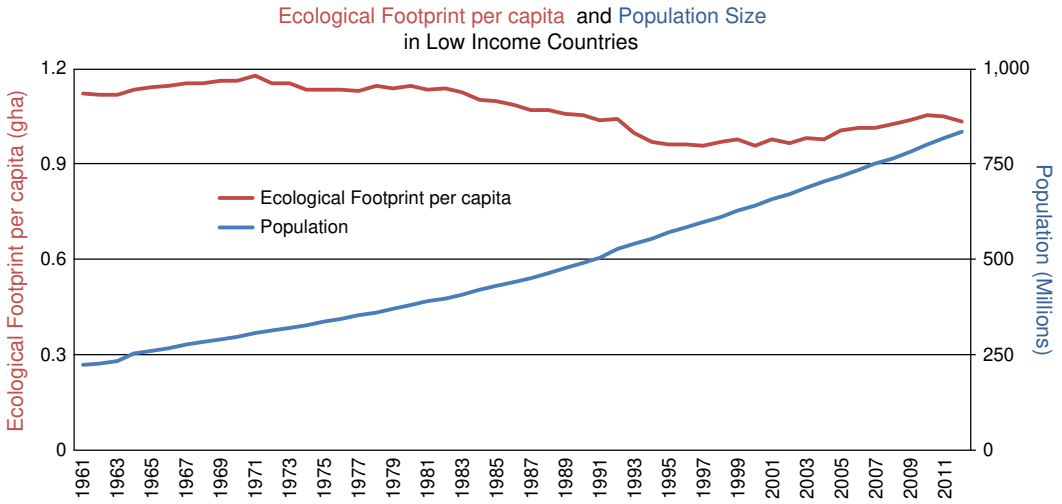

Fig. 5 Population size of current Low Income Countries over time, and their per person Ecological Footprint, 1961–2012. This graph shows in blue the population trend and in red the per person Ecological Footprint averaged across all people in Low Income Countries, from 1961 to 2012. The population nearly quadrupled in those countries, with their Ecological Footprint per person slightly declining. This decline is from a human health and development perspective particularly troubling given that the Ecological Footprint in these countries is already at a very low level. Also note that in these countries the Footprint per unit of cereal and animal protein is typically higher than world average because they need specialty cereals for marginal land areas and because animals are kept as savings leading to a high ratio between feed and fodder input to animal product output. Source: Global Footprint Network (2017). National Footprint Accounts, www.footprintnetwork.org.

By offering accounts that summarize Footprint and biocapacity, the main factors which determine a biocapacity deficit or a biocapacity reserve become clear. Similar to Holdren and Ehrlich's IPAT equation (Ehrlich and Holdren, 1971), there are five factors that shape the biocapacity reserve or deficit. The per person Footprint is determined by two factors: how much is consumed, as well as the efficiency by which the consumed items are being produced. The per person biocapacity is determined by three factors: amount of biologically productive space; the productivity per hectare of this space; and the number of people sharing this space. Dissecting the accounts therefore allows analysts to separate out the various contributions to the overall Footprint, and to develop scenarios about how the ratio between Footprint and biocapacity can be altered. For instance, by comparing changes in per person demand with changes in number of people, one can see which factor is moving more rapidly (**Fig. 5**).

Academic articles on the Footprint have multiplied. Particularly notable is the strong interest among Chinese scholars which could be driven by the Chinese government's focus on Eco Civilization, as noted in their 13th five-year plan. Google Scholar search finds, as of May 2017, 55,000 documents containing the phrase "Ecological Footprint."

An overview of the uses from a UK perspective has been provided by Collins and Flynn (2015), published in their above mentioned book. Earth Overshoot Day (www.overshootday.org), which marks every year the day by which humanity has used the annual renewable budget of planet Earth is reaching increasing number of audiences. For instance, Earth Overshoot Day 2016 (marked on Aug 8th of that year) generated at least 1.9 billion media impressions through 1800 media events in 84 countries. On September 25, 2016, Switzerland voted on whether it wanted to achieve the goal of living within the means of one planet by 2050. 36% of the voters agreed, recognizing that the current Footprint, which would take more than three planet Earths if everybody lived like the Swiss, does ultimately not serve Switzerland (www.achtung-schweiz.org/en).

Economic planning still has not embraced biocapacity as the ultimate biophysical resource on which economic activity depends. Providing robust, relevant data is only one piece for changing that mindset. But we hope it is a productive contribution to a necessary change in the way we hold and act upon humanity's dependence on Earth's regenerative capacity.

More information about Footprint results, methodologies, and applications can be found on Global Footprint Network's website at www.footprintnetwork.org.

Environmental Protection and Ecology☆

Clive Hamilton and Andrew Macintosh, Australian National University, Canberra, ACT, Australia
Nicoletta Patrizi and Simone Bastianoni, University of Siena, Siena, Italy

What Is Environmental Protection

Environmental protection can be defined as the prevention of unwanted changes to ecosystems and their constituent parts. This includes

- the protection of ecosystems and their constituent parts from changes associated with human activities; and
- the prevention of unwanted natural changes to ecosystems and their constituent parts.

One issue associated with this definition is whether "ecosystems and their constituent parts" include humans and communities, or whether environmental protection is only concerned with the protection of natural capital. From an ecological perspective, humans are regarded as an integral part of the ecosystem. Separating humanity from the natural environment can therefore be seen as artificial. While this is true, the phrase environmental protection is not used to refer to measures that are designed to regulate or mediate direct interaction between people. For example, laws prohibiting assault are not regarded as environmental protection measures. Environmental protection is concerned with the relationship between people and the natural environment rather than the relationships between people and communities.

Another issue is whether environmental protection relates to preservation, conservation, or both. Preservation refers to the protection of an ecosystem or natural environment from change, while conservation is generally associated with the sustainable use of natural resources. The objective of conservation is to ensure the maintenance of a stock of renewable resources that is being exploited for human purposes rather than the protection of the natural environment from any anthropogenic modifications. The exploitation of natural resources for human purposes is not environmental protection as it is not associated with the prevention of unwanted changes. The change associated with exploitation is deliberate and wanted, at least by those doing the exploitation. However, measures that are put in place to prevent overexploitation of natural resources do constitute environmental protection. They are designed to prevent exploitation beyond a point that is deemed desirable or sustainable. For example, catch quotas in fisheries and air pollution limits are environmental protection measures because, while they accept some environmental degradation, they aim to limit it.

The distinction between preservation and conservation has dissipated in recent years with growing recognition of the dynamic nature of natural systems, humanity's place in the biosphere, and the need for active human involvement to maintain the integrity of certain ecosystems. Consequently, environmental protection is now generally used to refer to measures that have traditionally been associated with preservation (e.g., reserves, including national parks), as well as conservation and natural resource management initiatives.

A critical aspect of environmental protection is that it is driven by the values that humans attribute to different aspects of the environment. These values need not be instrumental, but the motivating factor for environmental protection is always the prevention of changes to the environment that humans do not want. This is why measures associated with the prevention of unwanted natural changes to ecosystems—like the prevention of coastal erosion or systematic burning in reserves to reduce the risk of wildfires—can be included as environmental protection. Such measures do not aim to protect ecosystems from human activities but rather from natural forces that are deemed to threaten human interests.

☆*Change History:* March 2018. Simone Bastianoni and Nicoletta Patrizi updated the article. Recent initiatives on the field of Environmental Protection and Ecology have been added in the Conclusion section as well as their references.

Environmental remediation is distinct from environmental protection as its primary objective is to restore an ecosystem or natural environment to a previous state; that is, like exploitation, it is associated with deliberately induced change, as opposed to the prevention of change.

Domestic Policy Instruments

There are a number of ways to classify domestic policy instruments that are used to protect the environment. Some people divide them into voluntary and mandatory instruments, while others place them into regulation-based and incentive-based, or command-and-control and economic instruments. The method preferred here is to divide them into four broad categories: regulatory, economic, voluntary, and education and information.

Regulatory Instruments

Regulatory instruments impose legally enforceable restrictions on economic agents to realize environmental protection objectives. They are sometimes referred to as "command-and-control" mechanisms because they prohibit or mandate certain actions (i.e., the command), while using various forms of punishment to motivate compliance (i.e., the control mechanism). Environmental regulations can take many different forms, including

- prohibitions on specified activities (e.g., discharging pollutants into a water body or the atmosphere, or taking a threatened species);
- requirements to obtain a governmental approval (or permit) before undertaking a specified activity (e.g., pollution permits, operating licenses, and development approvals);
- requirements to follow certain procedures when carrying out specified activities (e.g., to use certain equipment, abide by operating standards, or to monitor pollution emissions); and
- requirements to undertake specified actions that are deemed to be environmentally beneficial (e.g., weed control in agricultural areas).

The use of regulatory instruments can be justified on the basis of deterrence or similar choice theories of criminology. According to this approach, people are assumed to make choices by rationally weighing the costs and benefits associated with alternative courses of action and selecting the action that is most likely to maximize their utility. Regulations can affect this process by altering the costs and benefits associated with environment-related activities. For example, by outlawing the emission of pollutants into a river and incarcerating or imposing fines on people who violate the law, the government is able to increase the costs of emitting pollutants. In doing so, it makes alternative nonpolluting options more attractive. In countries where the rule of law prevails, provided the penalties and probability of enforcement are high enough, and punishment is swift, the desired pattern of behavior should emerge.

The difficulty with this theory is that humans are not always rational utility maximizers, meaning that environment regulations may not always result in the desired outcomes. Regulatory approaches can also fail to achieve their objects because of poor design (e.g., ambiguous regulations and unworkable administrative arrangements), strategic avoidance by polluters, and an absence of monitoring and enforcement due to a lack of resources or political will. There are even cases where regulatory instruments have aggravated the environmental problems they were designed to solve.

Regulatory instruments are criticized not only for being ineffective, but also for their inefficiency. This is because they can impose inflexible restrictions on producers, thereby limiting the choices that are available as to how producers meet the desired environment target. Regulatory mechanisms can also have large administration and compliance costs. Government agencies are required to constantly monitor compliance and undertake costly litigation when breaches are discovered, while producers incur legal and other costs while attempting to abide by the environmental regulations. In addition, regulatory mechanisms do not provide incentives to encourage the reallocation of resources toward producers with the lowest marginal costs of environmental protection. As a result, it is difficult for regulatory mechanisms to satisfy the equimarginal principle, which requires that the marginal cost of environmental protection be equalized across polluters to achieve the desired environment target at the lowest possible cost.

The other main criticism of environment regulation is that it can be inequitable. Disputes about whether regulatory mechanisms are unfair are usually framed in terms of the alteration of preexisting property rights. Some people may believe they have a right to pollute or use the environment in a particular way. When environment regulations are introduced, these property rights may be taken away, prompting calls for compensation. In the absence of compensation, the people who are affected by the regulations may feel they are being forced to shoulder a disproportionate amount of the financial burden associated with the provision of public good environmental outcomes. This problem is often confronted with laws that prohibit the removal of native vegetation or the taking of native species, or that restrict the development of real property for commercial purposes.

In several countries disputes about the impact of environment regulations on property rights have been a central part of environmental policy debates. For example, in the United States, the Fifth Amendment to the Constitution provides that private property shall not be "taken for public use without just compensation." This has led to numerous Supreme Court cases and an extensive literature on so-called "regulatory takings." The Australian Constitution contains a similar provision, which provides the

Federal Government with the power to make laws with respect to the "acquisition of property on just terms." In both jurisdictions, courts have found that these constitutional provisions limit the extent to which the government can abolish property rights for environmental purposes.

While issues surrounding the abrogation of property rights have been influential in framing equity issues associated with environmental regulations, it is often forgotten that most regulations alter property rights. The elevated status of property right issues in the context of environmental debates is arguably due to the reverence accorded to real property and preferential treatment given to certain primary industries in western countries.

Despite the criticisms of regulatory measures, they remain the most widely used instrument for environmental protection. There is an ongoing debate about why states tend to prefer regulatory instruments, with supporters of economic instruments often attributing it to ignorance of alternatives, simplicity, and pressure by special interest groups. Yet, regulatory instruments have a number of attributes. The most important of these is the certainty they can provide when faced with imperfect information about environmental risks and the irreversibility of certain forms of environmental harm (e.g., species extinction). In these circumstances, relying on economic, voluntary, or information instruments can lead to suboptimal outcomes by permitting excessive exploitation of the environment. Regulatory instruments are well suited to these situations as they allow distinct boundaries to be placed on the use of environmental resources. This has led to the advocacy of decision-making tools like the precautionary principle and collective choice processes like the safe minimum standards approach.

Another benefit of regulatory instruments is they can be more cost-effective than other measures in dealing with certain types of environmental issues. As discussed, regulatory instruments are often criticized for having large administrative and compliance costs. Yet, in some cases, alternative economic and voluntary approaches may have higher administrative and compliance costs because of the nature of the environmental problem and the complexity in the required program. For example, addressing land clearing with voluntary measures can require agreements to be negotiated with large numbers of landholders, leading to high transaction costs and a plethora of different standards. In contrast, regulations can provide a uniform standard that does not require case-by-case negotiations and is easier to monitor and enforce. Regulatory instruments can also overcome free-rider problems by forcing recalcitrant polluters to abide by the necessary standards.

Economic Instruments (Market-Based Measures)

Economic instruments can be defined as mechanisms that force economic agents to internalize all or part of the social costs associated with environmentally harmful activities and that rely on market forces to promote efficiency. In doing so, they seek to impose additional costs on producers that harm the environment and reward those that improve environment outcomes, while utilizing market forces to improve the allocation of resources. (Some analysts include subsidies among economic instruments but as they are voluntary and economic agents are not forced to internalize the social costs they are more appropriately classified as voluntary instruments.)

This approach to environmental protection is usually associated with environmental economics, a school of economic thought that is a subdiscipline of neoclassical economics. According to environmental economists, environmental problems arise because of the existence of externalities—impacts involuntarily incurred by a person or persons without compensation or payment as a result of the actions of another. Because of the existence of externalities, markets are unable to guarantee the efficient allocation of resources. For example, if producers emit pollution into the atmosphere without paying for it, the price that consumers pay for the producers' outputs will not reflect the full social cost of the transaction. As a result, there will be excessive output and consumption of the relevant good or service. If producers are forced to internalize the social costs associated with the air pollution, there would be a more efficient tradeoff between air pollution and output, leading to higher net social welfare.

The more recent trend in environmental economics has been to characterize environmental problems as being a product of the incomplete allocation of property rights. According to this approach, if a property right over the relevant environmental resource were appropriately defined and allocated to individuals, and there was perfect information and no transaction costs, the operation of market forces would lead to efficient outcomes. For example, if the atmosphere were owned by someone and producers had to pay to emit pollution, then negotiation between the owner and producers would ensure the most efficient allocation of atmospheric resources. On the basis of these theories, economic instruments either

- require polluters to pay for all or part of the costs associated with pollution (e.g., pollution fees, individual liability, and removal of subsidies that promote overuse);
- place a restriction on the amount of pollution that can be emitted or resource that can be used and then allow pollution or resource entitlements to be traded among economic agents (called "marketable permit" or "cap-and-trade" schemes, e.g., tradable emission, water, catch and development rights schemes); or
- seek to create well-defined, secure, and transferable property rights over environmental resources and allocate these to relevant individuals or groups ("pure property rights" approaches, e.g., land titles and fishing area rights).

Marketable permit schemes and pure property rights approaches are similar in that both rely on the creation and exchange of property rights to promote environmental and economic outcomes. But pure property rights approaches place no external restrictions on the use of the relevant resource and rely on market incentives to achieve the desired environmental outcome,

while marketable permit schemes rely on a cap or limit on the use of the relevant resource to achieve the desired environmental outcome.

One of the major benefits associated with economic instruments is that by utilizing market forces they can encourage a more efficient allocation of resources. For example, when tradable emission quotas are used, the operation of market forces should ensure that the necessary emission reductions are achieved at least cost (i.e., the equimarginal principle should be satisfied). Further, economic instruments provide an incentive for producers to reduce pollution, which encourages innovation. Advocates of economic instruments also claim they are more flexible than regulatory instruments, although this is not always the case.

Although economic instruments can be more efficient than alternative policy mechanisms, they can suffer from a number of weaknesses. In relation to pollution fees, individual liability and pure property rights approaches, there can be a considerable amount of uncertainty associated with environmental outcomes. For example, producers may choose to absorb the increase in costs associated with a pollution fee, or demand may be unresponsive to price rises, meaning the level of pollution may not decline by the desired amount. Consequently, where policy-makers are faced with uncertainty regarding environmental risks and questions regarding irreversibility, alternative approaches can be preferable.

Like regulatory approaches, marketable permit schemes (or cap-and-trade approaches) can place an upper limit on the permissible amount of pollution or resource extraction. Hence, they can be useful in dealing with uncertainty and threshold effects. The advantage that marketable permit schemes offer is that having set a specified limit on pollution or resource extraction, they allow market forces to determine the allocation of pollution or extraction rights among producers. One of the most successful marketable pollution permit schemes has been the United States Environmental Protection Agency's Sulfur Dioxide Program, which is part of the broader Acid Rain Program. The cost of reducing emissions was substantially lower than predicted because producers had an incentive to find cheaper ways to do so.

Problems arise with marketable permit schemes when there is a lack of equivalence between the environment or pollution units that producers are expected to trade (i.e., the resource is not homogeneous). For example, tradable development permit schemes that place a limit on the amount of development in an area but allow developers to exchange development rights can lead to the rights moving toward the developments with the highest economic returns. However, they will not necessarily achieve biodiversity objectives as each parcel of land may contain different biodiversity values. Similar problems can arise with emission schemes that allow emission permits to be generated through the enhancement of sinks (i.e., there can be uncertainty about whether the enhancement of sinks will offset the additional emissions).

Transaction costs can also pose problems for economic instruments. Devising schemes that can be administered in a cost-effective manner can sometimes be difficult. Further, if there are excessive costs associated with the negotiation and exchange of marketable permits, the efficiency benefits may not materialize.

As with all environmental policy mechanisms, politics can impede the effective use of economic instruments. However, economic instruments can be especially vulnerable to political influences if it is necessary to constantly adjust the price signals provided through the scheme. For example, if a carbon tax is used to address climate change, it will be necessary to adjust the tax over time to account for unexpected events and new information. Special interest groups may impede this process, thereby undermining the efficacy of the tax.

There has been a tendency in the past for regulatory instruments and economic instruments to be presented as substitutes. In practice, these two types of instruments are generally used as complements and economic instruments always require a regulatory framework. Indeed, there is a growing recognition of the need for policy packages or policy mixes that use a range of instruments to achieve environmental protection objectives.

Voluntary Approaches

Voluntary approaches can be defined as any mechanism or program that aims to protect the environment where relevant economic agents are able to decide whether or not to participate; that is, involvement in the program is voluntary and no direct penalties are imposed on nonparticipants, although incentives may be used to encourage participation.

There are three broad types of voluntary approach.

- Unilateral initiatives where polluters act without direct government involvement to protect the environment. The defining features of unilateral initiatives are that they are initiated, designed, and operated by polluters. Hence, government involvement is generally limited, which raises questions about whether unilateral initiatives are a policy mechanism or a type of market behavior. Yet governments can encourage unilateral initiatives by suggesting them to polluters or threatening mandatory measures. There are three main types of unilateral approaches: voluntary adjustment of internal processes (e.g., under an environmental management plan); industry self-regulation (e.g., codes of conduct); and environmental certification schemes (e.g., organic producer associations).
- Bilateral agreements between the regulator and a polluter or group of polluters. These initiatives involve negotiation between the parties about how environmental protection will be achieved. Both parties have obligations under the agreement with polluters generally expected to meet certain targets and abide by conditions to protect the environment and the regulator generally expected to provide some sort of incentive. The incentives provided by regulators can include subsidies (e.g., monetary payments and technical assistance), public recognition, and undertakings not to enforce regulations or to introduce new regulations. The

agreements need not be legally binding, but there must be negotiation and some sort of understanding about the obligations of the parties.

- Voluntary public (or government) programs where the regulator determines who is eligible to participate, the obligations of participants, and the incentives used to encourage compliance. The key to these types of programs is that they are initiated and designed by the regulator, and relevant producers are invited and encouraged to participate. Again, the types of inducements include grants, technical assistance, and public praise.

The main advantages of voluntary approaches are that they are flexible (which provides polluters with the freedom to find cost-effective solutions) and noninterventionist. In addition, where disputes arise about the fairness of polluter-pays instruments like regulations and pollution fees, voluntary instruments can help overcome political resistance by enabling governments to pay polluters for the loss of property rights (i.e., they can resort to a beneficiary-pays approach). Due to these characteristics, voluntary approaches are often supported by polluters, which can assist in reducing the political costs for regulators. Further, it is sometimes claimed that voluntary approaches have lower administrative costs than other instruments and that in certain circumstances they can be more effective than mandatory approaches.

Although voluntary approaches can offer some benefits, because of the public good characteristics of many environmental goods and services (i.e., they are nonrival and nonexcludable) they are unlikely to result in an optimal level of environmental protection. In particular, there is a risk that some producers will seek to free-ride on the environmental protection measures undertaken by others. Like some economic instruments, voluntary mechanisms also lack certainty and are ill-suited to dealing with uncertainty and irreversibility.

Voluntary approaches can also be expensive to operate and administer. The incentives necessary to encourage participation can impose a significant burden on taxpayers. These problems can be exacerbated by gaming on behalf of polluters where they seek to take advantage of information asymmetries to extract excessive economic rent. In addition, the transaction costs associated with voluntary approaches can be high if there is a need to negotiate agreements with a significant number of producers.

Given the weaknesses associated with voluntary mechanisms, they are often seen as being used when political resistance blocks the introduction of more effective instruments or as a mechanism that supports or complements other programs.

Research has shown that if voluntary approaches are to be effective, the existence of a strong and credible threat of regulation is essential. The existence of an appropriate threat of regulation increases the incentive for polluters to participate and bolsters the bargaining position of regulators. It can also reduce the financial incentives needed to ensure participation, which can improve the cost-effectiveness of the program.

Information and Education Instruments

Information and education instruments aim to promote environmental protection by improving people's awareness and understanding of environment issues and building their capacity to respond to environmental threats. They include such things as environmental and sustainability reporting by governments and corporations, and advertising and education campaigns.

Many environmental problems arise at least partly because of imperfect information about environmental risks and a lack of awareness about how to respond. These types of instruments can help overcome these issues and can be effective where the threats to the environment are known and producers have an economic incentive to improve environmental outcomes. Information instruments can also be an important tool for encouraging greater support for environmental protection in the community, which can reduce the political costs associated with various environment policy instruments.

The main flaw associated with information instruments is that they will rarely get at the root causes of environmental degradation. As a result, on their own, they are generally an ineffective means of achieving environmental objectives. However, information instruments are commonly viewed as an essential part of environmental policy packages. Without information instruments it is very difficult for policy-makers to select appropriate policy instruments and it is unlikely that environmental protection measures will attract the political and community support that is necessary to ensure their success.

The advantages and disadvantages of the four approaches are summarized in the Table 1.

International Dimensions of Environmental Protection

Under international law, states have the sovereign right to exploit, manage, and conserve the natural resources and natural systems within their jurisdiction, including resources located in their territorial sea and exclusive economic zone, and sinks such as the atmosphere. States also have a broad right to engage in fishing on the high seas. However, the expansion of the world economy has placed increasing pressure on natural systems that overlap or transcend political boundaries. This has gradually led to the development of a large number of international agreements, systems, and processes to address transnational environmental issues.

The international governance system that has emerged over the past 60 years to facilitate environmental protection can be divided into three main parts: international environmental law, international environmental bureaucracy, and international environmental financial mechanisms.

Table 1 Domestic environmental policy instruments—pros and cons

Policy instrument	*Definition*	*Advantages*	*Disadvantages*
Regulatory	Instruments that impose legally enforceable restrictions on economic agents to realize environmental protection objectives	Certainty about environmental outcomes Ability to limit free-riding Clarity of standards—easy to comply with, monitor, and enforce No need to negotiate individual standards, which lowers administration costs	Inefficiencies—regulations impede the operation of market forces and can lead to the misallocation of resources Can stifle innovation Potentially inequitable because some may shoulder a disproportionate burden
Economic	Instruments that force economic agents to internalize all or part of the social costs associated with environmentally harmful activities and that rely on market forces to promote efficiency	By utilizing market forces they are able to achieve the desired outcomes in an efficient manner Promote innovation Provide flexibility as they often enable individuals to determine the best method of achieving the desired outcomes Ability to limit free-riding	Can lack certainty about environment outcomes Can be complex and have high administration costs Potentially inequitable
Voluntary	Any mechanism or program that aims to protect the environment where relevant economic agents are able to decide whether or not to participate	Noninterventionist, meaning they are likely to have high levels of acceptance by producers Low political costs for regulators High levels of flexibility	Lack certainty about environment outcomes Can have high administration costs Risk of free-riding Risk that producers will engage in gaming to extract excessive economic rents from regulators
Information and education	Instruments that aim to promote environmental protection by improving people's awareness and understanding of environment issues and building their capacity to respond to environmental threats	Noninterventionist Low political cost for regulators Flexibility Relatively low administration costs	Lack certainty about environment outcomes Risk of free-riding Inability to address main reasons for market failure

International Environmental Law

At the heart of the international environmental governance system lies the body of legal principles and agreements that collectively constitute international environmental law. Although international environmental agreements have existed for centuries, the number, scope, and complexity of these agreements has increased considerably since the 1940s. By the mid-2000s, there were more than 500 multilateral environment agreements (MEAs) in existence. Around 270 of these MEAs were broad international agreements, while the remainder had a regional focus and a relatively limited number of signatories. Not surprisingly, these agreements cover a wide range of topics, including climate change, biodiversity, transport and disposal of hazardous materials, and fisheries management.

One of the most basic principles of international environmental law is that, while states have sovereignty over the resources in their jurisdiction, no state has the right to use or permit the use of its territory in such a manner as to cause injury to the another's territory, person, or property. This principle, which is generally traced to the Trail Smelter Dispute that commenced in the 1920s between Canada and the United States, concerns environmental obligations between particular states (i.e., reciprocal obligations).

Growing awareness of the interrelated nature of natural systems and the scale of environmental problems in the later part of the twentieth century resulted in growing support for the notion that states should also have obligations to protect global commons and the interests of humanity, including future generations. This has led to the formation of a significant number of international agreements that promote the protection of a broader range of interests in the environment. The guiding principle regarding the rights of states to exploit natural resources is now viewed as incorporating a fundamental duty to protect global commons. For example, the Rio Declaration on Environment and Development (1992) provides that states have a "responsibility to ensure that activities within their jurisdiction or control do not cause damage to the environment of other States or of areas beyond the limits of national jurisdiction." There are also a number of international agreements, such as the United Nations Framework Convention on Climate Change (UNFCCC), that seek to protect certain aspects of the environment for "the benefit of present and future generations of humankind."

The notion of sustainable development has been a common element of MEAs since the late 1980s and 1990s. This has led to greater concern about intragenerational equity and encouraged the inclusion of the so-called principle of "common but differentiated responsibility" in MEAs. This principle has two parts. The first is that states have a shared responsibility for the protection of the environment, or relevant parts of it. The second part is that the extent to which each individual state is responsible for environmental protection should be determined with regard to the state's capacity to respond and historical contribution to the

relevant problem. One of the clearest articulations of the principle is found in the Rio Declaration on Environment and Development (1992), where it provides that

> States shall cooperate in a spirit of global partnership to conserve, protect and restore the health and integrity of the Earth's ecosystem. In view of the different contributions to global environmental degradation, States have common but differentiated responsibilities. The developed countries acknowledge the responsibility that they bear in the international pursuit to sustainable development in view of the pressures their societies place on the global environment and of the technologies and financial resources they command.

The principle of common but differentiated responsibility also features prominently in the UNFCCC (1992) and the Montreal Protocol on Substances that Deplete the Ozone Layer (Montreal Protocol) (1987). For example, Article 3(1) of the UNFCCC states that

> The Parties should protect the climate system for the benefit of present and future generations of humankind, on the basis of equity and in accordance with their common but differentiated responsibilities and respective capabilities.

International Environmental Bureaucracy

The second element of the international governance system is the collection of international bodies whose functions include the oversight of environmental issues. At the heart of these is the United Nations, which has established a collection of agencies who are responsible for developing policy and promoting better environmental stewardship. These include the United Nations Environment Programme (UNEP), United Nations Development Programme (UNDP), Commission on Sustainable Development (CSD), and the United Nations Educational, Scientific, and Cultural Organisation (UNESCO). The agencies associated with the United Nations are complemented by other international and regional bodies like the World Bank, Organisation for Economic Cooperation and Development (OECD), European Union, and the Organisation of American States (OAS) that play a role in the development and implementation of environment policy.

International Environmental Financial Mechanisms

The final element of the international governance system is the financial mechanisms that have developed to support the work of international environment agencies and to assist in the achievement of international environmental objectives. These range from the general (e.g., the financial arrangements governing the World Bank and United Nation) through to the more specific, which concentrate solely on environment issues. The Global Environment Fund (GEF), established by the OECD in the early 1990s, is one example. Consistent with the principle of common but differentiated responsibility, many MEAs now include provisions requiring developed countries to transfer technology and financial resources to developing countries to assist them to meet their environmental obligations. One of the earliest examples was the Multilateral Fund established under the Montreal Protocol to assist developing countries phase out the use of ozone-depleting substances. In some cases, including under the Montreal Protocol, the obligation of developing countries to comply with the terms of the agreement has been made contingent on the extent to which developed countries provide the specified financial and technical assistance. For example, Article 4(7) of the UNFCCC states that

> The extent to which developing country Parties will effectively implement their commitments under the Convention will depend on the effective implementation by developed country Parties of their commitments under the Convention related to financial resources and transfer of technology . . .

Despite considerable progress being made in some areas, the international environmental governance system has generally failed to bring about substantial and sustained changes in the stewardship of natural resources and environmental systems. In many cases, this is due to the difficulties associated with designing agreements and systems that can accommodate the divergent interests of the states that are involved in transnational environmental issues. Negotiations can be tediously slow and the need to reach consensus can lead to lowest common denominator outcomes. Similarly, due to the reluctance of states to place constraints on their sovereign rights over natural resources, it has been difficult to establish appropriate mechanisms for monitoring compliance and enforcing the terms of the agreements. The international governance system has also been hampered by a lack of resources for key institutions and programs.

Conclusion

Environmental protection has always been practiced by humans in one form or another. However, as anthropogenic pressures on the environment have escalated over the past century, the need for systematic environmental protection has increased. This has led to considerable experimentation with the domestic and international measures that are used to achieve environmental protection objectives. Some of these have been successful, but the overall picture is one of failure.

Due to the failings of the past and greater awareness of the complexity of environmental problems, there is a growing acceptance that environmental protection is best achieved through the use of a multipronged approach. This requires the use of a combination of regulatory, economic, voluntary, and information instruments, where the policy mix is determined on the basis of the available evidence regarding cost-effectiveness.

The international challenge lies in the development of effective and equitable approaches to global environmental problems that are supported by a well-resourced bureaucracy and appropriate financial mechanisms.

However, in the last few years, a new initiative has come out bringing together recent scientific advancements in our knowledge of the Earth System functioning, environmental and ecological law as well as economic instruments to propose a new global governance system aimed at favoring environmental protection. In 2009 a group of scientists developed the "Planetary Boundaries" framework to measure and monitor the state and functioning of the Earth System (Rockström et al. 2009; Steffen et al. 2015). The framework, has been developed to define a planetary safe operating space within which humanity can survive and thrive, and to highlight risks that destabilization of the system creates for human well-being. The identification of such safe operating space for humanity has then helped to recognize the need of an evolution of the current international legal system. In this light the concept of "The Common Home of Humankind" has been proposed as a social construct, based on legal solutions to represent the global natural reality (Magalhães et al., 2016). The legal recognition of a specific, functioning state of the Earth System (i.e., a Holocene-like state, as defined by the planetary boundaries framework) as a common natural intangible heritage of mankind would allow to include all positive and negative externalities in the governance and maintenance of the Earth System thus possibly constituting a new legal environmental protection framework.

That legal systems are not ready to face these challenges is shown also by the fact that a group of law experts have launched the Ecological Law & Governance Association (ELGA) to reframe law according to ecological limits. In their *Oslo Manifesto* it is reported that "Ecological Law requires human activities and aspirations to be determined by the need to protect the integrity of ecological systems. Ecological integrity becomes a precondition for human aspirations and a fundamental principle of law. In other words, ecological law reverses the principle of human dominance over nature, which the current iteration of environmental law tends to reinforce, to a principle of human responsibility for nature. This reversed logic is arguably the key challenge of the Anthropocene".

Ecological Systems Thinking☆

David W Orr, Oberlin College, Oberlin, OH, United States
Valentina Niccolucci and Simone Bastianoni, University of Siena, Siena, Italy

Introduction

The greatest discovery of the past century had nothing to do with nuclear physics, or computer science, or genetic engineering. Rather it was the discovery of the essential connectedness of life and environment. The primary discipline of interrelatedness is ecology beginning with the work of Ernst Haeckel in the nineteenth century. The discovery of evolution extended the awareness of our connections to life in time and more extensively to the story of life on Earth. Fields such as ecology, general systems theory, systems dynamics, operations research, and chaos theory added details and theoretical depth, but with each advance in the precision and extent of knowledge the larger story remained the same. Living systems are linked in food webs and ecological processes into larger systems whether called the noosphere, biosphere, ecosphere, or Gaia. The boundaries between life forms and between what we take to be living and nonliving things shift and sometimes morph into other forms and processes. In Earth systems, small changes can have large effects somewhere else and at some later time. Natural systems and the world made by humans are intertwined in more ways than we can possibly imagine. The result is less like a machine than it is like a web stretching across all life forms and back through time. The effects of human actions millennia ago still ripple forward, intersect with other changes sometimes amplifying, sometimes diminishing in intensity. Some human-wrought changes, such as deforestation and saline soils throughout much of the Middle East, are permanent as we measure time.

Nothing in the preceding paragraph is particularly new or controversial. But the idea of interrelatedness has yet to take hold of us in a deep way. We still live in thrall to a world created by Descartes, Bacon, Galileo, and their heirs who taught us to dissect, divide, parse, and analyze by reduction but not how to put things back together or see the world as systems and patterns. The results were intellectual power without perspective so that, in time, overspecialization became a kind of a cultural disease. There are many reasons why things do not change long after their deficiencies are apparent: the inertia of habit, economic inconvenience, the preservation of reputation, and intellectual laziness. But the most important barrier to change remains simply that science and the technology it spawned works and is a powerful presence in our daily lives. Automobiles, airplanes, the cornucopia evident in every supermarket, miracle cures, and the wonders of computers and communications are a constant reminder of the powers of a particular kind of science and a promise of things to come. That much of our technology also "bites back" and incurs costs that we do not see is mostly lost on us. Many live in what has been called a "consensus trance," believing that things will go well for us, which is to say that progress will continue indefinitely. Beneath such ideas is the faith that nature does not "set traps for unwary species," as biologist Robert Sinsheimer once put it or that progress itself is not a self-made trap.

There have always been skeptics, however. Toward the end of his life, H. G. Wells could see no grounds for hope. More recently, Joseph Tainter, Martin Rees, and Jared Diamond have expressed doubts about our longevity based in no small part on their views of scientific progress. Rees, for example, believes that our odds of making it to the year 2100 are no better than fifty-fifty. Diamond has cataloged the reasons why past societies have collapsed and they bear more than a passing resemblance to our present behavior. James Lovelock, coauthor of the Gaia hypothesis, believes that we are approaching a climate-tipping point somewhere between 400 and 500 ppm CO_2 in the atmosphere after which "nothing the nations of the world do will alter the outcome and the Earth will more irreversibly to a new hot state." In various ways, each of these attributes our vulnerability to the failure to see systems, patterns, and to exercise foresight. As a result, we stumble toward a time of severe climate destabilization, biotic impoverishment, and ecological surprises.

The failure of ecological knowledge to penetrate very deeply into the larger society and its decision-making systems ought to be a matter of grave concern. The early work of ecologists Howard and Eugene Odum on the productivity of salt marshes, for example, may have slowed but certainly did not stop the juggernaut of development that has severely damaged coastal ecosystems virtually everywhere. Similarly, we know a great deal about the services of natural systems and the impossibility of duplicating these by human means. Yet the drawdown of natural capital and the destruction of ecosystems are still trumped by narrow short-term

☆*Change History*: March 2018. S Bastianoni, editor in chief of this section of the Encyclopedia of Ecology, has updated the "Ecological Systems Thinking" chapter with the coauthor V. Niccolucci. Section "Applied System Thinking" has been integrate to better emphasize the importance of Systems thinking within sustainability science and the methods or indicators used to appraise it. Section "Environmental Education" has been updated with a paragraph dedicated to the central role played by Education within the SDGs framework proposed by UN in 2015. Edited entries were also added in Further Reading.

concerns of profit and economic expansion. Sometimes the costs of ecological folly become starkly apparent as they did following hurricane Katrina in the fall of 2005 in which the damage done by a class III hurricane (at landfall) was amplified by the removal of mangroves and coastal forests that would otherwise have absorbed much of its energy and dampened the destructive effects. That, too, was known in many circles but did not have much effect on the policies that prevailed along the Gulf Coast, where oil extraction, commerce, and gambling ruled the day.

Public attitudes toward science are often undermined by poor education, inadequate public funding, and, sometimes, religious dogma. In the United States, evolution, once thought to be an established part of science, is hotly contested as just another "theory" by advocates of "intelligent design." The scientific evidence about human-driven climate change is indisputable, but ignored or underestimated even when alternatives are economically advantageous. The results are evident in the considerable data describing ecological deterioration virtually everywhere and the failure to seize better alternatives as well. Law based on ecological knowledge and the hope that we might calibrate our public business with the way the world works as a physical system is under constant assault. Evidence about the health and ecological effects of toxins is downplayed. Public access to information about the release of toxics is restricted. The result is a significant gap between what is known about how the world works as a physical system and the public policy in every country. The cumulative result is that we are much more vulnerable to ecological ruin and extreme events than we might otherwise be.

What can be done with ecological knowledge? One answer is that ecology as a science ought to do what it has been doing, which is to say document the deterioration of ecosystems in ever finer detail. Ecology, the argument goes, is a science and its practitioners ought to maintain their credibility as scientists and not assume the role of advocates and risk losing their credibility even when they recognize folly disguised as public policy. If that is the future of the discipline it will, I think, flourish for a time while the human prospect withers.

There is, however, another perspective on the uses of ecology. Paul Sears in 1964 and later Paul Shepard and Daniel McKinley in 1969 once called the discipline "the subversive science." They proposed ecology as an integrative discipline, "a kind of vision across boundaries" and a "resistance movement"—an alternative to being "man fanatic." Ecology in their view "offers an essential factor . . . to all our engineering and social planning." In their perspective, the world needs to know what ecologists know and needs to take that knowledge seriously enough to transform the ways by which we provision ourselves with food, energy, materials, shelter, and livelihood. Ecology as a subversive science would be integrated with building, industry, agriculture, landscape management, economics, and governance. In short, the idea of interrelatedness would move from the pages of obscure scientific journals out to the main street, and into board rooms, editorial offices, courtrooms, legislatures, and classrooms. It would progress from being just one more interesting but obsolete idea to become the design principles for a better world—the default setting for everyday behavior.

Applied Systems Thinking

In this regard, the news is guardedly optimistic. The art and science of high-performance building is growing. The result is a new generation of buildings that require a fraction of the energy of conventional buildings, use materials screened for environmental effects, minimize water consumption, and are landscaped to promote biological diversity, moderate microclimates, and grow foods. The best of these are highly efficient, powered substantially by sunlight and feature daylight, water recycling, and interior green spaces. They are a finer calibration between our five senses and the built environment and tend to promote higher user satisfaction and productivity. The costs of building green, as it turns out, are not necessarily higher than conventional buildings while having lower operating costs. The goal is to design buildings as whole systems, not as disjointed components. The green building movement is now a worldwide movement and is transforming the practice of architecture, landscape architecture, and engineering. It could, in time, transform the design of communities and cities as well.

Business, too, is beginning to go green. The best example of a well-run environmentally sensitive business is that of Interface, Inc., a global manufacturer of carpet tiles and raised flooring. In the mid-1990s, company founder and CEO, Ray Anderson, decided to transform the company to eliminate waste and carbon emissions. Interface launched a pioneering effort to develop carpet products that were returned to the company as a "product of service" not otherwise discarded in a landfill. Interface now leases carpet to its customers and takes it back to be remade into new products, thereby eliminating much of the petrochemical sources at one end and waste at the other. In the past decade, the company has eliminated 56% of its carbon emissions and is on track to becoming carbon neutral. The model for the company is consciously that of ecology all the way down to carpet products that mimic a forest floor. Interface is not alone. Other companies like Wal-Mart and DuPont are beginning to transform themselves as well. Some day, perhaps, all business will be powered by sunlight with materials cycles that mimic the circular flow of nutrients in ecosystems.

In agriculture, Wes Jackson, cofounder of the Land Institute, is pioneering the development of natural systems agriculture. The goal is to model agriculture on ecological systems such as forests and prairies. If successful, the end product will be agricultural polycultures of high yield perennials, long thought to be a biological impossibility. The early results, however, have confirmed Jackson's hypothesis that the two can be stitched together, thereby eliminating a great deal of fossil energy and soil erosion.

Materials science is a fourth area in which ecology is being taken seriously. Nature, as chemist Terry Collins has noted, uses only a relatively few ingredients while industrial chemistry uses virtually the entire periodic table, creating ecological havoc. The field of biomimicry has grown in response by studying how nature works in fine detail. Natural systems are a carnival of color, for instance, but nature does not use paints. To answer such questions, Janine Benyus, author of *Biomimicry*, is developing a database of the ways

nature works to filter, reduce, recycle, color, purify, form, and join—all done without the use of toxics and fossil fuels and all of it biodegradable. The result could be a transformation of materials and industry that dramatically reduce pollution and energy use.

Systems thinking is also fundamental to provide useful support in addressing the complex challenges that sustainability science needs to solve. With the introduction of this concept, many interesting holistic methods or indicators have been proposed to appraise the human dependence from Nature and its resources, and to support policy making decisions. Among others, there are some methods that are widely used for the simplicity and the immediacy of their message, that is, ecological footprint accounting, emergy evaluation, material flow accounting, and (partially) life cycle assessment (LCA), to make some examples.

All these methods have different perspectives, rationales, pro and cons, but a common *modus operandi*, that is, all inputs needed for the functioning of the analyzed system are converted into a common unit. The unit is the element of diversity among the methods: it is expressed in term of solar emergy joules needed, directly and indirectly, to produce and input or product (in emergy evaluation), of biologically productive land needed to make available life supporting resources or to absorb wastes (ecological footprint), etc. In this way, flows of different kinds can be accounted for, at the same time, in order to make a picture of the system according to systems thinking.

In these examples and elsewhere, the science of applied ecology has begun to seriously influence decisions and behavior and the evolution of architecture, engineering, materials science, agronomy, urban planning, and economics. The driving force is partly economic (to reduce the costs of unnecessary energy, materials and water use) and partly a matter of conviction (that it is wrong to leave a legacy of ruin behind us). While promising, such measures are necessary but insufficient. Ecological thinking, in one way or another, must become a more central part of global society and this is the task of education.

Environmental Education

The idea of specifically environmental education entered the public discourse in the late 1960s. Among the recommendations of the Stockholm Conference in 1972 was to "establish an international program in environmental education." UNESCO and UNEP subsequently undertook to prepare curricular materials, establish priorities, develop pilot projects, and organize meetings. The result was a UN-sponsored Conference at Tbilisi, Georgia, in 1978 that produced a consensus statement including the words:

Environmental education . . . should constitute a comprehensive lifelong education . . . it should prepare the individual for life through an understanding of the major problems of the contemporary world, and the provision of skills and attributes needed to play a productive role toward improving life and protecting the environment with due regard given to ethical values. By adopting a holistic approach, rooted in a broad interdisciplinary base, it recreates an overall perspective which acknowledges the fact that natural environment and manmade environment are profoundly interdependent . . ..

The Tbilisi Conference produced 41 recommendations spanning the needs for environmental education between developed and less-developed countries. In the subsequent decades, initiatives, including those spawned by Agenda 21 **(see article 36)** and discussions about the Earth Charter, have advanced the discussion of environmental education into a major part of the dialog about the role of education relative to the human prospect. There is no serious discussion about the transition to sustainability launched by the Brundtland Report in 1987 that does not include changing the goals and methods of education. From Tbilisi (US Department of Health, Education, and Welfare, 1978) and Talloires (UNESCO, 1977), and subsequent international gatherings, a strong consensus about the importance of environment in higher education is clearly apparent.

Despite considerable progress, both conceptually and practically, there are serious differences about the goals and methods of environmental education that reflect and, in some ways, amplify larger disagreements about education. At the lowest level, there is a general consensus that the young ought to know something about how nature works as a physical system—the rudiments of biology and planetary science. There is considerably less agreement about how this should be incorporated into the standard curriculum or at what level. Most elementary schools include curricular components such as "project learning tree" or "Wet and Wild" that introduce children to what was once called natural history along with some field experience and practical outdoor skills. But the later inclusion of values or discussion about the causes of environmental ills has often been controversial, especially when it has led to questions about conventional economic or political wisdom.

In important respects, all education is environmental education, that is, by what is included or excluded students are taught that they are part of or apart from ecological systems. The standard, discipline-centric curriculum may have contributed to a mindset that helped to create environmental problems by separating subjects into boxes and conceptually by separating people from nature. As a result, graduates are often ignorant of ecological relationships or why they are worthy of consideration. Not surprisingly, the first response to proposals for environmental education attempted to accommodate environmental issues and ecology into formal education as a kind of add-on. More radical critics proposed that formal education ought to be reformed along ecological lines, raising another and no less contentious issues. From either perspective, environmental mismanagement and the larger discussion of sustainability raise questions about the meaning of human mastery over nature, or more accurately as C. S. Lewis once put it: what does it mean for some men to control other men through the mastery of some parts of nature? What is the core knowledge of the environment that ought to be standard in an educational curriculum? At the heart of such questions are important differences about what it means to be human, what part of that definition ought to remain inviolable, and about the manipulation of natural systems through technological means such as genetic engineering. Is the problem, in other words, one in education or one of education?

What can be said with certainty is that public schooling and higher education have been underachievers in the task of inculcating essential knowledge about the environment. Public opinion surveys show high levels of support for environmental quality but little

ecological knowledge. In the words of one typical survey, people have acquired a "substantial familiarity with environmental issues, but [have] a long way to go in developing a working environmental/energy knowledge." Much of what people know about the environment is derived from television in bits and pieces and not through direct experience with nature or through cultural transmission.

One particularly encouraging aspect is the development of environmental education in institutions of higher education. Stemming from innovations in the 1980s, a vibrant campus ecology movement has emerged in Europe, Australasia, and the United States, along with a wide discussion of sustainability of educational institutions. Beginning with the studies of college food, energy use, and pollution, the movement has grown in subsequent decades to a worldwide scale. Hundreds of colleges and universities globally have organized efforts to systematically reduce energy use, water consumption, and material flows. Campus sustainability and climate stability have come to the center of institutional planning, purchasing, and construction. Beginning in the late 1990s with the advent of means to promote and measure environmental performance of buildings, the construction of academic facilities is undergoing a rapid revolution. Green or high-performance building standards are increasingly regarded as necessary to reduce energy and maintenance costs as well as laboratories for research and education. Many of the problems of sustainability—ecological design, applications of solar energy, water purification, food production, ecological restoration, and landscape management—can be studied in buildings and adjacent landscapes at a scale that is both significant yet manageable. Given recent developments on many campuses, it is not inconceivable that educational institutions at all levels will one day become models of ecological design mirroring the larger solutions necessary to the transition to sustainability.

A decisive step forward in the awareness of the importance of education in sustainability has been done in 2015, when the state members of the United Nation approved the so-called sustainable development goals (SDGs), a set of 17 goals and 169 target, to support the country transition toward sustainable development, by 2030. The SDGs framework recognize a central relevance to Education and include it in most of the 17 SDGs. In particular, the SDG4 is specifically aimed to "Ensure inclusive and equitable quality education and promote lifelong learning opportunities for all" and the target 4.7 entitled "Education for sustainable development and global citizenship" is dedicated to a sustainable and equitable education "*by 2030, ensure that all learners acquire the knowledge and skills needed to promote sustainable development, including, among others, through education for sustainable development and sustainable lifestyles, human rights, gender equality, promotion of a culture of peace and non -violence, global citizenship and appreciation of cultural diversity and of culture's contribution to sustainable development.*"

Education is specifically mentioned also in other targets: target 12.8 (*by 2030, ensure that people everywhere have the relevant information and awareness for sustainable development and lifestyles in harmony with nature*) and target 13.3 (*Improve education, awareness—raising and human and institutional capacity on climate change mitigation, adaptation, impact reduction and early warning*) are the most relevant among the others.

Summary

In the decades since the Stockholm Conference in 1972, environmental education has emerged as a significant component of education virtually everywhere in the world. It has, for the most part, flourished at all levels of education. There are magazines and journals such as *Sustainability in Higher Education*, professional associations, and regular conferences. It is not difficult to imagine all of this as the start of something like an ecological enlightenment emerging in the decades or centuries ahead. But no such thing is certain. If education is to be midwife to a deeper, broader, and sustainable transformation, it will have to surmount serious challenges.

Ecosystem Services Evaluation

Luca Coscieme and Jane C Stout, Trinity College Dublin, Dublin 2, Ireland

Introduction

Ecosystem services are the outputs of nature which have benefits to people. These include provisioning services such as food and fresh water; regulating services such as climate control; and cultural services such as recreation and spiritual and educational values (Costanza et al., 1997; MA, 2005; TEEB, 2010). Ecosystem functions and biodiversity are part of the natural capital stock that yields ecosystem service flows into the future (Costanza and Daly, 1992; Maseyk et al., 2016). Nature cannot provide any benefits without the presence of people (human capital), their communities (social capital), and their built environments (built capital) (Costanza et al., 2014; Pulselli et al., 2015) (Fig. 1).

However, the contribution of natural capital to human well-being is often expressed purely in terms of human, social and built capital, whilst the contribution of many ecosystem services are largely neglected, poorly understood, and scarcely monitored. This biases cost-benefit analyses and trade-offs between positive and negative outcomes of policies and actions. Increasing well-being by expanding the role of the economy is a priori perceived as more valuable than increasing well-being by preserving or improving environmental quality and the flow of ecosystem services.

The fact that no, or little, value is associated with the provision of ecosystem services has resulted in conversion of ecosystems, habitat fragmentation, landscape alterations, and anthropization of the natural environments. It also means that we lack signals of increasing scarcity of ecosystem services, with consequent continuous depletion and overuse of natural resources. In more general terms, this gap in the way we evaluate factors that contribute to well-being fosters a worldview by which the conservation of biodiversity and functioning ecosystems constrains human development.

As a consequence, the loss of vital ecosystem services may produce short-term positive effects for the economy. For example, it has been suggested that a sharp decline in pollinator populations would actually produce immediate benefits for the economy because the pollination service will have to be replaced by, for instance, commercially produced managed pollinators or by hand-pollinating the crops (Allsopp et al., 2008). This will mean employment, economic growth and tax revenues. However, pollinator decline will be disastrous for the agricultural economy in the long-term (Gallai et al., 2009) and for the production of food crops essential for our health and well-being (Chaplin-Kramer et al., 2014; Smith et al., 2015; Garratt et al., 2014). Pollinators generally provide their services for free and on a massive scale, and their disappearance will influence the biosphere in unpredictable ways, not just in terms of crop production. This makes pollination an irreplaceable ecosystem service whose loss will have long-term negative outcomes that outweigh by far any positive short-term effect on economic growth.

An evaluation system that risks the production of such distorted signals is an evaluation system that is failing us. The fact that values are assigned to man-made contributions to well-being, while Nature's contributions are underestimated or ignored, explains why financial economists are the primary advisors of governments. Climate change and resource scarcity mean that it is necessary for natural/environmental scientists and environmental economists to have the same power in the decision-making process.

In this vein, an evaluation system for ecosystem services is needed for (1) informing policymakers on the scale of human activities in relation with the biosphere; (2) fairly distributing resources within this generation, among future generations, and between humans and the rest of Nature; (3) allocating in the most efficient way resources for maximizing sustainable human development and socio-ecological resilience (Liu et al., 2010).

Different Kinds of Values

A value can be defined as the degree by which an object contributes to reaching an objective. In the case of ecosystem services, values should reflect the contribution of the particular service to human well-being. A distinction can be made between "use" and "non-use" values. Use values derive from the direct or indirect use of ecosystem services, also including the option value, that is, the satisfaction from possible future uses. Non-use values reflect the intrinsic value of ecosystems and biodiversity. This refers, for example, to the satisfaction derived from knowing that a pristine environment, or a particular species, exists, and that other people and next generations will have the opportunity to enjoy it (existence and bequest value).

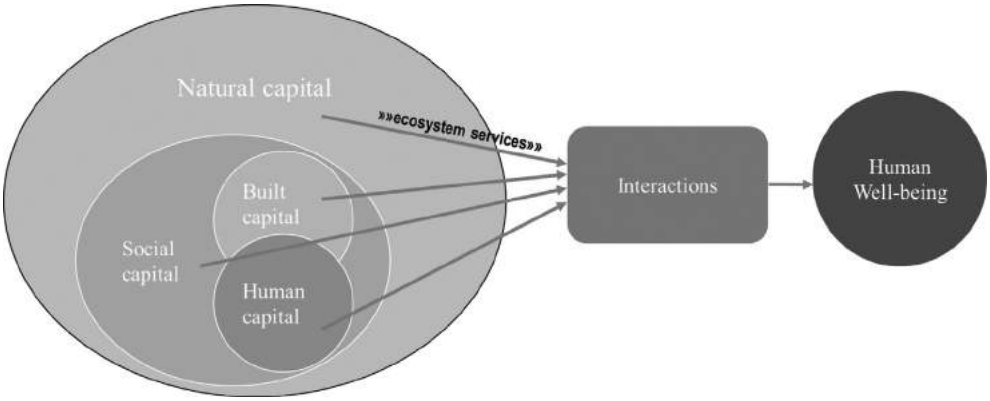

Fig. 1 Interactions between natural, social, built and human capital are required for human well-being. A relational order exists between the different forms of capital, with human and built capital (including the economy) embodied into social capital, and social capital embodied into natural capital. Changes in the global value of ecosystem services. *Global Environmental Change* **26**, 152–158 and Turner, K.G., Anderson, S., Gonzales-Chang, M., Costanza, R., Courville, S., Dalgaard, T., Dominati, E., Kubiszewski, I., Ogilvy, S., Porfirio, L., Ratna, N., Sandhu, H., Sutton, P.C., Svenning, J-C., Turner, G.M., Varennes, Y-D., Voinov, A., Wratten, S. (2016). A review of methods, data, and models to assess changes in the value of ecosystem services from land degradation and restoration. *Ecological Modelling*, 319, 190–207.

Ecosystem Services Evaluation Methods

Broadly speaking, ecosystem services evaluation methods can be grouped into two main categories: (1) monetary valuation techniques, that require ecosystem services to be assessed in monetary terms; (2) biophysical accountings, that rely on more robust techniques and are less controversial, but at the same time are unsuitable for highlighting the importance of ecosystem services relative to, and in combination with, other contributors to human well-being.

Monetary valuation techniques of ecosystem services derive from environmental economics and aim at expressing in monetary terms ecosystem service values. These techniques can be divided into three categories: (1) direct market evaluations; (2) indirect market evaluations; (3) preference-based evaluations. Direct market evaluations are suitable to assess the monetary value of ecosystem services that already possess an explicit market. This is the case of a wide set of provisioning services (e.g., food, materials) that are sold and bought through conventional markets, but it is also the case of some cultural services that imply monetary transactions, such as the recreational service provided by protected areas and national parks that can be accessed by paying a fee. For these services, market prices are assumed to provide good estimations of the value people associate to the good or service provided by the ecosystem. However, market users might be faced with incorrect information through prices not embodying, for example, positive or negative externalities generated to include the ecosystem service in the market.

Indirect market evaluations aim at assessing the monetary value of ecosystem services that do not possess an explicit market. These evaluations rely on proxy measures of the contribution of the ecosystem service to human well-being, expressed in monetary terms. For example, coastal wetlands reduce the damaging effects of storms on coastal communities by absorbing the storm energy on a larger extent than solid land or open water (i.e., through increasing resistance on water motion, reducing direct wind effect on the water surface, absorbing wave energy and maintaining shallow water depths). This service can be directly relatable to the costs avoided by the presence of the coastal ecosystem that reduce the total damage to buildings and infrastructures during a storm. The monetary value associated with these avoided costs is intended to be a sufficiently accurate estimate of the contribution of the ecosystem service for human well-being. Coastal wetlands in the US were estimated to provide US $23.2 billions per year in storm protection services (Costanza et al., 2008). Similar assumptions are at the basis of indirect market evaluations of ecosystem services that rely on estimating the costs of artificially replacing ecosystem services. Preference-based methods rely on values expressed by stated preferences collected through surveying a sample of individuals/stakeholders, or by nonstated preferences revealed through observing people behaviour and choices (see De Groot et al., 2002; Christie et al., 2012 for an overview).

Ecosystem service values expressed in monetary terms can generate controversies when confused with prices (intentionally or unintentionally). The main critique of this evaluation approach is that by assigning a monetary value to services provided for free by Nature, there is a risk of commodification of ecosystems and biodiversity. Other critiques are based on assigning finite values to natural goods and services that are essential and irreplaceable, and thus of infinite value. Despite these critiques, monetary evaluation of ecosystem services is proving to be useful to accounting for the role of Nature in cost-benefit analysis, allowing the inclusion of the costs of environmental degradation and natural resource depletion in macroeconomic indicators. These methods are also effective in communicating the importance of environmental protection to policymakers and the business sector.

Biophysical accounting methods are evaluation techinques that do not express Nature's contribution to human well-being in monetary terms. For example, the value of provisioning services can be expressed in physical units, without relying on market prices. The value of a lake for fish production can be expressed in tons of fish per year, instead of using the market value of the fish. The carbon absorbed by a tropical forest can be expressed in terms of CO_2 equivalent, or the recreational value of a protected area in

number of visitors per year (Remme et al., 2014). Biophysical accounting is less controversial but produces results that are less impactful for policymakers, difficult to be aggregated in a total ecosystem value and to be compared with economic costs/benefits of alternative uses of the ecosystem.

Different evaluation methods are more suitable for evaluation of particular categories of ecosystem services. However, the choice of a specific method is largely dependent on the objectives of the evaluation and the specific audience and socio-economic context. This explains why the same ecosystem service type, provided by the same ecosystem, can be valued very differently case by case. For example, the value of coral reefs for tourism has been evaluated in a range going from tens to millions of US $ per hectare per year (*TEEB Summary: Responding to the value of nature*, 2009), depending on the geographical area, the kinds of tourist activities, and the environmental status of the reef, among other elements (Table 1).

Main Ecosystem Service Evaluation Initiatives

Ecosystem service evaluation can be performed at different spatial and temporal scales and refer to different categories of biomes, ecosystems, and socio-ecological systems. At the global scale, the earliest estimation of the overall ecosystem service values was performed by Robert Costanza and coauthors, and published in the journal *Nature* in Costanza et al. (1997). This analysis relied on a broad literature review, and some original calculations, to estimate the monetary value of the ecosystem services generated by our biosphere in a year. It was calculated that ecosystems at the global scale annually produce goods and services to a total value of around US $46 trillion, which is almost twice the total annual value produced by the global economy. This estimate has been updated in 2011 to US $125 trillion.

Ecosystem services evaluation gained broader attention after the publication of the Millennium Ecosystem Assessment (MA, 2005). Initiated by the United Nations in 2001, this global assessment provided a scientific evaluation of the conditions and trends of ecosystem services. The Millennium Ecosystem Assessment inspired several other international initiatives such as The

Table 1 List of the most common methods used to evaluate the different categories of ecosystem services

Approach	*Method*	*Ecosystem services*	*Rationale*
Monetary valuation	Market price	P, C	Actual market prices are used as a proxy for the good or service value
	Shadow price	All	Values are estimated as prices in hypothetical markets
	Production function	P	The indirect role of the ecosystem in the production of a marketable good is modeled and assessed
	Factor income	P, C	Some ecosystem services create or enhance incomes. The income (or income surplus) is considered as a proxy for the service value
	Hedonic pricing	All	The value of a good or service can be influenced by the quality of the environmental context where people benefit from it
	Travel cost	All	The money and time people spend to go enjoy an ecosystem service may serve as a proxy of its value
	Avoided cost	All	Ecosystem services allow society to avoid costs that would have been incurred in the absence of those services
	Replacement cost	P, R	The costs of artificial replacement of an ecosystem service are considered as a proxy of the service value
	Contingent valuation	All	People are asked about the value they attach to ecosystem services (through direct questions; hypothetical scenarios; trade-off choices between alternative services)
	Group valuation	All	A group of people is asked to discuss about the value they attach to ecosystem services, and provide a common value
	Benefit transfer	All	Ecosystem service values previously calculated are adapted to different contexts
Biophysical accounting	Changes in stocks/ quantities	P	Increasing/decreasing quantities of an ecosystem good indicate increasing/decreasing values
	Ecological integrity	All	The higher the ecological integrity, the higher the value of that ecosystem for that service
	Biodiversity indexes	All	The higher the biodiversity, the higher the service value of that ecosystem
	Ecological Footprint	P	The area and productivity of ecosystems within a territory (i.e., the Biocapacity) are used as proxies for the ecosystem service value of that territory
	Changes in efficiency	P, R	The more efficient an ecosystem is in producing goods and services, the higher its value
	Emergy	All	The more equivalent solar energy embodied in the ecosystem components, the higher the ecosystem service values
	Eco-exergy	All	The higher the level of genetic information and biomass in the ecosystem, the higher the ecosystem service values

P, Provisioning services; C, Cultural services; R, Regulating services.

Economics of Ecosystems and Biodiversity (TEEB, www.teebweb.org) and the ongoing Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES, www.ipbes.net). These initiatives are mainly based on state-of-the-art reviews and aim at highlighting knowledge gaps and promoting the message that a correct management and conservation of ecosystems is highly valuable (also in economic terms) for human well-being. The final reports produced are often addressed to policymakers and the business sector and the results are disseminated through impactful key messages shaped to reach the general public.

In some cases, ecosystem services evaluation have been implemented into policy strategies and business partnerships. The European Union Biodiversity Strategy for 2020 includes targets and actions specifically centred around the concept of ecosystem services and their evaluation. For example, Target 2 "Maintain and restore ecosystems and their services" dictates actions on mapping and assessing ecosystem service values in the member states' national territories, and ensure no net loss of ecosystem services. The Wealth Accounting and Valuation of Ecosystem Services (WAVES) project of the World Bank (https://www.wavespartnership.org/) aims to include the value of ecosystem services in development planning and national economic accounts. In 2008 and 2012 the World Resource Institute published The Corporate Ecosystem Services Review, that presents guidelines for including ecosystem services into business risks and opportunities management, recognizing the business sector's dependence and impact on ecosystems.

At country level, several nations produced National Ecosystem Services Assessments, such as the UK NEA. In Europe, Portugal, Spain, Norway, the Netherlands, Finland and Germany represent the most complete examples. Due to the very different approaches and methods used in these assessments, comparisons among them are not easy. A standarsization process of data collection, methods and indicators for ecosystem services evaluation is underway through intiatives such as the European Environmental Agency's Common International Classification of Ecosystem Services (CICES), or the EU Mapping and Assessment of Ecosystems and their Services (MAES).

Despite the diversity of methods used in ecosystem services evaluation, which ensures a plurality of perspectives and an interdisciplinary approach, standardization of evaluation and accounting methods is important for including ecosystem service values into alternative "beyond GDP" macroeconomic indicators. Through this operation, policymakers will be able to rely on development indicators that do not ignore the role of the environment for human well-being.

Thematic initiatives have been promoted to assess the value of specific ecosystem types, specific services, or with a focus on specific environmental elements such as soil, for example, or on particular species or, also, on the effects on ecosystem services of particular activities, such as deforestation or land degradation. The latter is the case of The Economics of Land Degradation (ELD) Initiative, a global study on the economic costs and benefits of land management practices, land degradation, and restoration.

Several initiatives, and research in general, have been recently focused on a particularly important ecosystem service, pollination, which is important for food production, but increasingly threatened by human activities, and thus a good example of the risks associated with ecosystem service loss. Due to the variety of methods used for assigning a value to pollination and pollinators, and due to the broad relevance of the status and trend of this service, we consider it a useful example of different approaches to ecosystem services evaluation.

Examples of Ecosystem Services Evaluation: Pollination Services

The majority (87.5%) of the world's flowering plants are pollinated by animals (Ollerton et al., 2011), including 87 of the leading 115 global food crops (Klein et al., 2007). Because of this, market values of food crops are often used to illustrate the economic value of pollination services. However, the total economic value of pollination services incorporates both market and non-market benefits (Hanley et al., 2015).

Market values of pollination service, in terms of the contribution to agricultural and horticultural production, have been quantified in a variety of ways. An early approach was to equate the total value of insect pollinated crops, or the cost of renting hives from beekeepers, with pollination services (Hanley et al., 2015). However, this approach is simplistic, as insect-pollinated crops are often able to produce some yield in the absence of pollinators (and thus the total crop value is an over-estimate of pollination value), hive-rental is usually not the only input to crop production, and in many places farmers do not pay to rent hives from local beekeepers (thus under-estimating pollination value) (Allsopp et al., 2008).

More recently, pollinator "dependence ratios" (DR) of crops have been used. A DR is calculated as the difference in yield in the presence and absence of pollinators (Klein et al., 2007) and thus provides a measure of crop loss in the absence of pollinators. It is usually measured in the field by comparing yield of plants protected from pollinator visitation (either grown in cages or covered with netting to exclude visitors) with plants open to natural levels of pollinator visitation. This ratio can then be multiplied by the area of crop planted and farm gate price of those crops in any given year, to give a figure representing the amount of farmer income attributable to pollination service. This method has been used to estimate the value of pollination services to crops for human consumption globally (e.g., Gallai et al., 2009), and regionally (e.g., Carreck and Williams, 1998; Losey and Vaughan, 2006). This enables identification of crops vulnerable to loss of pollination service and of areas where conservation of pollinators is critical, and is easily calculated using national statistics (Hanley et al., 2015). However, estimates vary temporally (year to year) and spatially (country to country), depending on crop types and market forces (Leonhardt et al., 2013).

In addition, there are several other problems with this approach. One is that data on DR are often taken from crops grown in different environmental conditions or of different varieties or cultivars and are not collected in a standardized way (Hanley et al., 2015). For example, yield may be expressed in terms of various functions of fruit or seed production from individual flowers or

whole plants. Another problem is that other outputs (such as crop quality) and inputs (such as agrochemical inputs, irrigation or managed pollination) are often not taken into account (Garratt et al., 2014), although some studies have incorporated crop quality (in terms of shelf-life) into estimates of pollinator value (Klatt et al., 2014). Thirdly, mean values do not incorporate the marginal variation in demands for pollinator dependent crops and how these change over space and time, that is, crop values are not "fixed" and vary according to consumer demand (Ricketts and Lonsdorf, 2013). This means that the assumption that loss of pollination will decrease crop value does not hold (Melathopoulos et al., 2015). In addition, these methods do not account for farmers switching to less pollinator dependent crops or varieties due to falling pollinator numbers.

Another approach to estimating the value of pollination services in agriculture is to estimate how much it would cost to pollinate crops using alternative methods. Replacement cost estimates have been based on pollen dusting and various methods of hand pollination by humans. An assessment of these methods, conducted on the Western Cape deciduous fruit industry of South Africa, valued pollination services higher than current market prices for commercial pollination (Allsopp et al., 2008). A recent study incorporated several methods to assess the value of pollination for a watermelon in the United States; subtracting the cost of inputs, valuing only the pollen deposition that is required for fruit production, and not excess pollen deposition, and attributing value to different pollinating taxa (Winfree et al., 2011). Obviously, detailed data are required for this approach. The most comprehensive approach so far involves modeling pollination efficiency, effectiveness, abundance and visitation rates of different taxa to derive a community production function (Hanley et al., 2015), but again, often the data required to make this complete assessment are not available.

It is predicted that in the future the demand for, and the area planted with, insect-pollinated crops (both field and covered crops) will increase (Aizen et al., 2009; Breeze et al., 2014). With changing climate, policy and consumer demands, insect pollinated crops could become increasingly important and so accurately valuing these services may become important in influencing agri-environmental decision-making to promote pollinator conservation. Furthermore, insect pollinated nonfood crops (e.g., fibers, fuel, animal fodder), as well as medicinal, cultural and/or symbolic plants, which may have market values, have not been subject to the same sort of analyses (but see Ollerton et al., 2016).

In addition to the short-falls in approaches used to value pollination services thus-far, few studies have attempted to consider the non-market values of pollination. To understand the real value of pollination services, non-market values need to be incorporated into assessments. Although a range of methods for capturing non-market values exist (e.g., contingent valuation such as willingness to pay and choice experiments, as outlined above), this has not yet been attempted for pollination services. In addition, studies so far have not addressed the value of services to maintenance of plant community composition, and how changes in plant community composition may affect the delivery of other ecosystem services, including supporting and regulating services, as well as cultural services.

Thus the valuation of pollination services is a good example of the overall approach to ecosystem services evaluation and illustrates that a joint effort among different disciplines is required. This enables a very broad variety of methods, some of which are already widely implemented, while some others need further improvements and applications. The need for a common framework, and for the standardization of the evaluation methods, is highlighted and partially fulfilled by initiatives such as the recent IPBES "Assessment report on pollinators, pollination and food production: summary for policymakers." Similar documents have been, and will be, produced regarding other types of ecosystem services.

Conclusions

Ecosystem service evaluation aims at considering the contribution of ecosystems to human well-being into cost-benefit analyses, macro-economic indicators and, finally, policies and decision making. A vast amount of literature testifies the efficacy of different evaluation methods, while a series of governmental and non-governmental intitatives testify the increasing interest in relying on ecosystem service evaluations to improve environmental management at different scales.

The many different evaluation methods developed so far represent the added value that a transdisciplinary approach can bring to theoretical and applied research. However, ecosystem services evaluation methods need to be further improved, in particular for including non-market values.

The criticisms, especially to monetary evaluation techniques, often address real issues such as the risks of commodification of the environment and of misusing the calculated values.

Finally, the rationale behind monetary evaluation of ecosystem services is to express the contribution of ecosystems to our well-being in terms comparable with those used to express the economy's contributions to well-being. It is in effect a communication strategy to reach policymakers.

The fact that ecosystem services and services from the economy are expressed through a common language does not mean that they automatically assume the same characteristics. Once a common language is defined, it is up to the speakers to choose what to say within the rules of that language. One of the most impactful uses of monetary ecosystem service values will be their inclusion into national accountings and well-being indicators, in order to produce a measure of development that considers the role of the environment (and society), instead of merely considering economic growth.

On the other hand, biophysical accounting methods do not produce results that are easily translated into policies, and this limit needs to be overcome.

Emergy and Sustainability☆

Roberto Ridolfi, Federico M Pulselli, Fabiana Morandi, Mariana Oliveira, and Simone Bastianoni, University of Siena, Siena, Italy; State University of Campinas, São Paulo, Brazil

Introduction

Natural systems belong to an energy network in which transformation processes connect smaller scales and larger scales. In every transformation, energy remains constant while exergy (sometimes referred to as "available energy") at one level is consumed leaving a smaller amount at the next level.

It is recognized that different types of energy exist. Joules of energy of different kinds are not equivalent in their ability to do work. The energy that flows through all real processes is partially degraded. The second law of thermodynamics states that all real processes, including processing of energy and storage of materials, imply a dispersion of part of the energy in the form of heat. Nature is therefore organized in flows of energy of different qualities.

Odum recognized the implications of energy quality and introduced the concept of emergy (initially called "embodied energy") to quantify the available energy (exergy) of a given type directly and indirectly used to make a product. The type of energy chosen as reference was solar energy, since it is basically the source of all flows in the biosphere. The solar emergy (from now on simply emergy) of a product is, therefore, the solar energy (exergy) needed, directly and indirectly, to make that product.

A flow can be evaluated not only on the basis of the amount of exergy carried but also on the basis of the amount of solar energy directly and indirectly used to produce the flow. In this way, it is possible to differentiate flows of higher quality, that is, that need great quantities of energy or material for their production, from flows of low quality that need little energy or material.

Energy Language, Energy Modeling, and Hierarchical Web

To describe the flows of energy and matter in a system, a modeling language, called "energy system diagram," has been developed. Systems are made up of forces and energy pathways: the former are causal actions, the latter represent how and where these forces are directed. The symbols used in energy diagrams are summarized in Fig. 1.

The emergy concept was developed with hierarchical webs in mind (see Fig. 2). In these webs, quantity of energy associated with each transformation decreases at each step in the process. Every transformation is accompanied by production of "dispersed" heat.

In the energy diagram the productive units on the left produce goods and services for those on the right which return materials and control to the left. The different units reinforce each other so that the whole system self-organizes and maximizes power. Energy is transformed from left to right and in each transformation the output has less energy but of higher quality and controls other units of the system. To create quality on the right, a great amount of low-quality energy is necessary. The diagrams show an energy hierarchy with step-wise convergence from left to right. In a food web (see Fig. 2), the position in the chain represents different capacities for control and quality. For example, directly and indirectly, it takes about 1000 J of sunlight to make a joule of spatially dispersed organic matter, about 40,000 to make a joule of coal, and usually even more to make a joule of electrical energy. A joule of sunlight, a joule of coal, and a joule of human work have different qualities and different energy convergences to make them. According to this concept, Odum sustained that a more meaningful way to express quality is not to consider the energy content of a

☆*Change History*: March 2018. R. Ridolfi, F. M. Pulselli, F. Morandi and S. Bastianoni updated Emergy Algebra and further readings; added a new section "Emergy And Set Theory"; added new Fig. 4. The authors updated and added a new section "Emergy in an input-state-output framework."

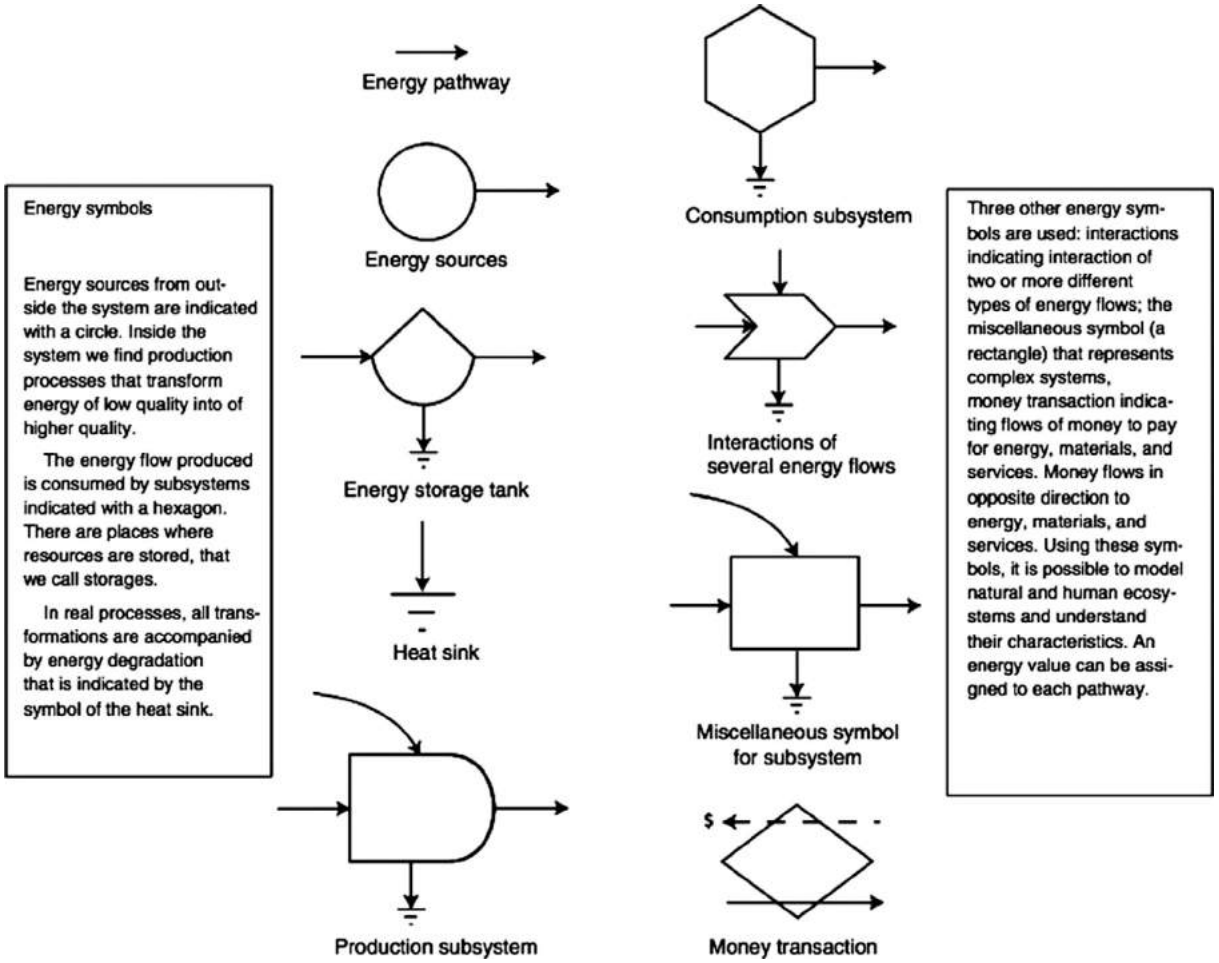

Fig. 1 Energy system symbols.

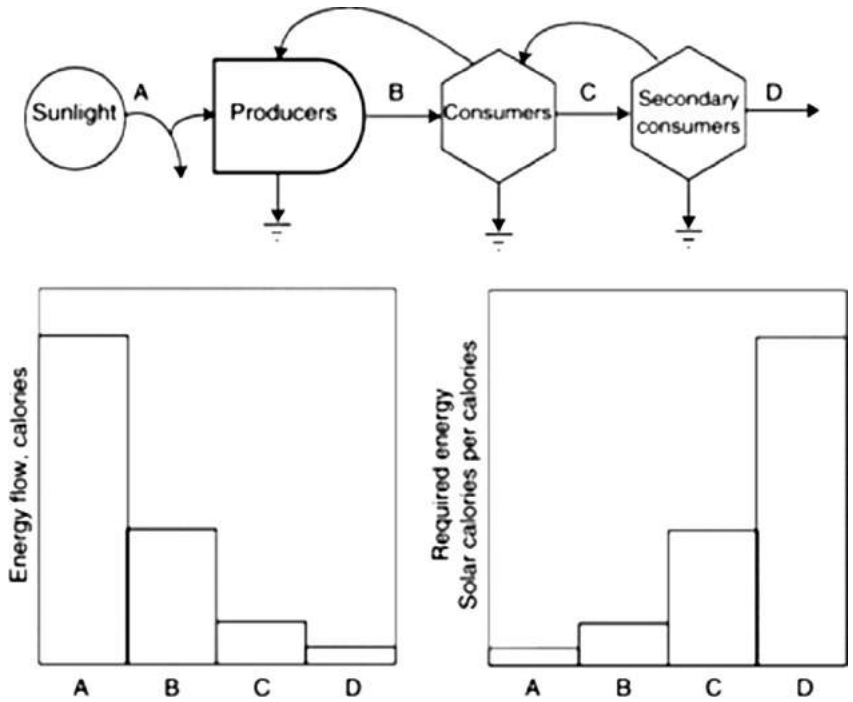

Fig. 2 Hierarchical webs and energy flows.

system but the energy embodied (emergy) in it, that is, how much energy was used to make or sustain the system starting from the lowest level of the web. For this reason, emergy is sometimes referred to as "energy memory."

Emergy

From its definition emergy is an extensive quantity; its unit is the solar emergy joule (sej) and its physical dimensions are those of energy (ML^2T^{-2}) of solar (or equivalent) type, where M = mass, L = length, T = time). It is not a state function, since it depends on the pathway that the process follows. In fact, the emergy of a product is related to the way it is produced. A joule of electricity generated from oil has a different emergy to one generated by wind power.

Emergy is a donor-referenced concept rather than a receiver-referenced one. It measures the source energies converging at system boundaries into processes or products. The total energy flowing through a system per unit time is its empower, with units sej/[time] and physical dimensions (ML^2T^{-3}) of solar type.

The basis of emergy evaluation is the conversion of all process inputs, including energy of different types and energy inherent in materials and services, into emergy by means of a conversion factor called transformity.

Transformity

Transformity is defined as the energy of one type directly and indirectly required to generate 1 J of another. Solar transformity is currently used in emergy evaluation. Unlike emergy, transformity is an intensive quantity, representing the inverse of classical energy efficiency and is measured in sej J^{-1}. It is dimensionless and system specific. To evaluate increased organization of concentrated matter, a mass-specific emergy (sej g^{-1}) is sometimes used instead of transformity. The emergy of a certain type of material is obtained by multiplying its mass with the emergy-to-mass ratio. As with energy-based transformities, matter evaluations are also system and process specific. In general we can call Unit Emergy Value (UEV) the ratio of emergy to any unit output.

Emergy and Transformity

As stated above energy decreases along transformation chains, therefore along a chain or a web, transformities increase and emergy, following "memorization" laws, may remain constant or grow down-chain. Fig. 2 is useful for evaluating emergy and transformity at different steps in an energy flow sequence. If the producers are forage plants and the consumers (C) are cows, the sun transfers energy to the plants from the boundary of the system, the plants use it by photosynthesis and transpiration, taking up soil nutrients and fertilizers. The transformity of the plants is clearly greater than 1 (i.e., the solar transformity of the sun) because the energy in the forage is obviously much less than that of the incoming solar energy, but the plant increases the organization of the sun–forage–cow system. Similarly, the forage transfers its solar-derived energy to the cow. The cow's transformity is much greater than 1 because of the cow's low energy with respect to the solar energy that has been used for it. Since the forage contains energy derived from the sun, so does the cow, and energy embodiment increases as energy dissipates along food chains.

As a general rule, the transformities of similar products are compared to obtain information about production efficiency. If, for instance, the transformity of forage from one field is 4×10^4 sej J^{-1} and that from another field is 1×10^5 sej J^{-1}, the forage from the first field can be said to be more efficient (less emergy per unit of product).

Transformities of different classes of product (e.g., forage and cow) can also be compared. In this case, transformities indicate the relative "position" in the global hierarchy of processes. All energy transformations can be represented in sequence and the position of each energy flow in the sequence is indicated by the transformity.

Energy system diagrams show energy hierarchy with small fast turnover units on the left and aggregations in space and time on the right (Fig. 3).

Emergy is the same from left to right (Fig. 3B and C), whereas available energy decreases after each transformation and the transformity increases. The higher the transformity, the greater the demand for energy to make that flow or product. So in order to overcome natural selection, systems reinforce their networks with feedbacks. Units receiving feedback from units further down the chain are reinforced by a small energy flow of high quality, that is, more concentrated and therefore more capable of doing work.

Emergy Algebra

As stated above, emergy analysis obeys a logic of memorization and therefore needs its own algebra, that is summarized in four main rules, which according to Brown are:

1. All source emergy to a process is assigned to the process's output (Em_k):

$$Em_k = \sum_i Tr_i E_i \tag{1}$$

where E_i is the energy of the ith component and

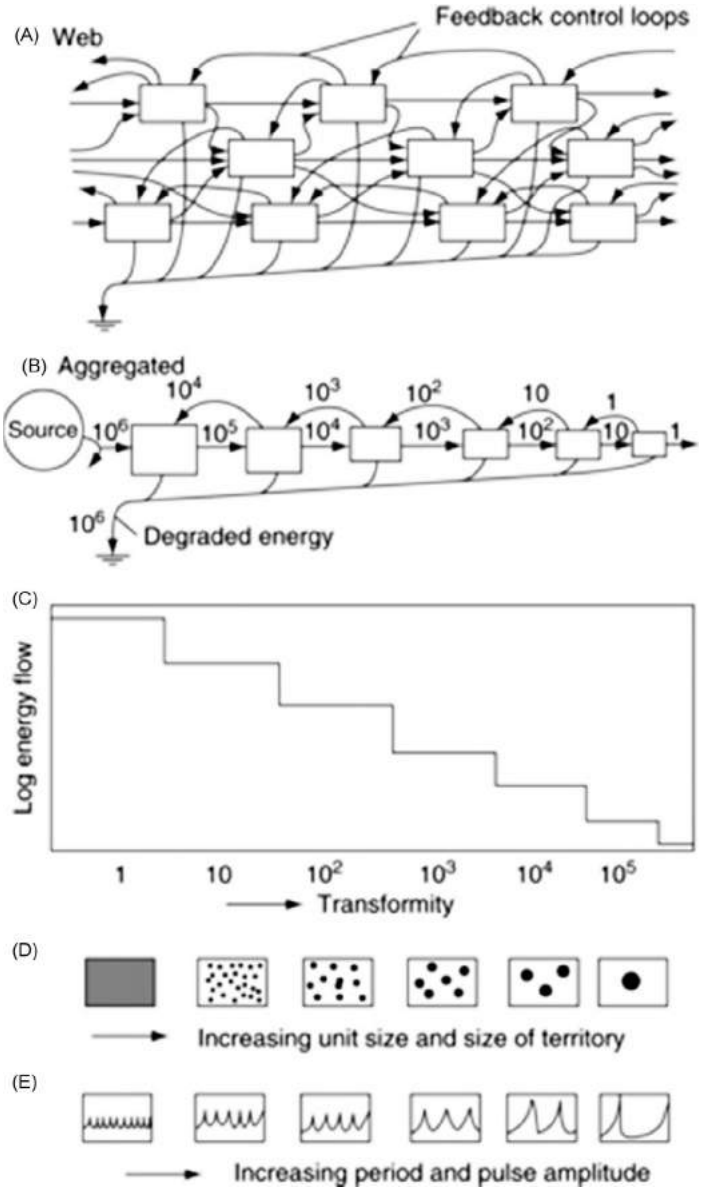

Fig. 3 Energy hierarchy in space and time. Reproduced with permission from Ridolfi, R., Pulselli, F. M., Morandi, F. and Bastianoni, S. (2013). Emergy. *Reference Module in Earth Systems and Environmental Sciences.* https://doi.org/10.1016/B978-0-12-409548-9.00590-X.

$$Tr_i = \frac{Em_i}{E_i} \tag{2}$$

2. By-products of a process have the total emergy assigned to each pathway.
3. When a pathway splits, the emergy assigned to each branch is based on its percentage of the total energy flow on the pathway (the two products are called splits).
4. Emergy cannot be counted twice in a system: (a) emergy in feedbacks is not counted twice; (b) when emergy of by-products is summed, it cannot be greater than the source emergy from which it was derived.

It follows that the transformities of two (or more) splits are identical, while their emergy contents are generally different (unless energy is distributed equally among the splits); on the contrary, the transformities of co-products are generally different (unless the same amount of energy went into the various co-products).

The first emergy rule indicates that it is necessary to know the emergy of the inputs in order to calculate the emergy of the output. Apart from the sun, that has a transformity of 1 by definition, it is necessary to calculate the transformity or emergy of natural resources. Emergy accounting starts with an evaluation of the Earth's emergy processes. Once the emergy of the main natural flows is calculated, it is possible to calculate the emergy of many resources, from minerals to fossil fuels. Over the years, depending on the

model used and on the combination of the main natural flows, other baselines have been developed but now an agreement has been reached: the reference baseline (that represents the reference for all the emergy calculations) has been updated to 12×10^{24}sej year^{-1}.

Emergy and Set Theory

A recent development has suggested that Emergy can also be defined as the set of the solar exergy that is directly and indirectly required to obtain a service or a product. In particular, emergy can be seen as the set of all the (equivalent) photons falling on certain portions of the biosphere in certain time intervals, that have been used directly and indirectly to make a product or service. In this way, because the emergy of a product (or service) is obtained through the convergence of several inputs, it can be seen as the union of the sets of solar exergy required to obtain each input, that is:

$$Em = \bigcup_i \{\text{direct and indirect solar exergies}\}_i \tag{3}$$

Eq. (1) is then corrected with:

$$Em = \bigcup_i Tr_i E_i \tag{4}$$

This formula is more general and correct than Eq. (1) because it is able to fully consider all the rules of emergy algebra. In fact, the union, with respect to the sum operation, does not require any restriction: if the emergy flows are independent, the union is replaced by the sum, otherwise only the independent parts (without intersections) should be added. In this way, all rules of emergy algebra can be encompassed in the property of union of sets because splits are represented by a partition of the out coming flow while by-products (that are associated to the operation of copy) and feedback are never counted twice when they interact in the process (Fig. 4).

Emergy, Sustainability, and Its Indicators

Unlike classical energy and economic analyses that only consider items that can be quantified in energy or money terms, thus omitting most free inputs from the environment, emergy analysis is a thermodynamic methodology which considers both the

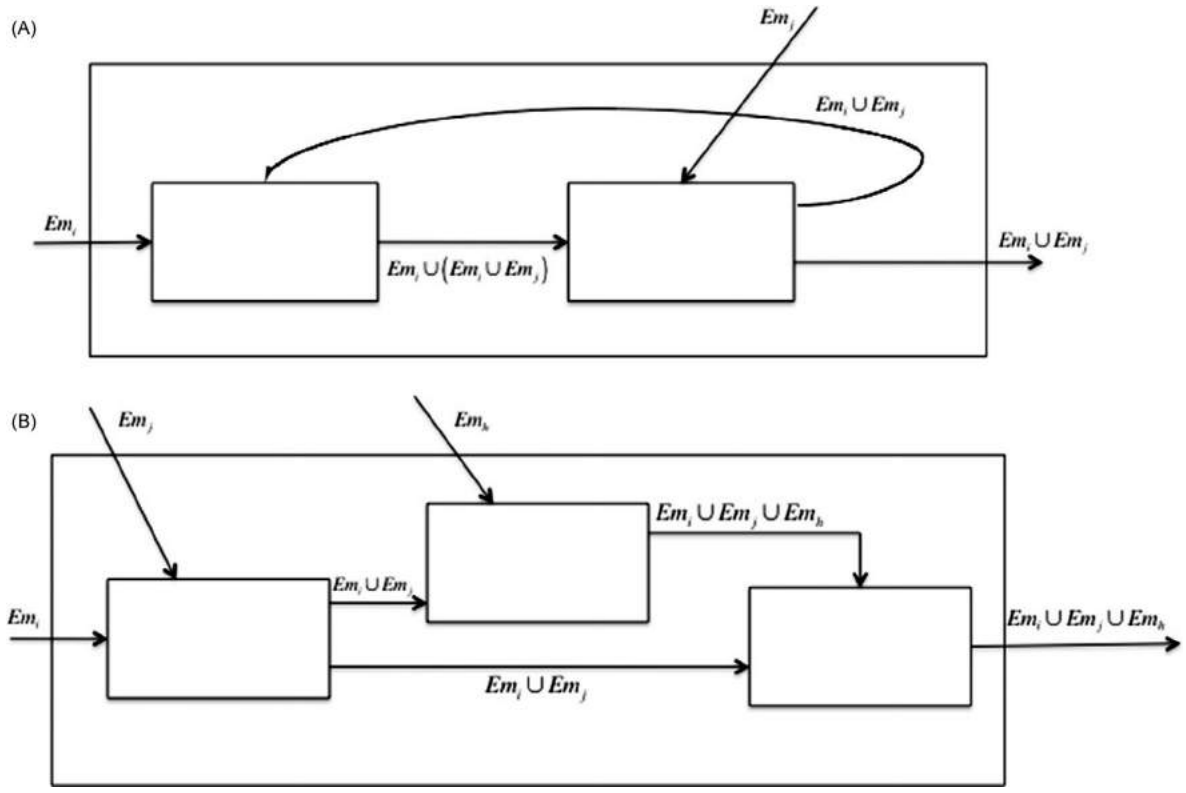

Fig. 4 Examples of (A) a process with a by-product that feeds back and (B) of a process where by-products are reunited.

economic and environmental aspects of a system by converting all inputs, flows, and outputs to the common denominator of solar energy, the basic energy behind all the processes of the biosphere.

This is a primary factor because, although the market only considers monetary value, the economy is also based on quantities from the environment, which must be considered and assigned a value, if resources are to be exploited sustainably in the long period.

Emergy analysis is useful to check applications of Herman Daly's first rule of sustainable development, the so-called sustainable yield principle, that states that resources should be exploited at a rate compatible with their replacement by nature. It can be used to define guidelines for consumption of resources compatible with their formation times.

Emergy can be regarded as the solar energy necessary to sustain a system; the greater the total emergy flow necessary for obtaining a product, the greater the consumption of solar energy necessary for its reformation once it has been used, and thus the greater the past and the present environmental cost to maintain it.

The intensive use of the services and products of an ecosystem can degrade its structures and functions, decreasing the capacity of the ecosystem to self-organize efficiently. In order to facilitate the measurement of a system's sustainability, some emergy indicators were introduced.

To explain them a simple model of a system is shown in Fig. 5. Emergy flows to the system are divided into the main categories as given in the following:

- local renewable resources (R);
- local nonrenewable resources (N);
- feedback (F): purchased resources and services from outside system; and
- the yield (Y): the output of the system ("virtual" in the case of territory).

These flows can be combined to obtain a set of indicators; here are most common ones.

1. Emergy yield ratio (EYR) is the ratio of the output of a system (Y) to the feedbacks from outside (F). Therefore, it is the ratio of total emergy to the nonrenewable, economic inputs. Considering that the total emergy is the sum of all local and external emergy inputs, the higher the ratio, the higher is the relative contribution of the local sources of emergy to the system. This index therefore shows the ability of a system to use the available local resources. Generally, EYR values less than 5 are typical of secondary energy sources and primary materials (e.g., cement and still), whereas values greater than 5 are shown by primary energy sources. In the case of processes that give products with EYR values less than 2, the processes are not considered an energy source but rather a consumer or a transformation process:

$$\mathrm{EYR} = \mathrm{Y}/\mathrm{F}$$

2. The environmental loading ratio (ELR) is the ratio of renewable to nonrenewable emergy use inside a system. It is a measure of the renewability of a production system or a system state. The higher the ratio, the lower the system's sustainability. A high ratio

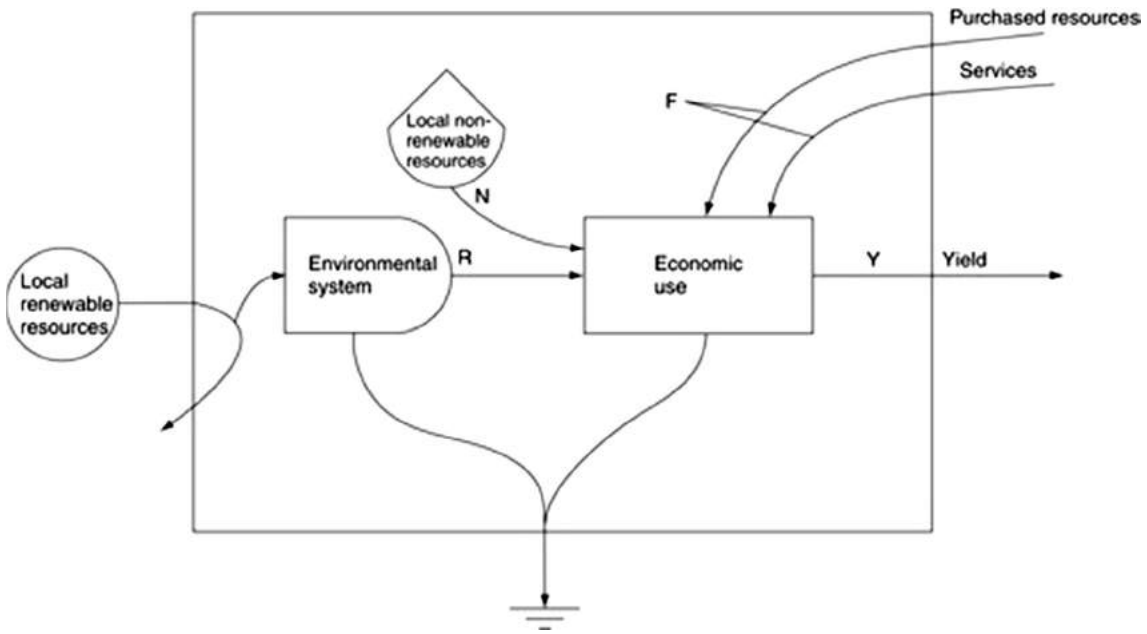

Fig. 5 Energy system diagram of a generic system.

suggests a high technological level of emergy use and/or a high level of environmental stress (either local or global). It sounds an alarm-bell of nonequilibrium which could become irreversible for a state or a production system:

$$\mathrm{ELR} = (\mathrm{F} + \mathrm{N})/\mathrm{R}$$

3. Emergy money ratio is the ratio of emergy use in a country (or a region) to its gross national product. It measures how much emergy is associated with the economic wealth of a state. The emergy money ratio provides a link between emergy evaluation and economics. The use of emergy with traditional economic evaluation methods can provide additional information to guide human activities, as in planning land use or designing production processes. This tool has a twofold function: (1) it provides information about systems, for example, comparison of national economies with different emergy flows and GDP, or evaluation of the trend of an economic system in time; (2) it can be used as a conversion factor for further emergy evaluations when monetary parameters must be converted into emergy and vice versa:

$$\text{Emergy to money ratio } (sej/\$ \text{ or } €) = \mathrm{Y}/GDP$$

where Y is the total emergy used in a territorial system in a year ($\mathrm{Y} = \mathrm{R} + \mathrm{N} + \mathrm{F}$) and the GDP is referred to the same year.

4. The emergy investment ratio (EIR) is the ratio of feedback to local resources (renewable and otherwise). It measures how much a system depends on the outside rather than on local resources, and how much a system or process uses invested emergy in comparison with alternatives:

$$\mathrm{EIR} = \mathrm{F}/(\mathrm{R} + \mathrm{N})$$

5. Emergy per person is the ratio of emergy used in a country divided to population. It measures how much emergy is available per person. This indicator suggests a measure of the standard of living in a country in terms of current availability of resources and goods, though it does not give any indication about the future availability of resources. Two different meanings are associated with emergy per person: in the case of a low ELR (low use of nonrenewable inputs), a high emergy per person ratio indicates resource availability, whereas when ELR is high (high use of nonrenewable inputs), emergy per person represents consumption and the system needs to invest in order to decrease emergy use and enhance renewable uses:

$$\text{Emergy flow per person } (sej/(\text{pers.year})) = \mathrm{Y}/\text{persons}$$

where Y is the total emergy used in a territorial system in a certain amount of time, typically 1 year ($\mathrm{Y} = \mathrm{R} + \mathrm{N} + \mathrm{F}$).

6. Empower density is the ratio of emergy flow into a system to area of the system. It measures the concentration of emergy in space and time. This indicator is a measure of spatial concentration of emergy flow within a process or system. It can be used to highlight areas under environmental pressure with respect to more natural areas. A high empower density can be found in processes in which emergy use is large with respect to the available area. This suggests that land is a limiting factor for the future economic growth. The emergy flow density can be used to plan environmental policy. Areas with high emergy densities have a concentration of emergy use and call for different policies than natural or agricultural areas. For example, cities and industrial districts should invest in increasing efficiency of energy use, transport and so on, whereas agriculture areas need more attention to soil management and fertilizer use:

$$\text{Empower density } \left(sej/\left(m^2 \text{ year}\right)\right) = \mathrm{Y}/\text{Area}$$

Emergy Applications

Ecosystems

Emergy evaluation is a method that works perfectly at the interface between human and natural systems. There have been many studies on this interaction; here we chose one that assessed the environmental impact of a fish farm. Aquaculture has many interactions with the surrounding environment using resources and producing changes in the ecological system.

The fish farm, in this application, is located in the Gulf of La Spezia (Ligurian Sea, NW Mediterranean Sea). The installation called Spezzina fish farm is a marine inshore fish farm located at Punta Pezzino; this area of Gulf of La Spezia is sheltered by the offshore breakwater and is thus characterized by a low circulation regime (Fig. 6). Reared fish are mostly gilthead sea bream (*Sparus aurata*) and sea bass (*Dicentrarchus labrax*) to a lesser extent. In the study only *S. aurata* production is considered in the emergy calculation.

The farm comprised of a total of 60 fish cages (for a total of 44,000 m^3) placed on floating wharves oriented from the coast toward the open sea (Fig. 6). The whole installation covers an area of 24,000 m^2 with a mean depth of about 12 m. Average production is reported to be 350 tons of fish per year.

Food supply takes place twice a day with an automatic system and the fish diet varies both in composition and quantity in relation to biological factors (i.e., age, biomass, and starving) and in relation to climatic and physical factors (i.e., water temperature, and dissolved oxygen).

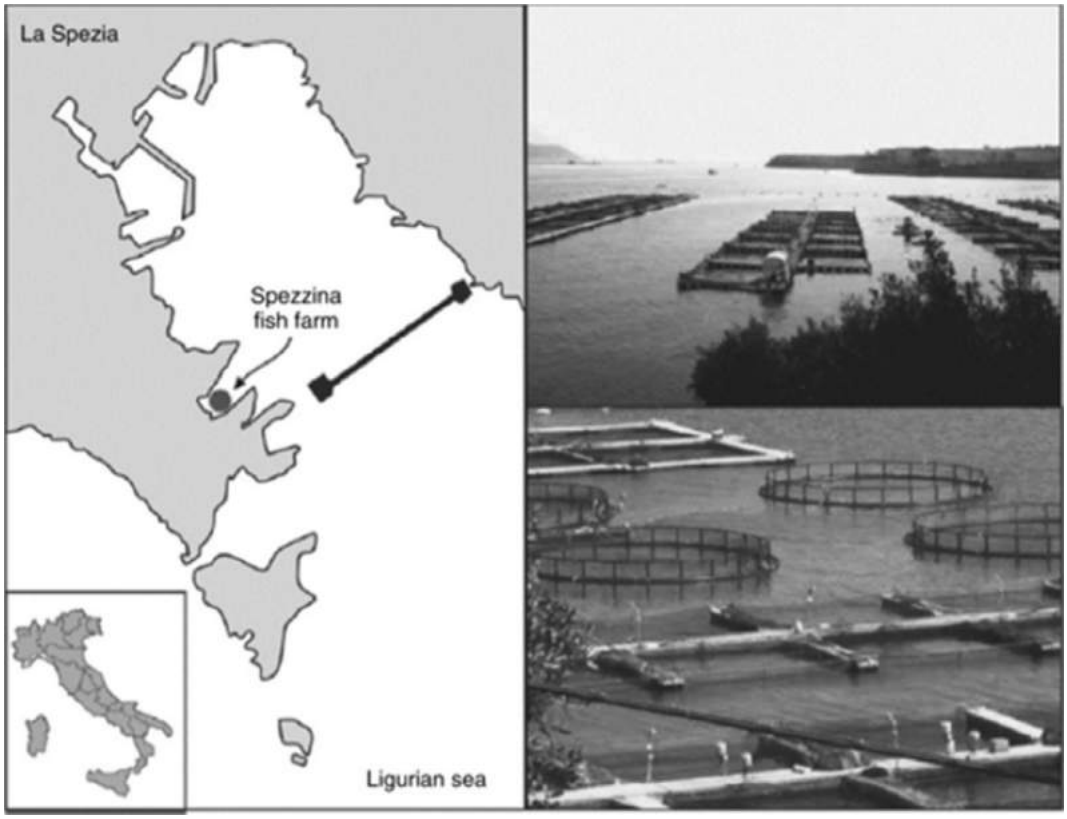

Fig. 6 Spezzina fish farm geographical position and cages disposition. Reproduced by permission of Elsevier.

Moreover, the farm is equipped with an automatic system for oxygen spreading installed under the cages; it is utilized when oxygen concentration falls below a threshold level considered dangerous for the health of the reared fish.

Fingerlings are introduced in to the cages in two periods: in spring (from March to June) and in autumn (from September to November). The total number of fish introduced is roughly 1,300,000 each year; fingerlings experience a 20% mortality rate. Fish reared in Spezzina fish farm spend 16–18 months (depending on weather, size, and period of introduction) to reach the size needed for the yield (350 g) and the farming is managed to obtain at least 7.5 tons of fish each week to meet the market demand.

The energy system diagram of the system, under study, is reported in Fig. 7.

Table 1, constructed from the diagram, shows the actual flows of materials, labor, and energy and all flows are evaluated.

For the analysis the different inputs have been identified and grouped in two categories: renewable and nonrenewable resources. The total emergy flow, obtained by summing all the independent contributions, made it possible to calculate the transformity of fish, given the quantities produced (see Table 1) and assumed that each kilogram of fish corresponds to 800 kcal (3.35×10^6 J kg^{-1}).

Three other systems producing fish are selected for comparison: two intensive fish-farming systems producing, respectively, salmons (*Salmo salar*) in the Umpqua river estuary and tilapia (*Tilapia mariae*) in the Nayarit, Mexico; the third system (Valle Figheri, in the Venice lagoon) produces *S. aurata* but in a seminatural extensive manner.

Assuming that the fish are all of the same quality if transformities are considered, *T. mariae* and *S. aurata* rearing showed the highest efficiencies, probably due to more favorable weather conditions of the areas that allow growth of the fish in an optimal temperature range. Furthermore, *T. mariae* is well known as an easily reared fish because of its very good adaptation to various conditions. Nevertheless, differences in transformities may also be due to the different species or to a different type of rearing system.

Considering the same type of systems, we can see that the transformities display increasing values from the lowest quality fish (*T. mariae*) to the highest one (*S. salar*) showing a good accordance with the maximum empower principle.

On the other hand, Spezzina fish farm and Valle Figheri produce the same kind of fish but in drastically different systems: one is very intensive in a narrow gulf in the Ligurian Sea; the other is an extensive system that tries to use all the natural resources available in this artificial ecosystem. The result is a much lower transformity for the system under study, meaning that Spezzina fish farm is more efficient in producing fishes, even though the production is much more dependent on external and nonrenewable inputs.

ELR for the Spezzina fish farm showed that fish rearing needs for the larger part, nonrenewable resources for its maintenance: nonrenewable external inputs are five times higher than renewable ones. If this result is compared with other similar production systems (Table 2), the dependence on nonrenewable resources of the *S. aurata* with respect to *S. salar* net pen culture in Oregon is higher, but much lower if compared with *T. mariae* rearing in brackish water in Mexico.

These results could be related to differences in the role of natural systems for the *S. salar* culture that take advantage of the wide tidal range that characterizes the Oregon coasts; while for *T. mariae* culture, value is strictly affected by the external inputs and is higher than what is detected in other systems. Nevertheless, all these results are very relevant if compared with the seminatural system in the lagoon of Venice, where renewable inputs are three times larger than nonrenewable ones. As a direct consequence of what is observed for the ELR, values of EYR in Spezzina fish farm are quite low and close to the unit. This is an indication of the prevalent dependence of the analyzed system on the economy and on human control. This kind of result is typical of systems unable

Table 2 Comparison between emergy indices from Spezzina fish farm and similar production system

	S. aurata	S. salar	T. mariae	S. aurata
Transformity	1.32E + 06	9.70E + 06	5.61E + 05	2.45E + 07
ELR	5.00	4.24	46.52	0.34
EYR	1.20	1.23	1.02	3.95

to exploit natural resources and is based on the import of inputs characterized by high emergy. This is true also for the other intensive systems: especially *T. mariae* rearing, which, in fact, is much more dependent on expensive, nonrenewable resources with respect to what is observed in Spezzina fish farm. On the contrary, the extensive system shows a very high contribution from the environmental inputs, although at the cost of a lower productivity.

According to emergy results, a significant improvement toward the environmental sustainability of the examined process could be derived from the modification of the productive cycle that should, for example, include the in situ fingerlings production that have the highest emergy input in the evaluation. Moreover, it is advisable that in Mediterranean conditions the fish farm installation was disposed in the widest possible area so that natural resource contributions could be more significant.

Regional Analysis

Regional systems are complex systems that for the purpose of this type of evaluation can be considered to be in a steady state. Their structure has many levels of organizations, and their openings to the outside and irreversible dynamics are typical features of complex systems. They require resources and energy to enhance internal order and to self-organize, while increasing the entropy of their surroundings. The increase in entropy exceeds the internal entropy decrease of the system, so the second principle of thermodynamics is observed. Hence, the region behaves like a dissipative structure.

For a rigorous and successful analysis, much historical and scientific information about the region must be collected. The first step of an emergy evaluation is energy modeling of the region with its inflows, outflows, and local stocks. Many emergy evaluations of states and nations have been done and can be found in the scientific literature (see, e.g., emergy evaluation of Italy, environmental accounting using emergy: West Virgina, etc.). In the analysis of nations, flows from outside the system (F) and flows exploited inside the system (R and N) are identified. Imported flows are considered nonrenewable as the transport component is mostly based on fossil fuel. Once inputs are expressed in emergy terms, it is possible to calculate emergy indicators. These can be useful to describe the characteristics of a region and to formulate future policy. Fig. 8 shows a simplified energy diagram for West Virginia.

In the diagram, purchased resources are indicated F (fuels), G (Goods), and PI (services): R and N indicate the renewable and nonrenewable resources, respectively, while B and PE represent the exported goods and services, respectively. *Dashed lines* represent the counter-current to emergy in exchanges. The main characteristics and storage of the system are indicated. In particular, the storage of coal is very important for the state.

Once the diagram has been made, the next step is to quantify the inputs; it is necessary to transform resource and energy inputs into emergy units. The next step is to sum the resources in categories as stated above (renewable, nonrenewable, etc.). Then emergy indicators can be constructed. For a detailed analysis of West Virginia, see the "Further reading" section; here, we only present the main characteristics to illustrate an application of emergy. The analysis shows that the largest renewable emergy input is growth of timber (44×10^{20} sej year^{-1}), while, among nonrenewable inputs, coal is the greatest emergy flow for production and consumption, followed by electricity, petroleum, and natural gas. Among imports the largest are imported goods, services embodied in goods, and petroleum fuels. Natural gas is not considered as it only passes through the state of West Virginia and then it is not used here but somewhere else. Coal and electricity generated from coal amount to 63% of the total emergy exported.

The emergy results (Table 3) indicate that West Virginia has a low investment ratio (2.39 vs. 7 of United States) and a high ELR (20). Thus, it is sustained by a flow of nonrenewable resources that is 20 times the size of renewable flows and needs little investment to exploit it. The system could sustain its future development by using its stocks of nonrenewable resources (e.g., coal), but it has to account for past consumptions of renewable resources (e.g., timber) and consider the negative effects of using nonrenewable resources, such as greenhouse gas emissions. At the current rate of use, West Virginia coal resources will be finished within 300 years.

By emergy evaluation, it is possible to assess whatever the emergy paid for a resource balances the real value of what the system is exporting. In economics, it is customary to relate the cost of a good to its cost of extraction; the real value of natural resources is often underestimated. This occurs in West Virginia, which exports twice as much emergy as it receives, causing a deficit of 1.46×10^{23} sej year^{-1} (about 66% of annual emergy use in the state). This is mainly due to export of coal that is about 1.50×10^{23} sej year^{-1}. As stated by Campbell et al.,

> West Virginia received 3.56 billion dollars in net transfer payments ... from the federal government. This money makes up about 14% of the existing emergy deficit when converted to emergy using the West Virginia emergy to dollar ratio. The question of the equity of exchange between West Virginia and the nation could be further resolved using emergy methods to systematically consider all the benefits and costs accruing to both the state and the nation as a result of their relationship.

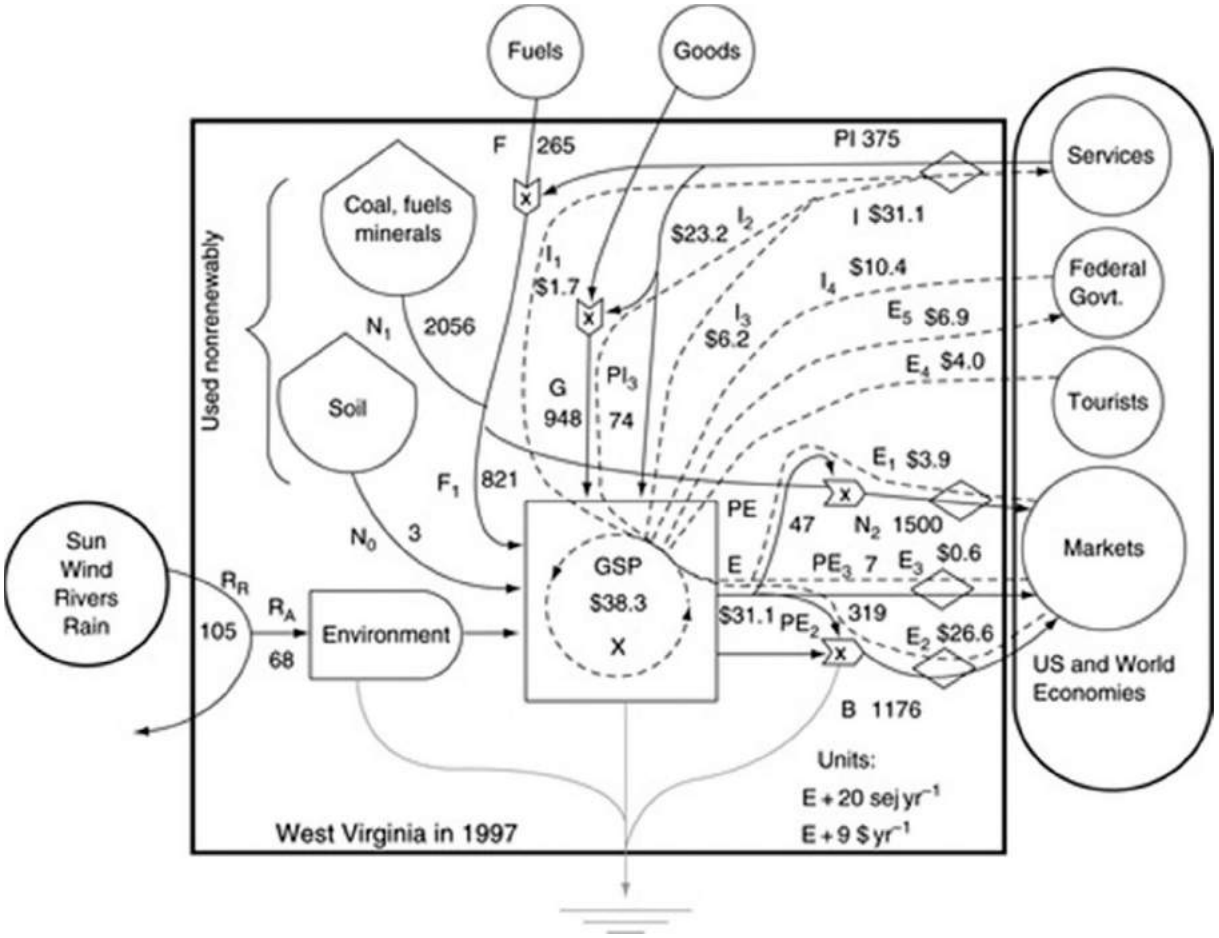

Fig. 8 Energy diagram of West Virginia. Reproduced from Campbell, D.E. and Brandt-Williams, S.L. (2005). Environmental accounting using emergy: Evaluation of the State of West Virginia, EPA/600/R-05/006, with permission from USEPA.

The emergy results also show a high emergy use per capita, in contrast to many social indicators. Emergy use is concentrated in the industrial sector while the rest of the population (58%) was in rural areas and does not benefit from the empower flows.

As in the case of West Virginia, it is appropriate to exclude flow that hides other characteristics of the system from emergy evaluation. In this evaluation export of coal and electricity were excluded, revealing that the development of West Virginia has similar characteristics to that of other American states, such as Maine and North Carolina.

Emergy in an Input-State-Output Framework

Ecosystems and human systems are open thermodynamic systems that self-organize, hopefully toward higher complexity and organization. An input-state-output framework has been developed to describe their functioning with a common feature: in both ecosystems and human systems emergy can represent the input upon which the structures of the systems are created, maintained and are able to produce outputs. For what concerns ecosystems, the "state" can be measured by systems indicators like ecoexergy (*link to entry*) and their outputs by means of the ecosystem services evaluation (*link to entry*). Starting from data available on different types of ecosystems and identifying a threshold at the average/median points of the three axes (emergy flow, ecoexergy and ecosystem services) determining a 3D space (a cube), eight categories, or classes of ecosystems, have been defined (high and low emergy flow, high and low ecoexergy, high and low ecosystem services). Results show that, in general, there is a good correlation between ecosystem services and ecoexergy, highlighting the fact that half of the subcubes obtained are practically empty: in case of high emergy those with high value of ecoexergy and low value of services or vice versa; in case of low emergy it seems impossible to have high ecosystem services regardless the degree of organization of ecosystems (ecoexergy).

This approach has been conceived also to depict the sustainability of economic systems starting from the environmental, social and economic viewpoints. In this representation, though, the three dimensions are taken as strictly separated and irreducible to each other: the environment provides the goods and services that are used by societies for their well-being; an organized society has a useful economic production that contributes to the well-being as well. We can therefore adopt a pyramidal representation of sustainability, that highlights the succession of stages rather than a partial overlapping among the three components.

Table 3 West Virginia emergy indices.

Name of index	*Expression*	*Quantity*	*Units*
Renewable emergy received	R_R	1.05E + 22	sej $year^{-1}$
Renewable emergy used	R_A	6.60E + 21	sej $year^{-1}$
In state nonrenewable	$N_0 + N_1$	2.06E + 23	sej $year^{-1}$
Imported emergy	F + G + PI	1.59E + 23	sej $year^{-1}$
Total emergy inflows	R_R + F + G + PI	1.70E + 23	sej $year^{-1}$
Total emergy used	$U = R_A + N_0 + F_1 + G + PI$	2.21E + 23	sej $year^{-1}$
Total exported emergy	$B + PE + N_2$	3.05E + 23	sej $year^{-1}$
Emergy used from home sources	$(N_0 + F_2 + R_A)/U$	0.282	
Imports–exports	$(F + G + PI) - (B + PE + N_2)$	−1.46E + 23	sej $year^{-1}$
Ratio of exports to imports	$(B + PE + N_2)/(F + G + PI)$	1.92	
Fraction of use, locally renewable	R_A/U	0.030	
Fraction of use, purchased import	(F + G + PI)/U	0.72	
Fraction of use, imported service	PI/U	0.17	
Fraction of use that is free	$(R_A + N_0)/U$	0.03	
Ratio of purchased to free	$(F_1 + G + PI)/(R_R + N_0)$	19.9	
Environmental loading ratio	$(F_1 + N_0 + G + PI)/R_R$	20.4	
Investment ratio	$(F + G + PI)/(R_R + N_0 + F_2)$	2.39	
Use per unit area	U/Area	3.55E + 12	sej m^{-2}
Use per person	U/Population	1.22E + 17	sej/ind.
Renewable carrying capacity at present	$(R_R/U)^*$(Population)	88.625	People
Standard of living			
Developed carrying capacity at same	8(R/U)*(Population)	709.003	People
Living standard			
WV State Econ. Product	GSP	3.83E + 10	$/year
Ratio of WV emergy use to GSP	U/GSP	5.78E + 12	sej/$
Ratio of US emergy use to GNP	U/GNP	1.20E + 12	sej/$
Ratio of electricity/emergy use	EI/U	0.072	
Ratio of Elec. Prod./emergy use	Elp/U	0.254	
Emergy of fuel use per person	Fuel use/population	3.41E + 16	sej/ind.
Population		1.81E + 06	People
Area		6.24E + 10	m^2

Reproduced from Campbell, D.E. and Brandt-Williams, S.L. (2005). Environmental accounting using emergy: Evaluation of the state of West Virginia, EPA/600/R-05/006, with permission from USEPA.

Several choices can be made for the three-axis representation. Emergy could be substituted for example by Ecological footprint (*link to entry*) on the environmental (input) axis. On the social axis indicators of Social Capital, indicators of equity within a society (e.g., Gini index or Palma Ratio), of labor or of education can be adopted; indicators like GDP, the Index of Sustainable Economic Welfare (ISEW) or Genuine Progress Indicator (GPI) on the economic one.

A first analysis was conducted by Pulselli et al. (2015) using the emergy flow per capita; the Gini index of income distribution and the Gross Domestic Product per capita (GDP) on the environmental, social and economic axes respectively. The Gini coefficient is a measure of inequality ranging from 0 (in the situation of perfect equality, where every unit has the same income) to 1 (in the situation of greatest inequality, where only one unit receives the whole income). Even if, strictly speaking, the Gini Index is an economic indicator it has been shown that inequality is strongly correlated with health and social problems (Wilkinson and Pickett, 2009).

GDP is the sum of the market value of the overall set of goods and services produced by an economic system in a given period of time (generally 1 year). It can thus be intended as an indicator of the economic output.

Pulselli et al. (2015) examined 99 national economies, grouping them into 8 subcubes separated by the median value of the three axes. Data are referred to the year 2008, since it was the last one available for emergy. Most of the economies (85) fall in four of the eight possible subcubes, while the other 14 points fall in less populated subcubes, but in zones that are very close to median values of at least one of the indicators.

From the results a strong relationship between resource use per capita and GDP per capita emerges, pointing out how economic growth drives, and depends on, an increasing requirement of energy and matter to be transformed by the economic system, while the level of inequality on societies is quite independent of the other two metrics.

The area of the cube where there should be nations with low level of resource use and high GDP is practically empty indicating that dematerialization is a goal hard to be reached.

The temporal dimension is a key factors of this representation: further than the ranking of the nations in 1 year, also the evolution of a single point in the diagram is meaningful in order to follow the behavior of a nation in time (see Fig. 5). This can be useful to evaluate the effects of national policies in economic but also in social and environmental terms.

Emergy Ecosystems and Network Analysis☆

Mark T Brown and Mathew Cohen, University of Florida, Gainesville, FL, United States

Definitions

Energy is sometimes referred to as the ability to do work. Energy is a property of all things which can be turned into heat, and is measured in heat units (BTUs, calories, or joules).

Emergy is the availability of energy (exergy) of one kind that is used up in transformations directly and indirectly to make a product or service. The unit of emergy is the emjoule (see below), a unit referring to the available energy of one kind consumed in transformations. For example, sunlight, fuel, electricity, and human service can be put on a common basis by expressing them all in the emjoules of solar energy that is required to produce them. In this case the value is a unit of solar emergy expressed in solar emjoules (abbreviated sej). Although other units have been used, such as coal emjoules or electrical emjoules, in most cases all emergy data are given in solar emjoules.

Emjoule is the unit of measure of emergy, the term is short for emergy joule. An emjoule is an expression of the units of energy previously used to generate a product; for instance the solar emergy of wood is expressed as joules of solar energy that were required to produce the wood. Solar emjoules is abbreviated "sej."

Empower is a flow of emergy (i.e., emergy per time). Emergy flows are usually expressed in units of solar empower (solar emjoules per time).

Exergy is the maximum useful work that can be extracted from a system as it reversibly comes into equilibrium with its environment. In other words exergy is the portion of the total energy of a system that is available for conversion to useful work.

Unit emergy values (UEVs) are based on the emergy required to produce something. UEVs are calculated by dividing the sum of all emergy required for producing an output by the units of product output. There are two types of UEVs appropriate for this article as follows:

Transformity is defined as the emergy per unit of available energy (exergy). For example, if 4000 solar emjoules are required to generate a joule of wood, then the solar transformity of that wood is 4000 solar emjoules per joule (abbreviated sej J^{-1}). Solar energy is the largest but most dispersed energy input to the earth. The solar transformity of the sunlight absorbed by the earth is 1.0 by definition.

Specific emergy is the unit emergy value of matter defined as the emergy per mass, usually expressed as solar emergy per gram (sej g^{-1}). Solids may be evaluated best with data on emergy per unit mass for its concentration. Because energy is required to concentrate materials, the unit emergy value of any substance increases with concentration. Elements and compounds not abundant in nature therefore have higher emergy/mass ratios when found in concentrated form since more work was required to concentrate them, both spatially and chemically.

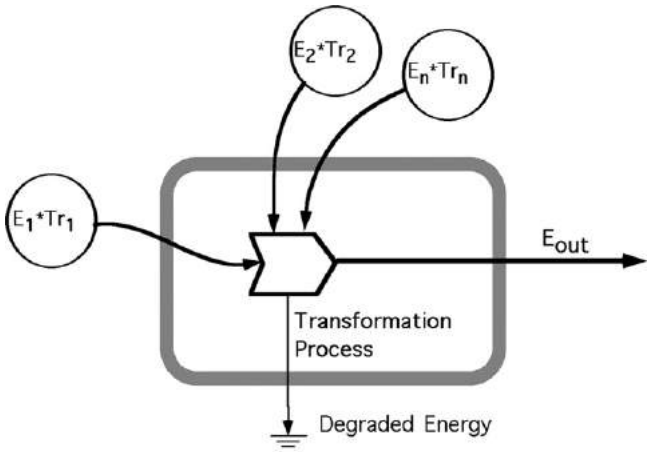
Emergy, Energy, and Quality

Emergy, defined as the available energy of one form (usually solar energy) required, directly and indirectly, through all processes and transformations to make a product or flow, provides a numeric framework for comparing different forms of energy and materials and providing a measure of quality in directly comparable units (solar emjoules, or sej). Emergy is often referred to as energy memory, reflecting that this system synthesis approach is effectively a form of accounting that traces energy flow and dissipation back through all necessary transformations to scale all flows relative to a common energy benchmark (solar emergy). Emergy accounting allows comparison of energy flows of different forms; Odum (1996) argues that different forms of energy have different qualities that arise from the energy required to make them. In self-organizing adaptive systems, he argues, forms of energy that require larger investment per unit available energy must provide commensurate higher quality cybernetic work in the form of feedback control. Transformity (T_R) is an index of quality and quantifies the emergy invested per unit available energy produced (i.e., emergy per exergy, sej J^{-1}) for each flow in a system of interest. In like manner, specific emergy (S_P) is an index of quality of material by quantifying the emergy investment per unit mass produced (sej g^{-1}).

The use and transformation of material and energy is system dependent; where the appropriateness of an energy in a particular system is dictated by its form and is related to its concentration. The processes of the biosphere are infinitely varied and are more than just thermodynamic heat engines. As a result, the use of heat measures of energy that can only recognize one aspect of energy, its ability to raise the temperature of things, cannot adequately quantify the work potential of energies used in more complex processes that span multiple levels of system processes, ranging from the smallest to the largest scales of the biosphere.

☆*Change History*: March 2018. Brown updated all sections Tables 1–3, Figs. 6.

This is an update of M.T. Brown and M.J. Cohen, Emergy and Network Analysis, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 1229–1239.



$$Em_{out} = \Sigma\, E_n{*}Tr_n$$

$$Tr_{out} = Em_{out} / E_{out}$$

Where;

$E_{1...n}$ = Available energy inputs

E_{out} = Available energy of output

Em = Emergy

Tr = Transformity

Fig. 1 All transformation processes utilize available energy inputs of varying qualities (E_1, E_2, ..., E_n) matching lower quality energy inputs (E_1) to higher quality inputs (E_2, ..., E_n). Energies are converted to emergies by multiplying by their appropriate Emergy Intensity (or transformities). In a static calculation the emergy of the output is equal to the sum of the emergy inputs over the time require to make the output.

Transformity and Specific Emergy

Transformity and specific emergy are unit emergy values calculated as the total amount of emergy required to make a product or service divided by the available energy of the product (resulting in a transformity) or divided by the mass of the product (resulting in a specific emergy). Figs. 1 and 2 illustrate a static method of calculating a transformity first in equation form (Fig. 1) and then with example numbers (Fig. 2). The transformity of the product is the *emergy* of the product divided by the *energy* of the product (units are sej J^{-1}). If the output flow is in mass then the specific emergy of the product is the emergy of the output divided by the mass (units are sej g^{-1}).

Emergy and Hierarchy

A hierarchy is a form of organization resembling a pyramid where each level is subordinate to the one above it. Depending on how one views a hierarchy, it can be an organization whose components are arranged in levels from a top level (small in number, but large in influence) down to a bottom level (many in number, but small n influence). In general, in ecology we consider hierarchical organization to be a group of processes arranged in order of rank or class in which the nature of function at each higher level becomes more broadly embracing than at the lower level. Thus we often speak of food-chains as hierarchical in organization.

Most if not all systems form hierarchical energy transformation series, where the scale of space and time increases along the series of energy transformations. Many small scale processes contribute to fewer and fewer of larger scale processes (Fig. 3). Energy is converged from lower to higher order processes, and with each transformation step, much energy loses its availability (a consequence of the 2nd Law of Thermodynamics), while only a small amount is passed along to the next step. In addition, some energy is fed back reinforcing power flows up the hierarchy. Note in Fig. 3 the reinforcing feedbacks by which some of each transformed power flow feeds backward so that its special properties can have amplifier actions.

Unit Emergy Values and Quality

Quality is a system property, which means that an "absolute" scale of quality cannot be made, nor can the usefulness of a measure of quality be assessed without first defining the structure and boundaries of the system. Self-organizing systems (be they the biosphere or an ecosystem) are organized with hierarchical levels (Fig. 3) and each level is composed of many parallel processes. This leads to two possible definitions of quality: (a) Parallel quality, and (b) Cross quality. The first, "parallel quality," is related to

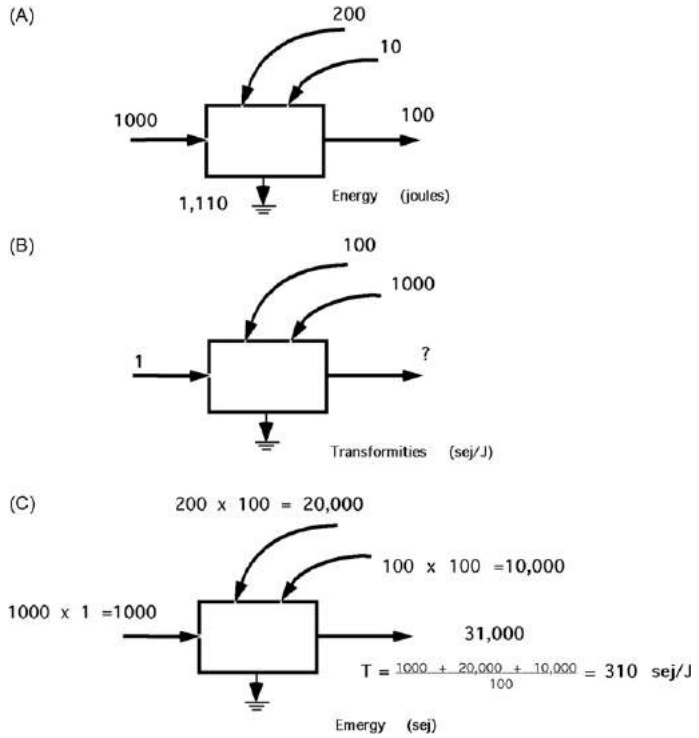


Fig. 2 The calculation of a transformity for a transformation process where (A) available energies of different qualities are used to produce a higher quality energy of a different form. (B) The different qualities are expressed by their different solar transformities. (C) The emergy on each pathway is determined by multiplying the available energy in (A) by its transformity in (B). The transformity of the output flow in (C) is found by summing the emergy inputs and dividing by the energy of the output.

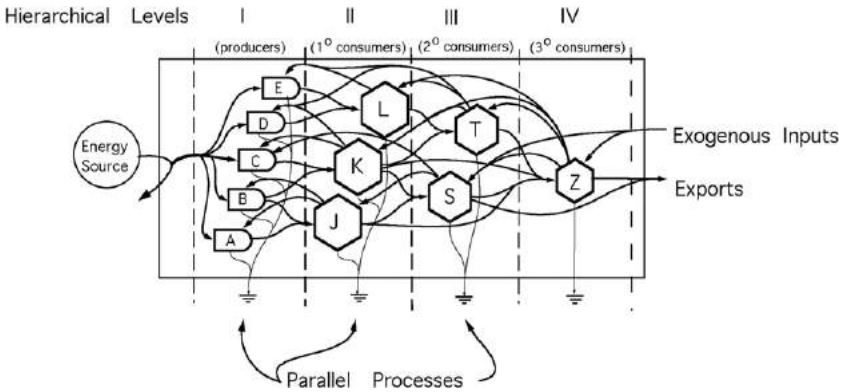

Fig. 3 Systems can be represented as hierarchical organization of energy flows and components. Hierarchical levels are aggregations of like components sometimes called trophic levels in ecosystems. At each level energy is converged into fewer components (less biomass) and much energy is degraded. Within each level there are parallel processes that have similar function. Larges energy flows are associated with components on the left (lowest quality), while small flows of available energy support components on the right (highest quality). Feedbacks from higher level components act as control actions on lower quality components.

the efficiency of a process that produces a given flow of energy or matter within the same hierarchical level (comparison among units in the same hierarchical level in **Fig. 3**). For instance, for any given output, say biomass, there are almost an infinite number of ways of producing it (all the various species in the myriad collection of ecosystems in the biosphere; each with slightly different efficiencies). A compilation of transformities for ecosystem level gross primary production yielded transformities from 1.0 E3 sej J^{-1} to 9.2 E4 sej J^{-1} depending on species composition, community type, and driving energies (Brown and Bardi, 2001). Since each individual process has its own efficiency, the output from the process has a distinct UEV. Quality as measured by UEV relates to the emergy required to make like products under differing conditions and processes. For the most part, UEVs of like products are within the same order of magnitude. When comparing parallel processes the UEV is a measure of biosphere efficiency suggesting that parallel products having lower UEVs are produced more efficiently requiring less emergy per unit of output.

The second definition of quality, "cross quality," is related to the hierarchical organization of systems. In this case, UEVs are used to compare components or outputs from different levels of the hierarchy, accounting for the convergence of emergy at higher and higher levels (comparison of different hierarchical levels, in Fig. 3). At higher hierarchical levels, a larger convergence of inputs is required to support the component (i.e., much plant biomass to support 1° level consumer, many 1° level consumers to support 2° level consumers, etc.). Also, higher feedback and control ability characterize components at higher hierarchical levels. Therefore, higher UEVs, as equated with higher level in the hierarchy, often exhibit greater flexibility and greater spatial and temporal effect. With this definition of quality—the higher the UEV the higher the quality of the process or product. UEVs of products from different hierarchical levels usually differ by at least one order of magnitude.

Unit Emergy Values, Efficiency, and Integrity

When an ecological network is expressed as a series of energy flows and transformation steps where the transformation steps are represented as Lindeman efficiencies, the resulting UEVs represent trophic convergence and a measure of the amount of solar energy required to produce each level in the hierarchy, As such, they play the role of quality indicators. This is true for systems selected under maximum power constraints (Lotka, 1922; Odum, 1983) and is therefore true in healthy ecosystems. However, in an ecosystem stressed by excess outside pressure, relationships among components are likely to change, some components may disappear, others may emerge, and the whole hierarchy may be altered. The efficiency of given processes within the system may therefore change and due to a simplified structure of the system, some patterns of hierarchical control of higher to lower levels may diminish or disappear. All in all, these changes will translate into different values of the UEVs, the variations of which become clear measures of lost or decreased system integrity.

Emergy of the Geobiosphere: The Basis for Computing Emergy and UEVs of Ecological and Techno-Ecological Processes

The exergy sources driving geobiosphere processes are varied and change with scale of the processes. The primary exergy sources are absorbed solar radiation, geothermal heating from the Earth's interior, and tidal energy absorbed by the oceans. These sources are, in turn, transformed into secondary and tertiary renewable flows, which combined with the primary sources not only drive the dearth's ecosystems, but also drive geologic processes and the formation of mineral ores and fossil fuels. Finally all of these sources are combined in the myriad ecological and technological process that ultimately generate the living and nonliving components of Earth.

Annual Budget of Emergy Supporting the Geobiosphere

The annual budget of emergy flow (empower) supporting the geobiosphere including the atmosphere, ocean, and earth crust, includes three sources of energy: solar energy, tidal energy, and geothermal energy from the deep earth (Fig. 4). When evaluated in

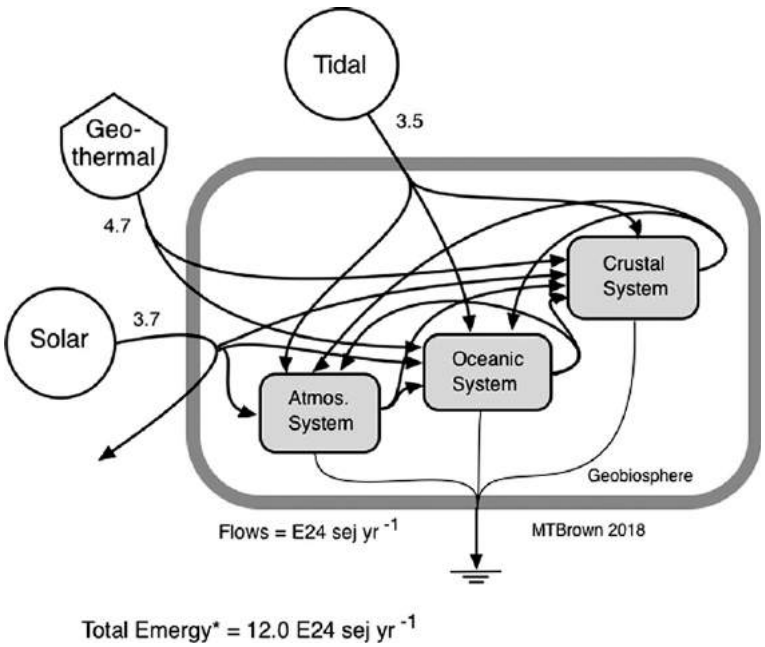

Fig. 4 The geobiosphere is drive by three main sources of energy: solar, deep heat (residual plus radioactive decay), and tidal momentum. For a full explanation of their solar equivalents see Brown et al. (2016). *Note*: total emergy is rounded to 12.0 E24 sej year^{-1}.

Table 1 Annual renewable emergy contributions to global processes

Input	*Unite*	*Exergy (units year^{-1})*	*SER*[a] *(sej unit^{-1})*	*Empower (E24 sej year^{-1})*
Solar energy absorbed	J	3.73 E24	1.0	3.7
Geothermal energy	J	9.52 E20	4,000	4.7
Tidal energy absorbed	J	1.14 E20	30,000	3.5
	Total global empower	–	–	12.0[b]

[a]Solar equivalence ratio (see Brown et al. 2016 for explanation).
[b]Rounded to whole number.

Table 2 Emergy of products of the global energy system

Note *Product and units*	*Emergy (E24 sej year^{-1})*	*Production (E20 J year^{-1})*	*Transformity (sej J^{-1})*
Global wind circulation, J	12.0	151.2	800
Global precipitation on land, J	3.74	5.34	7,000
Global precipitation on ocean, J	9.56	19.5	4,000
Average river geopotential, J	3.74	2.91	12,800
Average river chemical energy, J	3.74	1.76	21,300
Average waves at the shore, J	7.89	18.9	4,200

solar emergy (Brown *et al.*, 2016), these contributions to the geobiosphere, total about 12.0 E24 sej year^{-1} (**Table 1**). The sum of solar emergy, tidal emergy and geothermal emergy is termed the geobiosphere emergy baseline (GEB).

Average UEVs for Secondary and Tertiary Global Sources

The empower that is derived from GEB drives the productive processes of the geobiosphere and is responsible for developing exergy gradients that are transformed into secondary exergy products (wind, and chemical potential of rain water) and tertiary exergy products (chemical and geopotential energy of river discharges and the available energy of breaking waves). At the scale of the geobiosphere, the secondary and tertiary exergies are products of the GEB. At the scale of the ecosystem they become sources or external driving energies. **Table 2** lists these sources, their exergy and their UEVs. The UEVs of secondary and tertiary renewable emergy sources are useful for evaluating inputs supporting ecological systems including those dominated by humans.

UEVs of Global Minerals and Fossil Fuels

Human dominated ecosystems are dependent not only on renewable inputs but to a far greater degree on nonrenewables fossil fuels and mineral resources. The evaluation of techno-ecosystems relies on having UEVs of both renewable and nonrenewable sources as well as other technological products.

Table 3 lists the UEVs of the fossil fuels and some of the most important mineral resources. The methods of computing the fossil fuel UEVs relies on published estimates of historic global net primary production (NPP) on land and oceans, published preservation, and conversion factors of organic matter, and assessments of the present total global storages of coal, petroleum, and natural gas (Brown *et al.*, 2011). Mineral UEVs are far more difficult to compute, because of the varied geologic processes that produce them. An aggregated approach was undertaken to estimate the mineral formation exergy and the ore concentration exergy, leading to mineral specific emergy for 144 mineral ores and aggregates that represent the majority of commercial ores used in human technological processes (Brown and Ulgiati, 2018).

UEVs have been computed for thousands of technological products (Brown and Ulgiati, 2018). Computing UEVs of human techno-ecosystem processes requires a full accounting of all inputs converted to emergy. Recently the use of EcoInvent database has increased the number of technology UEVs and there is an online database (http://www.emergysociety.com/emergy-society-database/) that contains nearly 1000 entries as of this writing.

Calculating Unit Emergy Values

Several methods are used to calculate UEVs, they include: (1) static calculations, (2) dynamic simulation, and (3) network analysis. Most commonly, static calculations are used for processes where the flows of energy, materials, and services over a particular time period are multiplied by their UEVs, summed, and divided by the available energy, or mass of the product produced during that same time period. Dynamic simulation has been used for some resources that require long periods of time to generate, for instance forest wood (Tilley, 1999) or soils (Cohen, 2003a, b). The dynamic method uses rate of change equations for storages that add emergy as long as the storage of material is accumulating (Odum, 1996). Evaluating UEVs with a technique of network analysis uses what Collins and Odum

Table 3 UEVs of fossil fuels and some common minerals

	UEV	
Item	*(sej J^{-1})*	*(sej g^{-1})*
Fossil fuels		
Coal—subbituminous and lignite	56,700	20,000
Coal—anthracite and bituminous	69,000	29,500
Crude oil	132,160	5.78E + 09
Natural gas	140,000	7.46E + 09
Minerals		
Limestone		2.41E + 09
Copper		5.71E + 09

Lead		2.33E + 09
Iron ore		1.75E + 09
Uranium		3.24E + 13

Data are from Brown, M. T. and Ulgiati, S. (2018). Emergy and environmental accounting; Coupling systems of humanity and nature. New York: Springer, (Forthcoming).

(2000) called a "minimum Eigenvalue method" built on the earlier work of Patterson (1983). The Eigenvalue method was refined using linear equations and the EXCEL solver routine by Cohen (2003a, b) and further by Zarba and Brown (2015). Termed emergy-network analysis, it uses a set of simultaneous equations to partition emergy throughout an interconnected network of components that may include feedback, assigning emergy and calculating UEVs for all flows between components of the network.

Each of the methods is applicable to different situations and if applied to the same systems might yield slightly different results. Generally, the static method has been used most widely, with the vast majority of published UEVs having been calculated using this method. Static calculations are appropriate for relatively established, continuously operating processes, like production of electricity, where a snapshot in time will produce inflows and outflows that vary little from a snapshot at a different time. UEVs that result from static calculations do not include emergy used during startup or early phases of a production process, which may make only minor difference if the process has been long running and well established. Nor does the static method consider feedbacks or cycling within systems.

There is no doubt that H.T. Odum recognized cycles and cybernetic feedback as major phenomena in ecological systems. However in terms of the static emergy accounting rules (Brown and Herendeen, 1996), feedbacks are disregarded to avoid double counting. They do not contribute any emergy to the elements they are flowing into (Odum, 1996; Odum and Collins, 2003). Several studies have raised the issue that the static emergy algebra does not allow a proper comprehension of the emergy dynamics of systems with recycling flows (Tilley, 1999, 2011; Cohen, 2003a, b; Cavalett and Ortega, 2007; Bastianoni *et al.*, 2011; Morandi et al., 2013; Winfrey and Tilley, 2013).

Dynamic calculation of UEVIs is appropriate for processes where the product accumulates over time and is "harvested" or used all at once (see Tilley, 2011). Since the product is accumulating the emergy used in production accumulates. Once the system reaches steady state, where inflows equal outflows, emergy no longer accumulates. In dynamic calculation, UEVs can be calculated at any time during a product's life, and they will be slightly different with each time period.

The network method incorporates feedback, and thus UEVs of products are somewhat different than those calculated using a static algebra method. Depending on system configuration, UEVs can be larger or smaller than those calculated using static methods. The calculations in general are carried out on a system that is assumed to be at steady state, although this is not a requirement. The flows of emergy are assigned to pathways according to some carrier that is conserved (i.e., energy or matter … in ecological systems often carbon).

Computing UEVs-Static Accounting

Static UEVs are calculated according to the classic emergy algebra procedure (Odum, 1996; Brown and Herendeen, 1996). The static transformity of a compartment *i* is computed as the sum of the emergy of all input flows (excluding feedbacks) multiplied by the storage turnover time divided by the energy of the storage:

$$\sum_{i}^{n} \mathrm{Em}_{(u_i)} * \mathrm{TT}_{(Q_i)} = \mathrm{Em}_{(Q_i)} \tag{1}$$

and

$$\mathrm{Tr}_{(Q_i)} = \mathrm{Em}_{(Q_i)} / \mathrm{En}_{(Q_i)} \tag{2}$$

where $\mathrm{Em}_{(u_i)}$ = Emergy of input *i*, $\mathrm{TT}_{(Q_i)}$ = Turnover time of storage *Qi*, computed as the storage energy divided by the sum of all input and output energy divided by 2, $\mathrm{Em}_{(Q_i)}$ = Emergy of storage *Qi*, $\mathrm{Tr}_{(Q_i)}$ = Transformity of storage *Qi*, $\mathrm{En}_{(Q_i)}$ = Energy of storage *Qi*.

Calculating UEVs From Network Flow Data

For each component in a system (Fig. 5A), five flows describe bilateral interactions (e.g., consumption, gross production, net production/transfer, respiration and egestion) with other components in the system. Energy or material inputs (1) arrive from exogenous sources (e.g., sunlight, hydrologic inputs) or from components within the network (e.g., plant biomass supporting herbivores). Gross production (2) quantifies the portion of that energy that is assimilated, while Egestion (5), though required for production and partially processed during digestion, is not incorporated. Respiration (3) represents the metabolic work of each compartment (i.e., internal feedbacks to secure energy), while transfer (4) is the energy that is eventually used by other components in the food web. The "heat sink" symbol represents energy unavailable to do work (i.e., entropy).

The UEV of a compartment is the incoming emergy (sej) flows driving biotic production (Flow 1, Fig. 5A) divided by the output (energy or mass) trophic transfer for that compartment (Flow 4 in Fig. 5A). Network UEVs calculated in this way represent the UEV of the flowing material, which in most cases is the same as the transformity of the storages from which they come (Odum and Collins, 2003).

A linear optimization technique that manipulates a set of unknowns (UEVs) to meet a set of constraints (emergy inflow = emergy outflow) is used to compute UEVs from network flow data. An example optimization table is given in Fig. 5B where each row and column represents a system component. The constraints to the right of each row are the constraints that emergy inflow and emergy outflow are equal. Specifically, if the flows are in energy, then the energy inputs multiplied by appropriate transformities (unknowns in this case) equals the net production or transfer of energy multiplied by its transformity:

$$\text{Emergy inflow}_j = \sum_i X_{ij} * \tau_j = \sum_i X_{ij} * \tau_j = \text{Emergy outflow}_j \tag{3}$$

where X_{ij} is the energy transfer from component i to component j, and τ_i is the transformity value of respective flows.

Ecological Network Model

The aggregated ecosystem diagram of a coastal Juncus spp. marsh in Fig. 6 shows inflows of solar emergy, rain and organic matter (expressed in solar emergy) driving the ecological food chain. Ecological network analysis provides the ability to evaluate the concentration factors traced throughout a food web along trophic pathways to explore and predict functional responses of the

ecosystems to structural changes. The topology of the high marsh food web in **Fig. 6** was constructed from literature values using niche model concepts developed by Williams and Martinez (2000). Network data, consisting of carbon flows (g C year^{-1}) from the published literature were compiled in a "To … From" matrix (**Fig. 7**).

The network model was used to compute UEVs for each of the compartments in the network. To compute the UEVs, the data in **Fig. 6** were organized in a square matrix (**Fig. 7**) where the value in the cells represents the flow from the element in the column to the element in the row. The matrices also included the driving emergy sources. Then we computed the transformities following the minimum eigenvector method (Odum and Collins, 2003) and Microsoft excel "solver" method (Bardi *et al.*, 2005). The network-based methodology considers all the information in the matrix simultaneously, in an integral fashion. Since there is no fixed sequential order for solving the equations, the occurrence of feedbacks does not prejudice the performance of the operation, allowing feedback flows to be accounted as inputs in the energy transformation equations. Although this method assumes steady state conditions, by adding the feedback information into the matrix, the temporal adjustments of the UEVs are "included" in the computational process. Since the ecosystem was aggregated into 11 compartments the transformities represent averages for each compartment.

Solar transformities for a more complex network, the Florida Everglades graminoid marsh (**Table 4**) were evaluated using the same technique (Brown *et al.*, 2006). Network data, consisting of carbon flows (g C year^{-1}) were compiled from published data (details for accounting, aggregation and assumptions in Ulanowicz *et al.* (1997, 2000). There were 66 ecosystem compartments in the graminoid marsh; some of which (ecosystem pools of labile and refractory detritus) were not living. The primary production compartments were partitioned into root, and leaf compartments. Many of the lower trophic level compartments represent aggregations of species (due to lack of data); for example, mesoinvertebrates, macroinvertebrates, centrarchid fish, snakes, and passerine birds are lumped categories for the Everglades system.

Emergy and Biodiversity

In practice, the conservation of biodiversity suggests sustaining the diversity of species in ecosystems as we plan human activities that affect ecosystem health. Biodiversity has no single standard definition. Generally speaking, biodiversity is a *measure of the relative diversity among organisms present in different ecosystems*. "Diversity" in this case includes diversity within species (i.e., genetic

diversity), among species, and among ecosystems. Another definition, is simply the totality of genes, species, and ecosystems of a region.

A main problem with quantifying biodiversity, especially in light of the definition above, is that there is no overall measure of biodiversity since diversity at various levels of an ecological hierarchy cannot be summed. If they were summed, bacteria and other small plants and animals, would dominate the resulting diversity to the total neglect of the larger species. Also consider that evaluating species importance based on biomass or available energy throughput alone, without adjusting for quality, will tend to

Table 5 System scale indices of biodiversity for the Everglades graminoid marsh in wet season

Exogenous emergy inputs[a] *(sej ha^{-1} year^{-1})*	*5.2E11 (wet season)*

dramatically underestimate the system-scale control potential of energy flows in upper trophic levels, since only a small fraction of total system physical throughput is incorporated at these levels. That is, the energetic importance of upper trophic levels is small compared with their actual role in ecosystem function, which includes cybernetic control (e.g., control of population at lower trophic levels, seed dispersal, commensal relationships, and ecosystem structural attributes). Odum (1996) argues that, methods for energy flow analysis should incorporate the relative energetic contributions (i.e., importance value) of each component by adjusting for transformity (quality) to avoid misrepresenting their influence. It therefore may be possible to develop a quantitative evaluation of total biodiversity within regions or ecosystems by weighting biodiversity at each hierarchical level by typical trophic level transformities (see, for instance **Table 5**).

An ecosystem level, quality-adjusted diversity can be computed in the typical manner, as the Shannon Diversity index (Eq. **4**).

$$H = -\sum_{i=1}^{j} p_i * \log [p_i] \tag{4}$$

except relative importance value (p_i in Eq. **4**) is defined as the proportion of total system emergy flow (sej year^{-1}) allocated to each component. The relative value calculated in this manner is an emergy importance value (EIV) computed as follows:

$$\mathrm{EIV}_i = \frac{\mathrm{NP}_i * \tau_i}{\sum_j \mathrm{NP}_j * \tau_j} \tag{5}$$

where EIV_i is the emergy importance value of component i, NP_i is the net production (J year^{-1}) and, τ_i(sej J^{-1}) is the computed transformity of component *i*.

In this equation, importance value is the relative contribution of each component to the total emergy flow through all biotic components (i.e., denominator of Eq. **5**), computed by summing net production times derived transformity (τ_j) over all components. It follows then that an the Shannon diversity index when modified to include the emergy importance value (EIV) becomes an index of biodiversity as follows:

$$\text{Biodiversity} = -\sum_{i=1}^{j} \mathrm{EIV}_i * \log [\mathrm{EIV}_i] \tag{6}$$

When physical flows are adjusted for quality, (i.e., expressed as emergy) evenness of flow across all ecosystem components results; in fact, emergy flow evenness is the postulated goal for network systems that are maximizing power (Odum, 1994). Therefore, maximum possible value for this biodiversity index occurs when the emergy on each pathway and each component's EIV, is equal. **Table 5** summarizes quality-adjusted diversity, the theoretical maximum diversity and the relative diversity as a percent of maximum for the Everglades graminoid marsh whose UEVs were given in **Table 4** above. If the observed diversity is compared to maximum diversity an index of ecosystem condition results since all things being equal, maximum potential diversity represents the highest ecological condition. Our evaluation of the Everglades marsh ecosystem suggests that it is operating at 42% of its maximum potential diversity.

Summary Comments

Emergy and Unit Emergy Values

Emergy and UEVs are useful measures that may be applied to systems of all scales to better understand hierarchy, control, development, stress, and ultimately ecosystem health. UEVs measure the convergence of biosphere work into processes and products of ecosystems and offers the opportunity to scale ecosystems and their parts based on the energy required to develop and maintain them. Systems are hierarchically organized and composed of physical structure (i.e., wood, biomass, detritus, animal tissue, etc.) and information found not only in genetic makeup of components but in the relationships and connections between individuals and groups of individuals. Because of the demands of thermodynamic costs with each transformation, the energy, materials, and information associated with higher hierarchical levels of systems are relatively small in comparison with lower levels. A failure to account for quality differences can result in an over emphasis of the importance of lower order components at the expense of the importance of higher order components and their control actions. Emergy Intensities may offer a useful indicator of the cybernetic role of components within ecosystems.

Emergy, Transformity, and Network Analysis

UEVs are a measure of the importance of components within systems (Odum, 1996). We believe that network analyses (Ulanowicz, 1986; Dame and Patten, 1981), while offering some insights into overall cybernetic control within systems, still requires the addition of emergy refinements to address the quality of particular services provided by each species in a system. Ulanowicz (1980), recognized the need to weight flow diversity at the system scale by total system throughput to make comparison between systems meaningful. We suggest that without quality correction (UEVs), cross-trophic comparison of importance within systems is somewhat hindered because of the inverse relationships between energy flows and trophic level. Further, comparison of development stage and/or stress between systems cannot be realized without accounting for quality of compartments.

Biodiversity

MacArther's (1955) original conceptualization of Shannon diversity was intended for determinacy of *flows* within systems, suggesting that the flows of energy and materials between components were a form of "information transfer". However, subsequent applications of Shannon diversity in ecology replaced flows with physical *stocks*. Margalef (1961) and Ulanowicz (2001) discussed the reasons and drawbacks for this convenient, but unfortunate tangent. As a result of the use of stocks (i.e., counts of individuals) the application of the Shannon diversity index have generally failed to effectively predict ecological properties (e.g., stability, resilience, or productivity).

The use of stocks instead of flows illuminates a second weakness in the Shannon diversity. The standard Shannon diversity metric ignores ecosystem food web hierarchy. Given a fixed number of ecosystem components, the Shannon diversity is maximum when the probability of observing each component is equal; that is, evenness in physical *stocks* increases diversity. However, given typical trophic transfer efficiencies (i.e., Lindeman efficiencies), maximum ecosystem diversity as maximum evenness of ecosystem physical stocks leads to obvious contradictions and as a result, Shannon diversity using physical stocks maybe only appropriate within a single trophic level and should not be used at the ecosystem scale. While we advocate the replacement of stocks with flows as per MacArthur's (1955) original intent, a similar argument against computing diversity using physical flows (energy, carbon) can be made. That is, evenness of physical flows is not expected for an entire food web because the energy/carbon throughput decreases geometrically with increasing trophic level because of thermodynamic limitations of transfers. Thus we advocate adjusting flows by quality factors (UEVs). Once corrected for quality, evenness can be expected.

While biodiversity assessments at the ecosystem scale have traditionally taken the form of species catalogs, sorted by different classes, they seldom address trophic interactions that stimulate the emergence of ecosystem properties. With the use of emergy combined with network analysis to derive whole ecosystem measures of importance and diversity the result is a new way to calculate across trophic level ecosystem diversity that takes into account trophic interactions.

There is an obvious limitation of this method of assigning UEVs to system components, in that the required level of specificity about compartments and flow details between them is not usually found in ecosystem studies. However this level of detail is required by MacArthur's (1955) original effort to link information theory with ecosystem organization. This approach is consistent with MacArthur's original effort since it uses flows instead of stocks, and is further extended by recognizing the need for quality adjustment of flows. Such adjustment better recognizes the cybernetic control of ecosystem processes by higher order components. UEVs offer a useful indicator of this cybernetic role within ecosystems.

Environmental Protection and Ecology☆

Clive Hamilton and Andrew Macintosh, Australian National University, Canberra, ACT, Australia
Nicoletta Patrizi and Simone Bastianoni, University of Siena, Siena, Italy

What Is Environmental Protection

Environmental protection can be defined as the prevention of unwanted changes to ecosystems and their constituent parts. This includes

- the protection of ecosystems and their constituent parts from changes associated with human activities; and
- the prevention of unwanted natural changes to ecosystems and their constituent parts.

One issue associated with this definition is whether "ecosystems and their constituent parts" include humans and communities, or whether environmental protection is only concerned with the protection of natural capital. From an ecological perspective, humans are regarded as an integral part of the ecosystem. Separating humanity from the natural environment can therefore be seen as artificial. While this is true, the phrase environmental protection is not used to refer to measures that are designed to regulate or mediate direct interaction between people. For example, laws prohibiting assault are not regarded as environmental protection measures. Environmental protection is concerned with the relationship between people and the natural environment rather than the relationships between people and communities.

Another issue is whether environmental protection relates to preservation, conservation, or both. Preservation refers to the protection of an ecosystem or natural environment from change, while conservation is generally associated with the sustainable use of natural resources. The objective of conservation is to ensure the maintenance of a stock of renewable resources that is being exploited for human purposes rather than the protection of the natural environment from any anthropogenic modifications. The exploitation of natural resources for human purposes is not environmental protection as it is not associated with the prevention of unwanted changes. The change associated with exploitation is deliberate and wanted, at least by those doing the exploitation. However, measures that are put in place to prevent overexploitation of natural resources do constitute environmental protection. They are designed to prevent exploitation beyond a point that is deemed desirable or sustainable. For example, catch quotas in fisheries and air pollution limits are environmental protection measures because, while they accept some environmental degradation, they aim to limit it.

The distinction between preservation and conservation has dissipated in recent years with growing recognition of the dynamic nature of natural systems, humanity's place in the biosphere, and the need for active human involvement to maintain the integrity of certain ecosystems. Consequently, environmental protection is now generally used to refer to measures that have traditionally been associated with preservation (e.g., reserves, including national parks), as well as conservation and natural resource management initiatives.

A critical aspect of environmental protection is that it is driven by the values that humans attribute to different aspects of the environment. These values need not be instrumental, but the motivating factor for environmental protection is always the prevention of changes to the environment that humans do not want. This is why measures associated with the prevention of unwanted natural changes to ecosystems—like the prevention of coastal erosion or systematic burning in reserves to reduce the risk of wildfires—can be included as environmental protection. Such measures do not aim to protect ecosystems from human activities but rather from natural forces that are deemed to threaten human interests.

☆*Change History:* March 2018. Simone Bastianoni and Nicoletta Patrizi updated the article. Recent initiatives on the field of Environmental Protection and Ecology have been added in the Conclusion section as well as their references.

Environmental remediation is distinct from environmental protection as its primary objective is to restore an ecosystem or natural environment to a previous state; that is, like exploitation, it is associated with deliberately induced change, as opposed to the prevention of change.

Domestic Policy Instruments

There are a number of ways to classify domestic policy instruments that are used to protect the environment. Some people divide them into voluntary and mandatory instruments, while others place them into regulation-based and incentive-based, or command-and-control and economic instruments. The method preferred here is to divide them into four broad categories: regulatory, economic, voluntary, and education and information.

Regulatory Instruments

Regulatory instruments impose legally enforceable restrictions on economic agents to realize environmental protection objectives. They are sometimes referred to as "command-and-control" mechanisms because they prohibit or mandate certain actions (i.e., the command), while using various forms of punishment to motivate compliance (i.e., the control mechanism). Environmental regulations can take many different forms, including

- prohibitions on specified activities (e.g., discharging pollutants into a water body or the atmosphere, or taking a threatened species);
- requirements to obtain a governmental approval (or permit) before undertaking a specified activity (e.g., pollution permits, operating licenses, and development approvals);
- requirements to follow certain procedures when carrying out specified activities (e.g., to use certain equipment, abide by operating standards, or to monitor pollution emissions); and
- requirements to undertake specified actions that are deemed to be environmentally beneficial (e.g., weed control in agricultural areas).

The use of regulatory instruments can be justified on the basis of deterrence or similar choice theories of criminology. According to this approach, people are assumed to make choices by rationally weighing the costs and benefits associated with alternative courses of action and selecting the action that is most likely to maximize their utility. Regulations can affect this process by altering the costs and benefits associated with environment-related activities. For example, by outlawing the emission of pollutants into a river and incarcerating or imposing fines on people who violate the law, the government is able to increase the costs of emitting pollutants. In doing so, it makes alternative nonpolluting options more attractive. In countries where the rule of law prevails, provided the penalties and probability of enforcement are high enough, and punishment is swift, the desired pattern of behavior should emerge.

The difficulty with this theory is that humans are not always rational utility maximizers, meaning that environment regulations may not always result in the desired outcomes. Regulatory approaches can also fail to achieve their objects because of poor design (e.g., ambiguous regulations and unworkable administrative arrangements), strategic avoidance by polluters, and an absence of monitoring and enforcement due to a lack of resources or political will. There are even cases where regulatory instruments have aggravated the environmental problems they were designed to solve.

Regulatory instruments are criticized not only for being ineffective, but also for their inefficiency. This is because they can impose inflexible restrictions on producers, thereby limiting the choices that are available as to how producers meet the desired environment target. Regulatory mechanisms can also have large administration and compliance costs. Government agencies are required to constantly monitor compliance and undertake costly litigation when breaches are discovered, while producers incur legal and other costs while attempting to abide by the environmental regulations. In addition, regulatory mechanisms do not provide incentives to encourage the reallocation of resources toward producers with the lowest marginal costs of environmental protection. As a result, it is difficult for regulatory mechanisms to satisfy the equimarginal principle, which requires that the marginal cost of environmental protection be equalized across polluters to achieve the desired environment target at the lowest possible cost.

The other main criticism of environment regulation is that it can be inequitable. Disputes about whether regulatory mechanisms are unfair are usually framed in terms of the alteration of preexisting property rights. Some people may believe they have a right to pollute or use the environment in a particular way. When environment regulations are introduced, these property rights may be taken away, prompting calls for compensation. In the absence of compensation, the people who are affected by the regulations may feel they are being forced to shoulder a disproportionate amount of the financial burden associated with the provision of public good environmental outcomes. This problem is often confronted with laws that prohibit the removal of native vegetation or the taking of native species, or that restrict the development of real property for commercial purposes.

In several countries disputes about the impact of environment regulations on property rights have been a central part of environmental policy debates. For example, in the United States, the Fifth Amendment to the Constitution provides that private property shall not be "taken for public use without just compensation." This has led to numerous Supreme Court cases and an extensive literature on so-called "regulatory takings." The Australian Constitution contains a similar provision, which provides the

Federal Government with the power to make laws with respect to the "acquisition of property on just terms." In both jurisdictions, courts have found that these constitutional provisions limit the extent to which the government can abolish property rights for environmental purposes.

While issues surrounding the abrogation of property rights have been influential in framing equity issues associated with environmental regulations, it is often forgotten that most regulations alter property rights. The elevated status of property right issues in the context of environmental debates is arguably due to the reverence accorded to real property and preferential treatment given to certain primary industries in western countries.

Despite the criticisms of regulatory measures, they remain the most widely used instrument for environmental protection. There is an ongoing debate about why states tend to prefer regulatory instruments, with supporters of economic instruments often attributing it to ignorance of alternatives, simplicity, and pressure by special interest groups. Yet, regulatory instruments have a number of attributes. The most important of these is the certainty they can provide when faced with imperfect information about environmental risks and the irreversibility of certain forms of environmental harm (e.g., species extinction). In these circumstances, relying on economic, voluntary, or information instruments can lead to suboptimal outcomes by permitting excessive exploitation of the environment. Regulatory instruments are well suited to these situations as they allow distinct boundaries to be placed on the use of environmental resources. This has led to the advocacy of decision-making tools like the precautionary principle and collective choice processes like the safe minimum standards approach.

Another benefit of regulatory instruments is they can be more cost-effective than other measures in dealing with certain types of environmental issues. As discussed, regulatory instruments are often criticized for having large administrative and compliance costs. Yet, in some cases, alternative economic and voluntary approaches may have higher administrative and compliance costs because of the nature of the environmental problem and the complexity in the required program. For example, addressing land clearing with voluntary measures can require agreements to be negotiated with large numbers of landholders, leading to high transaction costs and a plethora of different standards. In contrast, regulations can provide a uniform standard that does not require case-by-case negotiations and is easier to monitor and enforce. Regulatory instruments can also overcome free-rider problems by forcing recalcitrant polluters to abide by the necessary standards.

Economic Instruments (Market-Based Measures)

Economic instruments can be defined as mechanisms that force economic agents to internalize all or part of the social costs associated with environmentally harmful activities and that rely on market forces to promote efficiency. In doing so, they seek to impose additional costs on producers that harm the environment and reward those that improve environment outcomes, while utilizing market forces to improve the allocation of resources. (Some analysts include subsidies among economic instruments but as they are voluntary and economic agents are not forced to internalize the social costs they are more appropriately classified as voluntary instruments.)

This approach to environmental protection is usually associated with environmental economics, a school of economic thought that is a subdiscipline of neoclassical economics. According to environmental economists, environmental problems arise because of the existence of externalities—impacts involuntarily incurred by a person or persons without compensation or payment as a result of the actions of another. Because of the existence of externalities, markets are unable to guarantee the efficient allocation of resources. For example, if producers emit pollution into the atmosphere without paying for it, the price that consumers pay for the producers' outputs will not reflect the full social cost of the transaction. As a result, there will be excessive output and consumption of the relevant good or service. If producers are forced to internalize the social costs associated with the air pollution, there would be a more efficient tradeoff between air pollution and output, leading to higher net social welfare.

The more recent trend in environmental economics has been to characterize environmental problems as being a product of the incomplete allocation of property rights. According to this approach, if a property right over the relevant environmental resource were appropriately defined and allocated to individuals, and there was perfect information and no transaction costs, the operation of market forces would lead to efficient outcomes. For example, if the atmosphere were owned by someone and producers had to pay to emit pollution, then negotiation between the owner and producers would ensure the most efficient allocation of atmospheric resources. On the basis of these theories, economic instruments either

- require polluters to pay for all or part of the costs associated with pollution (e.g., pollution fees, individual liability, and removal of subsidies that promote overuse);
- place a restriction on the amount of pollution that can be emitted or resource that can be used and then allow pollution or resource entitlements to be traded among economic agents (called "marketable permit" or "cap-and-trade" schemes, e.g., tradable emission, water, catch and development rights schemes); or
- seek to create well-defined, secure, and transferable property rights over environmental resources and allocate these to relevant individuals or groups ("pure property rights" approaches, e.g., land titles and fishing area rights).

Marketable permit schemes and pure property rights approaches are similar in that both rely on the creation and exchange of property rights to promote environmental and economic outcomes. But pure property rights approaches place no external restrictions on the use of the relevant resource and rely on market incentives to achieve the desired environmental outcome,

while marketable permit schemes rely on a cap or limit on the use of the relevant resource to achieve the desired environmental outcome.

One of the major benefits associated with economic instruments is that by utilizing market forces they can encourage a more efficient allocation of resources. For example, when tradable emission quotas are used, the operation of market forces should ensure that the necessary emission reductions are achieved at least cost (i.e., the equimarginal principle should be satisfied). Further, economic instruments provide an incentive for producers to reduce pollution, which encourages innovation. Advocates of economic instruments also claim they are more flexible than regulatory instruments, although this is not always the case.

Although economic instruments can be more efficient than alternative policy mechanisms, they can suffer from a number of weaknesses. In relation to pollution fees, individual liability and pure property rights approaches, there can be a considerable amount of uncertainty associated with environmental outcomes. For example, producers may choose to absorb the increase in costs associated with a pollution fee, or demand may be unresponsive to price rises, meaning the level of pollution may not decline by the desired amount. Consequently, where policy-makers are faced with uncertainty regarding environmental risks and questions regarding irreversibility, alternative approaches can be preferable.

Like regulatory approaches, marketable permit schemes (or cap-and-trade approaches) can place an upper limit on the permissible amount of pollution or resource extraction. Hence, they can be useful in dealing with uncertainty and threshold effects. The advantage that marketable permit schemes offer is that having set a specified limit on pollution or resource extraction, they allow market forces to determine the allocation of pollution or extraction rights among producers. One of the most successful marketable pollution permit schemes has been the United States Environmental Protection Agency's Sulfur Dioxide Program, which is part of the broader Acid Rain Program. The cost of reducing emissions was substantially lower than predicted because producers had an incentive to find cheaper ways to do so.

Problems arise with marketable permit schemes when there is a lack of equivalence between the environment or pollution units that producers are expected to trade (i.e., the resource is not homogeneous). For example, tradable development permit schemes that place a limit on the amount of development in an area but allow developers to exchange development rights can lead to the rights moving toward the developments with the highest economic returns. However, they will not necessarily achieve biodiversity objectives as each parcel of land may contain different biodiversity values. Similar problems can arise with emission schemes that allow emission permits to be generated through the enhancement of sinks (i.e., there can be uncertainty about whether the enhancement of sinks will offset the additional emissions).

Transaction costs can also pose problems for economic instruments. Devising schemes that can be administered in a cost-effective manner can sometimes be difficult. Further, if there are excessive costs associated with the negotiation and exchange of marketable permits, the efficiency benefits may not materialize.

As with all environmental policy mechanisms, politics can impede the effective use of economic instruments. However, economic instruments can be especially vulnerable to political influences if it is necessary to constantly adjust the price signals provided through the scheme. For example, if a carbon tax is used to address climate change, it will be necessary to adjust the tax over time to account for unexpected events and new information. Special interest groups may impede this process, thereby undermining the efficacy of the tax.

There has been a tendency in the past for regulatory instruments and economic instruments to be presented as substitutes. In practice, these two types of instruments are generally used as complements and economic instruments always require a regulatory framework. Indeed, there is a growing recognition of the need for policy packages or policy mixes that use a range of instruments to achieve environmental protection objectives.

Voluntary Approaches

Voluntary approaches can be defined as any mechanism or program that aims to protect the environment where relevant economic agents are able to decide whether or not to participate; that is, involvement in the program is voluntary and no direct penalties are imposed on nonparticipants, although incentives may be used to encourage participation.

There are three broad types of voluntary approach.

- Unilateral initiatives where polluters act without direct government involvement to protect the environment. The defining features of unilateral initiatives are that they are initiated, designed, and operated by polluters. Hence, government involvement is generally limited, which raises questions about whether unilateral initiatives are a policy mechanism or a type of market behavior. Yet governments can encourage unilateral initiatives by suggesting them to polluters or threatening mandatory measures. There are three main types of unilateral approaches: voluntary adjustment of internal processes (e.g., under an environmental management plan); industry self-regulation (e.g., codes of conduct); and environmental certification schemes (e.g., organic producer associations).
- Bilateral agreements between the regulator and a polluter or group of polluters. These initiatives involve negotiation between the parties about how environmental protection will be achieved. Both parties have obligations under the agreement with polluters generally expected to meet certain targets and abide by conditions to protect the environment and the regulator generally expected to provide some sort of incentive. The incentives provided by regulators can include subsidies (e.g., monetary payments and technical assistance), public recognition, and undertakings not to enforce regulations or to introduce new regulations. The

agreements need not be legally binding, but there must be negotiation and some sort of understanding about the obligations of the parties.

- Voluntary public (or government) programs where the regulator determines who is eligible to participate, the obligations of participants, and the incentives used to encourage compliance. The key to these types of programs is that they are initiated and designed by the regulator, and relevant producers are invited and encouraged to participate. Again, the types of inducements include grants, technical assistance, and public praise.

The main advantages of voluntary approaches are that they are flexible (which provides polluters with the freedom to find cost-effective solutions) and noninterventionist. In addition, where disputes arise about the fairness of polluter-pays instruments like regulations and pollution fees, voluntary instruments can help overcome political resistance by enabling governments to pay polluters for the loss of property rights (i.e., they can resort to a beneficiary-pays approach). Due to these characteristics, voluntary approaches are often supported by polluters, which can assist in reducing the political costs for regulators. Further, it is sometimes claimed that voluntary approaches have lower administrative costs than other instruments and that in certain circumstances they can be more effective than mandatory approaches.

Although voluntary approaches can offer some benefits, because of the public good characteristics of many environmental goods and services (i.e., they are nonrival and nonexcludable) they are unlikely to result in an optimal level of environmental protection. In particular, there is a risk that some producers will seek to free-ride on the environmental protection measures undertaken by others. Like some economic instruments, voluntary mechanisms also lack certainty and are ill-suited to dealing with uncertainty and irreversibility.

Voluntary approaches can also be expensive to operate and administer. The incentives necessary to encourage participation can impose a significant burden on taxpayers. These problems can be exacerbated by gaming on behalf of polluters where they seek to take advantage of information asymmetries to extract excessive economic rent. In addition, the transaction costs associated with voluntary approaches can be high if there is a need to negotiate agreements with a significant number of producers.

Given the weaknesses associated with voluntary mechanisms, they are often seen as being used when political resistance blocks the introduction of more effective instruments or as a mechanism that supports or complements other programs.

Research has shown that if voluntary approaches are to be effective, the existence of a strong and credible threat of regulation is essential. The existence of an appropriate threat of regulation increases the incentive for polluters to participate and bolsters the bargaining position of regulators. It can also reduce the financial incentives needed to ensure participation, which can improve the cost-effectiveness of the program.

Information and Education Instruments

Information and education instruments aim to promote environmental protection by improving people's awareness and understanding of environment issues and building their capacity to respond to environmental threats. They include such things as environmental and sustainability reporting by governments and corporations, and advertising and education campaigns.

Many environmental problems arise at least partly because of imperfect information about environmental risks and a lack of awareness about how to respond. These types of instruments can help overcome these issues and can be effective where the threats to the environment are known and producers have an economic incentive to improve environmental outcomes. Information instruments can also be an important tool for encouraging greater support for environmental protection in the community, which can reduce the political costs associated with various environment policy instruments.

The main flaw associated with information instruments is that they will rarely get at the root causes of environmental degradation. As a result, on their own, they are generally an ineffective means of achieving environmental objectives. However, information instruments are commonly viewed as an essential part of environmental policy packages. Without information instruments it is very difficult for policy-makers to select appropriate policy instruments and it is unlikely that environmental protection measures will attract the political and community support that is necessary to ensure their success.

The advantages and disadvantages of the four approaches are summarized in the Table 1.

International Dimensions of Environmental Protection

Under international law, states have the sovereign right to exploit, manage, and conserve the natural resources and natural systems within their jurisdiction, including resources located in their territorial sea and exclusive economic zone, and sinks such as the atmosphere. States also have a broad right to engage in fishing on the high seas. However, the expansion of the world economy has placed increasing pressure on natural systems that overlap or transcend political boundaries. This has gradually led to the development of a large number of international agreements, systems, and processes to address transnational environmental issues.

The international governance system that has emerged over the past 60 years to facilitate environmental protection can be divided into three main parts: international environmental law, international environmental bureaucracy, and international environmental financial mechanisms.

Table 1 Domestic environmental policy instruments—pros and cons

Policy instrument	*Definition*	*Advantages*	*Disadvantages*
Regulatory	Instruments that impose legally enforceable restrictions on economic agents to realize environmental protection objectives	Certainty about environmental outcomes Ability to limit free-riding Clarity of standards—easy to comply with, monitor, and enforce No need to negotiate individual standards, which lowers administration costs	Inefficiencies—regulations impede the operation of market forces and can lead to the misallocation of resources Can stifle innovation Potentially inequitable because some may shoulder a disproportionate burden
Economic	Instruments that force economic agents to internalize all or part of the social costs associated with environmentally harmful activities and that rely on market forces to promote efficiency	By utilizing market forces they are able to achieve the desired outcomes in an efficient manner Promote innovation Provide flexibility as they often enable individuals to determine the best method of achieving the desired outcomes Ability to limit free-riding	Can lack certainty about environment outcomes Can be complex and have high administration costs Potentially inequitable
Voluntary	Any mechanism or program that aims to protect the environment where relevant economic agents are able to decide whether or not to participate	Noninterventionist, meaning they are likely to have high levels of acceptance by producers Low political costs for regulators High levels of flexibility	Lack certainty about environment outcomes Can have high administration costs Risk of free-riding Risk that producers will engage in gaming to extract excessive economic rents from regulators
Information and education	Instruments that aim to promote environmental protection by improving people's awareness and understanding of environment issues and building their capacity to respond to environmental threats	Noninterventionist Low political cost for regulators Flexibility Relatively low administration costs	Lack certainty about environment outcomes Risk of free-riding Inability to address main reasons for market failure

International Environmental Law

At the heart of the international environmental governance system lies the body of legal principles and agreements that collectively constitute international environmental law. Although international environmental agreements have existed for centuries, the number, scope, and complexity of these agreements has increased considerably since the 1940s. By the mid-2000s, there were more than 500 multilateral environment agreements (MEAs) in existence. Around 270 of these MEAs were broad international agreements, while the remainder had a regional focus and a relatively limited number of signatories. Not surprisingly, these agreements cover a wide range of topics, including climate change, biodiversity, transport and disposal of hazardous materials, and fisheries management.

One of the most basic principles of international environmental law is that, while states have sovereignty over the resources in their jurisdiction, no state has the right to use or permit the use of its territory in such a manner as to cause injury to the another's territory, person, or property. This principle, which is generally traced to the Trail Smelter Dispute that commenced in the 1920s between Canada and the United States, concerns environmental obligations between particular states (i.e., reciprocal obligations).

Growing awareness of the interrelated nature of natural systems and the scale of environmental problems in the later part of the twentieth century resulted in growing support for the notion that states should also have obligations to protect global commons and the interests of humanity, including future generations. This has led to the formation of a significant number of international agreements that promote the protection of a broader range of interests in the environment. The guiding principle regarding the rights of states to exploit natural resources is now viewed as incorporating a fundamental duty to protect global commons. For example, the Rio Declaration on Environment and Development (1992) provides that states have a "responsibility to ensure that activities within their jurisdiction or control do not cause damage to the environment of other States or of areas beyond the limits of national jurisdiction." There are also a number of international agreements, such as the United Nations Framework Convention on Climate Change (UNFCCC), that seek to protect certain aspects of the environment for "the benefit of present and future generations of humankind."

The notion of sustainable development has been a common element of MEAs since the late 1980s and 1990s. This has led to greater concern about intragenerational equity and encouraged the inclusion of the so-called principle of "common but differentiated responsibility" in MEAs. This principle has two parts. The first is that states have a shared responsibility for the protection of the environment, or relevant parts of it. The second part is that the extent to which each individual state is responsible for environmental protection should be determined with regard to the state's capacity to respond and historical contribution to the

relevant problem. One of the clearest articulations of the principle is found in the Rio Declaration on Environment and Development (1992), where it provides that

> States shall cooperate in a spirit of global partnership to conserve, protect and restore the health and integrity of the Earth's ecosystem. In view of the different contributions to global environmental degradation, States have common but differentiated responsibilities. The developed countries acknowledge the responsibility that they bear in the international pursuit to sustainable development in view of the pressures their societies place on the global environment and of the technologies and financial resources they command.

The principle of common but differentiated responsibility also features prominently in the UNFCCC (1992) and the Montreal Protocol on Substances that Deplete the Ozone Layer (Montreal Protocol) (1987). For example, Article 3(1) of the UNFCCC states that

> The Parties should protect the climate system for the benefit of present and future generations of humankind, on the basis of equity and in accordance with their common but differentiated responsibilities and respective capabilities.

International Environmental Bureaucracy

The second element of the international governance system is the collection of international bodies whose functions include the oversight of environmental issues. At the heart of these is the United Nations, which has established a collection of agencies who are responsible for developing policy and promoting better environmental stewardship. These include the United Nations Environment Programme (UNEP), United Nations Development Programme (UNDP), Commission on Sustainable Development (CSD), and the United Nations Educational, Scientific, and Cultural Organisation (UNESCO). The agencies associated with the United Nations are complemented by other international and regional bodies like the World Bank, Organisation for Economic Cooperation and Development (OECD), European Union, and the Organisation of American States (OAS) that play a role in the development and implementation of environment policy.

International Environmental Financial Mechanisms

The final element of the international governance system is the financial mechanisms that have developed to support the work of international environment agencies and to assist in the achievement of international environmental objectives. These range from the general (e.g., the financial arrangements governing the World Bank and United Nation) through to the more specific, which concentrate solely on environment issues. The Global Environment Fund (GEF), established by the OECD in the early 1990s, is one example. Consistent with the principle of common but differentiated responsibility, many MEAs now include provisions requiring developed countries to transfer technology and financial resources to developing countries to assist them to meet their environmental obligations. One of the earliest examples was the Multilateral Fund established under the Montreal Protocol to assist developing countries phase out the use of ozone-depleting substances. In some cases, including under the Montreal Protocol, the obligation of developing countries to comply with the terms of the agreement has been made contingent on the extent to which developed countries provide the specified financial and technical assistance. For example, Article 4(7) of the UNFCCC states that

> The extent to which developing country Parties will effectively implement their commitments under the Convention will depend on the effective implementation by developed country Parties of their commitments under the Convention related to financial resources and transfer of technology . . .

Despite considerable progress being made in some areas, the international environmental governance system has generally failed to bring about substantial and sustained changes in the stewardship of natural resources and environmental systems. In many cases, this is due to the difficulties associated with designing agreements and systems that can accommodate the divergent interests of the states that are involved in transnational environmental issues. Negotiations can be tediously slow and the need to reach consensus can lead to lowest common denominator outcomes. Similarly, due to the reluctance of states to place constraints on their sovereign rights over natural resources, it has been difficult to establish appropriate mechanisms for monitoring compliance and enforcing the terms of the agreements. The international governance system has also been hampered by a lack of resources for key institutions and programs.

Conclusion

Environmental protection has always been practiced by humans in one form or another. However, as anthropogenic pressures on the environment have escalated over the past century, the need for systematic environmental protection has increased. This has led to considerable experimentation with the domestic and international measures that are used to achieve environmental protection objectives. Some of these have been successful, but the overall picture is one of failure.

Due to the failings of the past and greater awareness of the complexity of environmental problems, there is a growing acceptance that environmental protection is best achieved through the use of a multipronged approach. This requires the use of a combination of regulatory, economic, voluntary, and information instruments, where the policy mix is determined on the basis of the available evidence regarding cost-effectiveness.

The international challenge lies in the development of effective and equitable approaches to global environmental problems that are supported by a well-resourced bureaucracy and appropriate financial mechanisms.

However, in the last few years, a new initiative has come out bringing together recent scientific advancements in our knowledge of the Earth System functioning, environmental and ecological law as well as economic instruments to propose a new global governance system aimed at favoring environmental protection. In 2009 a group of scientists developed the "Planetary Boundaries" framework to measure and monitor the state and functioning of the Earth System (Rockström et al. 2009; Steffen et al. 2015). The framework, has been developed to define a planetary safe operating space within which humanity can survive and thrive, and to highlight risks that destabilization of the system creates for human well-being. The identification of such safe operating space for humanity has then helped to recognize the need of an evolution of the current international legal system. In this light the concept of "The Common Home of Humankind" has been proposed as a social construct, based on legal solutions to represent the global natural reality (Magalhães et al., 2016). The legal recognition of a specific, functioning state of the Earth System (i.e., a Holocene-like state, as defined by the planetary boundaries framework) as a common natural intangible heritage of mankind would allow to include all positive and negative externalities in the governance and maintenance of the Earth System thus possibly constituting a new legal environmental protection framework.

That legal systems are not ready to face these challenges is shown also by the fact that a group of law experts have launched the Ecological Law & Governance Association (ELGA) to reframe law according to ecological limits. In their *Oslo Manifesto* it is reported that "Ecological Law requires human activities and aspirations to be determined by the need to protect the integrity of ecological systems. Ecological integrity becomes a precondition for human aspirations and a fundamental principle of law. In other words, ecological law reverses the principle of human dominance over nature, which the current iteration of environmental law tends to reinforce, to a principle of human responsibility for nature. This reversed logic is arguably the key challenge of the Anthropocene".

The Genuine Progress Indicator: A Measure of Net Economic Welfare

Ida Kubiszewski, The Australian National University, Canberra, ACT, Australia

Introduction

Countries need a way of measuring progress and goals to strive toward. Since about the 1950s, gross domestic product (GDP) has been the indicator used globally to determine society's progress. However, the goal that we are striving toward is never defined on the global scale.

The attempt was made to change this in 2000, when the United Nations established eight millennium development goals (MDGs). These goals were only created for 15 years, through 2000–15, and only targeted half the world, the developing countries. The sustainable development goals (SDGs) replaced the MDGs in 2016. Again, these goals are set for 15 years but, unlike the MDGs, they target both the developed and developing world.

Although a major step forward, the SDGs have certain limitations. The primary drawback is that with 17 goals, 169 targets, and over 300 indicators in the environmental, social, and economic areas, there is no single overarching goal or vision that society is striving toward (Griggs et al., 2013; Costanza et al., 2016). With 17 goals, there are tradeoffs that will be required, diluting the effectiveness of the SDGs toward a common goal.

But what if maximizing human wellbeing was the unstated goal that the SDGs, and even the MDGs, were aiming toward. If such a goal existed, society would need a measure other than GDP to ascertain whether we were making progress toward achieving this goal or moving backward. However, currently, GDP is the only measure we do use.

Problems With GDP

GDP was never designed to measure social or economic welfare. The original creators of GDP warned against using it for anything except as a specialized tool that measured only a narrow segment of society's activity. However, since the 1950s we have used the size of the economy as our primary indicator of overall progress (Nordhaus and Tobin, 1972). By that yardstick, the global economy (as measured by GDP) has grown more than threefold since 1950. However, economic welfare has actually decreased slightly since 1978 (Kubiszewski et al., 2013).

GDP's current role poses a number of problems. One major issue is that it interprets every expense as positive and does not distinguish welfare-enhancing activity from welfare-reducing activity. For example, an oil spill increases GDP because of the associated cost of cleanup and remediation, but it obviously detracts from overall wellbeing. Examples of other activities that increase GDP include hurricanes (and all other natural disasters), cancer (and other illnesses), crime, car accidents, and divorce.

GDP adds up all marketed deliveries to "final demand" (sales to households, government, net exports, and capital formation) that occur within a country, regardless of whether they represent a real benefit or a "defensive expenditure" like cleaning up an oil spill or treating pollution caused health effects (Leipert, 1989). This is because GDP is calculated using the input/output model. This means that the only things that can be included in GDP are those items that are produced and consumed by one of the sectors in the economy. Nothing else is included.

If the same method of input/output tables were to be used to calculate GDP, the entire process would have to be adjusted. The tables would have to distinguish between the economic activities that added to versus subtracted from economic welfare. Another major change would have to be the inclusion of goods and services that are not within the economic market but do have a large influence on welfare. Over the past few years, various groups, including the United Nation's Statistic Division and the World Bank have been working on creating national accounts that incorporate ecosystem services (Bartelmus, 2014; Hein et al., 2015). Some of these efforts modify the input/output model to incorporate services provided by nature.

Herman Daly, a former senior economist at the World Bank, once commented that, "the current national accounting system treats the earth as a business in liquidation." He also noted that we are now in a period of "uneconomic growth," where GDP is growing but economic welfare is not.

GDP also leaves out many components that enhance welfare but do not involve monetary transactions and therefore fall outside the market. For example, the act of picking vegetables from a garden and cooking them for family or friends is not included in GDP. Yet buying a similar meal in the frozen food aisle of the grocery store involves an exchange of money and a subsequent GDP increase. A parent staying home to raise a family or do volunteer work is also not included in GDP and yet they are potentially key aspects of someone's economic welfare.

There are problems with GDP including that it does not account for the distribution of income among individuals, which has considerable effect on individual and social wellbeing (Wilkinson and Pickett, 2009). GDP does not care whether a single individual or corporation receives all the income in a country, or whether it is equally distributed among the population. A dollar's worth of increased income to a poor person produces more additional welfare than a dollar's increased income to a rich person. Additionally, the distribution of income within a country influences a range of social problems and overall societal welfare.

And yet, even with all the problems surrounding GDP, it is the most commonly used indicator of a country's overall performance.

The Genuine Progress Indicator

Wellbeing is the outcome of a convergence of factors, ranging from good human relations, to greater equality as well as a healthy social and natural environment (Wilkinson and Pickett, 2009; Boarini et al., 2012). Indicators are essential to promote change in economic governance. As post-GDP measurements are integrated into institutional processes, they will be followed by relative rewards and sanctions, as is the case with GDP at present.

In recent years, much work has been done on alternative indicators to GDP—more comprehensive indicators that consolidate economic, environmental, and social elements into a common framework to show net progress. A number of researchers have proposed alternatives to GDP that make one or more of these adjustments with varying components and metrics (Smith et al., 2013). These indicators can be divided into three broad groups: (1) measures that modify economic accounts to address equity and nonmarket environmental and social costs and benefits; (2) measures that use weighted indices of "subjective" indicators based on survey results; and (3) measures that use weighted indices of a number of "objective" indicators.

One such indicator, which fits into the first category, is the genuine progress indicator (GPI). The GPI is a version of the index of sustainable economic welfare (ISEW), first proposed in 1989 by Daly and Cobb (1989) and later modified and renamed the genuine progress indicator (Redefining Progress, 1995).

GPI starts with personal consumption expenditures (a major component of GDP) but adjusts it using about 25 different components (seen in Fig. 1). These components subtract those aspects that are actually an overall negative activities in society, such as the costs of environmental degradation, biodiversity loss, and ecosystem services loss, cost of family breakdown, cost of unemployment, and cost of crime and pollution. They also add positive components left out of GDP, including the benefits of volunteering and household work, among others. GPI, unlike GDP, is also adjusted for income distribution (Cobb et al., 1995; Lawn, 2003; Bagstad and Shammin, 2012). By separating activities that diminish welfare from those that enhance it, GPI better approximates sustainable economic welfare. GPI is not meant to be an indicator of sustainability. It is a measure of economic welfare that needs to be viewed alongside biophysical and other indicators. In the end, since one only knows if a system is sustainable after the fact, there can be no direct indicators of sustainability, only predictors.

Over the past few decades, ISEW or GPI have been calculated in around 20 countries worldwide (Lawn and Clarke, 2008; Kubiszewski et al., 2013). These studies have indicated that in many countries, beyond a certain point, GDP growth no longer correlates with increased economic welfare. The trend is similar in many countries, GPI tracks GDP pretty closely as a country develops, but at a certain point the two diverge. In the United States it happened in the late-1970s while in China in the mid-1990s. GDP keeps growing while GPI levels off or decreases.

Recently, a global GPI was estimated using GPI and ISEW data from 17 countries, containing approximately 53% of the world's population and 59% of the global GDP (Kubiszewski et al., 2013). On the global level GPI/capita peaked in 1978 (Fig. 2). Interestingly, 1978 is also around the time that the human ecological footprint, a biophysical indicator that measures humanity's demand on nature, exceeded the Earth's capacity to support humanity. Other global indicators, such as surveys of life satisfaction from around the world, also began to level off around this time. In fact, a strikingly consistent global trend suggests that as income increases, wellbeing often decreases amidst rising rates of alcoholism, suicide, depression, poor health, crime, divorce, and other social pathologies.

An important function of GPI is to send up a red flag at that point. Since it is made up of many benefit and cost components, it also allows for the identification of which factors increase or decrease economic welfare. Other indicators are better guides of specific aspects. For example, Life Satisfaction, determined by surveys, is a better measure of overall self-reported wellbeing. By observing the change in individual benefit and cost components, GPI reveals which factors cause economic welfare to rise or fall even if it does not always indicate what the driving forces are behind this. It can account for the underlying patterns of resource consumption, for example, but may not pick up the self-reinforcing evolution of markets or political power that drive change.

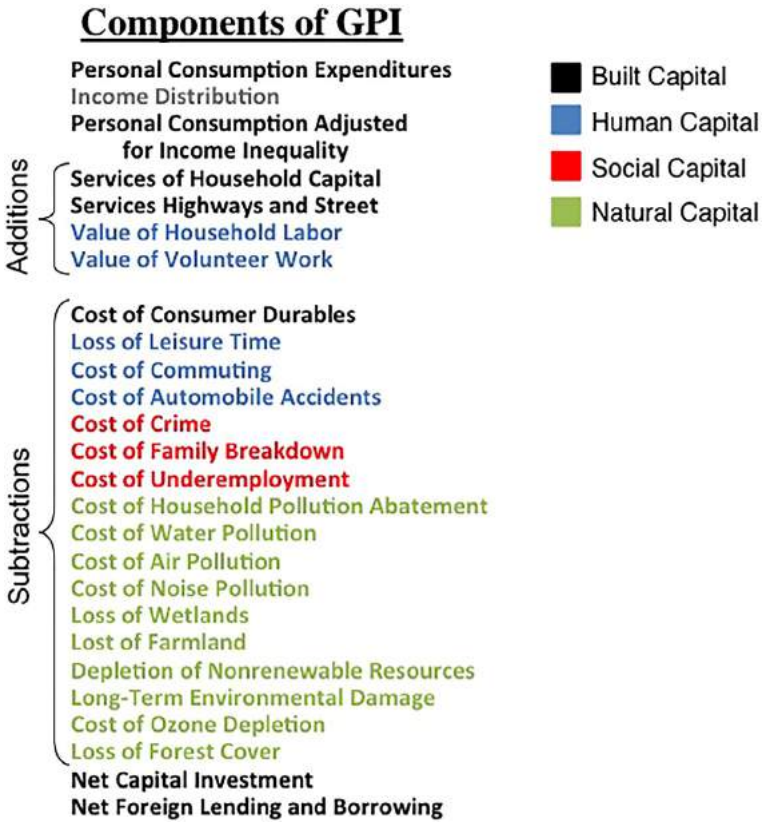

Fig. 1 Components of GPI separated into built, human, social, and natural capitals.

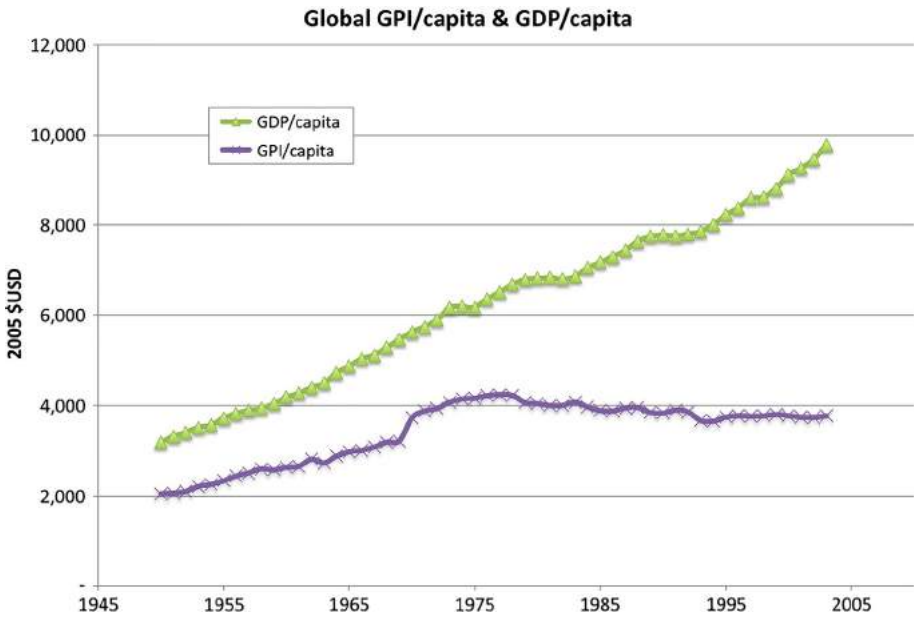

Fig. 2 Global GPI/capita and GDP/capita. GPI/capita was estimated by aggregating data for the 17 countries for which GPI or ISEW had been estimated, and adjusting for discrepancies caused by incomplete coverage by comparison with global GDP/capita data for all countries. All estimates are in 2005 US$. Source Kubiszewski, I., Costanza, R., Franco, C., Lawn, P., Talberth, J., Jackson, T. and Aylmer, C. (2013). Beyond GDP: Measuring and achieving global genuine progress. *Ecological Economics* **93**, 57–68.

Recently, two state governments in the United States have adopted GPI as an official indicator, the states of Maryland and Vermont, and others have begun calculating it (Berik and Gaddis, 2011; McGuire et al., 2012; Erickson et al., 2013; Stiffler, 2014; Kubiszewski et al., 2015). In addition, the data necessary to estimate GPI is becoming more available in many countries and regions. For example, remote sensing data allow better estimates of changes in natural capital and surveys of individuals about their time use and life satisfaction are becoming more routine. New means of measuring inequality are being developed, and more detailed data are being collected on the costs of crime, family breakdown, underemployment, and other measures that might be used in GPI in the future. The bottom line is that the costs of estimating GPI are not particularly high, the data limitations can be overcome, and it can be relatively easily estimated in most countries.

A Closer Look at National GPI Results

A 2013 study (Kubiszewski et al., 2013) looked at the GPI and other indicators for 17 countries from around the world. Four of those countries (China, Japan, the United Kingdom, and the United States) are used here as representative examples of the 17 countries for which data has been collated (Fig. 3).

China experienced rapid GDP/capita growth between 1950 and 2008 as it moved from an agrarian to an industrialized society. GPI/capita also increased during this time, albeit more slowly. After 1994, China joined the world market more completely and its GDP/capita, along with its GPI/capita, increased rapidly. However, this only lasted for about 5 years after which worsening income distribution (the Gini coefficient increased from 0.29 to 0.42) and high environmental externality costs began to become significant enough that they canceled out consumption-related gains. (The Gini coefficient is a measure of income distribution within a country, used as a gauge for economic inequality. This coefficient ranges between 0 and 1, with 0 representing perfect equality and 1 representing perfect inequality.) The change in these costs and benefits can be seen through the individual components that comprise GPI. Consequently, GPI/capita leveled off (Wen et al., 2008).

A similar trend is seen in India. A 1995 study by Manfred Max-Neef showed that the per capita GPI of wealthy nations started to fall when the per capita GDP reached around $15,000–20,000 (MaxNeef, 1995). He concluded at the time that this constituted a "threshold" level of per capita income. A subsequent study in 2008, showed that Thailand's per capita GPI started to fall when its per

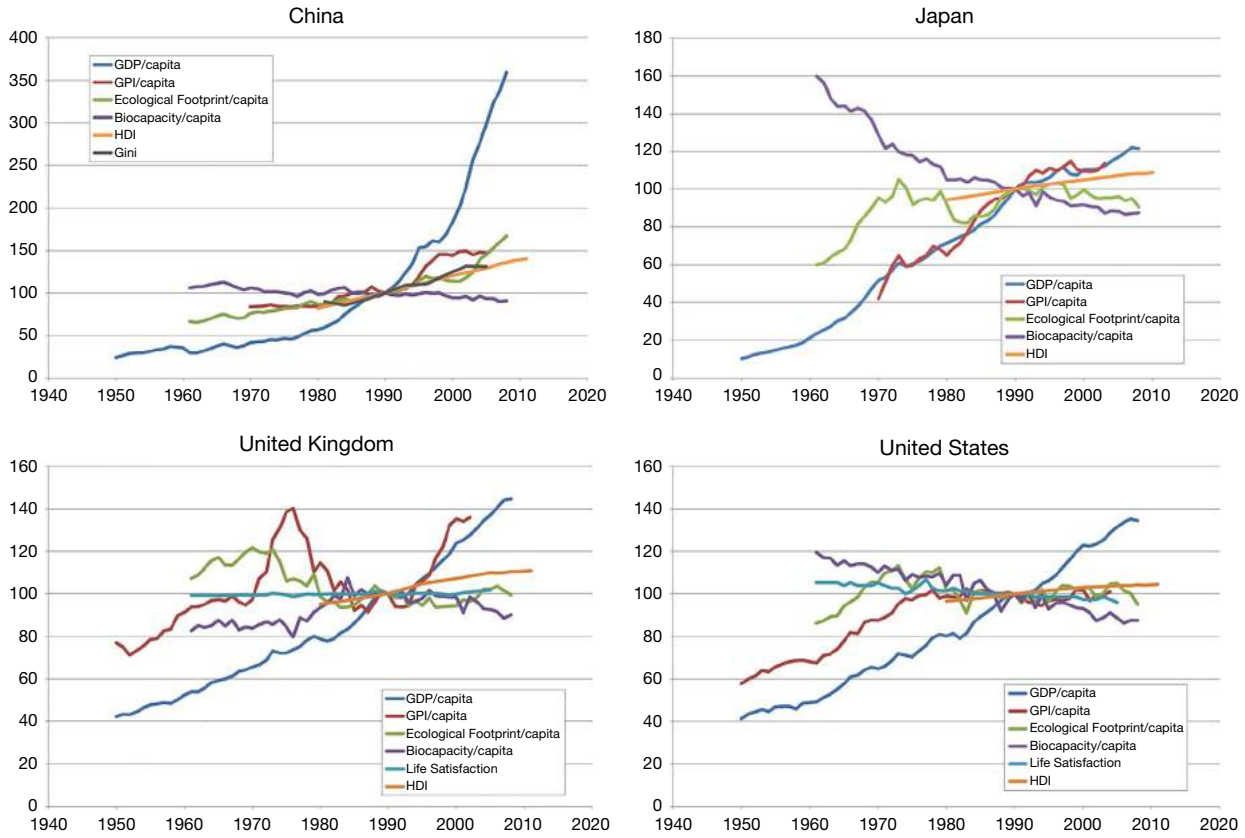

Fig. 3 Comparison with other indicators. The 4 out of the 17 countries comparing indexed trends for GPI/capita, GDP/capita, ecological footprint/capita, biocapacity/capita, HDI, life satisfaction, and the Gini coefficient. All graphs are indexed to 1990 = 100. Source Kubiszewski, I., Costanza, R., Franco, C., Lawn, P., Talberth, J., Jackson, T. and Aylmer, C. (2013). Beyond GDP: Measuring and achieving global genuine progress. *Ecological Economics* **93**, 57–68.

capita GDP reached $7500 (Lawn and Clarke, 2008). For China, the threshold is at $5000. One interpretation is that the threshold level of per capita income is contracting because poor nations are growing their GDP in a "full" world (Costanza, 2008). Hence the marginal cost of GDP growth appears now to be much higher for poor nations at the same stage of the economic development process. We conclude that the ability of poor nations to increase their economic welfare may now be dependent upon rich countries abandoning their obsession with GDP growth. This would provide the "ecological space" for poor nations to experience a phase of welfare-increasing growth.

Japan on the other hand, is one of the only developed countries that experienced a continuous rise in GPI/capita between 1970 and 2003. Much of this is due to the rebuilding after World War II, and is particularly striking in view of Japan's "lost decade" of faltering economic growth. As in China, much of this growth was based on intense natural resource use. In recent years, starting around 1990, the GPI rate of increase has diminished due to environmental degradation (Makino, 2008). Fig. 4 also shows that Ecological Footprint/capita and biocapacity/capita for Japan intersect around 1990. This means that after that point, Japan began using resources faster than it was generating them. However, Japan is a very heavy importer of raw materials and therefore its own environmental costs have not risen significantly (Makino, 2008). This creates a problem for GDP since it does not handle transboundary issues well. It also underscores the case for estimating a global GPI since an undervaluation of environmental costs in one country is counterbalanced by overvaluation in others.

The graph for the United Kingdom seems to show much variation over the course of 52 years. However, because these are indexed graphs, showing only trends, we see that the change in actual GPI/capita is small throughout that period. GDP/capita has been increasing steadily over that time period (Jackson et al., 2008) while GPI showed increases and decreases due to changes in government policies.

The United States shows GPI/capita and GDP/capita increasing at a relatively similar rate until about 1979 at which point GDP/capita continues to increase while GPI/capita flattens out. This occurred for reasons similar to those in other countries: a worsening of income distribution combined with environmental and social costs rising faster than consumption-related benefits.

Interestingly, HDI and Life Satisfaction do not change much within any of these 4, or even the original 17, countries. In three of our four countries, Japan, the United Kingdom, and the United States, the Ecological Footprint/capita remains significantly higher than biocapacity/capita.

There is also a general trend that appears from approximately 1950 until around 1975 where the GPI/capita for the majority of countries is increasing. Much of this is due to the rebuilding effort after World War II when consumption and built capital were the limiting factors for improving economic welfare in many countries and environmental externalities had not yet become significant. However, around the mid-to-late 1970s, much of the infrastructure was rebuilt while worsening income distribution and increasing external environmental costs canceled the growth in consumption-related benefits, causing GPI/capita to level off.

Fig. 4 shows that globally GPI/capita peaks at around $6500 GDP/capita. This estimate excludes African countries, as GPI has not yet been calculated for any African countries. However, since most African nations are poor economically, and given the GPI results for China (where the GPI started declining at a per capita GDP of $5000), a threshold per capita GDP value of $6500 is therefore a conservative one.

Until the $6500 GDP/capita peak, the GPI/capita and GDP/capita are highly correlated ($R^2 = 0.98$). This is consistent with some subjective life satisfaction studies showing leveling after around $7000 GDP/capita (Inglehart, 1997; Deaton, 2008). It is also

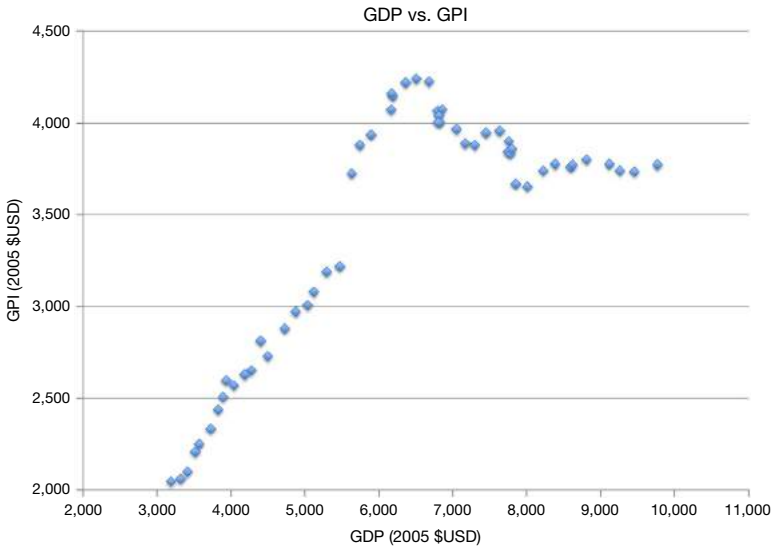

Fig. 4 GDP/capita versus GPI/capita. A plot of global GDP/capita versus estimated global GPI/capita. The two are positively correlated until about $7000/capita ($R^2 = 0.98$), after which they diverge with a negative correlation ($R^2 = 0.61$). All data in 2005 US$. Source Kubiszewski, I., Costanza, R., Franco, C., Lawn, P., Talberth, J., Jackson, T. and Aylmer, C. (2013). Beyond GDP: Measuring and achieving global genuine progress. *Ecological Economics* **93**, 57–68.

interesting that there is a negative correlation ($R^2 = 0.61$) between GDP/capita and GPI/capita after about $6500 GDP/capita. This is also consistent with the "threshold hypothesis" proposed by Manfred Max-Neef, which states that: "for every society there seems to be a period in which economic growth (as conventionally measured) brings about an improvement in the quality of life, but only up to a point—the threshold point—beyond which, if there is more economic growth, quality of life may begin to deteriorate" (MaxNeef, 1995).

We can use this GDP/capita maximum from Fig. 4 to estimate the maximum global GDP/capita consistent with a nondeclining GPI/capita. By assuming the 2010 levels of global GDP/capita of approximately $67 trillion were to be divided equally among the population to provide each person with $7000, the population would have to stabilize at around 9.6 billion people. This could be possible with better access to family planning services in high population growth nations (Engelman, 2011). An important note is that variations in income would need to exist between and within nations, however, these disparities should be much smaller than they are today.

Many scientists argue that even current consumption levels are not sustainable (Daily and Ehrlich, 1992; Rees, 2006). The global Ecological Footprint/capita exceeded global biocapacity/capita around 1978. As of 2011, humans were using 135% of the resources that can be sustainably generated in 1 year (Ecological Footprint, 2011).

Provided the technical efficiency of global production can be increased by 35%—which appears to be feasible—the global GDP of $67 trillion that is required to provide a welfare-maximizing GDP/capita of $7000 for 9.6 billion people may be sustainable. Once reached, continuing improvements in environmental protection, full employment (distributional equity), and product quality would allow the GPI/capita to rise without the need for further increases in global GDP. It is possible to increase economic welfare without having to grow GDP.

Rising environmental costs are directly related to the rise in the rate of resource use and waste generation, which is due to the growth in GDP, despite technological advances. Environmental costs could be reduced by reducing material and fossil energy throughput to the global economy, some of this may come with efficiency advances, but some will result in reductions in GDP—recognizing that this may actually be welfare enhancing. In addition, a more equitable distribution of income and opportunities will allow the welfare contribution of a given level of consumption to be increased. Welfare benefits can also be increased through the production of higher quality, longer lasting goods and the social capital benefits of a fairer and more just society.

Divergence Between GDP and GPI

GDP was created after the Great Depression in the United States and WWII, when the world needed to repair its built infrastructure and financial systems (Fioramonti, 2014). Natural resources were perceived as abundant and inadequate access to infrastructure and consumer goods represented the main limit on improvements to human welfare (Daly, 1992). During this time, it made sense to create an indicator that ignored relatively abundant natural resources, and the distribution of wealth and focused solely on increasing the production and consumption of market goods and services, which were relatively scarce (Costanza et al., 2014).

However, as a result of our success, the world has changed dramatically over the past few decades. We now live in a world full of human infrastructure. The human footprint has grown so large that, in many cases, limits on the availability of natural resources now constrain real progress more than limits to consumer goods (Costanza, 2008; Beddoe et al., 2009).

Between approximately 1950 and 1975, GPI per person for the majority of countries was increasing. Much of this was due to the rebuilding effort after World War II when consumption and built capital were the limiting factors for improving wellbeing in many countries and environmental externalities had not yet become significant. However, around the mid to late 1970s, much of the infrastructure was rebuilt. However, rising income inequality and increasing external environmental costs began to cancel the growth in consumption-related benefits, causing GPI/capita to level off.

As stated below, GPI is not a measure of overall human wellbeing since it emphasizes economic welfare and leaves out other important aspects of wellbeing. It is, however, a far better indicator of economic welfare than GDP, which was not designed to measure welfare at all. Societal wellbeing or economic welfare ultimately depends on stocks of natural, human, built, and social capital, and because the GPI makes additions and deductions to GDP to reflect net contributions to these stocks it is a far superior measure of economic welfare than GDP (Vemuri and Costanza, 2006). The disconnect between GPI and GDP, beginning in 1978, shows the aspects of our economic welfare that have been declining since that time. It also provides focus areas where societal improvement is necessary and possible.

Problems With GPI and Possible Responses

GPI is not a perfect indicator and as it has become more widely used, it has been often criticized (Harris, 2007; Brennan, 2008; Neumayer, 2010). Criticisms include that: (1) certain components are estimated through inappropriate valuation methods; (2) it makes the assumption that built capital and natural capital are substitutes; (3) although the GPI includes certain aspects that contribute to human-welfare it excludes others, for example political freedom; (4) the GPI is subjective in the components it includes and sometimes various slightly between countries; and (5) it does not have a solid theoretical basis.

Point 1: The use of cumulative cost as a valuation method for certain environmental items in the GPI is often criticized. This can be seen in components such as the cumulative cost of land degradation, lost wetlands, and long-term environmental damage. The

cumulative cost approach is used with these environmental costs due to the "strong sustainability" assumption (Lawn, 2005). One the major goal of GPI is to measure the economic welfare generated by economic activity. The assumption is that economic activity requires natural capital. Thus GPI to subtracts the *permanent* loss of natural capital services.

There are many possible ways to measure these permanent losses. The most obvious way is to assume that the current welfare cost equates to the amount that existing people should be compensated for inheriting a diminished stock of natural capital. To be consistent with strong sustainability, appropriate compensation should approximate what it would have cost past generations to have kept the stock of natural capital intact. This is equivalent to the cumulative rather than annual cost of some environmental losses.

Point 2: The second often heard criticism about GPI is that it assumes that built and natural capitals are substitutable. This criticism is based on the fact that GPI values and then combines the costs and benefits of these two forms of capital. By combining these two capitals into a single index, the assumption is that decreasing natural capital and turning it into built capital will make up the difference.

It is true that if one component is decreased by the same amount another component is increased, then one does compensate the other. This does create a substitutability situation. However, this does not mean that the total economic welfare currently being enjoyed is sustainable. If it were assumed sustainable, it would be wrongly assuming substitutability of current welfare benefits with the substitutability of the capital that yields the welfare benefits.

For example, benefits to welfare of a wooden table exactly match the costs of the losses of the forest that timber came from, than welfare remains unchanged. However, a forest provides many more services then a table or any other furniture can provide, including being a source of oxygen, carbon sink, and life-support services that are needed to sustain humanity and its economic activity in the future, which includes production of new wooden furniture. Although current costs and benefits have been offset for the present, in the long-term, the ability to create additional in the future has declined. GPI was never designed to be a measure of sustainability and only does measure the current value of welfare, not that of long-term potential. Other indicators, such as the ecological footprint, need to be used in conjunction with GPI to determine whether current use and conversion of resources is sustainable.

Point 3: Unfortunately it is not possible to measure every component that contributes to human welfare. Hence, GPI will not be able to measure every aspect. GPI was designed to measure the total economic welfare generated by economic activity. It is confined to measuring whether a certain economic activity is increasing or decreasing welfare, basically to measure whether marginal benefits of GDP growth are higher or lower than the marginal costs.

Because political freedom is not a benefit that is created by economic activity, it is not, and should not be, part of GPI. On the other hand, if greater political freedom has a positive effect on economic activity, that will be measured by other components of GPI, for example in lower inequality, crime, and underemployment. Hence, greater political freedom may be reflected in GPI, but indirectly. To include it separately would be double counting.

All indicators that are made up of various components are subjective. It requires judgments to decide which components to include, which to leave out, and what weights to give each component. This is also true about GDP. GDP is made up of hundreds of components that were decided by individuals as being most critical. These GDP components have also changed over the years as society has developed and new economic activities became important.

GPI 2.0

Over the past few years, as a growing number of GPI studies have been performed globally, a divergence in methodologies has occurred. This lack of standardization is due to variations in data availability, varying needs to ensure policy relevance in specific regions, and identification of new issues such as treatment of nonrenewable resources, government spending, and others issues as stated above. To address these variations, an international effort has recently started to update the current methodology of the GPI with the most up-to-date science. The goal of such an update is to ensure that GPI 2.0 has greater comparability between studies and an increased policy relevance (Bagstad et al., 2014).

Efforts in Use of Alternative Measures

In the United States, progressive states have turned to the GPI as a tool to assist state government in identifying public policy priorities and in the application of outcomes-based budgeting. Maryland, the first state to adopt GPI as an official indicator and the one that has progressed furthest in its use, has formalized GPI calculation and reporting (McGuire et al., 2012). Vermont, in 2013, became the first state to establish a system for GPI data collection by legislative mandate (Erickson et al., 2013). Other states, with little legislative support, have calculated GPI: the Colorado Fiscal Institute, the Utah Population and Environment Coalition, and the Hawaii Department of Health (Bagstad et al., 2014).

A Shareholder's Report

As demonstrated in previous sections, the GPI moves one-step beyond earlier benchmark categories, suggesting a "full cost" accounting system for economic growth. GPI assigns monetary value to flows of natural, human, social, and built capital and

their degradation or enhancement in the course of our economic activity. The GPI adjusts gross domestic product (GDP) to account for the effect of income inequality on personal consumption expenditures, adding the value of time spent at socially enhancing unpaid work such as volunteering, and deducting "unfortunate" expenditures for social ills such as crime, and the depreciation value of our natural resources. The result can be expressed as a GPI Net Income Statement.

The GPI Net Income Statement offers a substantially more complete accounting of economic activity and its impact on our quality-of-life than conventional GDP-based measures of progress. But net income is only one part of any financial report. As the shareholders and stewards of a country's or state's natural and other resources, citizens would be best informed by seeing GPI full-cost accounting applied to the remaining components of a shareholders' report: a balance sheet and cash flow statement. Just as an income statement does not tell shareholders about a company's net assets or shareholder wealth, GPI does not tell us about either the quantity or quality of stocks of natural, human, social, and built capital. Neither does it reveal anything about the region's accumulated liabilities, such as the cost of infrastructure maintenance, stores of toxic waste, or health problems caused by loss of leisure time. It is the balance sheet that signals whether an organization is either creating wealth for its shareholders by making wise investments, or endangering its future by accumulating liabilities and degrading or depreciating its capital assets.

As an example, one of the GPI indicators, Net Forest Cover Change, assumes an underlying value for the functions performed by a healthy forest ecosystem. In addition to producing marketable products such as timber, our forests provide a range of valuable services, such as storage and filtration of water, oxygen production, soil formation, nutrient cycling, wildlife habitat, and human recreation—to name a few that typically go unnoticed and unvalued. Unsustainable timber harvesting actually increases GDP, without accounting at all for the reduced asset value on the public balance sheet from lost forest cover. GPI is an improvement in that it accounts for the lost forest cover, subtracting it as an "unfortunate" cost of economic activity. But a GPI balance sheet would actually inform us as to our total stock of forest cover, accounting for each year's net change as an increase or diminution of total asset value. Like any capital asset, that value would be determined by calculating the net present value of the flow of goods it will yield and the services it will perform over its useful life. Regional funds spent to protect or restore forest cover would be characterized as investment to the extent that they increase our forests' value. Without this full accounting for the stock and value of our forest cover, it is difficult to evaluate the financial benefits of conserving versus depleting it.

Constructing a GPI Balance Sheet will require creating a chart of accounts that includes each of the domains addressed by GPI, and taking inventory of our accumulated assets and liabilities as they are found among those domains. Assigning value to multiple domains of capital, many of which are made up of nonmarket assets that have never been monetized, is a challenging endeavor. But it is one that some progressive governments and subnational entities have begun, with pioneering methodologies. The UK's Office of National Statistics released an experimental estimate of its human capital stock, including a detailed methodology for valuing the productive capacity of citizens (Jones and Chiripanhura, 2010). The United Nations' System of Integrated Environmental and Economic Accounts (SEEA) has been revised to include a framework for valuing the market and nonmarket goods and services provided by our natural capital. The Province of Nova Scotia, Canada, has officially committed to the task of valuing natural, human, and social capital, in addition to built and financial capital, toward the goal of producing "a new form of budget estimates, a new set of accounts, and a new economic paradigm" (Pannozzo and Colman, 2009). Canada has extended its System of National Accounts to value volunteerism and the nonprofit sector as an element of its social capital (Haggar-Guenette et al., 2007). Meanwhile, the most developed conceptual framework for expanded GPI accounting has been described by the Pembina Institute for the Province of Alberta, Canada (Anielski, 2001).

The balance sheet prototype proposed here for GPI accounting is an approximation in need of considerable development and refinement. Ultimately the identification of a regions assets—public goods, natural endowments, and accumulated commonwealth—should be informed, in part, by how citizens conceptualize quality of life.

Embarking upon the project of GPI balance sheet accounting would place a country at the vanguard of an emerging trend in progressive, public sector full-cost accounting. Over the next several decades, policy-makers at all levels of government around the world will develop methods to value the nonmarketed contributions to our common wealth from previously unaccounted-for sources. Just as corporations have established methods to value intangible assets such as patents, goodwill and brand names, we need to develop standardized methods for valuing assets such as strong civic engagement, good health, and an educated populace. Our quality of life and its sustainability depend on it.

Conclusion

If we hope to achieve a sustainable and desirable future, we need to rapidly shift our policy focus away from maximizing production and consumption (GDP) and toward improving genuine human wellbeing (a version of GPI or something similar). This is a shift that will require far more attention to be paid to environmental protection, full employment, social equity, better product quality and durability, and greater resource use efficiency. These changes are clearly within our grasp, and are underway in several countries and regions. Alternative measures of progress, like GPI, are useful to help chart and guide the course if appropriately used and understood. The future we want is within our grasp, but not while we remain in the grasp of a measure of progress (GDP) that has clearly outlived its usefulness. It has often been said that you get what you measure and we need to begin to measure what we really want if we have any hope of achieving it.

Human Ecology: Overview

F Steiner, University of Texas at Austin, Austin, TX, USA

Introduction

We interact with each other and with our physical environments. We are biological creatures who depend upon the living landscape to sustain us. Plants and animals are affected by our actions, and our existence is impacted by plants and animals. We exist within complex sets of interactions – that is, we live in an ecological world.

Learning to perceive the world as a never-ending system of interactions – that is, to think about our surroundings and our relationships with our environments and each other ecologically – is challenging. Such thinking forces us to rethink our views of economics, politics, and business. It suggests different ways to plan and design. In economics, for example, an ecological view suggests a much more complex set of relationships than supply and demand: supply of what and where from and at what cost, not only in dollars but to other species and other generations. Ecological understanding can also confront our values and religious beliefs, although most faiths address human connections to the natural world and stewardship responsibilities for future generations.

Ecology is, by definition, the reciprocal relationship among all organisms and their biological and physical environments. People are organisms. As a result, we can ask, Is the use of human as a modifier to ecology necessary?

Human with ecology helps reinforce the reality of our place in environments. Human ecology seeks to understand the multiple interrelationships between the human species and our environments. Human ecology is broader than biology, but also is grounded in biological concepts. The transdisciplinary field can be defined as the study of the complex and varied system of interactions between people and their environments.

Brief Early History of Human Ecology

Many overlaps between the social and biological sciences existed at the end of the nineteenth century and during the early twentieth century. Ecological concepts were prominent in both geography and sociology. Human ecology was recognized as a unique field of geography. Geographers went so far as declaring ``geography as the science of human ecology.'' Early twentieth-century geographers sought to make clear the relationships existing between natural environments and the distribution and activities of people. However, this approach unfortunately became linked with environmental determinism which suggested that our surroundings shape everything from skin color to behavior. These concepts led to rather simplistic, and even racist, notions about how environments shaped cultures, and environmental determinism was discredited in the 1920s.

Also during the 1920s, urban sociologists adapted ecological concepts to explain settlement patterns and human interactions in cities. Called the Chicago School, these sociologists adapted observation methods from anthropology to describe urban life and culture. They described Chicago as a series of concentric rings from the central business district to the commuter zone on the periphery. They also used the ecological concept of succession to describe how these zones build up one after another as a city grows. These sociologists suggested how various groups of people succeed others in the concentric zones. This small group of sociologists used ecological concepts more as metaphors than as a tool for scientific analysis. As a result, the connections between the two disciplines were not deep, in spite of promising beginnings. Meanwhile, the advances in geography were overshadowed by the environmental determinism criticisms. As a result, human ecology faded to the margins of geography and became a historical footnote in sociology for several decades.

Increasingly, the social sciences became disconnected from the physical sciences and, by extension, from the material world. The focus of the social sciences shifted from ecological models to the embrace of economic, political, and demographic approaches where the role of natural forces was more subtle. In order to bolster the validity of their science, some researchers emphasized quantitative analysis that favored data about people over the observation of the human condition. Meanwhile, ecologists, especially those in North America, concentrated on the study of natural, nonhuman environments. Some one-third of the land in the United States is in public ownership, enabling wildlife and vegetation research on vast expanses with little human interruption.

There are many ironies in this disconnection. For example, the Greek root for both ecology and economics is the same: *oikos*. Both disciplines involve the study of the household. Ecology is the study of the environmental house, including all its inhabitants, in which we live and in which we place our human-made structures and domesticated plants and animals. Economics is the study of the household of money. As we can track the flow of money, we can also illuminate other movements in the places where we live. But beyond their common Greek root, economics and ecology diverged with few clear connections persisting.

Beginning in the 1960s, the general public became alarmed by population growth and the consequences of pollution on water, air, and land quality. Biologists and ecologists used human ecology to emphasize how people are subject to the same environmental limitations as other animals. Also during this time, anthropologists used the term to help explain the impact of

 doi:10.1016/B978-0-444-63768-0.00626-0

environment on culture. Ecologically oriented anthropologists adapted concepts like population regulation and energy flow to explain community organization. In general, early use of ecological concepts in human ecology depended on traditional views of nature, such as the tendency of systems to evolve toward a steady state.

This past suggests the ongoing utility of human ecology. By understanding the interactions and interrelationships between people and their environments, human ecology can help to:

- consider and plan for the long-term consequences of human actions;
- avoid disastrous surprises resulting from environmental phenomena such as floods, earthquakes, tornadoes, wildfires, and tsunamis;
- generate ideas for dealing with environmental challenges and opportunities; and
- create a livable and sustainable relationship with the environment.

However, to realize this utility, it is necessary to understand changes in ecological thinking generally and how human ecology fits within this ever-changing discipline.

Toward a New Ecology

Since the first Earth Day in April 1970 and the rise of the modern environmental movement, social scientists have rediscovered the environment while biologists have probed social interactions. Meanwhile, several ecologists have addressed human communities, and planners and architects have attempted to provide syntheses to shape human communities. In addition to the stimulus from popular culture, as expressed in wide-ranging areas from politics to music, advances in theory through computing technologies, urban morphology (the study of how cities are structured physically), landscape studies, and ideas about complexity have contributed to this renewed interest in the environment by social scientists. From within the biological sciences, research has altered conventional views about organism–environment interactions. Increasingly, ecologists consider human influences on their environments.

This new human ecology emphasizes complexity over reductionism, focuses on changes over stable states, and expands ecological concepts beyond the study of plants and animals to include people. This view differs from the environmental determinism of the early twentieth century. The new ecology addresses the complexity of human interactions rather than how a specific physical environment shapes human anatomic variations. Because people form part of its scope, new ecology may be viewed as human ecology, or the evolution of traditional ecology to reconsider human systems.

New ecology represents a significant reorientation that has occurred in the field of biological ecology. For example, new ecology embraces disequilibria, instability, and even chaotic fluctuations in natural and human-impacted biophysical environments. Two primary changes have occurred in new ecology, differentiating it from its traditional progenitor. The first shift is from an equilibrium perspective, where local populations and ecosystems are viewed as in balance with local resources and conditions, to a disequilibrium perspective where history matters and populations and ecosystems are continually being influenced by disturbances. The second change is from considering populations and ecosystems as relatively closed or autonomous systems, independent of their surroundings, to viewing both populations and ecosystems as open that are strongly influenced by the input and output, or flux, of material and individuals across system borders.

Traditional ecology relied on the assumptions that nature could achieve balance and that ecosystems functioned as closed systems. Natural plant communities evolved through several stages, climaxing in a steady state, according to traditional theory. Since ecologists studied plants and animals in forests, deserts, and other environments relatively removed from human settlements, their interactions could be isolated for study within closed systems.

New ecology challenges both assumptions. Living systems are viewed as changing and complex rather than stable and balanced. In addition, the boundaries between communities blur. Open systems possess fluid, overlapping boundaries across several spatial scales from the local to the global.

Ideas Contributing to a New Human Ecology

Ecology lends itself to reinvention, to reinterpretation. Relationships link things, and how we view connections among elements changes. As early as the 1950s, anthropologists called for a `new ecology'. The ideas leading to the more recent, expanding view of ecology have come from many sources and a variety of disciplines, including anthropology. The catalysts for change include advances in technologies, the study of urban morphology and landscape ecology, a broader understanding of chaos theory, and increased interest in issues of sustainability. The emergence of urban ecology exemplifies a beginning in the synthesis of these sometimes divergent catalysts. Urban ecology focuses on organism–environment interactions within cities and other human settlements. By concentrating on urban areas, the interests of the new ecological perspective are woven closer together.

Fresh ways to observe nature, primarily as a result of computer and remote-sensing technologies, have altered our understanding of functions, structures, and patterns. These new (and evolving) technologies are yielding a deeper perspective, because many events can be considered simultaneously in a connected network.

A computer technology especially valuable for revealing complex, ecological relationships is geographical information systems, known by its abbreviation GIS. These computer software programs allow analysis to study overlapping spatial data and map the results. For example, the home range of a tiger beetle species can be mapped then compared with a similar map for a species of brown bear. In turn, both can be overlaid on the migration routes of Canada geese and the extent of a coniferous forest and so on. GIS emerged concurrently with new ways to see and to record the surface of the planet, such as remote-sensing technologies. Whereas GIS programs map information, remote sensing creates imagery of phenomena on the Earth's surface.

As the Apollo astronauts approached the moon, they relayed images back to Earth unlike anything previously seen. The hypnotic pictures of the moon riveted our attention, of course, but the photographs of the blue-green orb of Earth were perhaps even more profound. Continents and water bodies were clearly visible beneath swirls of clouds, but borders had disappeared (Fig. 1). No longer would we see Earth in the manner of the little globes in our classrooms. NASA continues to produce images of the planet, as do other governmental and private remote-sensing groups. In fact, NASA broadcasts continual images of our planet on its own television network.

Remote-sensed information is collected through satellites or high-flying aircraft. The images can be enhanced with computers to reveal specific phenomena, such as land cover, land use, and fault lines. Climate patterns can be tracked and future weather events forecasted. Remote sensors can also be linked to on-the-ground monitoring stations. Such connections allow phenomena to be observed through time. For example, a drainage basin can have several stream-monitoring gauges, which may be linked to a central data collection center. In turn, satellites may be able to collect rainfall and snowpack information daily that can be combined with the field data to predict future water supplies.

The use of GIS and remote-sensing technologies has spread rapidly among scientists during the past few decades. A geologist can overlay a map of bedrock on an aerial photograph to determine where a fault line intersects with settlement. Additional technologies likely will open more possibilities. For example, visualization techniques present three-dimensional representations of objects. Such visualization can be combined with GIS to show places more holistically. The maps of the geologist and the ecologist can be rendered in three dimensions to illustrate the relationships among phenomena such as aquifers, wildlife corridors, and land use. The Internet opens opportunities, too. For instance, a team of American students can work with a group of Italians in a virtual studio, and share GIS maps and photographs of a place, say, in Africa. Furthermore, one can use websites such as Google Earth for an aerial photograph and a map of almost anywhere on the planet.

Information stored and communicated via computers reveals more and more about our interactions, with each other and with our worlds. GIS combined with real-time satellite images and the Internet provides the equivalent of a central nervous system for the planet. Humans can aspire to provide the brain for that system. How we apply our brains to use these technologies and this information will transform how we live and, therefore, the patterns of our settlements.

As the information landscape advances, we can gain a better understanding of human ecology. For example, satellite imagery can produce daily climate information for settlements. GIS can be used to map these data over time and enable the climate information to be overlaid on land-use and land-cover maps. This process reveals how we use the land and how what we plant on its surface affects

urban climate. In this way, GIS and remote-sensing technologies enable us to visualize relationships. Since human ecology is essentially about relationships, our ecological understanding advances as we reveal previously unseen connections.

We especially gain insights into urban places. Urban morphology involves the study of human settlement patterns. People create nonurban settlements as well, ranging from farmsteads and rural villages to mines and ski lodges. While suburbia might lack urbanity, it is often classified as urban by geographers. Farmsteads and suburbia have specific morphologies as well which are important to understand. However, since we live in the first urban century, the morphologies of cities and metropolitan regions especially merit attention. Population trends indicate that the world is becoming more urban. For the first time in human history, over half the world's population lives in metropolitan regions. As the planet has urbanized, the structure of urban areas has attracted increased attention by scholars from many disciplines.

Urban morphology evolved from both the disciplines of geography and architecture in Europe, where a rigorous and thorough mapping of the physical structure of cities was promoted. Mapping revealed what the Italians call *tessuto*, or the tissues of the city – that is, clusters of structures, vegetation, and roadways that hold the urban body together. The Dutch use a similar concept and their word for tissue, *weefsel*, to describe urban tensegrity. The influence of urban morphology has spread among geographers, architects, and planners in Europe, North America, and Asia. Urban morphologists advocate reading the city as a text, or as a cultural palimpsest, to reveal culture.

Landscapes possess power such as both a cultural and a natural palimpsest. Landscapes offer a scale where social and physical processes and pattern can become evident. We see landscapes and all our senses react to their well-being.

Landscape ecology focuses on the ecological relationships at the landscape scale. Landscape ecology is a study of the structure, function, and change in a heterogeneous land area composed of interacting ecosystems. European scientists advanced landscape ecology before their American counterparts. The landscapes of Europe have been more densely settled than in North America, and, as a result, the human influence was recognized quickly by European scientists. American ecologists are more accustomed to studying relatively pristine landscapes. The refinement of the landscape ecology discipline, coupled with increased suburban sprawl nationwide, has changed this situation as more American ecologists acknowledge human interactions with natural systems. As landscape ecology has evolved through multiple interactions among European, American, and Australian contributors, it has crystallized into something new and powerful. Human settlements form mosaic-like patterns on landscapes and this land mosaic vision makes the landscape readily accessible to scientists, especially ecologists.

We can see change and interactions in landscapes. Edges – or interfaces – between land uses can be especially sensitive and rich. In rapidly growing regions, edges are unstable and conflicting. New homes replace farmland. The land sells relatively cheaply. The open land provides an attractive backdrop. Agriculture practices create dust and noise. Farming often depends on chemicals that have consequences for human health. Suburbanites possess different lifestyles and expectations that vary dramatically from those of their rural neighbors. Such landscape change lends itself to scientific analysis. For example, ecologists can ask, What interactions are driving the change and what patterns are resulting?

A growing interest in the ecologies of urban areas provides evidence of a coalescence of these catalysts for change. In the United States, National Science Foundation (NSF) established two urban Long Term Ecological Research (LTER) projects in 1997. Before setting up these projects in the Baltimore and Phoenix metropolitan regions, NSF located LTERs in nonurban places. Remote locations presented ideal places for ecologists to explore the traditional concept of stable states in relatively closed systems. Increasingly, influential American ecologists began to urge NSF to consider the ecology of metropolitan regions too in order to pursue the study of more complex systems. Urban ecological systems present multiple challenges to ecologists, including pervasive human impact and extreme heterogeneity of cities, and the need to integrate social and ecological approaches, concepts, and theories.

The Baltimore and Phoenix LTERs offer contrasting urban conditions. Baltimore, located in the northeastern region of the United States, is an older city than Phoenix and has a more dense urban fabric. The Sun Belt location of Phoenix offers a city developed as a result of automobile, airplane, air conditioning, and refrigeration technologies. Whereas growth in Baltimore is rather slow, population expansion in the Phoenix metropolitan region leads the nation. The humid Chesapeake Bay contrasts the arid Sonoran Desert. As a result, the Baltimore and Phoenix LTERs can help us understand constants in urban conditions as well as specific variations resulting from the natural surroundings and from the period of settlement.

Thus far, there has been relatively little interaction between the urban ecology camp dominated by scientists and the urban morphologists led by architects and planners. Geographers are present in both groups and likely will form bridges. The substance of such spans can be provided through better-understanding human ecology.

Human ecology is important if we are serious about sustainable development – that is, economic progress that meets all of our needs without leaving future generations with fewer resources than those we enjoy – a way of living from nature's income rather than mining its capital account. Sustainability requires that human communities are adaptable to change, that natural processes and landscape functions are protected, and that resources are conserved for future generations. To be adaptable, communities need to be resilient. We must understand the organization – the function, structure, and processes – of the communities that we inhabit in order to lay the foundations for the future.

Perhaps the growing interest in sustainable development – in seeking to make communities more livable – derives from a sense that we are living in places where something is out of whack. Perhaps the creative impulse derives always from a dread of the future, the feeling that the world may not improve for our children, and our desire to fend off doom to improve things for those who follow. To sustain things, we must keep them from falling apart, now and in the future. All around us, things indeed appear to be coming apart at the seams. Where once children played in the park, now homeless people sleep. Where there was once a vibrant downtown, there are now vacant lots.

The farm field, the park, the downtown; the convenience store, the homeless people, the vacant lots, all form pieces in larger mosaics, larger processes. In itself, the field or the convenience store is neither good nor bad. Both, however, are part of larger systems that may be either healthy or sick, that is, either capable of sustaining themselves or not. The individual farm field contributes to a regional agricultural system. The crops produced in the field help sustain the regional economy. The crops support not only the farm family that produces them, but the local co-op that processes the crop for the market and the tractor dealer as well. The convenience store has an asphalt parking lot. Its impervious surface contributes to regional drainage and flooding problems because of increased runoff. Because the parking lot is black, it adds to the urban heat island effect resulting in summer discomfort among nearby residents. The understanding of how living systems are organized from the local to the regional provides a means for assessing their capabilities to adjust to change.

Nested Networks

Living systems are organized hierarchically and communicate through feedback networks. The elements within a system may vary greatly in organization. According to urban morphologists, urban form can be understood at different levels of resolution. Commonly, four are recognized, corresponding to the building/lot, the street/block, the city, and the region. A building may be tall or short, with a pitched roof or a flat one, brick or wood or adobe. A lot, a street, or a block may be narrow or wide, straight or curved. A city may be densely settled or spread out. A region can be defined by a river or a mountain or a coastline or all three and by other factors.

Hierarchies help us understand how people are connected with one another – the basic idea of community. To understand human ecologies, the most relevant levels of organization include habitat, community, landscape, region, nation and state, and Earth or ecosphere. These levels present different, yet interconnected, scales of analysis. Each level possesses a history and a literature of analysis and debate. The habitat includes the building and lot. The community is comprised of buildings, lots, streets, and blocks. Landscapes can be urban, suburban, rural, and wild. Regions are hodgepodges of landscapes, while the distinctions between regions, and often those between states and nations, are even more blurred. But there is less ambiguity about the ends of the Earth.

Each level of human organization (nation, state, region, county, and city) is an element in a larger system, but is also comprised of smaller geographic units like neighborhoods and communities, which are, in turn, collections of single households. Home and work places form the habitats for people and are further divided into cells we call rooms. Hierarchy may be seen as a framework, a system of nested networks.

A critical feature of these nested networks is an asymmetric interaction in between levels. The larger, slower levels maintain constraints within which faster levels operate. There are, however, circumstances when slower and larger levels in ecosystems become briefly vulnerable to dramatic transformation because of small events and fast processes. Large, slow levels tend to keep things in place. Small, fast levels initiate changes when the larger levels are not functioning effectively.

Viewing the world hierarchically does not necessarily imply seeing it through a machine-like lens. Rather, it is to suggest components of a vocabulary to read our surroundings, our world.

Traditional ecology was commonly grounded in the assumption that somehow nature is in balance. Even the most casual observation of the human condition indicates that we are seldom balanced in our affairs. Nonequilibrium represents an important change in thinking. An equally, or perhaps even more important change derives from viewing environments at multiple, interacting scales. Landscape-level ecology, in particular, provides spatial form and function to nature's flows and human activities. New ecology, a deeper understanding of interactions at various scales, holds the prospect for better, although more complex, approaches to sustainable resource management, nature conservation, and environmental protection as well as the arts of environmental design and planning.

Practical Applications of Applied Human Ecology

Since the 1970s, natural and social scientists initiated multidisciplinary research addressing practical problems related to the environment. For example, the United States and many other nations require an environmental impact analysis of the consequences of larger projects. Such analyses are often performed by multidisciplinary teams, with human ecology providing a common set of concepts among disciplines.

Human ecology can also assist community and regional planning. For example, the Phoenix, Arizona (USA) metropolitan region is well known for its rapid growth and its suburban sprawl. Much of the post-World War II development has occurred in a similar pattern of low-density, single-family homes that is highly dependent on the automobile.

Beginning in the 1990s, city officials sought to encourage different patterns of development for North Area which comprised 20% of the land within the city. Using corridor, path, and matrix principles from landscape ecology, 28% of the most environmentally significant areas in the 110 square mile North Area were preserved as open space. Through an analysis of current and

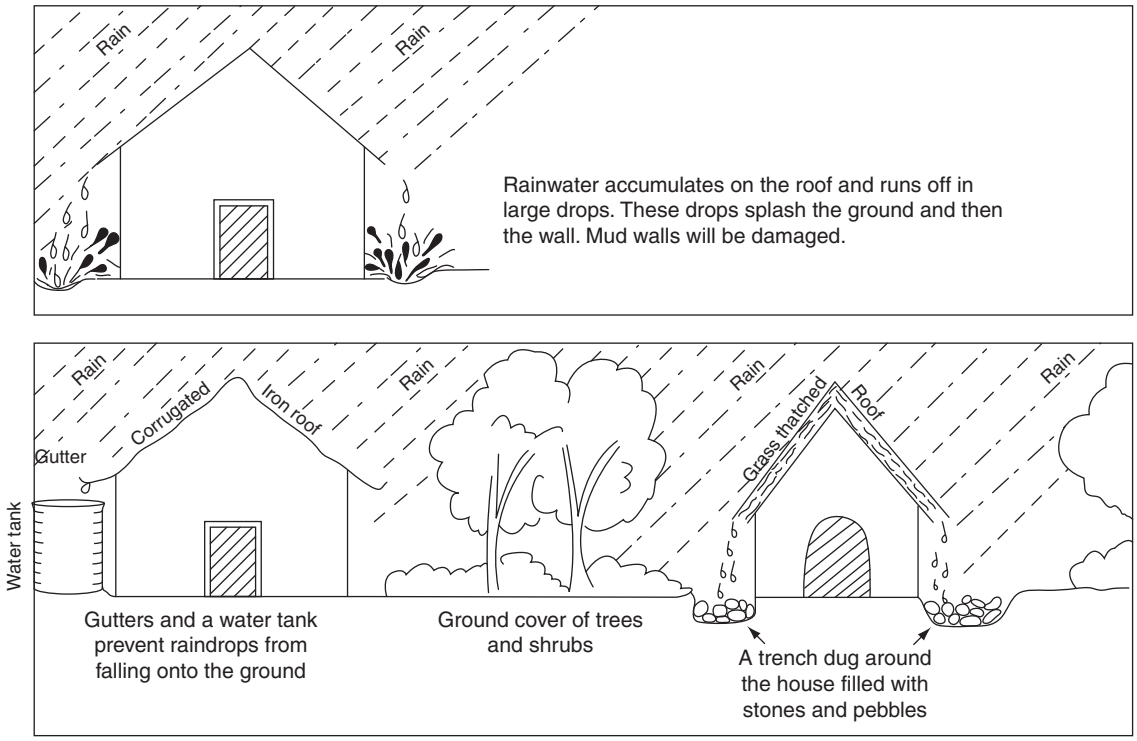

Fig. 5 Strategies for collecting rainwater in Kenya. From Duchhart I (2007) *Designing Sustainable Landscapes: From Experience to Theory*. Wageningen: Wageningen University.

potential residents, three future settlement patterns, instead of one, were suggested for the rest of the North Area. In suitable places along transportation corridors, greater urban density was recommended that included green ribbons of natural drainage. In other locations, a very low-density, low-impact rural desert settlement was suggested.

Since people in Phoenix are attracted to suburban development, suitable areas for such settlement were identified. However, a new form of desert suburban development was designed. This settlement would be aligned with natural drainage systems, preserve native vegetation and wildlife habitat, encourage the planation of native species, reduce the amount of impervious surfaces for roadways, use natural building materials with a local color palette, and keep building heights below the tree line (**Figs. 2** and **3**).

Around the world from Arizona, Kenya is also experiencing a growing population and declining natural resources. A multidisciplinary team of Kenyan and Dutch researchers conducted extensive landscape and human ecology analyses which led the Green Town program. The motto of the program was `make every town a green town'. In all, some 29 small towns across Kenya became involved in the effort which included considerable ecological training of local officials.

The Green Town program emphasized locally derived, sustainable designs. Shaded market areas were suggested as well as agroforestry practices to produce fuel and food. In addition to increasing fuel wood and food products, the agroforestry techniques reduced soil erosion and storm water runoff. The Green Town program suggested strategies for urban tree plantation as well as ways for individual homes to collect rainwater (**Figs. 4** and **5**).

Summary

Human ecology involves the interrelationships among people, other organisms, and their environments. Human ecology emphasizes complexity and change. Urban morphology and landscape ecology offer two approaches to study the structure, function, and processes of human settlements. Hierarchy also aids in the understanding of how people organize themselves spatially on various scales from the individual room within a house, office, school, or factory to the neighborhood and community on to the region, state or province, and nation. Applied human ecology presents many practical applications including the analysis of the environmental impacts from specific, proposed projects to the planning of communities and regions.

Human Population Growth☆

Anne Goujon, Wittgenstein Centre for Demography and Global Human Capital (IIASA, VID/OEAW, WU), World Population Programme/International Institute for Applied Systems Analysis, Austria

Glossary

Demographic transition It depicts the transition of a country or a region from a demographic regime of high birth and death rates to one of low birth and death rates.

Second demographic transition It is the phenomenon that occurs in a country or a region where sustained sub-replacement fertility eventually results in declining population if not compensated by new migrants.

Total fertility Rate The number of live children who would be born per woman if all women lived through their childbearing years bearing children according to a current schedule of age-specific fertility rates.

Under five mortality rate It is the number of deaths of infants and children under five years old per 1000 live births.

Human capital It is a collection of traits representing the capacity of the people to be part of the labor force and to produce economic value. In models, it is often operationalized using the parameters of education, skills and health.

Introduction

The sheer number of population has been for long the main (and only) consideration about human population growth in ecological engineering and in other fields that are reflecting on the sustainability of life systems on earth. The inflation in the availability of data on humans' behavioral patterns depending on the characteristics of these humans and their environment should change that. What is important is not only how many people there are or will be but what they do and will do in their everyday life which could impact life systems and how equipped they are and will be to face the challenges of the future. This gap in understanding has been the reason why most of the doom prognosis were not realized—starting with Malthus' theory about population growth outstripping food production. They failed to predict the capacity of humans to innovate and overcome the challenges they were faced with within the limiting capacities of earth boundaries. However, the challenges exist, and in the coming decades, the survival and well-being of humans and the security of environmental resources that support human existence will continue to be challenged by rapid population growth, particularly in less developed regions that are the main contributors to world population that is, sub-Saharan Africa and Southern Asia. Nevertheless it is clear nowadays that almost all societies that all started with patterns of high fertility and high mortality are moving through the demographic transition process. As we enter the new millennium, the capacity of humans to come up with innovations, solutions and adaptive measures will need to be strengthened in order to deal with the stark contrasts between the availability of natural resources and the billions of humans who require them to sustain life. Education will play an essential role in that.

The Demographic Transition Theory

The Demographic Transition Theory is the driving theory of the evolution of human population. Developed by Notestein in 1946, the theory categorized the several stages of historical and present population into a continuum of demographic development. Eventually according to this theory, all societies evolve from a pre-transition situation (stage 1) where fertility and mortality are unchecked and high producing low population growth to a stationary population (accomplished in stage 4) which is realized when a society reaches low levels of fertility and mortality. This is quite certain and the exceptions so far have been only of temporary nature. While fertility decline has stalled at several times and in different settings, for instance as a result of cuts in social government budgets in many sub-Saharan Africa following the implementation of structural adjustment policies by the World Bank and the International Monetary Funds, the fertility decline has resumed thereafter. The main uncertainty is about the pace of the fertility and mortality decline between stage 1 and stage 4, which has many implications for population growth. In the case of most industrialized countries, where the transition was slow and happened over many decades, population growth was not so dramatic. This was the case in many European and other industrialized countries. The situation has been different in countries that started their transition in the second half of the 20th century when many advances had already been made and hence mortality rates dropped relatively abruptly while fertility was kept at quite high level for some time. While it is very likely that the fertility will go down, it is difficult to know how long it will take. Whether for instance Nigeria reaches replacement fertility in 2070–75 according to the low fertility variant of the United Nations or in 2095–100 according to the medium variant, makes a different of about 130 million in 2100 (567 vs. 794 million): the population of Mexico nowadays. As we

☆*Change History*: March 2018. Anne Goujon updated text.

This is an update of D. Pimentel and M. Pimentel, Human Population Growth, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 1907–1912.

 doi:10.1016/B978-0-12-409548-9.10755-9

will see in the next section, the pace of the fertility decline has indeed huge bearing on the future number of humans, not only for Nigeria. The second uncertainty, also with important bearings is the number of children the population would eventually have. This goes behind the theory of Notestein, adding a further stage (stage 5), also called the second demographic transition in which fertility is so low that generations do not replace themselves and the population starts declining. Here again, most industrialized countries seem to be on this path. For instance in many Eastern Europe countries, women have less than 1.5 children on average and fertility does not seem to recover to replacement level fertility. In those countries, also with the effect of emigration, population is already declining for example, in Bosnia Herzegovina or in Hungary. Japan is another country where fertility has been declining for some time and since 2010, the population has been declining. Whether all countries that are at present going through the demographic transition will also experience the second demographic transition will also be key to the future number of people on the planet. Some researchers contend that the arrival of contraception has ruptured the evolutionary link that existed between the sex drive and reproduction, the fertility of women and couples will be more and more determined by their individual preferences for children (or not) and by norms that will be culturally ascertained. In that sense, it is not necessary that individuals and couples, and societies at large, will want to replace themselves. We will need a few more decades to see the evolution of that phenomenon and whether some societies are trapped in low-fertility. It is worth noting that the governments in countries that are faced with low levels of fertility most often engage in providing financial and structural benefits to support childbirth that are not crowned with success, for example, in South Korea, tending to support the point about an individualization of the fertility decision process (see also the case of China below).

But having the two uncertainties in mind, about the pace and the bottom level of fertility that tells us that there is hope that world population will eventually peak and diminish, it is still not automatic; it is also pretty certain that the 21th century will witness continued population increase, and that these will not occur globally but will be concentrated spatially in the poorest socio-economic settings. To halt the growing imbalance between human population numbers and their essential resources, humans must actively conserve cropland, freshwater, energy, and the other basic environmental resources. There is a critical need to alert the public worldwide to the serious issues of overpopulation and natural resource shortages. Education will be key in that both in developed and developing countries. While most of population growth will happen in developing countries, certainly populations in developed countries could contribute to the conservation effort by reducing their high consumption of all resources, especially fossil fuels. Focus is needed on improving food crops, such as developing perennial grains, pest-resistant crops, and improved nutritional makeup of crops. The development of ecological engineering can help encourage the development of sustainable ecosystems and aid human society to make better use of our natural resources. There is a critical need to educate the public worldwide in order to comb overpopulation and natural resource shortages.

In this article we will examine the current world population situation and how it might evolve depending on several scenarios. We will focus on the role that quality education could play in providing humans with the necessary capacity and ecological engineering requirements to deal with present and future environmental challenges.

World Population Growth

Global Picture

World population growth did not receive much attention until the end of the 20th century for several reasons: the first one being the absence of systematic population data collection exercises and the second that world population increase was minimal due to high mortality rates especially among infants and children. Hence it went unnoticed when the world population reached 1 billion at the turn of the 19th century. The current world population of more than 7.6 billion, doubled during the last 46 years. The uncertainties and impact of the several component of population growth are visible in **Fig. 1** showing estimates of the past and the future number of humans based on several scenarios developed by the United Nations. Although, no probabilities are attached to any of them some seem more plausible than others and some more desirable than others. Several lessons can be taken from this graph. The three top scenarios that give the highest population in 2100 are those where fertility stays constant or declines only marginally. According to those variants, the world population would be between 17 billion (high fertility) and 26 billion (constant fertility). These scenarios imply that fertility decline would come to a stall everywhere—which is very unlikely—and would have dire consequences in terms of population growth in poverty stricken countries. The five remaining scenarios all project the world population to be under 11.5 billion in 2015. The most likely one under present circumstances is the medium fertility variant—it shows the population increasing to 11.2 billion by the end of the century with the world population still not having reached a peak (but leveling off convincingly). It is interesting to see the impact of the momentum of population growth that can be seen in one variant showing a peak at 9.3 billion around 2060, and then started declining. Indeed, worldwide, a major obstacle to limiting population growth is the relatively young age structure—especially in the respective female fecund ages between 15 and 49—with high reproductive rate. Even if all the people in the world adopted a fertility pattern of bearing only two children per couple, it would take approximately 40 years before the world population would finally stabilize at approximately 10 billion. The momentum—also called population inertia—becomes also visible in the fact that until 2050, there is little deviation between the global population numbers although they follow different scenarios. While trusting more the five scenarios that result in a lesser population growth, it is still obvious that they lead to a 2–2.5 billion in population increase from today's level by the mid of century. The low fertility variant is interesting and seems the most suitable one from an ecological point of view as it means a world population peak in 2053 at 8.8 billion further declining to 7.3 billion in 2100. It is worth noticing that these scenarios do not and cannot take into account abrupt events that could occur at any time, such as the spread of a new epidemic, a war, or a baby-boom.

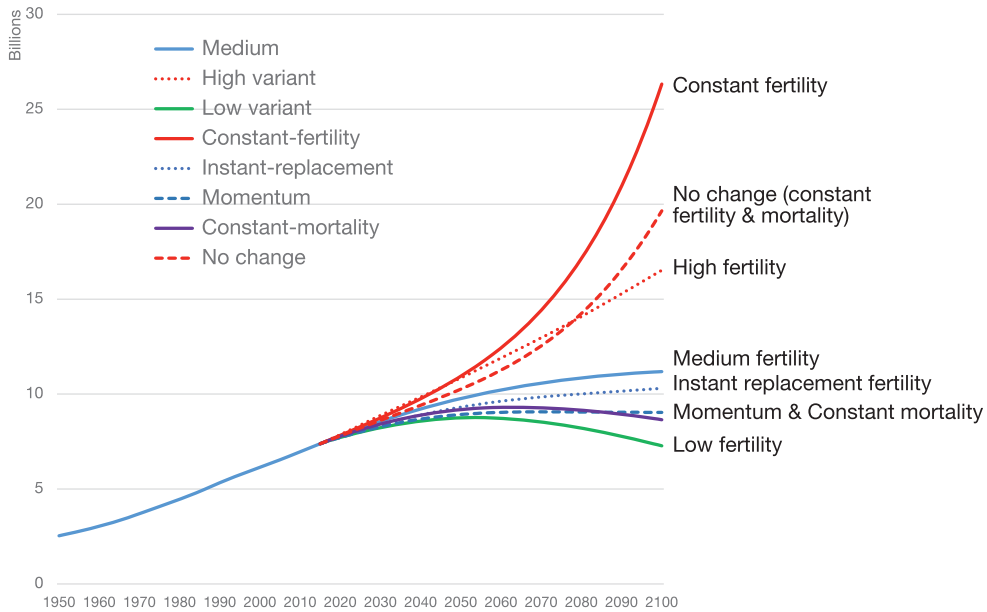

Fig. 1 World population, 1950–2100, estimates and projections according to eight variants. Source: United Nations World Population Prospects (2017).

Regional and Country Level

Global population levels hide important differences in the projected pace of population growth across continents, regions and levels of development (see **Table 1**). In 2010–15, while the world population was increasing at a rate of 1.2%, some regions were shrinking for example, Eastern and Southern Europe or close to stabilization, for example, Western Europe, some others were increasing at a strong rate, for example, Eastern, Middle, and Western Africa. However, population growth rates are on the decline in all countries of the world today—this is visible when comparing for instance the growth rates observed in 2005–10 and 2010–15—and are forecasted to do so in the future as well. **Table 1** shows that at present, less developed regions are the main contributors to world population growth and particularly sub-Saharan Africa and Southern Asia. What is clearly visible is that sub-Saharan Africa would be the main contributor and by far according to the United Nations medium variant in the second half of the century.

The population of China with 1415 million people will keep slowly increasing until 2030 when it would peak at 1441 million and then slowly decline back to 1021 by the end of the 21st century. In 2017, the government ended the one-child policy (that was in effect for more than 30 years) in order to balance rapidly aging population by allowing families to have two children. However, the first year of implementation supports the low-fertility-trap theory that the country has moved to a lower-than-replacement fertility norm and that couples are less likely to wish and bear more children than the previous generation for multiple reasons: strong urbanization and price constraints, women's participation in the labor force, decrease in the preference for boys, etc. India, with 1354 million people, and living on approximately one-third the land either of the United States or China, would keep growing albeit at a slow average annual rate of 0.5% until 2060—surpassing China's population around 2025—and then decline. Total fertility rates have declined very rapidly in all Indian States and in about half of them, women had below replacement fertility in 2016 (e.g., in the highly populated States of Tamil Nadu and West Bengal), and the increase in population is mostly due to the momentum of population growth. At present, the populations of China and India constitute more than one-third of the total world population. They would be around 23% in 2100.

As above mentioned, the sub-Saharan Africa sub-continent will experience most of the world population increase in the next decades. According to the medium variant of the United Nations, population in sub-Saharan Africa would more than double from around 1050 million in 2018 to more than 2.5 billion in 2060 and possibly exceed 4 billion in 2100. The strong increase can be explained by two main factors. The first is that against all expectations (in respect of levels of socio-economic development) infant and child mortality rates have recorded a substantial decline of more than 50% between 1970–75 and 2010–15. As a result, life expectancy has increased by more than 20 years since 1950, from 36 to 57 years, despite the HIV/AIDS epidemic that has slowed down and even reversed the progress made in many countries particularly in Southern Africa. The second factor is the fact that fertility has been slowing down at a snail's pace. Women were having on average more than six children between 1950 and 1995. Fertility started declining faster after the 1995 period but it was still around 5.1 children on average in 2010–15. The fact that the demographic transition to low fertility and mortality levels has adopted a slow pace stems from several reasons having to do the persistence of low levels of socio-economic development in mostly rural traditional societies. The pace of future declines will be an important determinant of population growth. Increase in the levels of educational attainment could play an important role, most notably through the impact it has on fertility and mortality (see section below). In some of the largest countries (Nigeria, Democratic Republic of the Congo, Tanzania, Uganda), the population would more than quadruple between now and 2100

Table 1 Contribution (absolute and percentage) of regions to world population growth from 2015 to 2100

		Increase in absolute (in million) between			*Contribution to global increase (in percent) between*

Table 2 Population of the top 10 most populous countries in 2018, at peak and in 2100

Country	*Population in 2018*	*Population at peak*	*Time of the peak*	*Population in 2100*
China	1,415,046	1,441,574	2029	1,020,665
India	1,354,052	1,678,656	2061	1,516,597
United States of America	326,767			447,483
Indonesia	266,795	324,763	2062	306,026
Brazil	210,868	232,845	2047	190,423
Pakistan	200,814	354,297	2090	351,943
Nigeria	195,875			793,942
Bangladesh	166,368	202,970	2057	173,549
Russian Federation	143,965	143,990	2017	124,013
Mexico	130,759	167,327	2063	151,491

according to the medium variant of the United Nations. Nigeria would have a population of almost 800 million in 2100 and Niger, one of the poorest country of the world would multiply its population eight times in the next 80 years (from 22 million today to 192 million in 2100).

The United States population is also still growing and currently stands at nearly 327 million, having doubled during the past 60 years. Based on the current trend, it is projected to reach 400 million by 2060 and 450 by the end of the century. Out of the ten most populated countries shown in **Table 2**, the United States and Nigeria are the only countries that are not forecasted to attain a maximum over the century. The population of the Russian Federation has peaked in 2017 according to the estimates/projections and is shrinking.

As world populations continue to expand, all global resources will have to be divided globally among increasing numbers of people and per capita availability would decline to ever lower levels. However and as already mentioned, the population pressure

will not be the same everywhere. At the level of less developed countries where this kind of pressure will be the strongest, improving personal health, and achieving prosperity, a suitable quality of life, and personal freedom will be more difficult and will require innovation and leadership. Population models and ecological engineering taken up by education may help people and governments better understand the critical situation and what, if anything, can be done to address the challenge.

The challenges that earth systems will face with an increasing population are serious and of different kinds. Malnourishment is one of them. In 2016, in a world where there is enough food to feed each and every one, about 815 million people (11% of the world population) were affected by hunger and for the first time, after declining over a decade, global hunger was on the rise again according to the 2017 United Nations State of Food Security and Nutrition in the World report. The increase is due to the proliferation of conflicts in combination with severe drought and flood episodes. Providing enough food to meet the nutritional need of the 2.5 billion people that will be added between now and 2060 is one of the biggest challenge of the century. Achieving food security requires a multi-sectoral approach from conflict resolution to strengthening the productivity of small-scale food producers, improving the resilience of food production systems and the sustainable use of biotechnology and genetic resources.

Education

Some population growth is certain. While many scientists including ecological engineers research on the way to optimize and increase the resources in terms of cropland, water resources, energy, while at the same time preserving biodiversity and avoiding as much as possible climate change, some other academic research focuses on the pathways to influence the number of human population and secondly the behavior of the population. Scientific findings tend to demonstrate that in both education has a role to play (Goujon, 2003).

Education and Sustainable Development

The transformative channels through which formal education affects demographic parameters are well known. Formal education is mostly important for its influence on the fertility of women that have been through the education system and on the mortality of children born to those women. The mechanisms are multiple: girls who go to school first of all are exposed to the environment and society outside of their own household and often of their neighborhood, breaking their isolation. There is often already a large difference between the number of children born to a woman who had been to primary school, even if she has not completed all grades and a woman who has never been to school; the difference is as large as two children on average in Kenya and in the Dominican Republic. If girls stay in school, they will delay marriage and hence the onset of fertility. Furthermore, having an education increases the chance of finding employment outside of the house and therefore increases the opportunity cost of having children. The more education a woman has the more likely she is to use modern contraceptives, space the birth of her children. By increasing her autonomy, education will increase her say in household (including fertility) decisions. The transition to lower fertility supposes that there is a time when fertility is not given anymore but becomes within the calculus of choice of couples, particularly women. Education is one of the most influential factor that will make sure that this happens. **Fig. 2** shows the difference in the number of children born to women with a higher education (any studies beyond upper-secondary) and those born to women who have never been to school (or less than a year). Differences are larger in sub-Saharan Africa and can exceed four children like in Angola (more than five-child difference), Mozambique and DR Congo.

As well, education will have an impact on the number of surviving children of these women. This is important for the demographic transition as limiting the number of surviving children will first occur when the probability of child survival increases. **Fig. 3** shows that the chance of survival to the 5th year is much higher for children born to mothers with a high education (secondary or higher) than to mothers who have a low education (primary or less) in many developing countries in recent years. For instance, in Burundi, the mortality rate of children born to mothers with a primary education or less was as measured in 2010 more than twice that of children born to mothers with a secondary or higher education (132 vs. 47 deaths for 1000 live-births). Many surveys confirm that maternal education is the single most significant determinant of child mortality. Educated mothers are more likely to seek treatment for their sick infant or child and break with tradition about illness. Having gained autonomy through education, educated women will be more apt to challenge their mother in law or the head of the household. The education of women is also likely to affect beneficial changes in nutrition that play a part in a decline in infant and child mortality.

What could be the impact of strong increases in educational attainment on future population growth is shown in **Fig. 4** which compares the results of two scenarios. The left-hand side graph assumes a future in which the world is moving toward a more sustainable path (so called "Sustainable world" scenario). It assumes that educational and health investments accelerate the demographic transition, leading to a relatively low world population with increased well-being. As a result in 2100, the world population is already shrinking and the vast majority is well educated. The graph on the right hand side refers to a fragmented world with an emphasis on security at the expense of international development. In this divided world, population growth is assumed to be high in developing countries and low in industrialized countries (so called "Fragmented world" scenario). As a result the world population is high at the turn of the century and population growth is unabated. Moreover large segments of the population particularly in less developed countries have low levels of educational attainment.

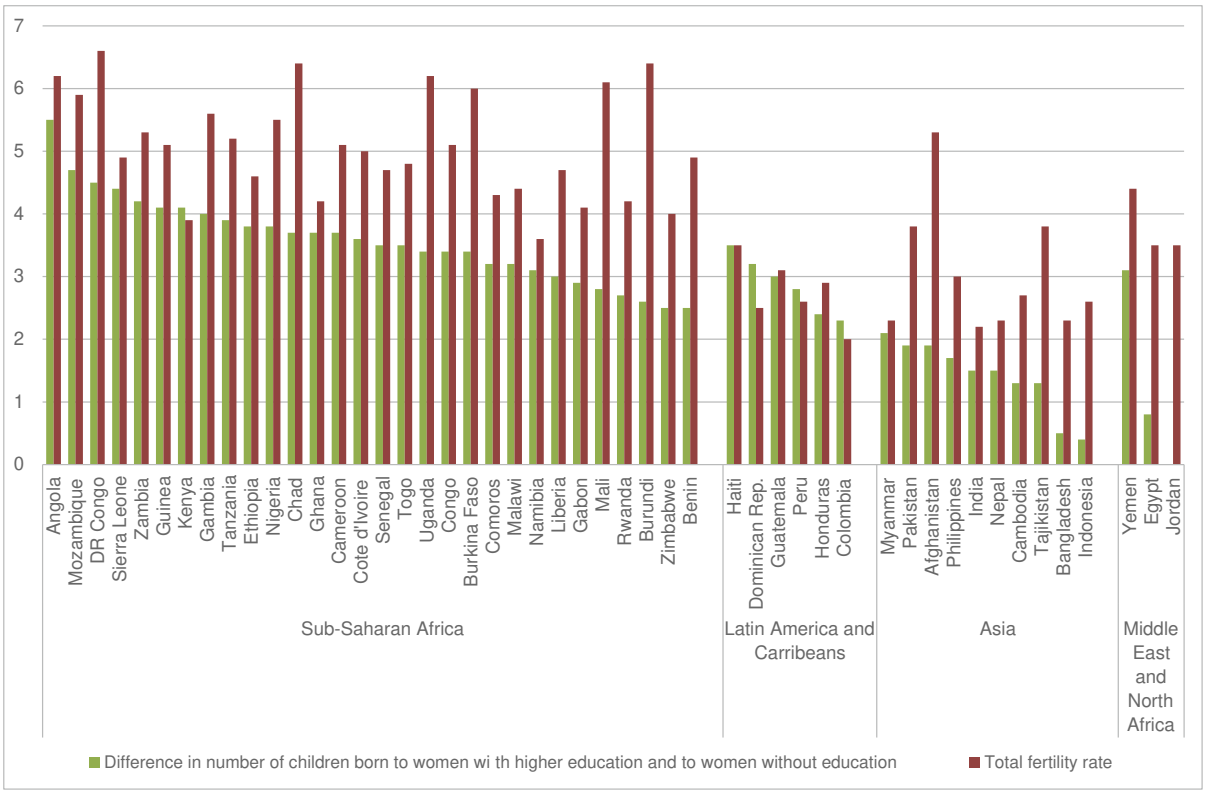

Fig. 2 Difference in the number of children born to women with a higher education and to women without education and total fertility rates, selected less developed countries, since 2010. Source: ICF International, (2015). The DHS Program STATcompiler. Funded by USAID. https://www.statcompiler.com, (February 9, 2018).

Beyond the purely demographic effect of education on the number of people, it is clear that education is key to development. It increases the innovation capacity which will be necessary to face the challenges. It also increases the resilience and adaptive capacity of humans in case of a disaster (such as a Tsunami) or another triggered climate change extreme event. The effect goes beyond the mere survival to extreme events as it was shown in a study of population in Thailand in the aftermath of the 2012 Indian Ocean earthquakes. Living in a community with a higher proportion of women with high education increased preparedness through community engagement of the more educated and carrying out disaster risk reduction measures. Overall the more educated have a longer time planning horizon, which is also the reason why they adopt healthier behaviors (related to nutrition, sport practice and smoking behavior for instance) and tend to be more supportive of environment-friendly behavior (vegan diet, consuming bio-product, biking to work, etc.).

Education for Sustainable Development

Education for sustainable development (ESD) was introduced as part of the targets of Sustainable Development Goal four on education (in Targets 4.7). It is accompanied by an approach to promote the Global Citizenship Education (GCED) within education for sustainable development. The main idea is that transformative ideas are better learned at young ages—the same as other competencies such as riding a bicycle or politeness. This will mean changing the curricula in many countries to have more global components and as well developing cross-cutting sustainability competencies in pupils. This would enable individuals to contribute to sustainable development by promoting societal, economic and political change as well as by transforming their own behavior. Educated people are also more likely to live in democracy and in less corrupted regimes as they may influence the system. Whereas the physical constraints of the planet are more or less set, the future innovative capacity and behavior of its inhabitants are not known. Education may be in this sense the missing link to sustainability.

Why Prediction of Human Dooms Were Wrong (Until Now)?

Along the centuries, concerns were often raised by scientists who were the witness of rapid population growth. The most cited essay by Malthus (1798) warned against the danger of exponential population growth that would ensue out of the evolution of the

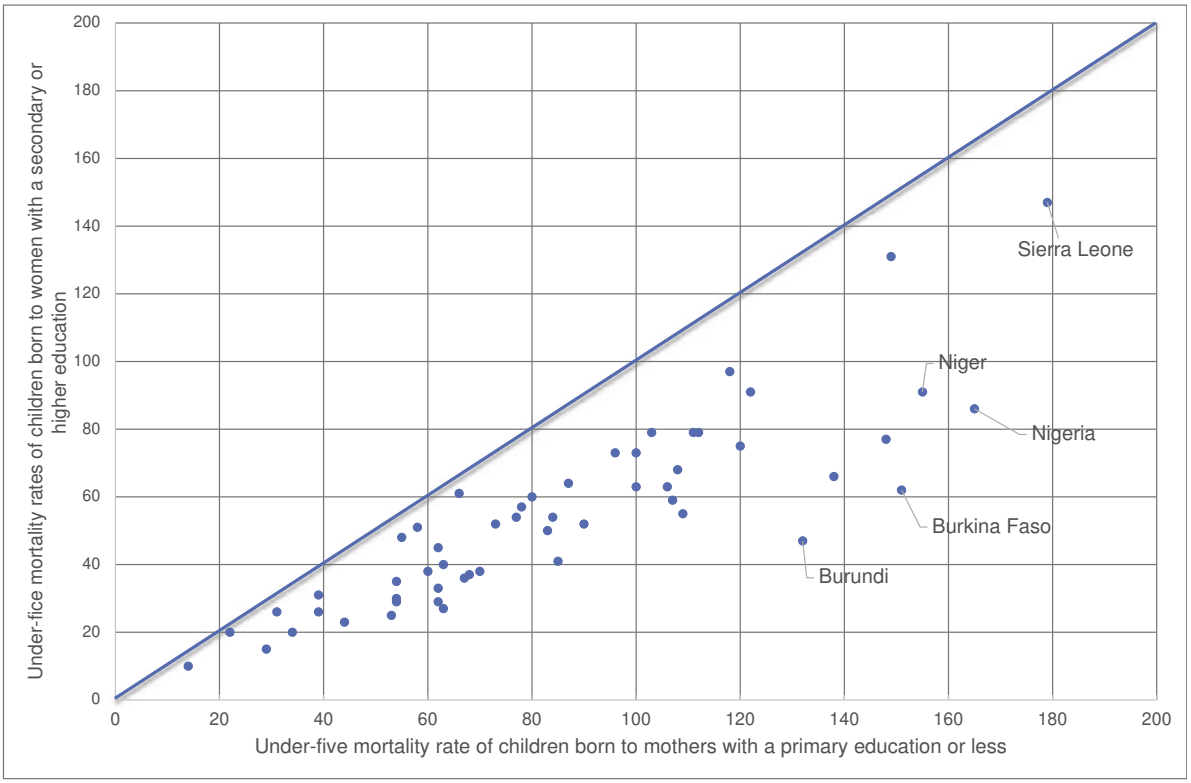

Fig. 3 Comparison in 54 countries of the under-five mortality rates of children born to mothers with a primary education or less (*x*-axis) and those born to women with a secondary education or more (*y*-axis). different components of population growth in the presence of limits to food production. At this time, the agricultural and industrial revolutions had improved the living conditions and healthcare in Europe, mortality rates were declining and fertility rates were unabated. This essay was the first of many alarmist theories by scientists such as "The Population Bomb" book authored by Paul Ehrlich in 1968 that predicted famines and civil-war in the 1970s and 1980s as a result of population growth. This book was a precursor to the "The Limits to Growth" report published in 1972 which projects the combined impact of exponential population growth with a finite supply of resources. So far those predictions have proved wrong because they take humans as irrational being incapable of changing and adapting to circumstances. Already at the time of Malthus, Condorcet (1743–94) was pointing at the power of an improved intellect. Democratic governance, access to family planning, and the education and economic empowerment of women has proven so far to be able to curve population growth.

The merit of these alarmist scientific works is that they brought to a wide audience, awareness about population and environmental issues.

Conclusion

While it seems almost certain that the world population will peak within the next 100 years, it will be preceded by the probable addition of 2–3 billion people. Most importantly these people will be born in countries that are at the moment most stricken by poverty. While this is a challenge for humanity and for the ecosystems surrounding them, it is also evident that it does not have to be a failure. There is a need for action at present and in the future for influencing the behavior of the people who live on the planet. Education might be key in bringing the change that will help societies to face the global challenges.

Industrial Ecology☆

F Duchin, Rensselaer Polytechnic Institute, Troy, NY, USA
SH Levine, Tufts University, Medford, MA, USA

Industrial Ecology: Human Activities and Global Ecosystems

The field of 'industrial ecology' was created to inform purposive human decision making about industrial production processes, especially as they impact the environment, by taking advantage of knowledge about the functioning of healthy ecosystems. These ecosystems are characterized by their vigor, maintenance of diversity, resilience, and relative stability over time. Other ecosystem properties seen as potentially desirable in industrial systems include minimal use of virgin materials and maximal use of renewable, biodegradable resources, minimal production of toxic waste products, and, more generally, sustainable use of resources. More recently the scope of industrial ecology has enlarged to include decision-making regarding consumption activities as well. Human decision-making is important because humans, while one species among many, are responsible for dramatic and far-reaching changes to the global environment and thus to the existence of other species.

Industrial ecology is not the only new, cross-disciplinary field employing the word 'ecology'. Among others utilizing the ecological metaphor are the ecology of the family, organizational ecology, and ecological economics. In all cases the intention is to suggest that the field in question constitutes a complex system, in some instances with direct relations to biological ecosystems. The 'ecology of the family' focuses on how family members are shaped by their interactions, both competitive and mutualistic, with one another. 'Organizational ecology' applies population dynamics models to the births and deaths of firms and industries and examines how the evolution of organizational structure is shaped by competitive and cooperative interactions. 'Ecological economics' departs from the observation that natural ecosystems uninfluenced by human activity no longer actually exist: counting both economists and ecologists among its numbers, it attempts to integrate the two professional domains. Industrial ecology is distinctive in its focus on the industrial system, literally treating it as an ecosystem or, more exactly, the subsystem of principal interest within a more inclusive ecosystem. The flows of energy and material characterize an industrial system and serve as the integrating focus of all description, design, and analysis in industrial ecology. Not merely analogous to the flows of energy and material in ecosystems, they actually constitute those flows. The production and consumption activities of humans can be described in terms of these flows just like the activities of any other animal. Given this focus on industrially valuable resources, it is not surprising that most of the field's founders were engineers or applied physical scientists with interests in chemical processes and effluents and, more generally, the reduction, reuse, and recycling of industrial wastes.

Industrial ecology is motivated by its concern for the well-being of the environment. As the inclusion of ecology in its name indicates, it puts special emphasis on developing and implementing solutions and policies at the system level, up to and including the global system. Central to the system perspective is the concept that the behavior of individual components cannot be fully understood without reference to the system in which they interact. Industrial ecology explicitly recognizes that human industrial activities in the modern industrialized world are characterized by the interdependence of many industries, each industry itself often performing many interconnected production processes, all reliant on inputs of energy and materials and discharging wastes.

System scientists have long understood that the basic features of a system of interacting components need to be understood in a top-down fashion, even though many processes operate at the level of component parts. In the case of system design, top-down and bottom-up contributions generally proceed in an iterative fashion. This system perspective influences the direction that industrial ecology takes in confronting environmental challenges: improving the environmental compatibility of individual industrial processes is evaluated in the context of improving the overall industrial system. A simple illustration is provided by Fig. 1, which combines two waste streams, fly ash from coal-fired power plants and waste plastic from plastic manufacturing, into a useful product, light-weight building blocks. At the same time the waste heat and carbon dioxide from the power plant can be supplied to a large-scale greenhouse, leading to increased production of fruits and vegetables. These are both examples of 'open loop' waste reuse. ('Closed loop' use of waste is represented in Fig. 1 by the recycling of waste plastics by the plastics factory.) Reducing any of these waste streams might both increase the unusable waste from the others while also reducing the quantity of useful product. Interestingly, recognizing the value of waste as a resource is a major theme of industrial ecology.

The tracking of resources, intermediate products, final products, and wastes can be conducted at the level of business establishments, towns, nations, or in the context of nations interacting in the global economy. The analysis of these flows, as a basis for action, can also take place at all these levels.

Resources and Products in Industrial Systems

The industrial system and the natural system were long seen as separate although overlapping domains. Economists, for example, used to treat resources as 'free gifts of nature' and therefore exogenous to their concerns, limiting the designation of so-called factor

☆*Change History*: August 2014. F Duchin and SH Levine updated the text and references.

 doi:10.1016/B978-0-12-409548-9.09407-0

inputs to built capital and labor. (Many still do, contrasting the built environment with the natural environment.) It was a contribution of industrial ecology to treat the industrial system as a subsystem of the natural system (see Fig. 2(a)).

As industrial ecology now broadens its concerns to include consumption as well as production, this simple diagram is being reconsidered because of the importance of human motives and human agency to the decision-making process. The built environment is part of the biophysical structure of the social–ecological system and subject to the laws of nature (see Fig. 2(b)), but the cultural sphere is better understood using the concepts and methods of the social sciences.

In the earliest societies, the built environment was insignificant. Humans in hunter–gatherer societies, like all other species, primarily take what nature makes available. They are not likely to severely overexploit a local ecosystem; when resources become scarce, they move on. However, even before the advent of agriculture, humans began to modify their local environments for the purpose of increasing its productivity (for humans) through the use of fire. With the transition from hunter–gatherer to settled agriculture, farming and herding societies greatly extended the modification and control of the natural system to overcome natural supply constraints and produce more of what humans desired. This control allowed for the possibility of individuals or groups producing more of agricultural and other goods than they required and thus making some of their production available for trade. With the development of trade and of markets, agricultural and other types of output were converted into products: goods (or services) exchanged for something else of value.

A second and related historical transition is the explosive growth of human requirements, the average of what is considered standard in a given society and the related changes in human consumption patterns. Early human requirements differed little from those of other social mammals, were closely related to physical survival, and were met by the output of nature. In modern times humans are unique among species in the volume, variety, and sources of their material requirements. Consumer demand in affluent societies is met by an extensive array of products – the goods and services output by the industrial system. Humans are not alone in producing products, but no other species even approaches the scale of human production. The modern built environment reflects the prevalence of these human products.

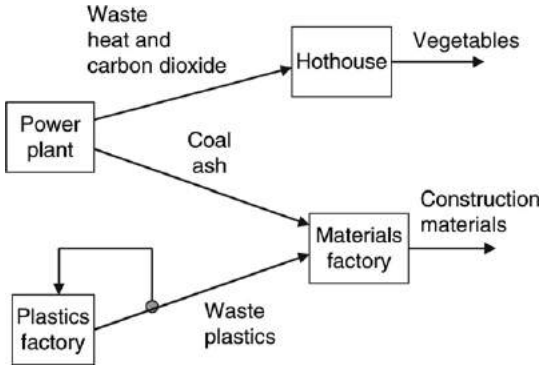

Fig. 1 A hypothetical system for the reuse and recycling of potential wastes.

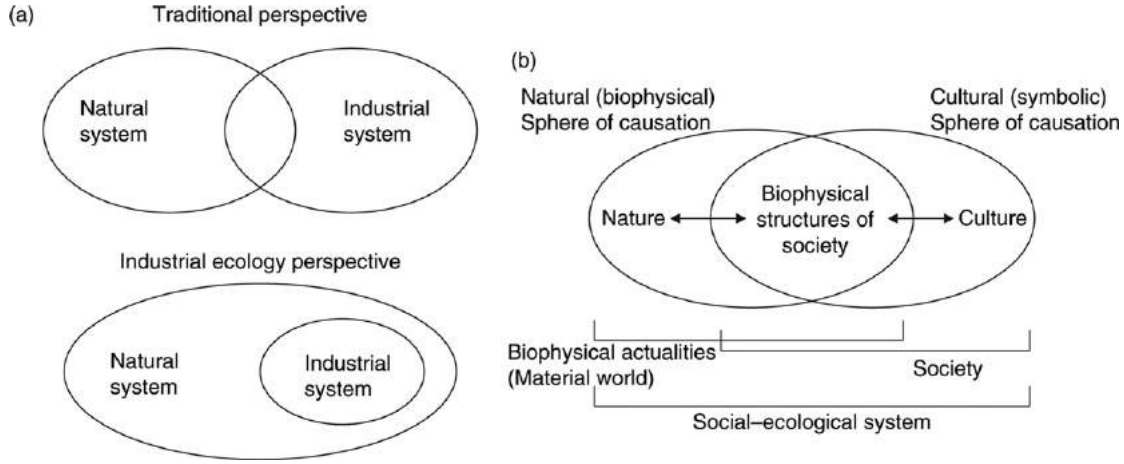

Fig. 2 (a) Conceptual framework of industrial ecology. (b) Social–ecological systems as overlap of a natural and a cultural sphere of causation. (a) Modified from Chertow. M., Portlock. M., 2002 *Developing Industrial Ecosystems*: *Approaches, Cases, and Tools*. New Haven, CT: Yale University. (b) Reproduced from Haberl H, Fischer-Kowalski M, Krausmann F, Weisz H, and Winiwarter V (2004) Progress towards sustainability? What the conceptual framework of material and energy flow accounting (MEFA) can offer. *Land Use Policy* 21: 199–213, with permission from Elsevier.

While the flow of mass and energy in 'natural' ecosystems is largely dictated by the consumption of resources to supply energy and nutrients to sustain life, many, if not most, products of modern industry have little to do with directly providing energy and nutrients, and a substantial number have little to do with that function even indirectly. The extent to which industrial systems are dedicated to producing such products contrasts them to the rest of the natural system. Industrial ecology is concerned with a unique feature of these industrial systems: the unprecedented degree to which the appropriation of resources – materials and energy – for the fabrication of products is not bounded by the metabolic constraints of the biological world, both in the quantity of those flows and in the variety of materials involved.

One could say that humans in a modern consumer society have developed extended metabolic needs, where consumer goods and services play a role similar to the need for proteins and carbohydrates in nature. To have toast in the morning requires not only bread but also a toaster and thus electric power as well. This concept of humans having extended needs is hardly new. Rousseau saw industrialization as creating a set of artificial (as opposed to natural) needs, and Marx made the distinction between human and inhuman needs. The material and energy requirements of the modern industrial system serve the extended needs of human consumers. The concept of distinct industrial metabolisms, reflecting the material realities of specific societies, and attempts to quantify them, is an active research area in industrial ecology.

Since the majority of industrial products do not satisfy biological metabolic requirements, they need not be composed of organic material. The relaxing of this constraint, coupled with the specialized functions of many products, leads to the development and use of a wide range of novel, often exotic, materials designed specifically to improve product function. In some cases the development of new products is made possible only by the development of new materials, which in turn often requires the development of new industrial processes. As a result the global ecosystem must cope with stocks and flows of materials that have undesirable properties such as toxicity or nonbiodegradability.

Most of these complex materials cannot be recycled easily, in contrast to the relatively narrow range of naturally occurring materials, which are readily recycled.

Within the realm of personal transportation, for example, the goal of making automobiles lighter in order to reduce fuel consumption has led to the substitution of a variety of high-technology materials in the place of steel, itself an exotic material when compared to the wood from which earlier forms of personal transportation such as wagons were constructed. Use of these materials impedes the recycling of automobiles due to the increased difficulty of separation and remanufacture. In many cases the performance of the product is dependent on its containing materials that are nonbiodegradable. These products are more likely to be toxic, require large quantities of energy for their production, and have long residence times in the environment, problems that are aggravated by the great quantities in which they are produced.

These materials and products are the output of what is often a multistage production process carried out within the industrial system. Just as the diet of a carnivore depends on the consumption of plants by herbivores, the end-product purchased by the consumer requires many indirect as well as direct inputs. Large volumes of consumer products, requiring diverse resources and intermediate inputs as they do, make it necessary to build what are often large-scale production facilities. The material and energy resources required for this part of the built environment, like other private and public buildings and infrastructure, must be counted among the extended metabolic needs of human consumers. Describing and analyzing the total requirements of consumers in a modern industrial economy ultimately rests on accounting for all of the indirect inputs. To do this industrial ecologists often make use of economic models, especially those with a joint focus on material stocks and flows as well as production technologies and consumption patterns.

Bottom-Up: Resources and Products

The objective of industrial ecology is to provide actionable input to those taking decisions about the industrial system. These decision makers include not only corporate managers, responsible for the extraction of resources and fabrication and distribution of products, and the policy makers who oversee them, but also consumers, acting both individually and as members of households or of the growing number of social institutions that operate in the public interest. The decisions may pertain to an individual resource or product or to an entire industrial system.

Even when studying an individual resource or product, industrial ecologists are concerned with its role in an industrial system. They gather data on system behavior and develop concepts and methods for analysis at the system level. Among industrial ecology's most fundamental activities is gathering data for describing the flow of energy and materials throughout an economic system. The scale of the economic system can range from a single factory to a regional economy to the global economy.

Many industrial ecologists are engaged in compiling information to describe the flow of a specific material from sources to sinks within the global industrial system or some geographically delimited portion of it. Conventions and procedures have been developed for material flow analysis (MFA, and its variants such as substance flow analysis), which is in certain ways similar to the study of nutrient cycling in ecology. The depiction of the global copper cycle, shown in **Fig. 3**, is reminiscent of illustrations of the carbon cycle in ecological systems, but closer inspection indicates that the copper cycle is nowhere near as efficient as the carbon cycle. A significant fraction of the copper is not recycled but instead ends up being lost to the system. Identifying and quantifying these major flows provides grounding for interventions that aim to modify the existing system to reduce its impact on the environment by making it more efficient in its use of resources. Similar approaches are applied not only to individual elements such as copper but also to compound materials. By pinpointing the presence of wastes that go unnoticed in conventional

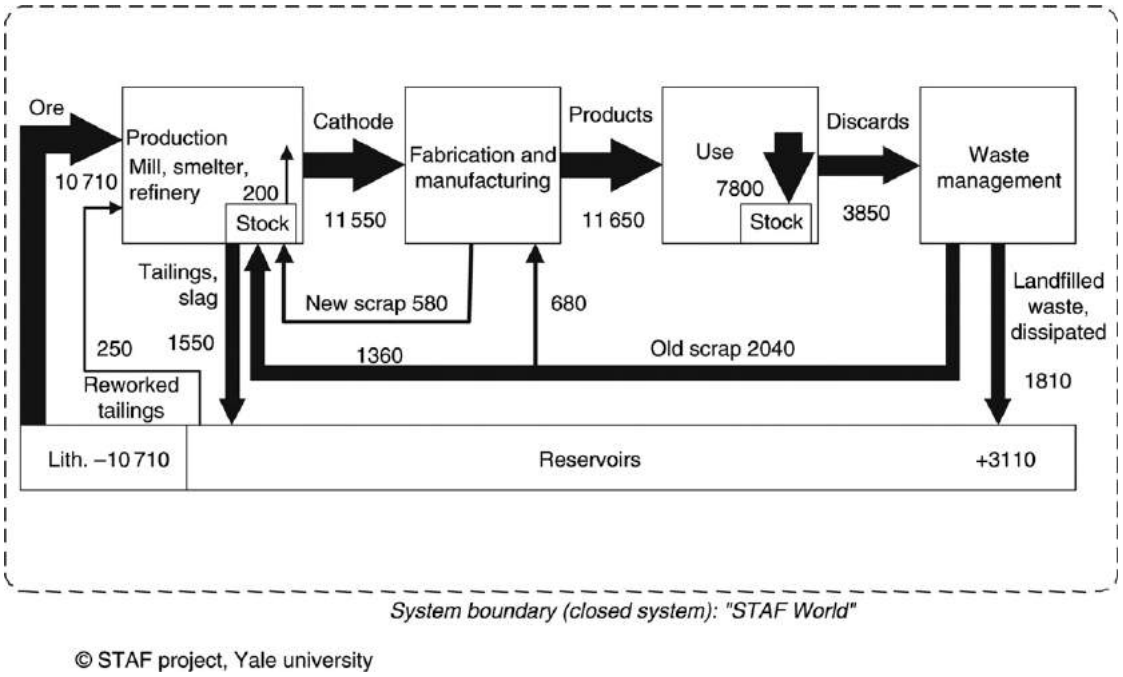

Fig. 3 The global copper cycle in the 1990s. Reprinted with permission from Graedel, T.E., van Beers, D., Bertram, M., *et al.*, 2004. The multilevel cycle of anthropogenic copper. Environmental Science and Technology 38 (4), 1242–1252. Copyright (2004) American Chemical Society.

economic monitoring systems, MFA can direct efforts to improve system performance. MFA has also been applied to the aggregate of all materials (measured in tons per person) in attempts to quantify a society's industrial metabolism.

The wide range of MFA studies underscores the increasingly great variety of distinctly different materials in use in the contemporary industrial system, each with unique properties, to support the great number of products required by consumers. The literature includes MFA studies of metals such as copper and zinc, forest products such as pulp and paper, and industrial chemicals such as bisphenol A and nonylphenol. This expansive range of materials contrasts industrial with ecological systems which, relying on the breakdown of complex biochemical compounds by digestion, is typically characterized by a few major cycles – carbon, nitrogen, phosphorous, hydrogen, oxygen – the principal, elemental constituents of biomass. Moreover, since the resources required by industrial systems often are found in specific locations distant from the site of production, which may also be distant from where consumption takes place, considerable amounts of transportation may be required, involving even more energy and material inputs. The material flow analyses of broadest conceptual scope trace simultaneously the physical movements associated with a variety of interrelated human activities. While the objective of most MFA studies is to quantify material flows, such flows can in an additional step provide inputs to a model of the industrial system that explicitly distinguishes their use in specific industrial sectors and modes of transportation to satisfy the product demand of different categories of consumers.

Moving up from resources to products, two additional research areas within industrial ecology are concerned with the individual product, situated in the context of its entire life cycle from resource extraction through resource processing and fabrication of the product to its utilization, reuse, recycling, and disposal. These are design for the environment (DfE) and life-cycle assessment (LCA). Both address the system-wide environmental impacts associated with products.

DfE involves the design of industrial products and processes to minimize their adverse environmental impacts over their lifetimes. Often it is a redesign of an existing product or process that is undertaken. The focus can be on different phases of a product's life cycle, such as design for product retirement. Actual applications are varied and have included the design of chemical processes, electronic products, mechanical components, and freezer insulation, as well as the increasingly important area of packaging design.

LCA involves the evaluation of the environmental impact of a product during its entire life history on the basis of detailed technical information. Each stage from extraction of resources through disposal of residuals is associated with distinct resource requirements and emissions or other forms of damage, and their impacts, which are experienced at specific times and places. LCA is often used to compare the environmental impacts of alternative products or production processes and has been applied to substances such as chlorine and aluminum, the entire mining industry, industrial materials like PVCs, and to alternative uses of agricultural land.

LCA studies quantify emissions and resource use per units of output or service delivered. The modeling of the production network, including the quantification of the amounts of inputs required from different production processes, is traditionally based on direct measurement or engineering analysis. This process inventory modeling has generally ignored the contribution of nonphysical inputs, such as legal and accounting services or wholesale and retail trade, and left out minor inputs to make the

analysis tractable. Empirical studies have established that such an approach overlooks a significant portion of the total impact. As a result, increasing numbers of LCA researchers are integrating their analyses with the use of input–output (IO) models of the economy to capture indirect as well as direct requirements associated with a single process or product. The integrated, hybrid approach has made it possible to go beyond examining individual products to examining the impacts of one entire bundle of consumption goods as compared to another.

LCA also includes an impact assessment step, in which different types of emissions are aggregated to a manageable number of indicators reflecting specific problem areas such as global warming or human toxicity. Alternatively, impact assessment can be based on the modeling of damages, for example, human health effects measured in years of life lost from both toxicity and climate change. The development of these impact assessment methods build on the knowledge and models of environmental scientists, including eco-toxicologists and ecologists.

Top-Down: Entire Industrial Systems

An early application within industrial ecology of ecological concepts to industrial systems is the design and implementation of so-called industrial ecosystems, or eco-industrial parks. Industrial ecosystems are characterized by the prevalence of what has been named industrial symbiosis, a relationship between two or more firms that involves the exchange of materials, energy, or information in a manner that is mutually beneficial. The most famous of these is located in Kalundborg, Denmark; its structure is illustrated in Fig. 4. By utilizing what would otherwise be waste products from one firm as input resources for others, the adverse environmental impact of this system of firms can be greatly reduced.

Industrial ecologists undertake to design industrial ecosystems either from scratch or around an existing plant. Kalundborg, however, emerged in the absence of advance planning and represents a sequence of accommodations and agreements between pairs of firms. Like any ecosystem, this eco-industrial park is continually evolving. New firms may be introduced. Some existing firms increase in size or modify their product lines and input requirements, while other firms decrease in size or disappear altogether.

Some industrial ecologists have turned their attention to larger systems, namely entire economies, using the concepts and methods of input–output (IO) economics, a systems approach to describing and analyzing an entire economy in terms of the inputs and outputs of dozens or even hundreds of individual industries, products, and resources. The use of IO models in

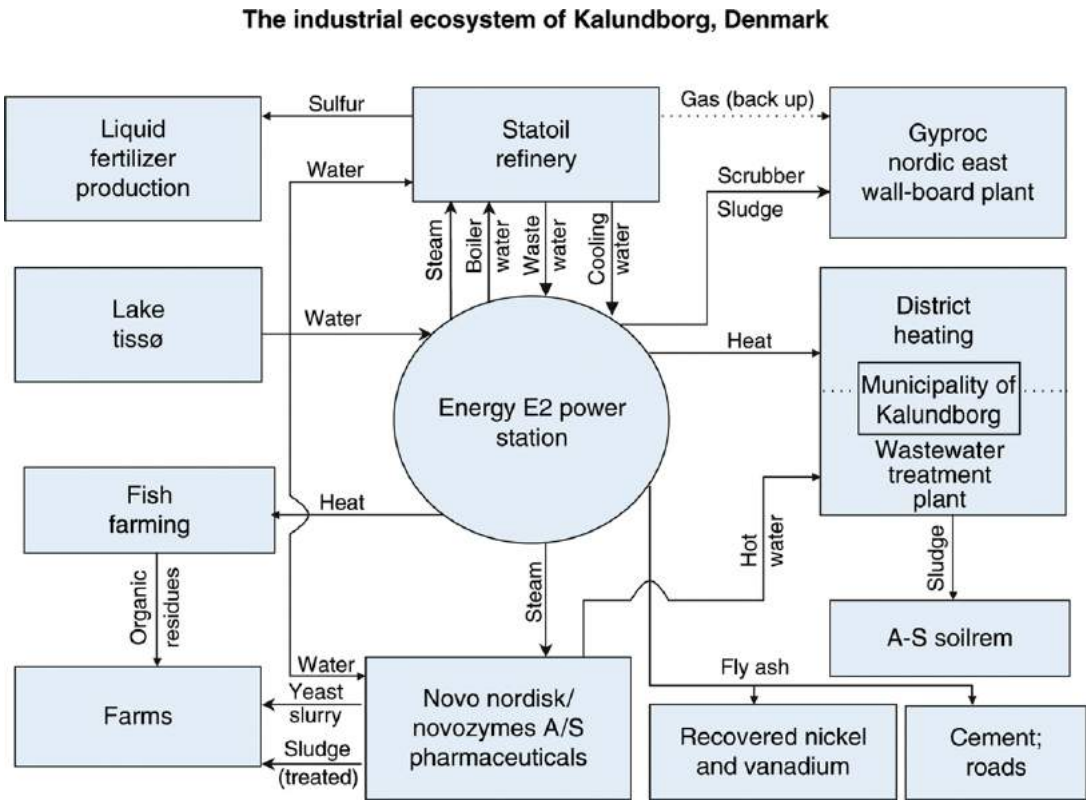

Fig. 4 The industrial ecosystem of Kalundborg, Denmark. Modified from Chertow. M., Portlock. M., 2002 *Developing Industrial Ecosystems: Approaches, Cases, and Tools*. New Haven, CT: Yale University.

industrial ecology has grown substantially in recent years as their ability to describe both physical stocks and flows and the associated money costs and prices has been emphasized and expanded. IO models require a database, a large portion of which for past years is provided on a periodic basis by national statistical offices around the world. When evaluating scenarios about the future, the framework is reliant on technical data about resources and products, and it increasingly makes use for this purpose of the kinds of information originating in MFA and LCA studies.

IO studies have investigated such environmentally significant challenges as water scarcity and water management in different parts of the world including China, Spain, and Southern Africa; emissions of carbon dioxide and other greenhouse gases; and the management of a variety of wastes. Emissions of carbon, sulfur, and nitrogen under alternative scenarios about future technological attributes have been estimated for the world economy described in terms of the production and trade in the outputs of a few dozen industrial sectors in over a dozen geographic regions. As concern builds that the industrialized countries are appropriating disproportionately large shares of the Earth's resources via resource-intensive imports from developing countries, IO models of the world economy that incorporate data from MFA and LCA studies are becoming more prevalent.

An IO model can represent the complex interplay of ecological and industrial system concepts. Since being introduced in a modified form into ecology, IO models have been valued by ecologists for their ability to track the paths of flows, thus accounting for indirect as well as direct interactions and allowing for a more accurate estimate of the total (direct plus indirect) energy and biomass requirements. IO techniques have also been the basis for developing measures of ecosystem structure, such as throughput and cycling, which have been applied to the analysis of numerous ecosystems. The direct relevance of these ecological system measures to industrial systems is evident, especially when recycling of resources is of major interest. As a result these ecological measures have recently been introduced into industrial ecology in, for example, analyzing material flow in the nylon tufted carpet industry.

Consumption and Sustainable Development

Since its origins, industrial ecology has been mainly concerned with reducing the environmental impact of the use of energy and materials in industrial production by improving the efficiency of production processes. Some industrial ecologists have claimed that material inputs could be reduced by substantial amounts (e.g., a factor of 4 or even 10) without diminishing economic growth. Such technological prescriptions are mainly addressed to public policy makers and corporate executives on the implicit assumption that they would not require much change in the motives or behaviors of consumers or negatively impact their well-being.

Recently, however, a new emphasis on consumers and consumption has emerged. Many researchers came to doubt that reliance on changes in the sphere of production alone could achieve the required scale of impact. The inflow of social scientists into industrial ecology brought the recognition that households are the major decision makers regarding consumption, and analysis about alternative consumption behaviors should be addressed in the first instance to them. In a consumer society, industrial stocks and flows are demand driven, in contrast to the dynamics governing the availability of traditional materials in ecosystems. In an ecosystem, predators have control over the number of prey they seek to consume, but they have no direct control over the number of prey potentially available for consumption. By contrast human consumers, particularly in the most affluent, industrialized economies, have control over not only how much gets consumed but also over what gets consumed and produced – and through this connection potentially over how it gets produced.

Life-cycle analysts and IO economists have produced a substantial body of work analyzing the environmental impacts of different types of households and their consumption activities. Most attention has focused on motorized mobility, housing, and intake of food because of the demonstrably intensive use of resources to satisfy consumption requirements in these areas. The objective of this research is to explore alternative ways for satisfying the human need for food, housing, and mobility with less environmental damage. Recent studies have provided a framework for bringing physical measures into the analysis of social accounting matrices, data sets compiled by a number of national statistical offices that describe the consumption patterns of distinct types of households. A special issue in 2005 of the *Journal of Industrial Ecology* is devoted to the industrial ecology of sustainable consumption.

Such investigations are part of a broader inquiry about the sustainability of systems and, in particular, sustainable development of the global economy. Development of alternate energy systems that can substantially reduce reliance on fossil fuels by making more direct use of solar energy in both production and consumption, thus moving industrial systems back in the direction of ecological systems, promises to be an active area of research. A shift in the diets of the affluent from animal-based toward more plant-based foods could have substantial impacts on resource use in agriculture. Such scenarios about the future will be analyzed using frameworks that integrate material flow data, life-cycle descriptions of products and processes, and IO models of individual economies and of the world economy. As increasing numbers of researchers with roots in different disciplines turn their attention to the challenges of sustainable global development, the distinctive contributions from industrial ecology will reflect its origins in the ecology of the industrial system.

Life-Cycle Assessment☆

MA Curran, BAMAC, Ltd, Rock Hill, SC, United States

Introduction

Life-cycle assessment, or LCA, is an environmental accounting and management approach for assessing industrial systems. It considers all the aspects of resource use and environmental releases associated with a system, as defined by the function provided by a product, process, or activity. This cradle-to-grave approach considers all relevant impacts upstream and downstream of the consumer or producer. Specifically, LCA is a holistic view of environmental interactions that covers a range of activities, from the extraction of raw materials from the Earth and the production and distribution of energy, through the use, and reuse, and final disposal of a product (for simplicity, the word "product" is used although the life-cycle concept applies equally well to processes and activities). LCA is a relative tool intended for comparison and not absolute evaluation, thereby helping decision makers compare all major environmental impacts when choosing between alternative courses of action (Fig. 1).

LCA evaluates all stages of a product's life from the perspective that they are interdependent, meaning that decisions made at one point along the life cycle can have consequences somewhere else. LCA enables the estimation of the cumulative environmental impacts resulting from all stages in the product life cycle, often including impacts that go beyond the boundaries of traditional analyses. By including the impacts throughout the product life cycle, LCA provides a comprehensive view of the environmental aspects and a more accurate picture of the true environmental tradeoffs in product or process selection. A life-cycle approach helps us recognize how our choices influence each point of the life cycle, so that we can balance potential tradeoffs and avoid shifting problems from one area to another, thereby positively impacting the overall environment. LCA is a way of thinking about the choices we make, when purchasing products, selecting materials, or identifying process alternatives by putting our decisions in context with facts related to all parts of the life-cycle system.

In connecting the different parts of the system, many LCAs lead to unexpected and nonintuitive results. For example, bio-based products, such as paper bags, paper cups, and cloth diapers, are not obviously superior in terms of using less energy and materials. Paper requires the harvesting and transportation of trees to pulp mills, activities which require energy. Paper making releases air pollutants and water discharges of chlorine and biological waste. After use, bags end up in landfills where they decay and release methane in the process. The amount of hot water needed to wash and dry cloth diapers is not inconsequential, especially for those who live where water is scarce or sewage is not treated. These kinds of analyses highlight how the environmental impacts of alternative products may lead to unanticipated consequences.

LCA identifies the potential transfer of environmental impacts from one media to another (e.g., eliminating air emissions by creating a wastewater effluent instead) and/or from one life-cycle stage to another (e.g., from use and reuse of the product to the raw material acquisition stage). If an LCA were not performed, the transfer might not be recognized and properly included in the analysis because it is outside of the typical scope or focus of product selection processes. By broadening study boundaries, LCA can help decision makers select the product or process that results in the least impact to the environment. This information can be used with other factors, such as cost and performance data, in the selection process.

The History of LCA

LCA had its beginnings in the 1960s. Concerns over the limitations of raw materials and energy resources sparked interest in finding ways to cumulatively account for energy use and to project future resource supplies and use. In 1969, researchers initiated an internal study for The Coca-Cola Company that laid the foundation for the current methods of life-cycle inventory analysis in the United States. In a comparison of different beverage containers to determine which container had the lowest releases to the environment and was least affected by the supply of natural resources, this study quantified the raw materials and fuels used and

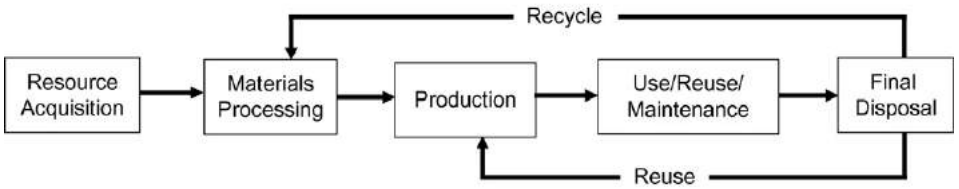

Fig. 1 Generic life-cycle stages (arrows represent transportation).

☆*Change History:* January 2016. MA Curran updated the text to this entire article.

the environmental loadings from the manufacturing processes for each container. Other companies in both the United States and Europe performed similar comparative life-cycle inventory analyses in the early 1970s.

The process of quantifying the resource use and environmental releases of products became known in the United States as a "resource and environmental profile analysis" (REPA) while in Europe it was called an "ecobalance." With the formation of public interest groups encouraging industry to ensure the accuracy of information in the public domain, and spurred on by the oil shortages in the early 1970s, a protocol or standard research methodology for conducting these studies was developed and further evolved.

From 1975 through the early 1980s, as interest in these comprehensive studies waned because of the fading influence of the oil crisis, environmental concerns shifted to issues of hazardous and household waste management. However, throughout this time, REPAs and "ecobalances" continued to be conducted and the methodology improved through a slow steam of about two studies per year, most of which focused on energy requirements. During this time, European interest grew with the establishment of an Environment Directorate (DG X1) by the European Commission. European LCA practitioners developed approaches parallel to those being used in the United States. Besides working to standardize pollution regulations throughout Europe, DG X1 issued the Liquid Food Container Directive in 1985, which charged member companies with monitoring the energy and raw materials consumption and solid waste generation of liquid food containers.

When solid waste became a worldwide issue in 1988, LCA again emerged as a tool for analyzing environmental problems. As interest in all areas affecting resources and the environment grows, the methodology for LCA is again being improved. A broad base of consultants and researchers across the globe has been further refining and expanding the methodology. The need to move beyond the inventory to impact assessment brought LCA methodology to another point of evolution.

Beginning in 1991, concerns over the inappropriate use of LCAs in making broad marketing claims by product manufacturers, along with pressure from other environmental organizations to standardize LCA methodology, led to the development of the LCA standards in the International Standards Organization (ISO) 14000 series (1997–2002, and updated in 2006). In 2002, the United Nations Environment Programme (UNEP) joined forces with the Society of Environmental Toxicology and Chemistry (SETAC) to launch the Life Cycle Initiative, an international partnership. The three programs of the initiative aim to put life-cycle thinking into practice and to improve the supporting tools through better data and indicators. In 2015, the Forum for Sustainability through Life Cycle Innovation (FSLCI) was created for people with common interest in creating and using life cycle information. By bringing together stakeholders, initiatives and activities around the world under one umbrella, the Forum organizers aim to link activities and allow members to be more effective by building on each other's strengths rather than duplicating them.

Conducting an LCA

Specifically, LCA is a technique (Fig. 2) to assess the environmental aspects and potential impacts associated with a product, process, or service, by:

- appropriately selecting a functional unit;
- clearly defining the goal and scope of the study;
- compiling an inventory of relevant energy and material inputs and environmental releases;
- evaluating the potential environmental impacts associated with identified inputs and releases;
- interpreting the results to help decision makers make a more informed decision.

This ability to track and document shifts in environmental impacts can help decision makers and managers fully characterize the environmental tradeoffs associated with product or process alternatives. By performing an LCA, analysts can, for example:

- develop a systematic evaluation of the environmental consequences associated with a given product;
- analyze the environmental tradeoffs associated with one or more specific products/processes to help gain stakeholder (state, community, etc.) acceptance for a planned action;
- quantify environmental releases to air, water, and land in relation to each life-cycle stage and/or major contributing process;
- assist in identifying significant shifts in environmental impacts between life-cycle stages and environmental media;
- assess the human and ecological effects of material consumption and environmental releases to the local community, region, and world;
- compare the health and ecological impacts between two or more rival products/processes or identify the impacts of a specific product or process;
- identify impacts to one or more specific environmental areas of concern.

Comparing Apples to Apples

When an LCA is used to compare two or more products, the basis of comparison should be equivalent use, that is, each system should be defined so that an equal amount of product or equivalent service is delivered to the consumer. For example, if bar soap were compared to liquid soap, the logical basis for comparison would be an equal number of handwashings. Another example of

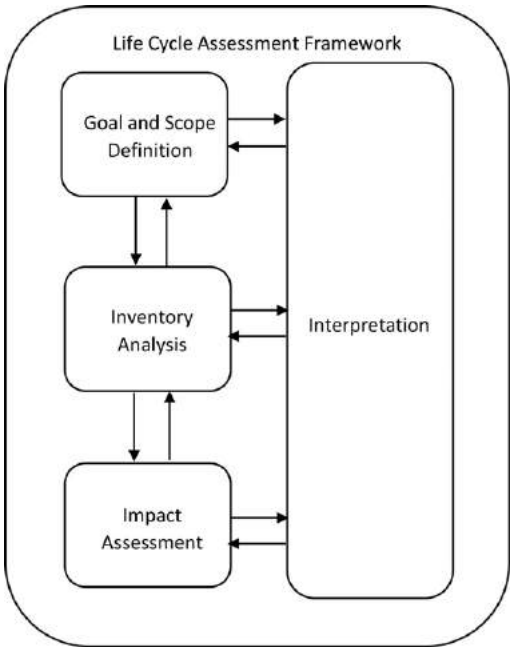

Fig. 2 Phases of an LCA. From International Standards Organization (2006) *Environmental management — LCA — principles and framework.* ISO 14040. Geneva: ISO.

equivalent use would be in comparing cloth diapers to disposable diapers. Cloth diapers need to be changed more frequently, or they are doubled whereas disposables are not. Thus, more cloth diapers will be used. In this case, a logical basis for comparison between the systems would be the number of diapers used over a set period of time.

Equivalent use for comparative studies can often be based on volume or weight, particularly when the study compares packaging for delivery of a specific product. A beverage container study might consider 1000 L of beverage as an equivalent use basis for comparison, because the product may be delivered to the consumer in a variety of container sizes having different life-cycle characteristics.

Life-Cycle Inventory

A life-cycle inventory is a process of quantifying energy and raw material requirements, atmospheric emissions, waterborne emissions, solid wastes, and other releases for the entire life cycle of a product, process, or activity. This step is typically supported by a flow diagram depicting the activities occurring within the system boundaries (**Fig. 3**). An inventory analysis produces a list containing the quantities of pollutants released to the environment (after treatment or control) and the amount of energy and material consumed. The results can be segregated by life-cycle stage, media (air, water, and land), specific processes, or any combination thereof.

In the life-cycle inventory phase of an LCA, all relevant data are collected and organized. Without a life-cycle inventory, no basis exists to evaluate comparative environmental impacts or potential improvements. The level of accuracy and detail of the data collected is reflected throughout the remainder of the LCA process. (No predefined list of data quality goals exists for all LCA projects. The number and nature of data quality goals necessarily depend on the level of accuracy required to inform the decision makers involved in the process.)

Resource constraints for data collection may be a consideration in defining the system, although in no case should the scientific basis of the study be compromised. The level of detail required to create a thorough inventory depends on the size of the system and the purpose of the study. In a large system encompassing several industries, certain details may not be significant contributors given the defined intent of the study. These details may be omitted without affecting the accuracy or application of the results. However, if the study has a very specific focus, such as a manufacturer comparing alternative processes or materials for inks used in packaging, it would be important to include chemicals used in very small amounts.

Life-cycle inventory analyses can be used in various ways. The data can assist an organization in comparing products or processes and considering environmental factors in material selection. In addition, inventory analyses can be used in policy-making, by helping the government develop regulations regarding resource use and environmental emissions.

Life-Cycle Impact Assessment

Although much can be learned about a process by considering the life-cycle inventory data, an impact assessment provides a more meaningful basis to make comparisons. For example, although we know that 9000 t of carbon dioxide (CO_2) and 5000 t of

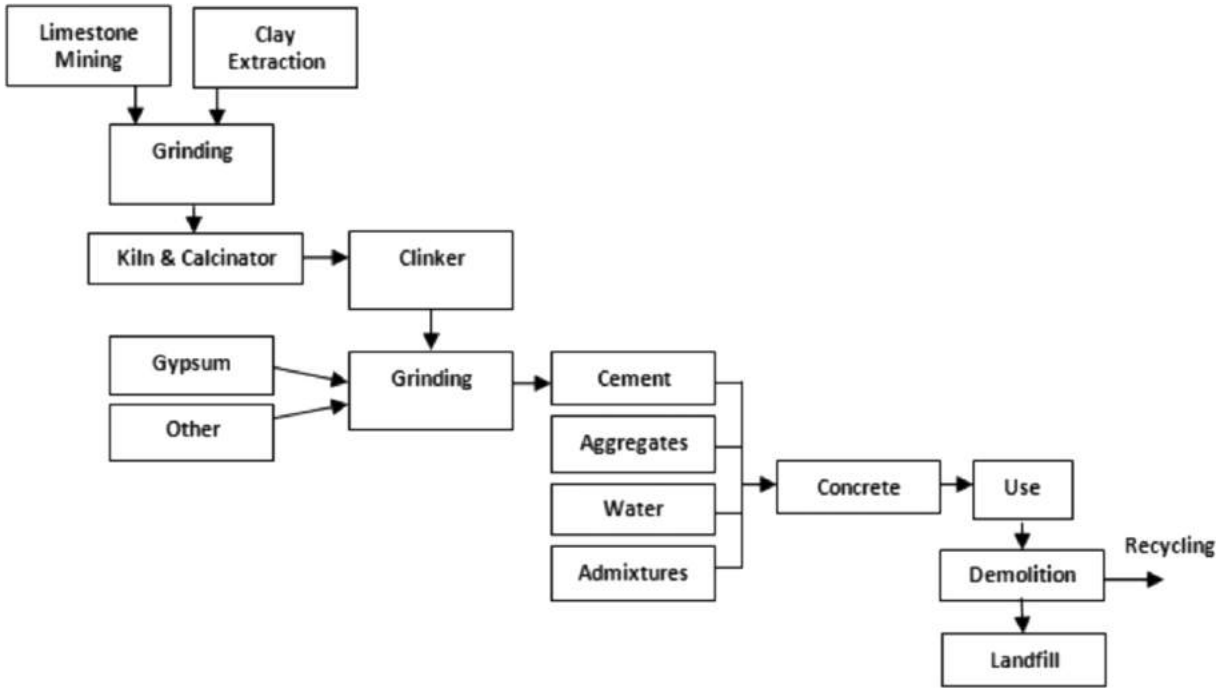

Fig. 3 Example of a flow diagram for a concrete product life cycle.

methane released into the atmosphere are both potentially harmful greenhouse gases, a life-cycle impact assessment (LCIA) can determine which would have a greater impact. Which is worse? What are their potential impacts on global warming? On smog? Using science-based characterization factors, an LCIA can calculate the impacts that each environmental release may have on problems such as smog or global warming.

The LCIA phase of an LCA is the evaluation of potential human health and environmental impacts of the environmental resources and releases identified during the inventory. Impact assessment should address ecological and human health effects; it can also address resource depletion. As shown in Fig. 4, an LCIA attempts to establish a linkage between the product or process and its potential environmental impacts.

Example Calculation of a Characterization Factor

The following calculations demonstrate how characterization factors can be used to estimate the potential contribution toward an impact category. In this example, global warming potential (GWP) is presented in terms of equivalent emissions of carbon dioxide (CO_2) using units of teragrams of carbon dioxide equivalents (Tg CO_2 eq.):

$$\text{of } CO_2 \text{ released} = 9000\,\text{t} = 0.009\,\text{Tg}$$
$$(CO_2 \text{ GWP factor value} = 1)$$
$$\text{Quantity of methane released} = 5000\,\text{t} = 0.005\,\text{Tg}$$
$$(\text{methane GWP factor value} = 23)$$

Therefore,

$$CO_2 \text{ GWP} = 0.009\,\text{Tg} \times 1 = 0.009\,\text{Tg } CO_2\,\text{eq.}$$
$$\text{Methane GWP} = 0.005\,\text{Tg} \times 23 = 0.115\,\text{Tg } CO_2\,\text{eq.}$$

GWP factor values are from the Intergovernmental Panel on Climate Change (IPCC) Model, 100 year time horizon, Third Assessment Report, 2001.

The key to impact characterization is using the appropriate characterization factor. For some impact categories, such as global warming and ozone depletion, there is a consensus on acceptable characterization factors. For other impact categories, such as resource depletion, consensus is still being developed.

An important distinction exists between LCIA and other types of impact analyses. The LCIA does not necessarily attempt to quantify any actual, site-specific impacts associated with a product, process, or activity. Instead, it seeks to establish a linkage between a system and potential impacts. The models used within impact assessment are often derived and simplified versions of more sophisticated models within each of the various impact categories. These simplified models are suitable for relative

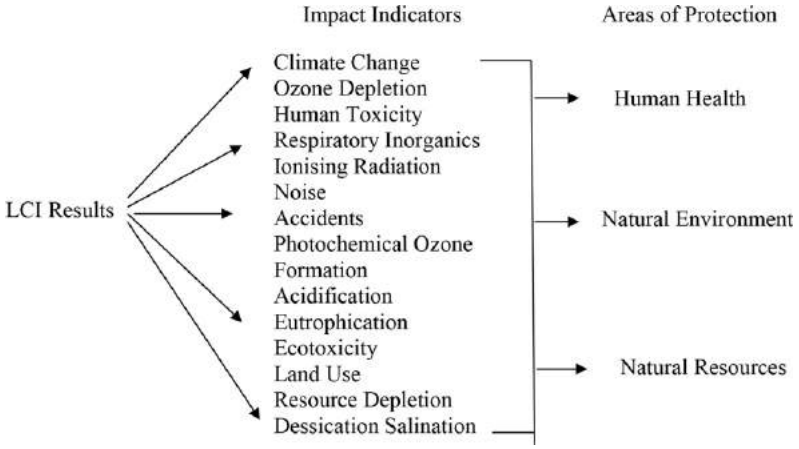

Fig. 4 Relationship between impact indicator categories and areas of protection.

comparisons of the potential to cause human or environmental damage, but are not indicators of absolute risk or actual damage to human health or the environment. For example, risk assessments are often very narrowly focused on a single chemical at a very specific location. In the case of a traditional risk assessment, it is possible to conduct very detailed modeling of the predicted impacts of the chemical on the population exposed and even to predict the probability of the population being impacted by the emission. In the case of LCA, hundreds of chemical emissions (and resource stressors) which are occurring at various locations are evaluated for their potential impacts in multiple impact categories. The sheer number of stressors being evaluated, the variety of locations, and the diversity of impact categories make it impossible to conduct the assessment at the same level of rigor as a traditional risk assessment. Instead, models are based on the accepted models within each of the impact categories using assumptions and default values as necessary. The resulting impact models are suitable for relative comparisons, though insufficient, for absolute predictions of risk.

The key concept in this component is that of stressors. A stressor is a set of conditions that may lead to an impact. For example, if a product or process is emitting greenhouse gases, the increase of greenhouse gases in the atmosphere may contribute to global warming. Processes that result in the discharge of excess nutrients into bodies of water may lead to eutrophication. An LCIA provides a systematic procedure for classifying and characterizing these types of environmental effects.

Midpoint versus Endpoint Impact Modeling

In order to simplify the process and make LCIA more broadly applicable, modeling is typically conducted at the midpoint level instead of modeling effects to specific endpoints (see the ozone depletion potential example below). Midpoint impact assessment models reflect the relative potency of the stressors at a common midpoint within the cause–effect chain. Analysis at a midpoint minimizes the amount of forecasting and effect modeling incorporated into the LCIA, thereby reducing the complexity of the modeling and often simplifying communication. Midpoint modeling can minimize assumptions and value choices, reflect a higher level of societal consensus, and provide more comprehensive than model coverage for endpoint estimation (**Fig. 5**; **Tables 1** and **2**).

The ILCD Handbook provides an extensive analysis of the existing characterization methods and recommendations for LCIA in the European context using reference year 2008. Since then methodological developments have continued, resulting in further advances of LCIA and others yet to come.

For consistency reasons, the choice of impact categories is often made on the basis of a recommended impact assessment guidebook or its implementation in software. Thus, in practice one often sees LCA studies reporting impacts according to the selected model. The most often used LCIA models include EPS 2000; IMPACT World+; LIME: Life-cycle Impact assessment Method for Endpoint modeling; ReCiPe; and TRACI: The Tool for the Reduction and Assessment of Chemical and other environmental Impacts. All these methods comprise a recommended set of impact categories with a category indicator and set of characterization factors. ISO does not specify any choice in these matters.

Comparing Alternatives Using Life-Cycle Interpretation

Life-cycle interpretation, the last phase of the LCA process, is a systematic technique to identify, quantify, check, and evaluate information from the results of the LCI and the LCIA, and communicate them effectively. However, interpreting the results of an LCA is not as simple as two is better than three, therefore, alternative A is the better choice. While conducting the life-cycle inventory and impact assessment, it is necessary to make assumptions, engineering estimates, and decisions based on one's values

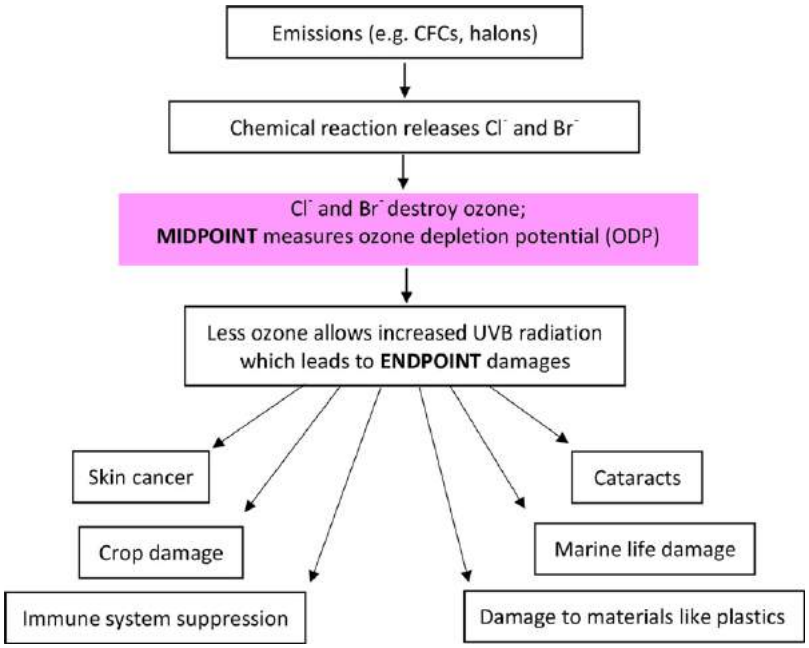

Fig. 5 Midpoint versus endpoint impact modeling.

Table 1 Best available characterization models to midpoint. Models classified as level I, II or III (ILCD Handbook)

Impact category	*Best among existing characterization models*	*Indicator*	*Classification*
Climate change	Baseline model of 100 years of the IPCC	Radiative forcing as Global warming potential (GWP100)	I
Ozone depletion	Steady-state ODPs from the WMO assessment	Ozone depletion potential (ODP)	I
Human toxicity, cancer effects	USEtox model	Comparative toxic unit for humans (CTU_h)	II/III

Eutrophication, aquatic	EUTREND model as implemented in ReCiPe	Residence time of nutrients in freshwater (P) or marine end compartment (N)	II
Ecotoxicity, freshwater	USEtox model	Comparative toxic unit for ecosystems (CTU_e)	II/III
Land use	Model based on soil organic matter	Soil organic matter (SOM)	III
Resource depletion, water	Model for water consumption as in the Swiss Ecoscarcity	Water use related to local scarcity of water	II
Resource depletion, mineral and fossil	CML 2002	Scarcity	II

I — Recommended and satisfactory; II — Recommended but in need of some improvement; III — Recommended, but to be applied with caution.
A mixed classification is related to the application of the classified method to different types of substances.

and the values of involved stakeholders. Each of these decisions must be included and communicated within the final results to clearly and comprehensively explain conclusions drawn from the data. In some cases, it may not be possible to state that one alternative is better than another because of the uncertainty in the final results. This does not imply that efforts have been wasted. The LCA process will still provide decision makers with a better understanding of the environmental and health impacts associated

Table 2 Best available characterization models from midpoint to endpoint (ILCD Handbook)

Impact category	*Best among existing characterization models*	*Indicator*	*Classification*
Climate change	Model developed for ReCiPe	Disability adjusted life years (DALY) for human health Potentially disappeared fraction of species ($PDFm^3yr$) for ecosystem health	Interim

Only three models recommended by the ILCD Handbook are classified above interim status.

with each alternative, where they occur (locally, regionally, or globally), and the relative magnitude of each type of impact in comparison to each of the proposed alternatives included in the study. This information more fully reveals the pros and cons of each alternative.

The purpose of conducting an LCA is to better inform decision makers, who could be government officials, multinational corporations, nongovernmental entities (NGOs), or, ideally, multi-stakeholder panels, by providing a particular type of information (often unconsidered) with a life-cycle perspective of environmental and human health impacts associated with each product or process. With LCAs moving us beyond examining a single impact or life cycle stage as the sole criteria for environmental goodness (or badness), much knowledge has been gained through the thousands of LCA studies that have been completed over the last 20 years. The movement now is toward life cycle sustainability assessment (LCSA) which integrates LCA, life cycle costing (LCC) and social life cycle assessment (SLCA). The development of the economic pillar is advancing through the efforts of various groups while the societal assessment is still in its infancy. Ultimately, all three complementary pillars of sustainability should be based on the same system boundaries and functional unit within a study.

Limitations of Conducting an LCA

Performing an LCA can be very resource and time intensive. Depending upon how thorough the user wishes to be, gathering the data can be problematic, and the availability of data can greatly impact the accuracy of the final results. Therefore, it is important to weigh the availability of data, the time needed to conduct the study, and the financial resources required against the projected benefits of the LCA.

LCA will not determine which product or process is the most cost effective or works the best. Therefore, the information developed in an LCA study should be used as one component of a more comprehensive decision process assessing the tradeoffs with cost and performance.

There are a number of ways to conduct LCIA. While the methods are typically science based, the complexity of environmental systems has led to the development of alternative impact models.

The role of impact assessment is to categorize and quantify potential environmental effects. Once this is done, deciding whether one impact is worse than another is necessarily a subjective process in which the perceptions of the decision maker are applied.

While LCA can help identify potential environmental tradeoffs, converting the impact results to a single score requires the use of value judgments, which must be applied by the commissioner of the study or the modeler. This can be done in different ways such as through the use of an expert panel, but it cannot be done based solely on natural science.

All assumptions or decisions made throughout the entire project must be reported alongside the final results of the LCA project. If assumptions are omitted, the final results may be taken out of context or easily misinterpreted. As the LCA process advances from phase to phase, additional assumptions and limitations to the scope may be necessary to accomplish the project with the available resources.

Summary

Adding LCA to the decision-making process provides an understanding of the human health and environmental impacts that traditionally are not considered when selecting a product or process. This valuable information provides a way to account for the full impacts of decisions, especially those that occur outside of the site that are directly influenced by the selection of a product or process. LCA is an environmental management tool that helps to inform decision makers and should be included with other decision criteria, such as cost and performance, in order to make a well-balanced decision. While there is not always a straightforward or easy choice, it is important to understand the potential impacts related to each choice.

Limits to Growth

C Jaeger, Potsdam Institute for Climate Impact Research, Potsdam, Germany

The Basic Idea

The concept of limits to growth is an attempt to understand the historical tension between global economic growth and environmental protection.

An important example of this tension is the danger of extinction for whales. For centuries humans have hunted whales, a difficult and dangerous enterprise whose mythical qualities have been highlighted by Herman Melville's tale of Moby Dick. With the expansion of the modern world economy, the catch was greatly increased as more and more ships were put to use with increasingly sophisticated technology. This, however, reduced the total population of whales, and as a certain minimum of whales is needed to secure mating and reproduction, extinction of whales has become a serious risk. It took strong and continued political action by environmentalists all over the world, supported by scientists and enhanced by mass media, to enforce limits on whaling. The tension between economic interests in increased catch and environmental interests in protecting the whales, however, is still there, and it applies to many other species, too.

This kind of situation can be modeled mathematically and the resulting models can be implemented on computers. In 1972, Meadows *et al*. published a highly influential book where a similar model was used to argue that economic growth should be stopped within a few decades in order to avoid environmental catastrophe.

Three Simple Models

A simple model of unlimited growth can be designed as follows. Let $r>0$ be the rate of growth, IR_+ the set of non-negative real numbers, and f the function

$$\begin{aligned} f:\quad & IR_+ \to IR_+ \\ & x \mapsto (1+r)\cdot x \end{aligned} \qquad [1]$$

For any given x', one can iterate f so as to get, for example, $f(f(f(x')))$ or $f(f(f(f(x'))))$. Writing n for the number of iterations, one can define a function $\phi_{x'}$:

$$\begin{aligned} \phi_{x'}:\quad & IN \to IR_+ \\ & n \mapsto (1+r)^n \cdot x' \end{aligned} \qquad [2]$$

This can be written as

$$\phi_{x'}(n) = x' e^{n \log(1+r)} \qquad [3]$$

As $\log 1 = 0$ and $(\mathrm{d}\log x/\mathrm{d}x)\big|_{x=1} = 1$ we have $\phi_{x'}(n) \sim x' e^{nr}$.

The exponential function provides a fundamental model of unlimited growth. It is worth noticing that the Euler number e and the exponential function itself were introduced into mathematical physics about three centuries ago on the basis of analyses of a key phenomenon of economic growth: the mechanism of compound interest. Later on, Malthus (1798) noticed that in many circumstances the exponential function was a good model for the dynamics of biological populations, including humans. Malthus also insisted that population growth could not go on without limits and therefore expected serious famines that would ultimately stabilize human population worldwide.

In 1838, the Belgian mathematician Verhulst modified Euler's exponential function so as to represent limits to growth. Call that limit K and let the variable rate of growth r' obey the formula

$$r' = r\left(1 - \frac{x}{K}\right), \quad r>0, \quad K>0 \qquad [4]$$

This implies that the rate of growth approaches 0 as the growing variable approaches its limit, while it approaches r as the growing variable approaches zero. Instead of [1] we get

$$x \mapsto \left(1 + r\left(1 - \frac{x}{K}\right)\right)\cdot x \qquad [5]$$

By introducing an auxiliary variable z, [5] can be simplified as follows:

$$\begin{aligned} & z = \frac{x(1+r)K}{r} \\ & z \to (1+r)\cdot z \cdot (1-z) \end{aligned} \qquad [6]$$

As long as r is smaller than 2, the variable growth rate r' gradually diminishes as x increases. The result is an S-shaped curve that

converges from below to the level $x=K$. In 1974, R. M. May discovered that for r above a threshold slightly larger than 3.57 the process generates a chaotic dynamics: it jumps to levels above K and from there falls back to levels below K, and it does so without repeating itself in a regular fashion. For values between 2 and about 3.57, the process generates various forms of oscillations. These findings make the argument about limits to growth more intricate, but the key idea can be developed with the simpler S-shaped curve.

Now suppose that some agent (e.g., the fisheries industry) is faced with a population whose dynamics can be described by [6] with $1<r<2$. The agent wants to maximize its utility from catching fish over an indefinite period. Make the usual assumption that the utility function is additive across time, concave and monotonically increasing in each period, discounting future utility by a discount factor $0<\beta<1$:

$$\begin{aligned} \max_{h\in H} \quad & \sum_{t=0}^{\infty} \beta^t \cdot u(y_t) \\ s.t: \quad & z_{t+1} = (1+r)\cdot z_t \cdot (1-z_t) - y_t \\ & y_t = h(z_t, t) \end{aligned} \qquad [7]$$

If the agent is sufficiently greedy, that is, if β is rather small, he will try to catch as much fish as he can and as fast as he can. He will then choose his strategy h accordingly. Suppose that it takes time to build up fishing capabilities. Then the strategy space H will be such that increasing catch becomes feasible in the course of time. This, however, will lead the agent to fish until the population is exhausted according to a pattern known as overshoot and collapse. The upper panel in **Fig. 1** gives an illustration.

If the agent cares more about the distant future, that is, if β is close enough to 1, a different strategy will be appropriate: build up fishery capacity up to the point where a constant catch is possible so as to maintain the population indefinitely. The lower panel in **Fig. 1** gives an illustration.

A Global Debate

J. W. Forrester, an outstanding electrical engineer and management scientist at MIT, proposed to advance this kind of analysis with a great leap forward. His model did not represent the management of a specific species like whales, but rather the interaction between humankind and planet Earth. It had not one, but two limiting factors: the capability of the Earth to provide resources like food, timber, metals, etc., and the capability of the Earth to absorb pollutants like toxic waste, smog generating aerosols, etc. The goal variable was quality of life, and humans were assumed to try to increase their quality of life by increasing their number as well as the size of their capital equipment. The result was a grim scenario of overshoot and collapse within a few decades.

Forrester's model was presented to a world audience by Meadows *et al.* in 1972. The model was not performing any optimization exercise; it was comparing different strategies, showing that many intuitively plausible strategies – such as increasing capital accumulation to abate pollution – could not avoid the pattern of overshoot and collapse. What was required, these authors argued, was an end to population growth as well as economic growth.

With regard to population growth, most authors agreed and still agree that it would be highly problematic if humankind would keep growing toward 10 billion people in the foreseeable future. However, there is also a widespread agreement that global population growth is declining and will come to an end without overshoot and collapse. In contrast to other biological species, with humankind, population growth is slowed down by increased well-being.

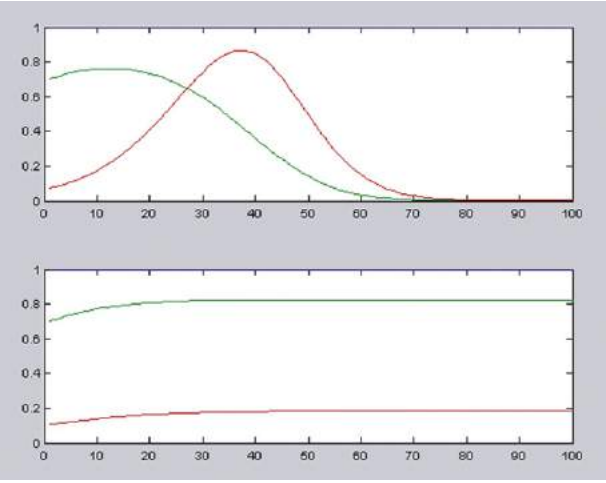

Fig. 1 Overshoot and collapse vs. sustainable management. Green: limited resource; red: resource use (resource use is scaled up for better visibility).

With regard to the economy, however, the claim of limits to growth immediately triggered a fierce debate. Robert Solow, also an economist at MIT (and Nobel Prize winner in 1987), wrote: ``I would like to state, briefly and bluntly, why I think the various `doomsday models' are worthless as science and as guide to public policy'' (Solow, 1972: 3832). His main point was that that the price mechanism would enable humankind to avoid overshoot in the face of limited resources by triggering substitution and innovation. During the following decades, economists developed models representing these mechanisms. A key claim of this kind of literature is that resource scarcity is not a big problem because it is precisely what markets can deal with, and that pollution increases with economic growth only in the early stages of economic growth. Once people get more affluent, they are supposed to be able and willing to abate pollution by technological means.

The debate took a new twist with the publication of the report *Our Common Future*. This report launched the concept of sustainable development, claiming that it was necessary and possible to develop new patterns of economic growth that would balance ecological, economic, and social needs. While the report steered clear of mathematical models and detailed empirical studies, it displaced the image of limits to growth in favor of the vague but attractive concept of sustainable development.

The debate on limits to growth is far from over, however. On one hand, the combination of environmental and political challenges raised by the globalizing economy of our time leads some authors to think again about the prospects of life beyond economic growth. On the other hand, there is a long-standing tradition of economists seeing economic growth as a transitory phase in the history of humankind – Ricardo, J. S. Mill, Marshall, Pigou, Keynes, Hicks all shared this view.

But while Ricardo emphasized the problem of limited resources already nearly two centuries ago, the main point of this tradition is a different one. In the famous words of John Stuart Mill, ``I confess I am not charmed with the ideal of life held out by those who think that the normal state of human beings is that of struggling to get on; that the trampling, crushing, elbowing, and treading on each other's heels, which form the existing type of social life, are the most desirable lot of human kind, or anything but the disagreeable symptoms of one of the phases of industrial progress'' (Mill, 1848: Bk iv, ch. vi, §iv.6.5).

Nitrogen Footprints

Adrian Leip, Joint Research Centre, Ispra, Italy
Aimable Uwizeye, Wageningen University & Research, Wageningen, The Netherlands; Food and Agriculture Organization of the United Nations, Rome, Italy; and Teagasc—Crops, Environment and Land Use Programme, Johnstown Castle, Wexford, Ireland

Introduction

General

Anthropogenic activities depend on nitrogen (N) to produce food and industrial products. This production causes the release of nitrogen into the environment in different forms (ammonia (NH_3), nitrous oxide (N_2O), nitrates (NO_3^-), organic nitrogen or di'nitrogen (N_2).

Nitrogen Footprints quantify the pressure of humans on the environment. They are expressed per unit of product or are aggregated at consumer level and expressed per capita. N footprints demonstrate the pressure from humans or production processes related to N losses into the environment. A precise definition for N footprints does not yet exist, and therefore the kind of pressure that is quantified varies between studies. A commonly used definition is that N footprint quantify N losses along the life cycle of a product, but it has also been used to quantify N mobilization by anthropogenic activities. There are some common characteristics of all N footprints values published: they are based on life cycle thinking, they are associated either with products—more often than not food products—or "consumers," and they describe a pressure on environmental systems or human wellbeing. Generally, footprints are understood as a tool with the potential to help on the road to more sustainability (Hoekstra and Wiedmann, 2014).

As such, the N footprint position itself clearly in the domain of environmental footprints reporting an inventory of N flows that are directly or indirectly of environmental relevance. N footprints do not attempt to quantify the environmental impact itself—thus they are not converted into a measure of increasing temperature with global warming potentials, or amount of coastal dead zones taking into consideration relative abundances of phosphorus and silica. Environmental impacts associated with N pollution are highly variable both in time and space and depend on numerous factors. N footprints thus usually serve as a proxy for such effects, but do not claim to quantify those effects. Rather, the main objective of N footprints is to give a robust measure for higher or lower possibility that a certain product or consumption contributes to N losses in a way that can be understood by peer scientists, stakeholders, decision makers, policy makers, and general public.

The idea of an N Footprint was developed by the Chesapeake Bay Foundation to raise awareness of people's impact on water pollution (https://secure.cbf.org/site/SPageNavigator/bay_footprint.html). The concept reached a wide audience with the paper by Leach *et al.* (2012) "A N footprint model to help consumers understand their role in N losses to the environment." Again, the main objective was to raise awareness amongst consumers that with their consumption choices they contribute to adverse effects related to N pollution.

This article reviews available N footprint concepts and provide recent results.

The Nitrogen Cycle

There is abundance of N stored in the atmosphere, oceans, and soils; however, most of it is not readily available for living organisms. The reason is that N is buried in sediments or rocks, or present as diN (N_2) which has a very strong triple bond ($N \equiv N$) that is difficult to break. Yet, N is an essential element for life on earth; it is a component of essential biomolecules, such as amino acids that build proteins, ATP, nucleic acids (e.g., DNA, RNA) and much of the N in plants is used in chlorophyll molecules. In nature, only specialized organisms are able to convert N_2 to N compound (NH_4^+) that can be used by organism. This is called "N fixation," which transforms "inert N" into "reactive N." The rhizobia bacteria and nodules associated with legumes roots perform N_2 fixation naturally from the atmosphere. The efficiency of legumes in fixing N_2 varies between species. At the industry level, N_2-fixation is achieved through the Haber–Bosch process which is energy intensive (Erisman *et al.*, 2008).

Reactive N is the term used for all N compounds other than N_2, as they are readily transformed from one form to another (Galloway *et al.*, 2004). Main reactive N groups distinguished are "oxidized" mineral N compounds such as NO_x (NO and NO_2), nitrate (NO_3^-), nitrite (NO_2^-), and nitrous oxide (N_2O), "reduced" mineral N compounds such as ammonia (NH_3), ammonium (NH_4^+), and organic N (Butterbach-Bahl *et al.*, 2011). Organic N exists in living organisms, humus or in the intermediate products of organic matter decomposition. N passes between the biotic environment (living organisms) and the abiotic environment (soil, water, air) via diverse processes, which altogether form the N cycle as illustrated in **Fig. 1**. Main transformation processes that are relevant for the N cycle are nitrification, converting ammonium to nitrate; denitrification, being a chain of reactions converting stepwise nitrate back to N_2; assimilation, incorporating mineral N into organic molecules; and mineralization releasing mineral N from organic matter.

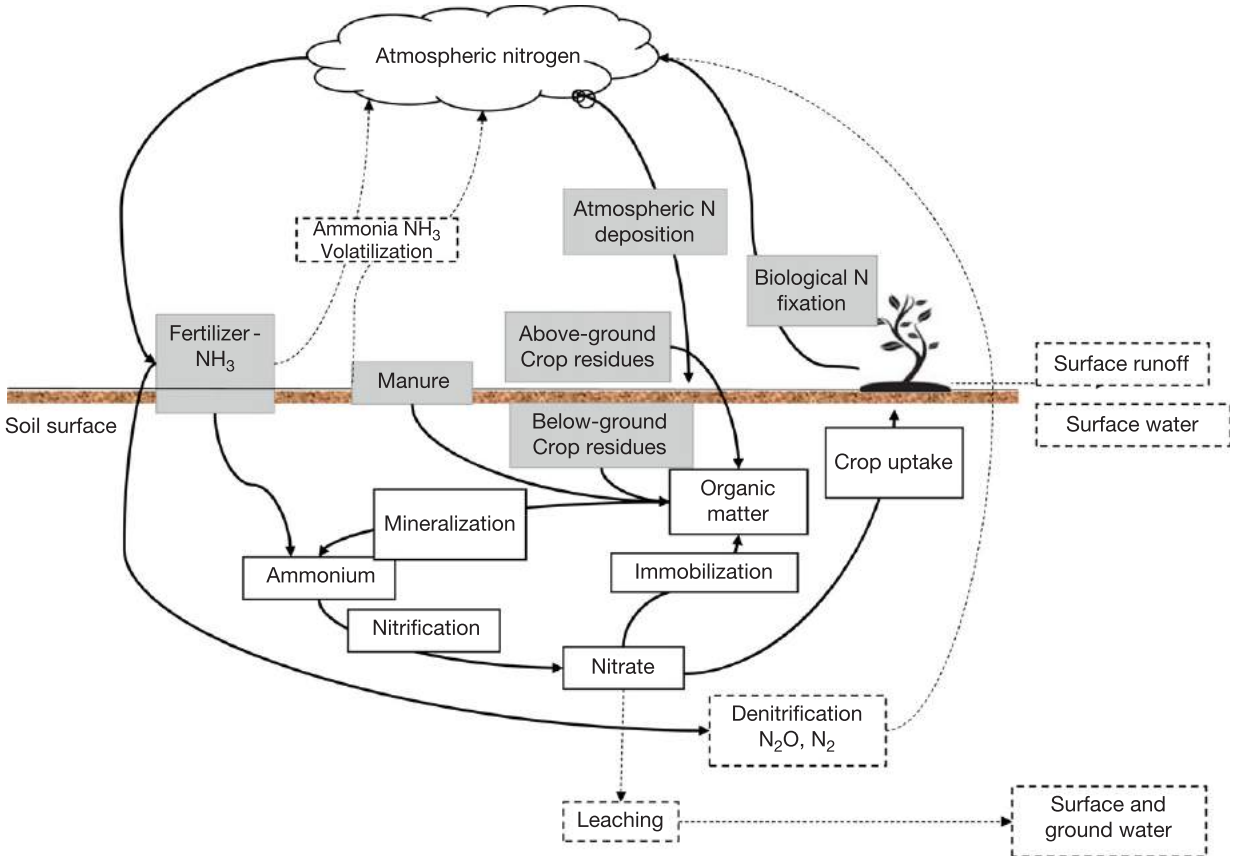

Fig. 1 The main pathways of the N cycle. Adapted from NRC, 1993. Soil and water quality: An agenda for agriculture. Washington, DC: National Academy Press.

Denitrification returns reactive N back into a stable form and thus closes the cycle. Other "sinks" for reactive N are accumulation in soils and sediments which "lock" reactive N making it effectively unavailable for further transformation processes at long time horizon.

Nitrogen Budgets

Before human intervention, about 200 Tg N were "fixed" annually, with the largest contribution from marine biological N fixation (140 Tg N $year^{-1}$), followed by terrestrial biological N fixation (58 Tg N $year^{-1}$) and a small contribution from N fixation by lightning (5 Tg N $year^{-1}$) (Fowler *et al.*, 2013). In preindustrial times, N was a scarce resource and limiting growth and agricultural production. Sources of N were cultivation of leguminous crops which are associated with N-fixing bacteria in rotation with nonfixing crops, transfer of N in manure from grassland with leguminous grasses, exploitation (and N depletion) of N-rich fertile soils, guano or mineral N deposits (Galloway and Cowling, 2002).

Only with the invention of the Haber–Bosch process early of the 20th century, it became possible to fix synthetically atmospheric N_2 into ammonia by a reaction under high temperature and pressure. Synthetic fertilizer creates now about 120 Tg N $year^{-1}$ new reactive N. Together with agricultural biological N fixation of 60 Tg N $year^{-1}$ it contributed to boost agricultural production and helped sustain the growing global population. Altogether, including ca. 30 Tg N $year^{-1}$ created in combustion processes, anthropogenic N fixation is at the same magnitude than natural N fixation (Galloway and Cowling, 2002). Recent estimates by Oita *et al.* (2016) suggested that 189 Tg N were realized worldwide in 2010, with 162 Tg from industries and agriculture through different loss pathways such as leaching, runoff and atmospheric emissions.

Area of Concern: The Environmental Impacts of Reactive Nitrogen

The increased release of reactive N compounds into the environment already surpassed the planetary boundary, with 150 Tg N losses annually (Steffen *et al.*, 2015). These N compounds are increasing the global environmental threats, through a complex net of interactions. The release of organic N and NO_3^- to surface water and groundwater contaminates the aquifers and freshwater resulting in impure drinking water. Moreover, in lakes and marine ecosystems. N pollution causes dead zones, hypoxia, fish kills

due to algal blooms, thus eutrophication that threatens the biodiversity. The air emissions of N_2O, which is a powerful greenhouse gas contributes to climate change, but N also contributes to global cooling with the formation of particles. N_2O is also contributing to stratospheric ozone depletion. Moreover, the emissions of NH_3 and NO_x degrade the air quality with direct impact to the human health. Furthermore, the deposition of N compound from atmosphere can also enrich the terrestrial ecosystem causing the disturbance of species, invasion of alien species causing impacts on biodiversity. Ammonia deposition can acidify natural and agricultural soils leading to soil degradation, fertility loss and erosion (Sutton *et al.*, 2011a,b).

Footprint Methods—Life Cycle Thinking

Production and Consumption Footprints

Human production and consumption processes are virtually always the result of a complex net of interactions and relationships. Basically, no product exists without the need of certain "inputs" that were consumed or appropriated in the production process. The smallest unit of which a footprint can be calculated is thus a specific product, such as an apple from a specific farm or 1 kWh of electricity from the local power plant. The scope of assessment can be broadened or generalized in two ways.

A scheme of the relationship between different footprints and the possibilities of increasing the scale of assessment is shown in Fig. 2. First option for aggregation of the footprint of a unit process is by production system, assessing the footprint of apples from a group of farms, differentiating, for example, by organic or conventional systems, or generalizing from apples to fruit or vegetable food products, usually measured in kg N (kg product)$^{-1}$. A second possibility of increasing the scale of assessment is by extending the boundaries from farm to processor, retailer. At this level, the N footprint assumes full responsibility of all actors in production systems, including farmers, businesses and industry sectors (Lenzen *et al.*, 2007), thus informing policy makers on the magnitude of the production activities affecting the natural resources and environment. Finally, the boundary are extended to the consumer, including or excluding the end-of-life phase of a product. Often, the two processes go in parallel yielding consumption footprints of product or product groups. Consumption footprints are often expressed on a per capita basis (kg N (capita year)$^{-1}$) or a (also temporary) community (then measured in kg N if boundaries are explicit), such as per capita footprint of canteen lunch. This requires the aggregation of individual consumption footprints of food (groups) taking into consideration consumption pattern and—in the case of processed foods—the footprints of the processed ingredients. Here, the assumption is that the demand of products is causing the N pollution, thus allocating full responsibility to the consumers (Lenzen *et al.*, 2007). Another approach that is not used so far for N footprint is to express the N footprint in function of incomes (Marques *et al.*, 2012, 2013).

Either production footprints or consumption footprints can be up-scaled increasing the regional scope from regional over country, continental and finally global scale. At all levels below the global scale, production and consumption footprints differ as long as products and/or inputs in the production process are traded across the geographical boundaries. N flows embedded in imported products that are consumed are included in consumption footprints, but not in production footprints unless they are

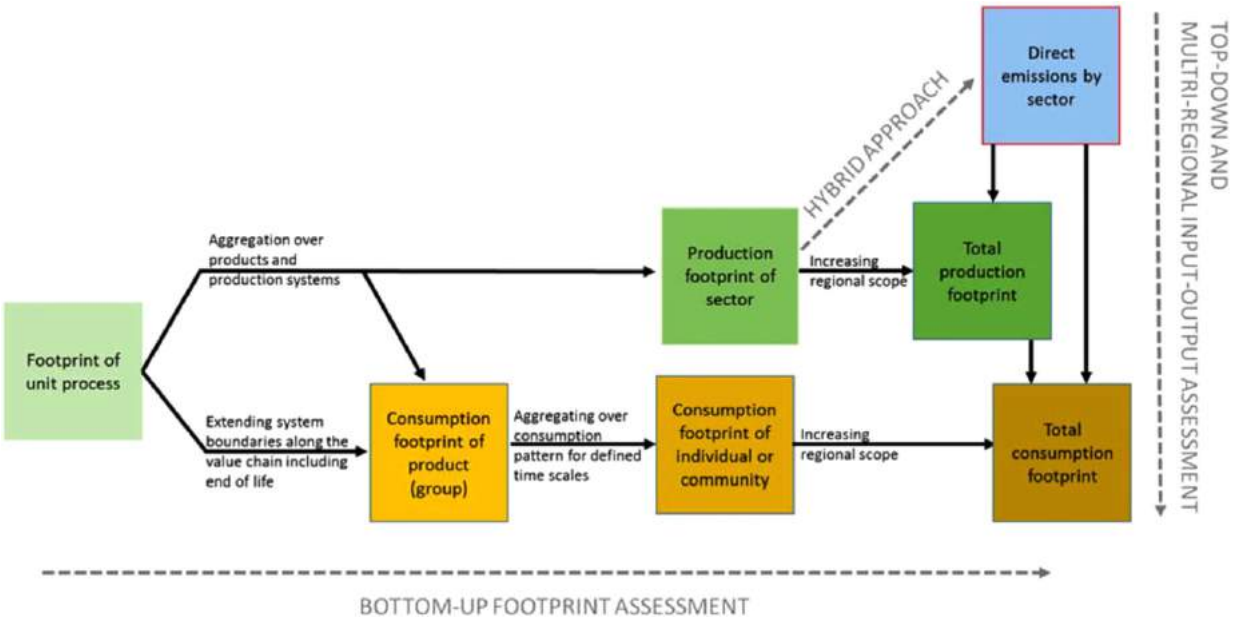

Fig. 2 Production and consumption footprints at different level of aggregation. Footprint estimates starting from unit processes are following a bottom-up approach. Footprint estimates based on total emission estimates per sector are following a top-down approach, often using multiregional input–output tables. The hybrid approach (Bruckner *et al.*, 2015; Cui *et al.*, 2016) combines both methods.

used in the production process. On the other hand, N flows embedded in exported products are considered in the production footprints but not in the consumption footprints (Galloway *et al.*, 2007; Oita *et al.*, 2016).

The most common applications of the N footprint concept has been done at the level of food products or food product groups, and at the level of annual per capita consumption of food and energy (Leach *et al.*, 2012). Per capita calculations take into considerations the choices made by an individual or by a "representative" individual of, for example, a country and typical or average product-level footprints of the products consumed. In some cases, footprints are also quantified for groups of persons for a limited time-period, for example, a group dinner, a conference or similar. These are discussed below in the section of N footprint derivatives. Multiregional input–output analyses "invert" the flow of monetary value to follow flow of environmental impact such as N losses embedded in products traded and highlighting losses distant from the place of production or consumption (Bruckner *et al.*, 2015; Kastner *et al.*, 2011; Oita *et al.*, 2016).

Life Cycle Assessment (LCA)

LCA is a methodological framework that quantifies all environmental impact caused during the life cycle of a product or a process. During the life of a product, other products are needed as input. For example, a bread requires the wheat to be harvested, energy for baking and transport, paper for packaging and so on. Wheat requires fertilizers, plant protection products, energy for cultivation, barns, etc. To produce the fertilizers, energy, natural gas and phosphorus ore are used. To fully account for all environmental impacts during the life cycle of the product under study (here the bread), this gives in theory a large network of products which contribution to the total environmental impact of the bread need to be quantified. As this is very difficult, an LCA study distinguishes "foreground" data, where the accounting of the relevant parameters for the impact (life cycle inventory) are measured or obtained from high quality data sources that are specific for the life cycle of the product, and "background" data where impact factors are obtained from databases, which are available (e.g., IPCC guidelines (http://www.ipcc-nggip.iges.or.jp/public/2006gl/) or OpenLCA (http://www.openlca.org/)).

LCA is used to support decisions and policies along production supply chains. It is a standardized method (ISO 14040:2006 and ISO 14044:2006) defined in four phases: goal and scope definition; life cycle inventory (LCI), consisting of the collection of data that identify the inputs and outputs of the systems, the algorithms to estimate the release of the pollutant into the environment; life cycle impact assessment (LCIA), where the emissions are converted to "impacts" with the help of impact models or impact characterization factors; interpretation.

A fundamental principle of a life cycle assessment (LCA) is that the impact of a so-called "functional unit" (such as a kg of bread) is assessed comprehensively without omitting one or several impact categories. This is based on the conviction that a comparison between different processes or value chain producing the same functional unit—or a comparison between different product cannot be done only if looking at, for example, greenhouse gas emissions or eutrophication or ozone depletion, but requires appreciation of all possible impacts.

Difference Between LCA and Footprints

In contrast to a LCA, an N footprint looks exclusively at the area of concern of N effects. This is similar to the water footprint looking at water issues, the carbon footprint quantifying total GHG emissions, or the ecological footprint being a comprehensive measure of the overall land requirement. Each of these footprints has been developed independently and consequently there are no common rules or definitions that apply to all of these—and other—footprints, even though recent efforts to classify footprints into a "footprint family" or providing rules for categorizing footprints try to overcome this situation.

Only recently first studies proposed classification systems for the "footprint family" or common definition (Fang *et al.*, 2016; Galli *et al.*, 2012). All footprints are based on life cycle thinking thus conceptually assessing supply chains and considering emissions from upstream processes. However, studies differ in which and how many processes are included (so-called system boundaries), and how emissions are to be distributed (allocated) if one process produces other products than the one of interest. Differences exist also in the methodology how N footprints are calculated. Therefore, it is important to be clear about those issues when using or comparing results from N footprint studies.

Nitrogen Footprints

In its "simplest" form, N footprints follow the flow of N in a supply chain and sums over all N losses that occur in the different stages. The total losses are then put in relationship to the N that is contained in the product at time of consumption. Losses of N occur also after consumption in the end-of-life stage of a product. All losses considered in N footprints of food supply chain are to be considered as anthropogenic.

In most cases, N footprints are quantified for food/agricultural products or food/agricultural commodities. This is because most nonagricultural products have little environmental relevance linked to N losses different than the losses occurring through energy consumption. This is true also for industrial products which contain N, such as nylon, adhesives, coatings, or explosives.

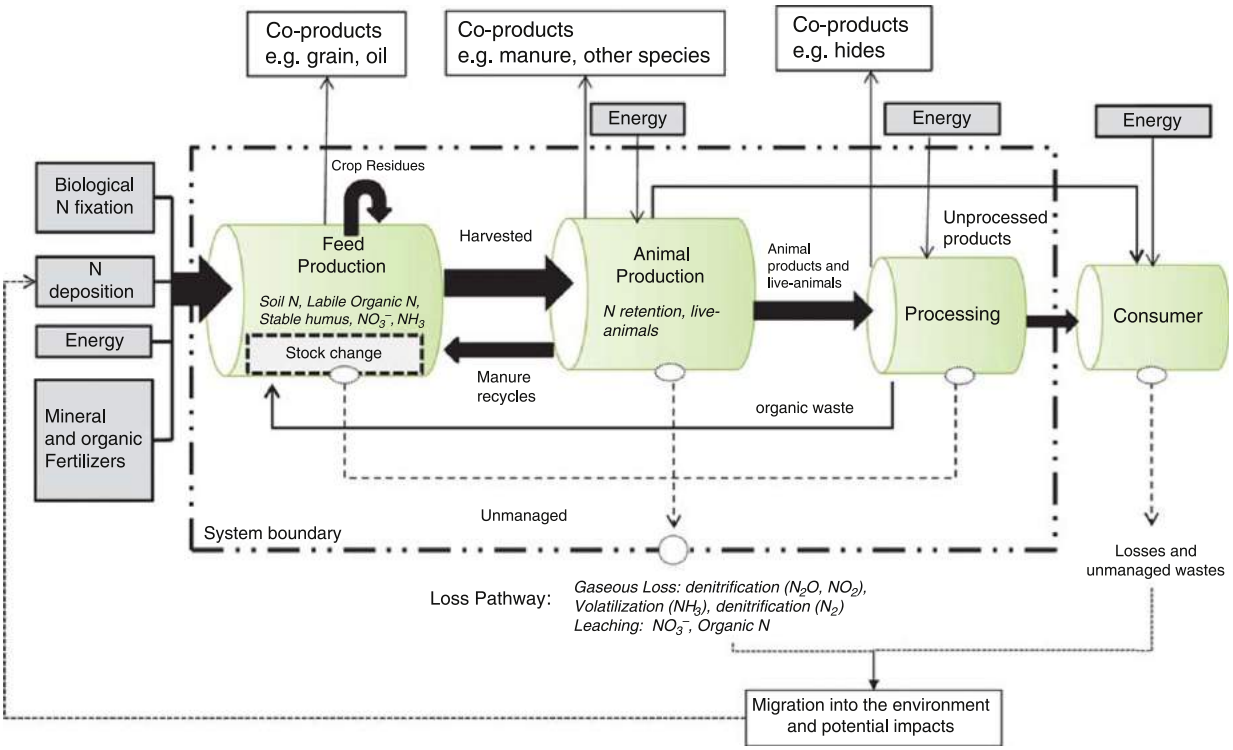

Fig. 3 Example for system boundaries and N flows in a livestock supply chain. Adapted from Uwizeye, A., Gerber, P.J., Schulte, R.P.O., de Boer, I.J.M., 2016. A comprehensive framework to assess the sustainability of nutrient use in global livestock supply chains. Journal of Cleaner Production 129, 647–658. doi:10.1016/j.jclepro.2016.03.108.

The ratio of total N losses N_{loss} and the consumption or intake of N N_{intake} is called the N-loss factor NLF (sometimes also called virtual N factor). It gives the amount of N, which is dispersed in the environment for each kg of N that is consumed. If the *NLF* is known, then the N footprint is obtained by multiplying *NLF* with the concentration of N in the product when it is consumed ($\frac{N_{intake}}{m}$).

The N footprint Φ_N calculates from:

$$\Phi_N = \frac{N_{loss}}{m} = NLF \cdot \frac{N_{intake}}{m}, \text{with } NLF = \frac{N_{loss}}{N_{intake}}$$

where Φ_N is the footprint of a product (kg N (kg product)$^{-1}$), N_{loss} are total N losses (kg N), N_{intake} is the consumption (intake) of N with the product (kg N), and m is the mass of the product (kg product).

These concepts are illustrated in **Figs. 3** and **4**.

Fig. 3 shows a simplified example of a supply chain, in this case for an animal product such as meat or eggs. The supply chain consists of four stages: cultivation of crops for feed, animal production, processing of the product and consumption. The figure shows the main types of input at each stage. Most diverse are the inputs in the crop cultivation stage, as N inputs are received in form of mineral and organic fertilizers, biological N fixation or from atmospheric deposition. In addition, N could be released from soils by mineralization of organic matter or—in contrast—be assimilated into organic matter and accumulate in the soil. For reasons that will be discussed below, such "input" is usually accounted for as a positive (if accumulation occurs) or negative (if soil N depletion occurs) coproduct. Reactive N emitted to the atmosphere during the combustion process for energy generation is considered as both "input" and "losses" so that the balance is closed. For all other stages than crop cultivation, emissions due to energy use is the only "input" into the process.

The most common N footprint—as also defined above—quantifies total N losses that are associated with a product consumed or with consumption of products and energy in general.

Several studies quantify only part of the N footprint, for example, only the N footprint from agricultural production ignoring N losses from energy consumption, or apply different methods for losses occurring in the agricultural supply chain and for losses related to energy consumption. It is therefore useful to distinguish "subfootprints" related to agricultural production and energy.

The total N footprint Φ_N is the sum of the agricultural N loss footprints $\Phi_{N_{loss,\ agri}}$ and the energy N loss footprint $\Phi_{N_{energy}}$.

$$\Phi_N = \Phi_{N_{loss,\ agri}} + \Phi_{N_{energy}}$$

The difference between N losses from agricultural production and energy consumption is illustrated in **Fig. 4**, showing schematically the different components of N inputs and outputs, emphasizing the occurrence of recycling flows.

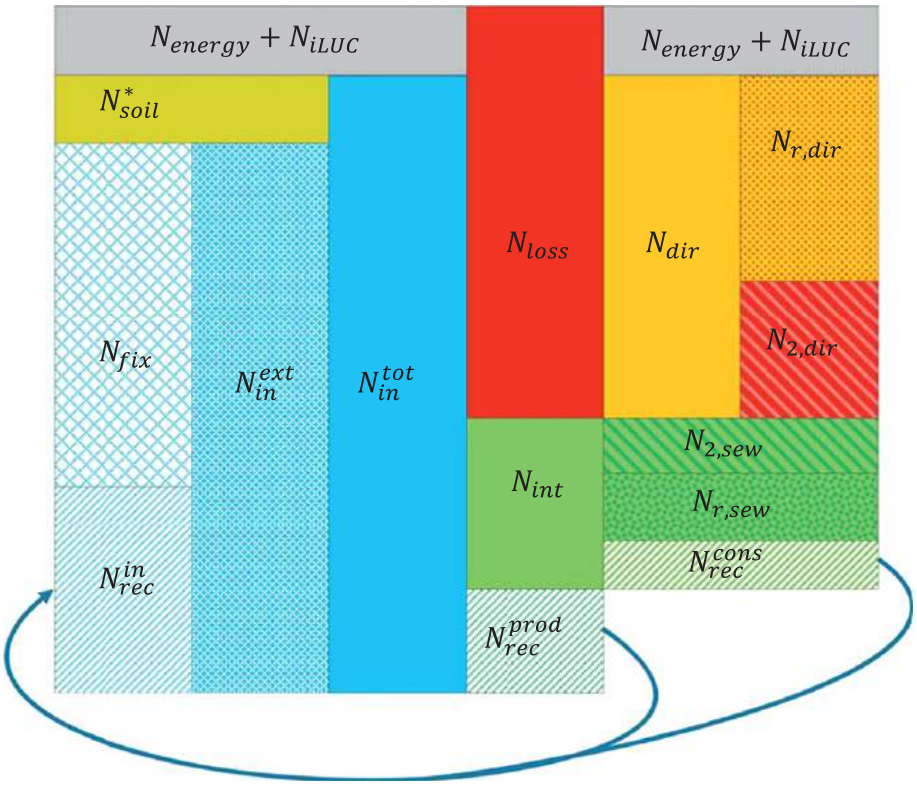

Fig. 4 Schematic representation of N input, N output and N recycling flows in a typical supply chain. Total N mobilization is the sum of N consumed (N_{int}), N lost to the environment (N_{loss}) and N that can be recycled in the process (N^{prod}_{rec}). The mobilized N is obtained from losses through the use of energy and land use changes (N_{energy}, N_{iLUC}) and through inputs to the soil (N^{tot}_{in}), either by mineralization of soil organic matter (N^{*}_{soil}) or by external input N^{ext}_{in} from newly fixed N (N_{fix}) which can be done either through biological nitrogen fixation or the Haber–Bosch process, or by recycling of N (N^{in}_{rec}). Losses of N are either the losses from energy and land use change or direct losses of reactive nitrogen or molecular nitrogen ($N_{r,\ dir}$, $N_{2,\ dir}$). N that has been consumed is partly converted to N_2, for example, in sewage system ($N_{2,\ sew}$) or lost ($N_{r,\ sew}$) or recovered (N^{cons}_{rec}) in sewage sludge. Hashed boxes represent losses of N with no direct impact on the environment, as molecular N is inert; double-hashed boxes represent creation of new reactive N (both synthetic and natural N fixation). Note that N^{*}_{soil} is indicated in the input-side, but is commonly accounted for as a coproduct in crop cultivation and thus as a positive output if soil N is accumulating or a negative output if N stocks are declining. This is denoted with the star-superscript. Reprinted from Leip, A., Leach, A., Musinguzi, P., Tumwesigye, T., Olupot, G., Stephen Tenywa, J., Mudiope, J., Hutton, O., Cordovil, C.M.dS., Bekunda, M., Galloway, J., 2014a. The nitrogen footprint of food products in the European Union. The Journal of Agricultural Science 152. https://doi.org/10.1017/S0021859613000786.

Table 1 shows an example of different N loss and N input footprint for food production in the European Union (EU27), calculated for the year 2004 with the CAPRI model (Leip *et al.*, 2015) (Data available at https://doi.org/10.5281/zenodo.58514), with the objective to quantify the contribution various environmental pressures from agriculture and livestock production system in Europe. Losses correspond to total N losses from agricultural production and energy consumption; N input corresponds to N sources of crop production. The authors calculated also some agricultural N input footprints as shown in **Table 1**.

Agricultural Nitrogen Footprints

Even though the agricultural N loss footprint includes the loss of N_2 which does not have any adverse effect. It is an indicator for the anthropogenic mobilization of N (Pelletier and Leip, 2014). Thus, it is closely linked with the concept of the planetary boundary for N (Steffen *et al.*, 2015), and with the concepts of N use efficiency (NUE) and gross N balance (GNB)—the latter two indicators commonly use to describe the environmental performance of agricultural systems.

NUE and GNB can be estimated at a process level or at a supply chain level (Mu *et al.*, 2017; Uwizeye *et al.*, 2016, 2017). These indicators are more relevant for the production and indicate the ability of a supply chains to recover the N inputs into the end-products. NUE is a complementary indicator to N footprint, whereas GNB is slightly different from N footprint, because it doesn't account for soil N stock change. Beside the NUE and GNB a number of agri-environmental indicators are commonly used to describe the environmental performance of farms, amongst those the input of mineral fertilizer, total nitrogen input, emissions of ammonia, nitrogen leaching or the nitrogen surplus which is calculated as the difference of total N inputs and total useful N

outputs. These indicators are particularly linked to the stage of agricultural production and are usually expressed as kg N per hectare and year. Such indicators are thus available to describe farms, but they have limited value of describing the environmental performance with respect to nitrogen of food products obtained from different production systems or for which the land requirement is unknown. The nitrogen budget footprints use life cycle thinking for quantifying all terms in a full nitrogen budget and refer it to the final product.

It makes therefore sense to broaden the concept of N footprints and apply it not only to N losses, but also to N input sources, which allows to quantify indicators in analogy to the agro-environmental indicators already commonly used.

Thus, the nitrogen budget footprints can be regarded as a footprint "group," which encompasses:

- Agricultural N input footprints: footprint of synthetic fertilizer nitrogen application; footprints of organic fertilizer nitrogen application (manure, compost, sewage sludge …), and footprints of biological nitrogen fixation and atmospheric deposition. These footprints account for new nitrogen input with regard to agricultural production, thus newly fixed nitrogen or nitrogen that comes from a different sector. A manure footprint accounts only for manure application, which comes from other supply chains.
- Agricultural N loss footprints: NH_3 footprint, NO_x footprint, N-runoff and N-leaching footprints, N_2O and N_2 footprints.

Each of these agricultural N footprints quantifies the total agricultural flow in supply chains. They give all information required to calculate the NUE or GNB at product—or consumer level. Roughly the input footprints can be classified as "resource footprints" and the loss footprints can be classified as "emissions footprints," both with an orientation of inventorying flows rather than being impact-oriented (Fang *et al.*, 2016).

Both sets of agricultural N footprints—the total agricultural N input footprint and the total agricultural N loss footprint are closely related, as the different of the two are the N content in the product, as long as the losses in the end-of-life phase (after consumption) are not included.

$$\Phi_{N_{input}} = \Phi_{N_{loss}} + N_{intake}$$

$$N_{intake} = N_{loss}^{EoL} + N_{recycled}^{EoL}$$

Where EoL refers to the end-of-life stage of the life cycle of a product, and the subscripts *loss* and *recycled* refer to the quantities of N that are lost to the environment or re-used as fertilizer in agricultural production.

Energy N Footprint

NO_x and N_2O emissions occur both from agricultural systems and from energy consumption and some industrial processes including fertilizer production. $\Phi_{N_{energy}}$ all Nr emissions caused by the consumption of energy. They include energy-related emissions along the full supply chain, including the production of agricultural inputs (fertilizer, plant protection, etc.), energy use on the farm (fuels for tractors, heating, milking machines, electricity etc.) and postharvest processes such as drying, transport, processing, retailing, etc. depending of the system boundaries of the study.

Methodological Choices

Quantifying soil stock changes

Amongst the largest uncertainties for agricultural N indicators and N footprints is the level of changes in the N content in soils. Soil organic matter is an important factor determining soil fertility, which contains next to carbon also N. The build-up of soil organic matter is usually regarded as a positive outcome of farm activities, with positive effect on future crop yields and contributing to carbon sequestration. Carbon sequestration is considered amongst the most important mitigation options available today to farmers in the fight against climate change. Losses of soil organic matter over time instead is regarded as "soil mining," has the potential of jeopardizing future crop yields, causes soil degradation, and contributes to greenhouse gas emissions.

It has therefore been argued that even though mineralization of soil organic matter serves as a source of N for crop growth, the accumulation of N in newly created soil organic matter must be regarded as a positive outcome of the farming activity worth equal to the production of crops—in fact, N which accumulates in soil organic matter can be used in a later year for crop growth, in which case the N is to be accounted for as "negative" output.

However, quantification of soil stock changes is very difficult, as it is a relatively slow process and the detection of statistically significant differences in soil stocks requires measurement of soil N concentrations in distant points in time, for example, after 10 years. This is in most cases not possible. Therefore, different methods have been proposed to approximate soil stock changes in N budget or N footprint studies.

The simplest method is the "balance" approach. It considers soil stock changes as the most uncertain term in the N balance:

$$N_{input} = N_{output} + N_{stockchange}$$

Whereby N_{output} includes all output flows of N, both losses N_{loss} and N in products $N_{products}$. We use here $N_{products}$, as this N balance refers usually to the soil–crop continuum, thus the product is the crop harvested or otherwise removed from the soils, but additional losses can occur downstream of the supply chain before the food is consumed as N_{intake}. The problem with this method

[a]Methodology: bottom-up (BU), top-down (TD), multiregional input–output assessment (MRIO), or hybrid (bottom-up/MRIO).

[b]Reference year often approximate as values from different years are used. The year usually refers to the year for which the consumption pattern was estimated. n.d. = no specific reference year was given.

[c]Calculated on the basis of total N emissions from the European Nitrogen Budget and total EU27 population. The N footprint accounts that about 70% of agricultural supply are used for domestic consumption, 30% for export.

[d]Calculated on the basis of food production footprints in g N/kg product and quantities used for human consumption as used in Leip *et al.* (2014a,b).

is that it requires other N output flows to be determined with high accuracy, which is often not the case, as the amount of diN produced is virtually never measured, but can constitute a considerable share of the total output flows.

Another method uses data sets for conditions where soil stock changes are assumed to be absent or very small. These data can be used to extrapolate to conditions where soil stock changes are very likely. In order to identify which data set is or is not likely to represent conditions with soil stock changes the "apparent" N use efficiency can be used, ignoring soil stock changes:

$$\mathrm{NUE} = \mathrm{N}_{output}/\mathrm{N}_{input}$$

In conditions where a share of the crop uptake N originates from mineralized soil organic matter, the NUE will assume higher values. Apparent NUE of more than 100% have been measured, in particular in Sub-Saharan African countries where soil mining is a severe environmental problem. A threshold of 85% has been proposed as a NUE, which could possibly be reached without drawing on soil resources. On the other hand, soil accumulation—if not quantified—pushes the apparent NUE down. This method has been tested over a multiannual data set for the soil N budget in Turkey at the regional level (Özbek and Leip, 2015).

A third method has been developed for countries with poor data availability and generally low N input level. In Tanzania, only a small share of soils is fertilized—on most fields crops grow on N supplied by atmospheric deposition, possibly biological N fixation and manure. The difference in the yield in fertilized versus un-fertilized yields has been used to approximate the possible order of magnitude for soil mining under Tanzanian conditions (Hutton *et al.*, 2017).

N_2 as nonharming N loss

The first definition of a N footprint was given by Leach *et al.* (2012) who developed a N-footprint model "[…] that defines an N footprint as the total amount of Nr that is lost to the environment due to individual's consumption of food and energy". This definition is explicitly given for their "per capita" N footprint model, thus the definition does not exclude that N footprint be quantified at product level or for groups of products or persons.

It has been argued that this definition was not completely clear in that the model included losses of N_2 in the food production chain, but excluded losses of N_2 in the food consumption part of the food N footprint. Leip *et al.* (2014a,b) interpreted this by differentiating between Nr releases, which refer to the status of N that is lost (such as fertilizer or manure N). This is in contrast to N_2 emissions which describe the status of N when it leaves the system boundaries (e.g., the crop root zone).

Generally, it is debated whether N_2 emissions should be included in N footprints. Arguments supporting it include the close relationship to other indicators such as N use efficiency and N surplus. These indicators are already established and are readily

calculated from in- and outputs of N, as least under those conditions where soil N stock changes are not significant. This makes interpretation easy. Moreover, N_2 emissions can be included due to its relevance for a measure of anthropogenic mobilization of N. On the other side, mainly the argument of lacking environmental relevance is made, as N_2 is inert and does not contribute to any environmental impact.

National N Footprint Estimates

Table 2 provides an overview of N footprint estimates at national scale and from a consumer perspective. Most of these studies include the entire economy, thus consider N losses from agriculture and energy consumption in all sectors, some focus on food the agricultural N footprint.

Most studies use a bottom-up approach for calculating the food footprint according to the methods proposed by Leach *et al.* (2012), estimating N-loss factors for different food or food groups and applying those factors to typical consumption rates obtained from surveys or food balance sheets. The energy footprint is often obtained from a combined bottom-up/top-down approach by quantifying typical consumption of energy per household or person for housing, cooking, transport and applying emission factors. More indirect energy-related emissions are calculated from a input–output table calculating the Leontief inversion (Leontief, 1966). Leip *et al.* (2014a,b) uses a bottom-up approach for food production footprint only, using data for representative farm at regional (province) level and calculating typical N footprints for 12 food groups. The authors present the results at farm-gate footprint, here the consumption footprint has been calculated using national consumption and population data.

A top-down method to calculate the N footprint has been applied by the studies of Gu *et al.* (2013) and Leip *et al.* (2011). These studies are based on a national material flow analysis of N in China and Europe, respectively, accounting for all Nr losses in agriculture and forestry, industry, energy and transport, waste and associate it with human consumption. This top-down method is not an input–output analysis, therefore does not account fully for trade flows. The data based on Leip *et al.* (2011) are corrected for an average ratio of domestic supply used for human consumption and export, however, as Europe exports high-footprint animal products in greater shares as crop products, this leads to an overestimation of the food production footprint.

Full accounting of global trade flows is possible in multiregional input–output analysis as done by Cui *et al.* (2016) for China and Oita *et al.* (2016) for 188 countries globally. These models are able to capture also indirect flows of embedded nitrogen losses such as export of goods, which are based on imported raw materials.

Nitrogen Footprint Derivatives

The idea of N footprints was very closely connected to the importance of the nitrogen–environment interaction being a highly complex multipollutant multieffect problem on one hand that stands in contrast to the lacking knowledge or mono-causal thinking in the population. Thus, N footprints shall serve both for awareness rising and giving a relatively simple instrument that helps reducing N pollution.

Different tools have, therefore, been proposed that can be used for different target groups and with a wide range of focus. An overview of such tools is given in Galloway *et al.* (2014).

N Calculator

The N calculator http://n-print.org/ (Leach *et al.*, 2012) is an online tool that asks for information on the normal consumption habit of a person and calculates the N footprint on the basis of representative N loss factors for the country the person lives in. Data are collected as average weekly servings of food groups such as poultry, pork, beef, seafood, cereals, potatoes, cheese, legumes and so on. Additionally, energy consumptions is estimated based on weekly energy and gas consumption and mobility behavior. The N calculator presents the results of the calculated footprint, indicating the share of food production, food consumption, housing, transportation, etc. on the total footprint and in comparison with the countries' average composition of the N footprint. Additionally, information is given, for example, on how the N footprint could be reduced, the difference of new and recycled N in food production, and organic versus conventional farming systems.

N Footprint for Institutions

The N footprint for institutions http://www.n-print.org/N-Institution (Castner *et al.*, 2017) is a tool that helps institutions such universities to quantify their N footprint, work out solutions for reducing it and developing indicators for monitoring progress. Castner *et al.* (2017) compare seven U.S. institutions. About 50% of the institution's footprint was associated with food production, one-third with utilities and about 8% with transportation. Novel metrics such as the share of animal product purchases relative to total purchases by weight, the average protein content of food purchases, or institution "virtual N factor" (N-loss factor,

Box 1 Definition of N neutrality

Definition of N neutrality

To achieve N neutrality,

1. first decrease the release of reactive nitrogen (Nr) into the environment by
   a. reducing over-consumption of food and reducing food wastes and minimizing energy consumption, and
   b. choosing sustainable sources of energy and food;
2. then, contribute to a measured compensation of the remaining Nr releases by a measured
   a. reduction of Nr releases elsewhere *to balance the remaining releases*,
   b. increased sustainability in the production of food *where sustainable land management is not yet achieved*.

Definition of sustainable land management

3. With respect to N neutrality, sustainable land management is a farming system which
   a. minimizes the ecological footprint of the farming products (incl. The C footprint, N footprint, water footprint)
   b. keeps the farmed land in good environmental conditions
   c. satisfies human food needs and enables the farm worker(s) and their families to a decent living standard

measures in kg N losses per kg of N in purchased food) help the institutions to evaluate their performance in comparison to other institutions and thus identify possible directions for changes.

Nitrogen Neutrality

The N-neutrality concept (Leip *et al.*, 2014a,b) was developed for the 6th International N Conference to raise awareness amongst both conference participants and conference caterer about the consequences of N losses and possible reduction options. N neutrality is a concept similar to carbon-neutrality. In brief, it quantified the level of N pollution caused by and during the conference, implements reduction measures, and "offsets" the remaining N pollution by sponsoring a project that reduces N pollution elsewhere. The concept is thus a "hierarchical" one and allows N compensation only if all possibilities of N-loss reductions are exhausted. The definition of N neutrality as proposed by Leip *et al.* (2014a,b) is given in Box 1.

The concept of N neutrality has been challenged:

- It does not stop at the mere quantification of the N footprint and suggestion of N-loss reduction options, but it engages the conference organizers and participants to actively reduce the N footprint and "pay" for the N footprint that could not be reduced which might raise questions of responsibility and a possible reference level of N losses.
- This aspect of compensation has been criticized as favoring a mentality of "greenwashing" any N pollution (when the hierarchy of N neutrality is ignored or weakly interpreted), while impact of the offsetting project that is sponsored might be questionable.
- It might difficult to find a compensation project that reduces losses of N with equivalent impact, given the multitude of possible impacts that Nr losses have, and their huge variability in space and time. The N-neutrality concept can therefore embraced only if a more generic interpretation of "equivalent impact" is accepted andEncyclopedia of Ecology, 2nd edition reduction of N pressure rather than N impact is seen as the objective.

Since its introduction, the N-neutrality concept has been tested under different circumstances in a number of workshops and conferences.

Nitrogen Labels

Amongst the main purposes of the quantification of N footprints is to inform the "consumer" on the effect of his or her choices on the environment. Food labels are mandatory in many countries and give information on the nutritional value of the food. Quality labels inform about certain sustainability aspects, such as organic agriculture, fair trade, rainforest protection, GMO free etc. However, information on the environmental pressure in general such as greenhouse gas emissions, N pollution or water use are not established. Four possible designs of such labels are being discussed by Leach *et al.* (2012): (a) stars label; (b) stoplight label; (c) nutrition label add-on (based on the U.S. label design indicating the percent of daily recommended value for each nutrient—here the percent of the N footprint relative to a reference diet); and (d) detailed comparison table giving easy-to-interpret comparisons.

Ozone Layer☆

D Karentz, University of San Francisco, San Francisco, CA, USA

Introduction

Exposure to sunlight is generally an unavoidable consequence of being alive and life on Earth relies on the ozone layer to attenuate biologically harmful ultraviolet B (UVB: 280–315 nm) wavelengths of the solar spectrum. While ozone depletion has initiated concern about the effects of increased UVB on the biosphere, UVB filtered through a normal ozone column is still a considerable environmental stress. UVB exposure can cause declines in growth and reproduction that can eventually lead to reduced productivity or death; and although damage and protective/repair mechanisms are common across taxa, there is wide species-specific variation in UVB responses. In order to understand the ecological impact of the ozone layer as a UVB filter, the UV photobiology of species, populations, and individuals needs to be understood in the context of primary productivity, biodiversity, trophic energy transfer, and biogeochemical cycling.

Ozone and UVB

Ozone and the Spectral Quality of Incident Sunlight

Atmospheric attenuation of the solar spectrum

Radiation emitted by the Sun ranges from gamma rays (10^{-18} m) to radio waves (10^{7} m). Fortunately, at sea level, solar radiation has been stripped of its most biologically damaging wavelengths by gases in the atmosphere, most notably water vapor and ozone. All X-rays, some UVC (100–280 nm) and some UVB (280–315 nm) wavelengths are absorbed in the outermost atmospheric layers, the thermosphere and the mesosphere. The stratosphere contains 90% of the ozone in the atmosphere, and this ozone layer filters out the remaining UVC and most UVB (Figures 1 and 2). The shortest UVB wavelengths reaching the ground are 285–290 nm.

The attenuation of UVC and UVB is through the photochemical dissociation of ozone and its subsequent reformation from the diatomic and singlet oxygen products ($O_3 \leftrightarrow O_2 + O$). UVA (315–400 nm), visible (400–750 nm), and infrared

☆*Change History:* March 2013. D Karentz updated graphic and legend of Figure 3; and edited entries in Further Reading and list of Relevant Websites.

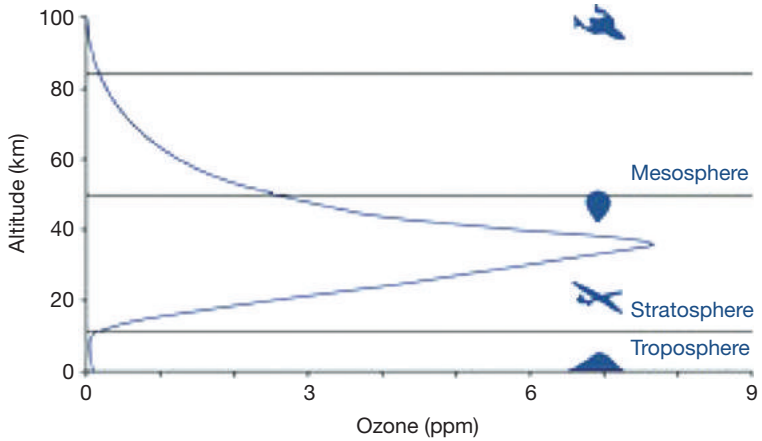

Figure 1 Vertical distribution of ozone in the atmosphere and location of the ozone layer. Redrawn from US National Aeronautics and Space Administration (http://www.nasa.gov).

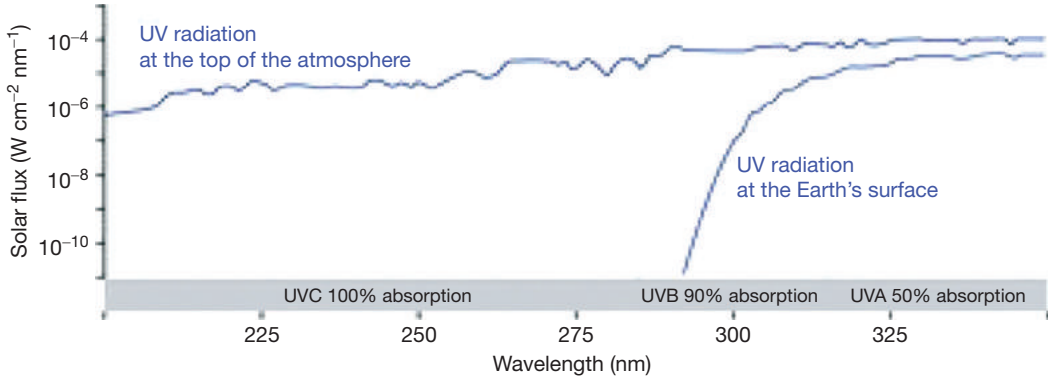

Figure 2 Differences in spectral quality and intensity of UV radiation at the top of the atmosphere and at the Earth's surface. Redrawn from US National Aeronautics and Space Administration (http://www.nasa.gov).

(750 to 1×10^6 nm) wavelengths also reach sea level and are partially attenuated by atmospheric gases and aerosols, but are not affected by ozone concentrations.

Clouds play a dominant and complex role in reducing UVB intensities. Clouds do not attenuate UVB wavelengths as efficiently as UVA or visible light; therefore, while cloudy skies lower incident radiation intensities, they may enhance the ratio of UVB to higher wavelengths.

Ozone depletion

From the 1970s to the turn of the century, synthetic halogenated compounds (e.g., chlorofluorohydrocarbons, CFCs) initiated declines of 3–6% in stratospheric ozone levels over tropical and temperate latitudes (60° N–60° S). More ozone was depleted over polar regions, with the largest-magnitude depletion (over 50%) still occurring seasonally over Antarctica (**Figure 3**). While the pollutant compounds are quite stable in the troposphere with long residence times (40–80 years), they eventually migrate into the stratosphere and disrupt the equilibrium of ozone dissociation and reformation described above (**Figure 4**). International compliance with the Montreal Protocol on Substances that Deplete the Ozone Layer has successfully limited the release of ozone-depleting substances, and ozone layer recovery to pre-1980 status is expected within the next 100 years.

Considerations for UV Exposure

In addition to ozone and clouds, numerous other factors can influence the amount of UVB exposure received by an organism. Latitude affects the intensity of sunlight through solar zenith angle (greatest at the poles) and thickness of the atmosphere (greatest at the equator). In terrestrial habitats, UVB doses are modified by canopy layers and availability of shaded microenvironments. In aquatic ecosystems, dissolved substances and particulate matter in the water column usually eliminate biologically harmful intensities of UVB within the upper 20 m. Vertical mixing will further determine actual exposures of planktonic organisms.

Temporal exposure factors of seasons and photoperiod are also defined by latitude, and local weather will affect the intensity of UVB on scales of minutes or days or longer. At latitudes below 60°, changes in ozone concentration occurred gradually over two

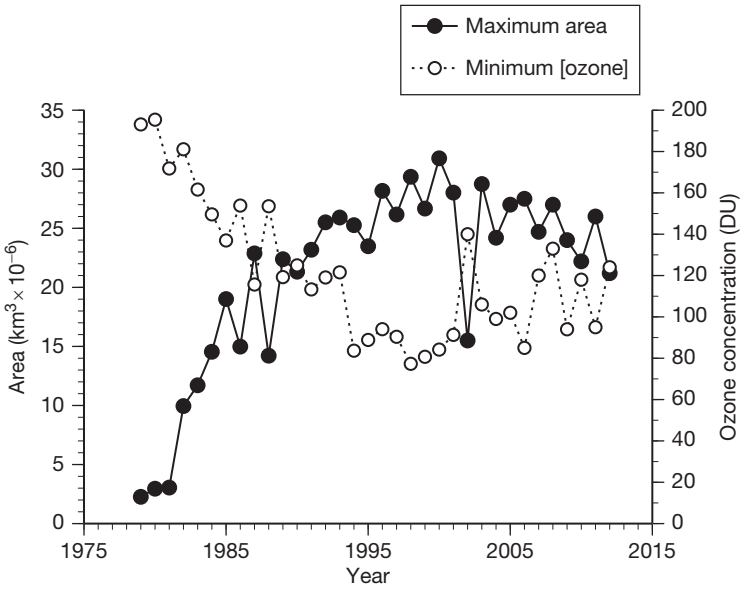

Figure 3 Maximum area (millions of km^3) and minimum column ozone concentration (Dobson units, DU) from 1979 to 2012 during the annual springtime ozone depletion cycle over Antarctica. Normal ozone concentrations are in the range of 350–400 DU. Data from US National Aeronautics and Space Administration (http://www.nasa.gov).

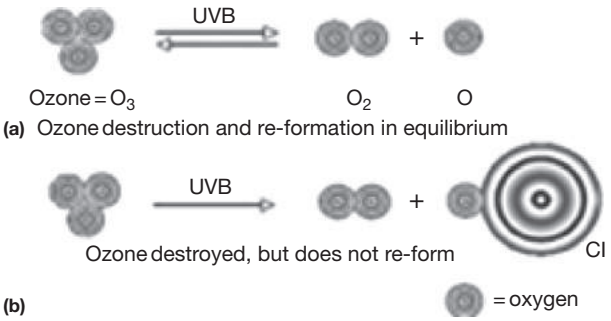

Figure 4 Simplified model of the photochemistry of ozone depletion. (a) Ozone dissociates when UVB is absorbed and re-forms to absorb more UVB. This sequence depicts the normal equilibrium state of this photochemical reaction. (b) Components of pollutant molecules, such as the chlorine shown here, can react with singlet oxygen producing compounds with very long dissociation rates, greatly slowing down the re-formation process of ozone by sequestering singlet oxygen molecules. Thus, ozone breaks down at a rapid rate and is not regenerated to maintain equilibrium concentrations.

decades and were accompanied by measurable increases in UVB. Over Antarctica, large predictable springtime declines of ozone cause substantial short-term increases in UVB radiation.

Origin of the Ozone Layer and Evolution of Life

Early Earth atmospheres (>3 billion years ago) did not contain the 21% oxygen content that we have today. When life on Earth originated (~3.5 billion years ago) the first prokaryotic cells were anaerobic chemoautotrophs, most likely occupying deep ocean and subterranean habitats. With no oxygen in the atmosphere and no ozone layer, incident UVC and UVB levels would have been extreme, forcing life to remain in dim and unlighted habitats. It was the evolution of photosynthesis that added free oxygen to the atmosphere and resulted in the formation of the ozone layer. The subsequent removal of UVC and reduction of UVB from incident sunlight very likely contributed to life moving from the oceans into illuminated terrestrial environments.

A Note on Ozone Pollution

While stratospheric ozone lessens environmental stress by attenuating UVB, there is also an issue of ozone pollution in the troposphere. Photochemical reactions of oxygen with by-products from automobile exhaust and industrial emissions result in surface accumulations of ozone. Ozone is a very reactive compound and direct contact with cells and tissues causes oxidative

damage which can lead to death in plants and animals. Tropospheric ozone pollution is a growing concern for potential impacts on human health and ecosystems, but it is not related to the stratospheric ozone layer.

Biological Consequences of UVB Exposure

Molecular Damage and Cellular Impacts

Damage of biological components by UVB can be manifested in two ways: (1) direct absorption of UVB by organic molecules, or (2) oxidation of organic molecules by reactive oxygen species (ROS) and other radicals that are produced by the UV photolysis of water (e.g., hydroxyl ions, peroxyl ions, singlet oxygen, superoxide) or dissolved substances in the extra- or intracellular environment.

Many organic molecules absorb UVB and undergo conformational modifications that interfere with physiological processes. There are a number of UVB-induced DNA photoproducts such as cyclobutane pyrimidine dimers (CPDs), 6-4 pyrimidine-pyrimidone adducts, pyrimidine hydrates, and DNA–protein crosslinks. CPDs are the most abundantly formed type of DNA damage, but the presence of any lesions in the DNA molecule can interfere with DNA replication and RNA transcription processes, affecting physiological rates, cell growth, and viability. ROS and other radicals also cause specific types of oxidative damage to DNA that can be detrimental. UVB-induced DNA damage can result in debilitating, mutagenic, and lethal effects.

UVB can also damage proteins by direct absorption or oxidation by UVB-induced radicals. Aromatic amino acids (tyrosine, phenylalanine, and tryptophan) absorb strongly at the lower end of the UVB range (280 nm) and account for the UV-absorbing properties of polypeptides. UVB exposure can alter rates of protein synthesis and turnover. Since proteins have diverse functions (e.g., enzymes, protective and structural components, energy storage, molecular motors, hormones, etc.), UVB-induced damage can have a wide range of effects.

Lipid molecules can also be damaged by UVB with the greatest biological hazard manifested in damage to membranes. Peroxidation of lipids by the action of UVB is a significant stress for cells to overcome.

Biological Defenses

Organisms have two main lines of defense against UVB: (1) avoidance of exposure (e.g., moving away from UVB, having external layers that block UVB transmission, synthesizing specific compounds that function as natural sunscreens); and (2) repair pathways that can recognize damage and either correct the UVB-induced defect or destroy the compromised molecules. While species have various combinations and efficiencies of these strategies, there is a high degree of similarity in UV defenses across prokaryotic and eukaryotic taxa. Life originated before the ozone layer formed and early organisms had to deal with more dangerous portions of the solar spectrum; thus, acquired effective defenses for avoiding or mitigating UV-induced damages have been retained. However, these highly conserved biological measures against UVB are not 100% successful. Nearly all organisms have a threshold limit for solar UV exposure.

UV detection

Before organisms can take the obvious step to avoid UVB exposure, they must be able to detect the presence of UVB wavelengths. Many species can detect and respond to changing intensities of white (visible) light with positive or negative phototaxis, or physiological adjustments (e.g., induction of sunscreening compounds). While UVA vision is an important aspect of mate selection and feeding in some birds, fish, and insects, there are only a few reports of UVB vision. This may be related to lack of research in this area and past limitations of technology for measuring UVB fluences. UVB perception may be more widespread and new methods could provide more complete information.

Avoidance by mobility

Most protists, invertebrates, and vertebrates are capable of moving away from too bright levels of sunlight, thus avoiding excessive UVB exposure. Taking advantage of shade, burrowing, or swimming deeper into the water column will effectively reduce the dose of UVB received. Nonmotile organisms (e.g., plants, fungi, macroaglae) cannot make such adjustments and must rely on other mechanisms for sufficient protection.

External barriers

The outer covering of any organism, such as hair, feathers, skin, shell, exoskeleton, cell wall, or only the cell membrane, serves as the first layer of protection against the environment. Many of these structures have evolved to minimize mechanical damage from physical stresses and predation pressure, but these external layers also serve to attenuate and often completely block the transmission of UVB before it can reach vital internal targets.

Natural sunscreens

The majority of prokaryotic and eukaryotic species synthesize UV-absorbing compounds that can serve as natural sunscreens (Table 1). Many of these compounds are common across taxonomic groups and have multiple functions; they not only provide protection from UV, but can act as antioxidants, signal transducers, osmoregulators, structural components, etc. UV-absorbing

Table 1 Some of the common UV-absorbing compounds that serve as sunscreens and examples of representative taxa. Many of these compounds absorb most strongly in the UVA, but attenuate UVB wavelengths as well. Within each of these groups, some compounds also can act as antioxidants. Presence in a particular taxonomic group does not necessarily indicate the ability to synthesize the UV-absorbing compounds; animals often bioaccumulate UV protectants (e.g., MAAs, carotenoids)

Compound	*Occurrence*
Carotenoids	Widespread in prokaryotes and eukaryotes
Melanins	Widespread in prokaryotes and eukaryotes
Mycosporine-like amino acids (MAAs)	Cyanobacteria, algae, marine invertebrates, fish
Polyphenolics (includes flavinoids, phlorotannins)	Plants, algae
Pteridines	Widespread in prokaryotes and eukaryotes

Table 2 Examples of biological compounds involved in antioxidation

Carotenoids
Catalase
Glutathione
Melanins
Polyphenolics
Pteridines
Superoxide dismutase (SOD)
Ubiquinone (coenzyme Q)
Uric acid
Vitamin A (retinol)
Vitamin C (ascorbic acid)
Vitamin E (tocopherol)

compounds can be colorless substances (e.g. mycosporine-like amino acids) or pigments (e.g., melanin). Many are secondary metabolites produced via pathways involved with the synthesis of aromatic amino acids.

Antioxidants

The generation of radicals by UVB interactions with aqueous solutions inside and outside of cells can be counteracted by the presence of antioxidants (Table 2). These compounds are capable of safely quenching ions before they oxidize DNA, proteins, and lipids. Several vitamins (e.g., A, C, E) and some enzymes (e.g., superoxide dismutase, catalase) play major roles in capturing and stabilizing free radicals in cells. Like the sunscreening molecules discussed above, antioxidants can often have multiple functions in cell metabolism.

Physiological repair pathways

A universal activity in cells is DNA repair, and there are several ways by which cells can identify and repair UVB-induced photoproducts. Nucleotide excision repair is the most common pathway and involves a suite of enzymes that can identify, remove, and replace damaged portions of DNA. Some taxa can directly reverse CPDs by photoreactivation, a process that requires the enzyme photolyase and the presence of UVA or visible light. Species might have a single or multiple repair pathways. An important factor in the successful mitigation of UVB effects is the balance between rates of DNA damage and repair.

Organismal Responses

The consequences of UVB exposure on an individual organism are dependent on intensity, spectral quality, duration of exposure, and effectiveness of protection and repair capabilities. The biological effects of UVB are wavelength dependent and best described by spectral weighting functions (Figure 5). Doses comprised of short intense exposures can have different effects from the same amounts of UVB delivered over longer time periods (i.e., reciprocity usually does not hold).

Differential species responses are an important consideration relative to biodiversity and ecological implications of UVB stress. In addition, there are intraspecies variations at the population and individual level. Life history and stage of development also need to be considered. Eggs, embryos, larvae, and juveniles are more sensitive to UVB exposure than larger adult stages; thus, UVB exposure can play a significant role in the age structure and maintenance of populations.

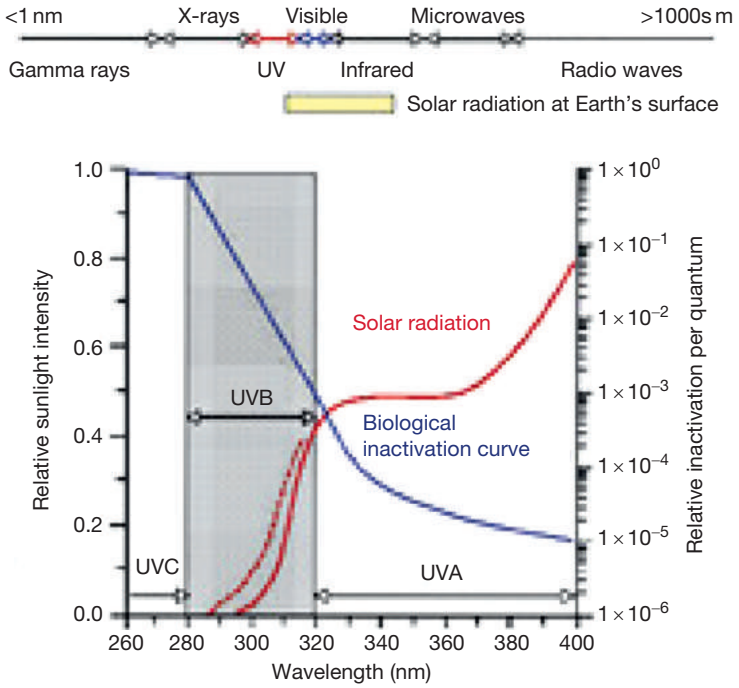

Figure 5 Comparison of intensity of incident UV wavelengths (solid red line) and generalized biological inactivation curve (blue line, data from Tyrrell, R. M and Pidoux, M. (1987). Action spectra for human skin cells: Estimates of the relative cytotoxicity of the middle ultraviolet, near ultraviolet, and violet regions of sunlight on epidermal keratinocytes. *Cancer Research* **47**, 1825–1829). The estimated shift in UVB wavelength and intensity with 50% ozone depletion is represented by the interrupted red line. The electromagnetic spectrum shows the full scale of solar radiation at the top of the atmosphere. Incident radiation falls within the wavelengths bracketed by the yellow bar.

Ecosystem Effects

What is the effect of UVB on the biosphere? While the UVB photobiology of individual species can be studied and characterized, evaluating the quantitative aspects of the ozone layer (with or without depletion) relative to species interactions or ecosystem-level processes has proven to be very difficult. First, concerted research efforts on ecological aspects of ozone depletion were initiated a decade after ozone depletion had begun (1970s). Organisms that are being studied today are already the result of population responses to increasing UVB. Second, isolating UVB effects from those of other solar wavelengths and the myriad of other environmental variables that regulate physiology, growth, and reproduction poses technological challenges. Third, is the issue of determining the proper biological endpoints to use as a measure of ecosystem UVB stress.

Characterizing UVB exposure in a particular environment is also not straightforward. Long-term studies are required to compensate for the high degree of temporal variability in UVB fluences caused by seasons and weather. There are limited data available on incident UVB fluences from before the 1970s, and it is only with the discovery of ozone depletion that networks for long-term monitoring are being established (see http://uv.biospherical.com/ for international listing of programs).

Biodiversity

Differential species and life-history responses to UVB exposure have dictated species distributions and shaped population and community structure over geologic time. One of the largest concerns about the impact of increased UVB caused by recent ozone depletion is that the changes in ambient UVB may have occurred on a much more rapid timescale that can naturally be accommodated by adaptation and natural selection. This would be especially true for unicellular organisms and those with short life-cycle times. Even now, UV-sensitive species may have already been replaced by more UV-tolerant taxa. Larger organisms are usually considered less susceptible to the direct effects of UVB, but more likely to be impacted through UVB-induced changes at lower trophic levels. Assessing changes caused by ozone depletion is a challenge as minimal baseline data (pre-1970s) relating to UVB effects are available.

The issue of variable species responses to UVB is more than expecting a shift in the taxonomic structure of communities. For example, in unicellular organisms, size can play a key role in UV tolerance. Smaller cells tend to be more sensitive than larger cells. In aquatic environments, many organisms are size-selective filter feeders. Restructuring the size distribution of microorganisms could have ramifications at all trophic levels and include functional aspects such as reorganization of niches, alterations in trophic transfer, and changes in pathways of biogeochemical cycling.

Trophic Dynamics

Primary productivity

The majority of ecological research on ozone depletion has focused on primary production in both aquatic and terrestrial systems. Numerous studies have demonstrated enhanced photosynthesis in algae and vascular plants when UVB wavelengths are excluded in experimental exposures. Conversely, reduced photosynthesis is observed in laboratory and mesocosm studies when UVB is enhanced. The results from field and lab clearly indicate that ambient levels of UVB limit global primary productivity and justify concerns that increasing UVB levels would lead to declines in primary production.

UVB limitation on photosynthesis can be manifested in a number of ways. Phytoplankton cells may maintain a constant cell size and divide less frequently, or maintain a constant division rate and produce smaller cells. Vascular plants can grow as tall, but have smaller leaves. The impact of UVB on primary productivity in terrestrial environments is often positively correlated to rainfall, with significant differences in the same area between wet and dry years. Secondary effects of UVB exposure can also be important. These include increased synthesis of UV-absorbing compounds, thickening of leaf cuticles and epidermal tissues, changes in morphology, and increased susceptibility to disease. Some of these physiological and structural alterations can result in reduced palatability and nutritional value, directly affecting the transfer of energy to higher trophic levels.

Consumers

Smaller consumer species may suffer from the direct effects of UVB and exhibit stunted growth, reduced reproduction, and increased fatalities. This is true in aquatic systems where some microheterotrophs are more sensitive to UVB exposure than their photosynthetic food source. Large consumers often have adequate size and external protective layers so that the direct effects of UV exposure are minimal with molecular damage limited to surface cells. In these organisms, deleterious UVB effects are more likely translated through the food web where lower trophic levels are negatively impacted.

Biogeochemical Cycles

UVB impacts on the biological component of carbon and nutrient cycles in ecosystems occur through alterations in productivity and other physiological processes of primary producers, consumers, and decomposers. Direct photochemical reactions with the physical environment also occur. Photodegradation of organic and inorganic components of soils (e.g., leaf litter) and dissolved and particulate matter in aquatic systems is an important aspect of chemical cycling in the environment. As with biological effects, UVB is already an important aspect of these processes and the potential impact of increased levels of UVB is not fully understood.

Future Outlook

Throughout the history of life on Earth, UVB has been an environmental hazard for organisms, and ozone depletion occurring from the late 1970s to the late 1990s may have exacerbated already stressful conditions. The current stabilization and gradual reduction in the concentration of synthetic ozone-depleting substances should result in restoration of the ozone column to pre-1980 concentrations within the next 100 years. However, UVB-induced ecological changes that have occurred or will continue to occur in the coming decades are irreversible. Although some dire predictions were made in the past, there is no evidence of any ecosystem collapse, even in Antarctica where ozone depletion annually continues to exceed 50% and declines in primary productivity have been measured at up to 12%. Ecosystem modification has certainly taken place, but the long-term ramifications are not known.

There are indications that global warming could enhance ozone depletion even in the absence of anthropogenic pollutants, so the fate of the ozone layer is still uncertain. However, even without ozone depletion (i.e., with a normal ozone column), the amount of UVB passing through the atmosphere is sufficient to have measurable negative impacts on organisms and understanding the role of UVB in biosphere continues to be an important ecological issue.

The Emergence of Political Ecology

Political ecology is a field within socio–environmental studies with a core focus on power relations in environmental governance as well as the coproduction of nature and society within a wider political economy (Robbins, 2012). The field has gained momentum during the last couple of decades especially within Anglo-American geography, but also in anthropology, development studies, and environmental history. This momentum is witnessed through a rapid increase in university courses as well as in academic publications internationally. Power is studied as contestations over material assets (land, natural resources) as well as over meaning. The latter leads to studies of how various actor groups produce social constructions such as discourses and narratives, which again have implications for the distribution and control over resources.

Building on critical theory, scholars in political ecology try to combine a focus on values with empirical transparency and theoretical development. In this way, research in political ecology has contributed to new perspectives on both people-nature and science-policy linkages.

Political ecology emerged from the 1970s as a result of two confluent trends. First, the field developed as a Marxist critique of Malthusian ideas in environmental thinking. The argument was that the population centered scholarship by ecologists, such as Ehrlich (1968) and Hardin (1968), were inherently political, and that studies of human ecology are never neutral or apolitical, but involve interests, norms, and power. While Marxist critics tended to accept the environmental impacts of human production described by Neo-Malthusians, they pointed to the inherent lack of social and political analysis in such studies, arguing that Malthusian thinking invariably leads to policies of "blaming the victims."

For example, Enzensberger (1974) pointed out that ecologists and other natural scientists may claim to be "objective" and "apolitical," but they become political actors when engaging in environmental debates, because they inform political choices creating winners and losers, and because their analyses, questions, and categories are inevitably informed by normative assumptions. Hence, there is an issue of environmental justice that often escapes ecologists whose normativity, generally associated with biocentrism, may impact on marginalized people's lives.

The presumed neutrality of ecology as a science when entering environmental debates is therefore illusory. While Enzensberger referred to natural science with apolitical pretensions (but with political implications) as "political ecology," political ecologists have later labeled such practices "apolitical ecology" (Robbins, 2012). This distinction refers to the difference between fields that admit and openly engage with their inevitable, normative assumptions (political ecologies) and those that do not (apolitical ecologies) (Robbins, 2012).

The second trend that contributed to the emergence of political ecology was the evolution of human ecology and cultural ecology. Anthropologists in these fields, such as Nietschmann (1973) and Rappaport (1968), had long employed ecological methods to explain human behavior. However, as the communities they studied were impacted by national governments as well as global and national markets, it became increasingly clear that the explanatory power of their ecological methods was limited by not being able to include the state or markets in the analysis. Researchers in this field had hit a "conceptual wall," which led some cultural ecologists to seek more powerful conceptual and theoretical tools, especially tools from political economy (Robbins, 2012).

From the late 1980s, a second phase in the short history of political ecology started, drawing on a wide range of theoretical and methodological resources. Piers Blaikie's book, *The Political Economy of Soil Erosion in Developing Countries* (Blaikie, 1985) paved the way for an approach to political ecology that employs the lens of political economy, while explicitly engaging with rigorous natural science. The book provides a critique of environmental conservation policies in the Global South and presents three central arguments (Neumann, 2008).

First, there is often lack of sound scientific data on soil erosion and other environmental processes, which leads to a high level of uncertainty. Second, actors have varying perceptions of environmental change depending on their "ideology." Blaikie (1985, 149) argues "that all approaches to soil erosion and conservation are ideological—they are underpinned by a definite set of assumptions, both normative and empirical, about social change." Third, environmental policies always hold implications for control over resources and rights to land. A critical question to asks would therefore be: Who wins and who loses from resource and conservation

policies? This leads to the study of "where power lies and how it is used" (Blaikie, 1985, 6). Blaikie proposed an approach to understanding environmental problems by, on the one hand, problematizing the quality and uncertainty of scientific data and, on the other hand, insisting that the production, interpretation and use of environmental data are inherently political. A process such as soil erosion could therefore only be fully understood with the help of the tools of political economy (Rigg, 2006).

These ideas are further discussed in Blaikie's next book, coauthored with Harold Brookfield, *Land Degradation and Society* (Blaikie and Brookfield, 1987), in which "land degradation" is presented as a perceptual term, stressing that environmental changes are perceived in differing ways by the various actors involved. Hence, "degradation" is not simply a process that can be measured with natural science methods, but instead one in which environmental processes interact with human perception, biases, and interests. Whether processes such as deforestation or soil erosion are perceived as "degradation" depends on the position of observers engaged in inevitably political contests over what should be done with land and over the authority to control land change outcomes.

Our understanding and interpretation of environmental change was thus seen as guided by our norms, interests, and values. However, while environmental data are constructed and subject to ideological interpretations, Blaikie and Brookfield (1987, 16) still insisted on the necessity of improving scientific techniques of measurement in order to obtain "those data which are beset with least uncertainty".

From the mid-1990s, political ecology evolved further to reflect poststructural influences (e.g., Peet and Watts, 1996), in which the norms, interests, and values governing human understanding of environments and environmental change are themselves the product of political processes that determine control over what ideas are taken-for-granted or seen as "true." This perspective was notably brought to bear on a range of critical environmental issues in the Global South, including natural resource scarcity, overpopulation, soil degradation, and the notion of carrying capacity. Research in political ecology sought not only to show that such concepts were problematic and inapplicable, but also sought to explain how, despite their imprecision, they became assumed to be true. Political ecology in this vein is typically critical of received wisdom, especially as dominant and powerful views, narratives and ideas often support dominant and powerful interests.

While political ecology in its inception focused predominantly on the governance of renewable natural resources in the rural Global South, political ecology has later expanded to industrialized nations in the Global North, to urban areas, and to include nonrenewable resources.

However, while the above history may relate to developments within Anglo-American political ecology, it is important not to overlook the southern European tradition of political ecology (*écologie politique, ecología política*) that has developed closer connections with fields such as green politics, environmental justice and the emerging agenda of "degrowth" (e.g., D'Alisa et al., 2014).

A Critical Approach

Political ecology is said to be a "critical approach," which usually refers to its questioning of the role and status of powerful actors as well as of what is taken for granted in leading discourses on environment and development. But political ecologists are also engaged academics committed to improvements to more just and sustainable societies. In this way, political ecology can be said to trace its roots back to the critical theory of the Frankfurt school. Max Horkheimer, one of its founders, argued that traditional theory only attempts to understand and explain certain aspects of society, while critical theory also has a liberating aspect as it indicates the components of society that should be changed, making a broadly multidisciplinary approach necessary (Horkheimer, 1970). In the 1960s, Jürgen Habermas, another representative of this school, put forward a critique of positivism in which he suggested that traditional science claims objectivity on a false basis. The alternative proposed by Habermas is a critical theory of science in which natural, human and social sciences are related to specific epistemological interests that are respectively technical, practical and liberating (Habermas, 1968).

Although political ecology has to date made an effective contribution to showing what people should be freed from (see *Liberation Ecologies* by Peet and Watts, 1996), it is nonetheless limited in regard to determining what this liberation should lead to. Following up on this insight, Robbins (2012) argues that political ecology has two faces, and two missions—"the hatchet" and "the seed." The hatchet side is dominant and represents political ecology's critical approach, whereas the seed aspect forms the contribution of political ecology to a world in which development is fairer and more sustainable. Walker (2006), however, criticizes political ecologists for largely neglecting the seed function. He argues that most of the writings produced in political ecology are internal and aimed at academics working in the same field. The relations between political ecology and politics feature not only apathy, he continues, but also antipathy; this is in fact mutual antipathy between those who have power and those who practise political ecology.

The southern European tradition of political ecology has, however, a longer history of engaging with the seed function with its links to environmental justice movements as well as to activists for alternative sustainabilities such as "degrowth." The Anglo-American tradition, however, remains to some extent torn between on the one hand deconstructions of environmental narratives and claims presented by conservationists and how these narratives may lead to injustice and marginalization, and on the other hand contributing to alternative sustainabilities (Cavanagh and Benjaminsen, 2017). This is, however, an on-going debate within the field. There is also recently increased communication and interaction between these two main branches of political ecology.

Some Key Theoretical Influences

Political ecology can be said to be an eclectic approach taking inspiration from a wide variety of sources. There are, however, some key theoretical influences in the field. We will here only mention three of these; political economy following Karl Marx, poststructuralism inspired by Michel Foucault, and peasant studies with James Scott as one of the key contributors.

Marx has already been mentioned as an essential source of inspiration in the early days of political ecology, and more recently there seems to be a revival of Marxist thinking in this field. A large number of political ecology studies have documented how degradation narratives serve to justify elite capture and the dispossession of marginalized people from land and natural resources. The result may be seen as another example of "primitive accumulation," which Marx saw as a historical process of divorcing the producer from the means of production.

According to Harvey (2003: 149), "primitive accumulation as Marx described it . . . entailed taking land, say, enclosing it, and expelling a resident population to create a landless proletariat, and then releasing the land into the privatized mainstream of capital accumulation." Since accumulation is an on-going process, Harvey (2003) proposes the term "accumulation by dispossession" to describe current processes. The introduction of this term has sparked a renewed interest in the combination of dispossession and capital accumulation in development studies and in political ecology in particular.

For instance, Benjaminsen and Bryceson (2012) use the lens of accumulation by dispossession to analyze enclosures in wildlife and coastal conservation in Tanzania. They show how recently established conservation initiatives steadily lead to local people's loss of access to land and natural resources. Dispossession has been gradual and piece-meal in some cases, while it involved violence in other cases, but does not primarily take the usual form of privatization of land. The spaces involved are still formally state or village land. It is rather the benefits from the land and natural resources that contribute to capital accumulation by more powerful actors (rent-seeking state officials, transnational conservation organizations, tourism companies, and the state Treasury). In both wildlife and coastal management, restrictions on local resource use are justified by degradation narratives, while financial benefits from tourism are drained from local communities within a system lacking in transparent information sharing.

Michel Foucault has demonstrated the importance of analysing how dominant discourses establish what is generally accepted as "truths" in a society. In political ecology, a number of scholars inspired by Foucault have questioned what is taken for granted or seen as true on issues of environment and development (e.g., Adger et al., 2001).

The Foucauldian conception of "governmentality" is also applied within political ecology. This concept denotes the techniques and tactics of government, which again implies that the governing of citizens involves the use of certain techniques to implement certain ways of thinking. The "governmentality" concept that appeared in Foucault's last works is a logical follow-up to his thinking on the relations between power and knowledge. For Foucault, power and knowledge are closely inter-connected.

As an example of a political ecology application of governmentality, Fletcher (2010) outlines four distinct environmental governmentalities ("environmentalities") that are played out in current environmental governance: *Neoliberal governmentality* (commodification and increased use of the market in environmental governance); *Disciplinary governmentality* (efforts to influence individuals—create environmental subjects—through diffusion of ethical norms); *Sovereign governmentality* (the use of force and threats of using force); and *Truth governmentality* (the art of government according to truth). It should be noted, however, that these four forms of governmentality are not mutually exclusive. They may coexist and work together or in opposition to each other.

James Scott is a key representative of what is called "peasant studies" in which the rationality of small-scale farmers, pastoralists or other marginalized groups is analyzed, for example the reasons why they often resist modernization. This type of peasant studies often leads to a critique of the commonly held idea that small-scale farmers or pastoralists are irrational actors. Scott (1976) observes that peasants tend to try to prevent risks by developing social redistribution systems for surpluses in good years in order to protect themselves against the effects of bad years. This can be in the form of the sharing of land and labor with others. Scott (1985) describes everyday forms of peasant resistance to modernization and exploitation holding that this opposition to interventions from the outside world is much more global and has greater scope than armed revolt, even if the latter is more discussed.

Hence, those who are to be governed are variously able to ignore, avoid, fight, transform or reclaim the intervention in question through tactics of noncompliance and everyday acts of resistance, which require little or no coordination or planning and may include "foot dragging, dissimulation, false compliance, pilfering, feigned ignorance, slander, arson, sabotage, and so forth" (Scott, 1985: 29). These are the "weapons of the weak"; the "weak" being subjects who use a variety of "weapons" to defend their interests against superordinate groups. Such everyday resistance typically avoids direct confrontation with the authorities and does not make headlines; it is an informal form of resistance, often covert and concerned with immediate gains. Scott explains that in some cases resistance can be more effective when hidden than when open, because cognizance of such activities may entail a rapid and ferocious response from the superordinate group. Though the acts of hidden resistance do not openly "contest the formal definitions of hierarchy and power" (Scott, 1985: 33), it is possible to determine to what degree, and in what ways, subordinate groups accept the social order (and structure of domination) propagated by elites by studying the subordinates"behaviour and "offstage" comments and conversations (Scott, 1985: 41).

These "offstage" presentations, or "hidden transcripts" as Scott (1990) calls them, are accounts that the subjects communicate in the absence of the powerful. The hidden transcripts include both the subjects' critique of power and practices and claims that the dominating actor would not acknowledge openly. The concept of hidden transcripts also includes accounts that are expressed openly, but disguised in the form of rumors, proverbs, jokes, parodies, gossip, gestures, folktales, and so on. "Public transcripts," on the other hand, are comments and conversations that the actors (the dominant and the subjects) present in each other's presence.

While public transcripts can inform us about power, they are "unlikely to tell the whole story about power relations" (Scott, 1990: 2).

While local and indigenous practices may represent complex and "messy" realities, implementations of governmentality can be seen as attempts to simplify and standardize landscapes and practices and to make both society and territory "legible" (Scott, 1998). For example, in the art of governing smallholder land-use, the state first needs to establish a serious problem that its policy will solve. This will often take the form of claims of environmental degradation or economic inefficiency. Such techniques of governmentality and their continuing power and traction in contemporary policy making are widely highlighted in contemporary political ecology. Second, the state may need to claim that this problem can only be solved through scientific and technical means. These techniques were described by Foucault and further developed by Li (2007) who calls these two steps "problematization" and "rendering technical," wherein the deployment of "scientific" or "expert" reasoning plays a key role. Scientists and scholars may, however, also assist in questioning such processes, not least through the application of the tools and insights of critical political ecology.

Where Is the "Ecology" in Political Ecology?

Political ecology has been criticized from the outside for being founded on a priori judgments by giving priority at the outset to political explanations (Vayda and Walters, 1999) and for overlooking ecological dynamics (Peterson, 2000). But also within political ecology itself, there has been a debate about the place and role of ecology. In a key contribution to this debate, Walker (2005) asks where the ecology is in political ecology and whether the field has become "politics without ecology."

This critique may for instance be seen as relevant for some of the Marxist inspired contributions to political ecology. This literature reflects in some way Marx's idea that ". . . all progress in capitalist agriculture is a progress in the art, not only of robbing the worker, but of robbing the soil" (Marx, 1990: 638). Hence, market integration and the expansion of capitalism would tend also to lead to environmental degradation, according to this thinking.

In a seminal contribution to this literature, Watts (1983) studying small-scale farming in northern Nigeria found that commodification caused starvation and economic marginalization among peasants. Increasingly dependent on an unstable market, they became more vulnerable, and had to take up loans and generally take more risks. Previously self-sufficient, peasants gradually became underpaid farm workers. This in turn led to decreasing investments of labor on their own land, resulting in the degradation of soils on land where food crops were grown.

However, from the late 1980s, a number of students and scholars who were inspired by the research agenda proposed by Blaikie (1985) and Blaikie and Brookfield (1987) carried out empirical studies in the global South unpacking the "ecology" in the political ecology equation. This implied extending the focus on peasant rationality and agency within peasant studies and cultural ecology to environmental dynamics. Many of these studies focused on Africa and generated new knowledge and critiques of environmental orthodoxies in several fields.

An example of this was the edited book entitled *The Lie of the Land: Challenging Received Wisdom on the African Environment* by Leach and Mearns (1996). This was a collection of key critical contributions on various environmental issues in Africa (e.g., range ecology, desertification, deforestation, biodiversity conservation, and soil erosion). A series of chapters challenged received wisdom on these issues and reflected a broader literature that had emerged during the late 1980s and early 1990s. Henceforth, a large number of case studies from different parts of the African continent and on various environmental issues have continued to question dominant (often Neo-Malthusian) narratives on environmental degradation through carefully collected environmental data.

Blaikie (1999), however, pointed out that political ecological critiques of claims of "degradation" in fact owe more to realist science than to postmodern deconstruction. Hence, critical political ecology has to a large extent been based on realist investigations of environmental change to construct counter-narratives or alternative narratives to those dominating policies or academic debates. A "critical political ecology" would critically and empirically examine all environmental representations whether based on Malthusianism or a critique of capitalism. This also implies investigating rather than assuming "the essentialist link between capitalism and environmental degradation" that one often finds in the development literature (Forsyth, 2003).

Critical political ecologies would combine deconstructions of narratives with a realist belief in science as a means to achieve more accurate descriptions and understandings of environmental realities. Such combinations of realist and constructivist positions are referred to in political ecology as a critical realist position. According to Forsyth (2001), critical realism seeks to understand ecological change through a combination of epistemological skepticism and ontological realism.

Michael Watts has, however, also criticized some political ecology for paying too close attention to natural aspects ("ecology") and too little attention to "political" aspects (Peet and Watts, 1996; Watts, 1997). Watts holds that this leads to an atheoretical approach, which lacks a general theory of social change that would explain environmental degradation. This debate reflects a tension within political ecology between an approach engaging actively with natural science and ecology and one focusing on social theory and "politics."

Feminist Political Ecology

Within political ecology and particularly the subfield of feminist political ecology (FPE), gender is emphasized as one of the central factors in questions of power, access and benefits associated with natural resources. In specific contexts, scholars examine gender together with other factors such as class, race, ethnicity, and age. So far, two seminal volumes have been published in FPE. In 1996, Dianne Rocheleau, Barbara Thomas-Slayter and Esther Wangari edited *Feminist Political Ecology: Global Issues and Local Experiences*, and in 2015, the book *Practising Feminist Political Ecologies: Moving Beyond the "Green Economy"* was edited by Wendy Harcourt and Ingrid L. Nelson (2015). As in political ecology as such, FPE is characterized by a plurality of approaches and openness to incorporation of new thoughts. Rocheleau (2015) states: "FPE is more about a feminist perspective and an ongoing exploration and construction of a network of learners than a fixed approach to a single focus on women and/or gender." Elmhirst (2015) argues that FPE has gained from a long string of feminist traditions, starting with gender and development studies, and then encompassing feminist science studies as well as recent poststructuralist, posthumanist and postcapitalist feminist theory.

The ecofeminism of Shiva (1988) and others is a field that has contributed to bringing gender into thinking about environment and development, and it can be seen as an important source of inspiration and predecessor of FPE. Many contributors to FPE, however, follow the criticism that Jackson (1993) and Braidotti et al. (1994) and others have posed at ecofeminism as entailing biological essentialism instead of an empirical openness and examination of ways that gender might play out in specific contexts. This criticism also highlights gender stereotyping where women due to biology are seen as more environmental friendly than men.

Through several decades, Rocheleau (2015) has conducted seminal FPE work based on case studies from different parts of the world and especially in Kenya. She has shown how landscapes and livelihoods are gendered with mosaics of various responsibilities, labor and control of resource, processes and/or products. Among other contributions are Leach (1994) on Sierra Leone, Schroeder (1999) on the Gambia, Paulson (2005) on Bolivia and Nightingale (2011) on Nepal.

In the 2015 volume on FPE, several contributors address the current hegemonies of marketizations and neoliberalization of nature. Drawing on a combination of FPE and feminist political economy, Wichterich (2015) criticizes initiatives for gender equality in neoliberal climate policies such as carbon trading and the clean development mechanism (e.g., "women's carbon standard"—www.womenscarbonstandard.org). She warns about neoliberal empowerment of women that provides uncertain and limited influence or economic returns, and at the same time legitimizes the use of the global South as carbon sink and the continued consumerism of the global North and global middle classes.

As in political ecology in general, most contributions to FPE so far tend to come from case studies in the global South. Nevertheless, the approaches and issues are also relevant in the North, as some studies from Norway demonstrate. Although this country usually has high scores on gender equality indicators, gender equality has recently been left out in important issues of conservation and environmental management. This is not because women have chosen themselves not to get involved in these policy issues. Instead, a broad range of actors at various scales have been involved in setting aside laws that otherwise apply on gender equality in politics, and this again is due to power struggles and alliance building in a field that traditionally is controlled by men (Svarstad et al., 2006, 2009; Benjaminsen and Svarstad, 2017). In an examination of gender aspects in a new governance system for protected areas in Norway, Lundberg (2017) shows that legal requirements for gender equality in Norway have finally been implemented, but in a way that still hides that few local women take part in conservation boards.

Conclusions

Political ecology is a field in environmental studies focusing on power relations that has gained momentum during the last couple of decades. Power is studied as contestations over material assets (land, natural resources) as well as over meaning. The latter leads to studies of social constructions, which again have implications for the distribution and control over resources.

From the 1970s, political ecology emerged as a Marxist critique of Malthusianism and as a further development of a human and cultural ecology approach including also the impact of states and markets in the analysis of human-environment interactions. From the 1980s, this approach further focused on how norms, interests and values form our interpretation of environmental change. These norms, interests and values are again the product of political processes that determine control over what ideas are taken-for-granted or seen as "true."

Political ecology is an eclectic approach that has been taking inspiration from a wide variety of sources. Key theoretical influences discussed here are political economy following Karl Marx, poststructuralism inspired by Michel Foucault, and peasant studies with James Scott as one of the key contributors. An on-going discussion in the field is also the place and role of "ecology" within the political ecology equation. Some contributions within the field engage actively with natural science, while other parts of this literature remain within more social science-based theoretical debates where "ecology" refers to the environment more broadly. Finally, this article discusses feminist political ecology as a subfield reflecting political ecology's eclecticism where the role of gender and power in relation to access to and benefits from natural resource governance is discussed, again taking inspiration from a variety of scholarly directions and theories.

In the wake of recent debates about "posttruth" and increasing political pressure on science, especially related to global climate change, a future key tension and point of discussion within political ecology will be how to balance a continued critique of the production of environmental science promoting certain biocentric values with a belief in science as the best bulwark against

political gerrymandering. This conundrum may best be solved through adhering to a critical realist approach combining deconstructions with a realist reliance on science as a means to achieve the most accurate descriptions and understandings of environmental realities. Such a critical realism combines a critical scrutiny of available "truths" with continuously seeking to identify the best available science, which is quite similar to how science should work under normal circumstances, if left without political interference.

Precaution and Ecological Risk

O Renn, University of Stuttgart, Stuttgart, Germany

The Different Meanings of Precaution

This article presents a scientific overview of the meanings and applications of the precautionary principle in ecological risk assessment and management. The term risk is understood in this document as an uncertain consequence of an event or an activity with respect to something that humans value. Risks always refer to a combination of two components: the likelihood or chance of potential consequences and the severity of consequences of human activities, natural events, or a combination of both. Such consequences can be positive or negative, depending on the values that people associate with them. In addition to the strength and likelihood of these consequences, characterizing risks includes contextual aspects such as the distribution of risks over time, space, and populations. With respect to ecology, risk denotes the probability of ecosystem damage as a result of human interventions or natural events (such as earthquakes, wildfires, or flooding).

The focus on ecological risk should be seen as a segment of a larger and wider perspective on how humans transform the natural into a cultural environment with the aims of improving living conditions and serving human wants and needs. These transformations are performed with a purpose in mind (normally a benefit to those who initiate them). When implementing these changes, intended (or tolerated) and unintended consequences may occur that meet or violate other dimensions of what humans value. These are the risks. It is the major task of risk assessment to identify and explore, preferably in quantitative terms, the types, intensities, and likelihood of the (normally undesired) consequences related to the consequences that human actions or events exert on ecosystems. In addition, these consequences are associated with special concerns that individuals, social groups, or different cultures may associate with these risks. Ecosystem changes can be physically measured or observed but they only get meaning through interpretation by humans. Different individuals, different groups, and different cultures have different criteria and perspectives of what kind of physical changes matter to them and how they are valued. These social processes of attributing value and meaning to consequences of actions and events also need to be assessed and included in the risk evaluation for making prudent judgements about the tolerability or acceptability of risks.

The Precautionary Principle

Once that judgement is made, it is the task of risk management to prevent, reduce, or alter these consequences by choosing appropriate actions. Risk management is always confronted with the following questions: How much transformation of ecosystems is tolerable? Where do societies set the boundary between acceptable and nonacceptable risks? Such a fundamental judgment cannot be justified by an all-encompassing substantive rule. Rather, one needs procedural principles that help societies to make tolerability judgments and to select risk management options. One of these rules refer to the precautionary principle. This principle has been formulated in many different ways in many different places (one root may be the `foresight principle' adopted to German environmental law in the 1960s). The most widely used formulation of the principle can be found in the Rio Declaration:

> In order to protect the environment, the precautionary approach shall be widely applied by States according to their capabilities. Where there are threats of serious of irreversible damage, lack of full scientific certainty shall not be used as a reason for postponing cost-effective measures to prevent environmental degradation. (Rio Declaration 1992, Principle 15)

This articulation of the principle allows risk managers to initiate regulatory actions even if the scientific evidence about risks is not yet conclusive. But how much evidence is evidence enough to trigger such actions? Is the precautionary principle an instrument to ban all new activities because one can always find claims for serious harm regardless of the `true' nature of the intervention? How accountable are risk managers if they can (freely or even arbitrarily) decide what evidence they will accept as sufficient to invoke the precautionary principle?

Despite the intensity of attention that the principle has received in the policy arenas, there remain a number of serious ambiguities and queries concerning the nature and appropriate role of the precautionary principle in governance. These are addressed – if not resolved – in a burgeoning academic and more policy-oriented literature. In order to understand the principle in the context of a larger array of risk management strategies, it is necessary to look more deeply into the fabrics of ecological risks. This is done in the next section.

Components of Risk

Risks are mental `constructions'. They are not real phenomena but originate in the human mind. Actors, however, creatively arrange and reassemble signals that they get from the `real world' providing structure and guidance to an ongoing process of reality

enactment. The status of risk as a mental construct has major implications on how risk is looked at. Unlike trees or houses, one cannot scan the environment, identify the objects of interest, and count them. Risks are created and selected by human actors. What counts as a risk to someone may be an act of God to someone else or even an opportunity for a third party. Since risks represent mental constructs, the quality of their explanatory power depends on the accuracy and validity of their (real) predictions. Unlike some other scientific constructs, validating the results of risk assessments is particularly difficult because, in theory, one would need to wait indefinitely to prove that the probabilities assigned to a specific outcome were correctly assessed. If the number of predicted events is frequent and the causal chain obvious (as is the case with car accidents), validation is relatively simple and straightforward. If, however, the assessment focuses on risks where cause–effect relationships are difficult to discern, effects are rare and difficult to interpret, and variations in both causes and effects are obscuring the results (as is often the case with ecological risks), the validation of the assessment results becomes a major problem. In such instances, assessment procedures are needed to characterize the existing knowledge with respect to complexity, remaining uncertainties, and ambiguities. What do these terms mean?

1. *Complexity*. It refers to the difficulty of identifying and quantifying causal links between a multitude of potential causal agents and specific observed effects. The nature of this difficulty may be traced back to interactive effects among these agents (synergism and antagonisms), long delay periods between cause and effect, interindividual variation, intervening variables, and others.
2. *Uncertainty*. It is different from complexity but often results from an incomplete or inadequate reduction of complexity in modeling cause–effect chains. Whether the world is inherently uncertain is a philosophical question that we will not pursue here. It is essential to acknowledge in the context of risk assessment that human knowledge is always incomplete and selective and thus contingent on uncertain assumptions, assertions, and predictions. It is obvious that the modeled probability distributions within a numerical relational system can only represent an approximation of the empirical relational system with which to understand and predict uncertain events. It therefore seems prudent to include other, additional, aspects of uncertainty. Although there is no consensus in the literature on the best means of disaggregating uncertainties, the following categories appear to be an appropriate means of distinguishing the key components of uncertainty:
   - target variability (based on different vulnerability of targets such as ecosystems);
   - systematic and random error in modeling (based on extrapolations from animals to humans or from large doses to small doses, statistical inferential applications, etc.);
   - indeterminacy or genuine stochastic effects (variation of effects due to random events, in special cases congruent with statistical handling of random errors);
   - system boundaries (uncertainties stemming from restricted models and the need for focusing on a limited amount of variables and parameters);
   - ignorance or non-knowledge (uncertainties derived from lack or absence of knowledge).

The first two components of uncertainty qualify as epistemic uncertainty and therefore can be reduced by improving the existing knowledge and by advancing the present modeling tools. The last three components are genuine uncertainty components and thus can be characterized to some extent using scientific approaches but cannot be reduced to numeric confidence intervals.

3. (*Interpretative and normative*) *ambiguity*. This is the last term in this context. Whereas uncertainty refers to a lack of clarity over the scientific or technical basis for decision making, (interpretative and normative) ambiguity is a result of divergent or contested perspectives on the justification, severity, or wider `meanings' associated with a given threat. In relation to risk, it is understood as `giving rise to several meaningful and legitimate interpretations of accepted risk assessments results'. It can be divided into interpretative ambiguity (different interpretations of an identical assessment result: for example, as an adverse or nonadverse effect) and normative ambiguity (different concepts of what can be regarded as tolerable referring, for example, to ethics, quality of life parameters, distribution of risks and benefits, etc.). A condition of ambiguity emerges where the problem lies in agreeing on the appropriate values, priorities, assumptions, or boundaries to be applied to the definition of possible outcomes.

Risk Management Principles

In accordance with the three major components `complexity, uncertainty, and ambiguity', one can design different risk assessment and management strategies depending on the degree or intensity of each component. For example, if a risk is characterized by high complexity, low uncertainty, and low ambiguity, the main emphasis will be on scientific modeling and consensual methods for performing a most accurate assessment. If a risk is characterized by high uncertainty, the main emphasis will be on reducing vulnerability of the system to cope even with surprises. In a situation of high ambiguity, a more discursive approach with stakeholder participation is asked for in order to find an acceptable way to reconcile conflicting values and world views. More specifically, risk handling can pursue one of four strategies or a combination thereof. These strategies are summarized in **Table 1** and described in the following paragraphs.

1. *Simple risk problems*. This class of risk problems requires hardly any deviation from traditional decision making. Data are provided by statistical analysis, goals are determined by law or statutory requirements, and the role of risk management is to

Table 1 Risk characteristics and their implications for risk management

Knowledge characterization	*Management strategy*	*Appropriate instruments*	*Stakeholder participation*
`Simple' risk problems	Routine based:(tolerability/ acceptability judgement) (risk reduction)	Applying `traditional' decision making	Staff members and specialists in the field
		Risk–benefit analysis Risk–risk trade-offs Trial and error Technical standards Economic incentives Education, labeling, information Voluntary agreements	
Complexity-induced risk problems	Assessment-based strategy	Characterizing the available evidence	Wide range of experts and scientist, including social scientists
		Expert consensus seeking tools like: Delphi or consensus conferencing Meta analysis Scenario construction, etc. Results fed into routine operation Improving buffer capacity of risk target through: Additional safety factors Redundancy and diversity in designing safety devices Improving coping capacity Establishing high-reliability organizations	
Uncertainty-induced risk problems	Resilience-based strategy	Using hazard characteristics such as persistence, ubiquity, etc., as proxies for risk estimates	Inclusion of major stakeholders such as industry and environmental groups
		Tools include: Containment ALARA (as low as reasonably achievable) and ALARP (as low as reasonably possible) BACT (best available control technology), etc. Improving capability to cope with surprises Diversity of means to accomplish desired benefits Avoiding high vulnerability Allowing for flexible responses Preparedness for adaptation	
Ambiguity-induced risk problems	Discourse based	Application of conflict resolution methods for reaching consensus or tolerance for risk evaluation results and management option selection Integration of stakeholder involvement in reaching closure Emphasis on communication and social discourse	Wider public, including different social and cultural interests and values

IRGC (2005) *White Paper on Risk Governance: Towards an Integrative Framework.* Geneva: International Risk Governance Council.

ensure that all risk reduction measures are implemented and enforced. Traditional risk–risk comparisons (or risk–risk trade-offs), risk–benefit analysis, and cost-effectiveness studies are the instruments of choice for finding the most appropriate risk reduction measures. Additionally, risk managers can rely on best practice and, in cases of low impact, on trial and error. Staff members of risk management agencies, industrial risk managers, and experts in the field are the only groups that need to be involved for dealing with simple risks.

2. *Assessment-based strategy, including the search for numerical thresholds* (*emission levels, concentration levels, performance standards, tolerance levels, etc.*). Within this second strategy of scientific risk analysis, risk management relies on the best scientific estimates of probabilities and potential damages and uses expected values as main input to judge the tolerability of risk as well as to design risk reduction measures that are cost effective, proportional to the threat, and fair to the affected population. In this frame, precaution may best be interpreted as being conservative in making risk judgments and choosing cautious assumptions when calculating exposure or determining safety factors (of 10, 100, or more) to cover intertarget variability. Since risk assessments for complex problems rely on sophisticated models and simulations, a broad representation of the various scientific communities, including the social scientists, is required to assure a broad and inclusive handling of the risk.
3. *Resilience-based strategy*. This strategy refers to risk reduction activities that are derived from the `application of the precautionary principle'. Within this third frame, the concept of risk is seen from the perspective of pervasive uncertainty and in particular

ignorance and non-knowledge. Precautious risk management entails to ensure prudent handling of decision options in situations of high uncertainty about causes and effects and of high vulnerability of the ecosystems under risk. Instruments of precaution include minimization requirements such as ALARA (as low as reasonably achievable) or ALARP (as low as reasonably possible), diversification of risk agents, containment in time and space, and close monitoring. It is difficult to draw the line between too much precaution and not enough precaution in the face of uncertainty. How can one judge the severity of a situation when the potential damage and its probability are unknown or highly uncertain? In this dilemma, risk managers are well advised to include the main stakeholders in the evaluation process and ask them to find a consensus on the extra margin of safety in which they would be willing to invest in exchange for avoiding potentially catastrophic consequences.

4. *Deliberation-based strategy*. This strategy includes `discursive processes' such as roundtables, consensus conferences, deliberative rule-making, mediation, or citizen panels. This third frame has been advocated as an alternative or an addition to purely analytical procedures of both assessing and managing risks. The task of risk management here is to organize in a structured and effective manner the involvement of stakeholders and interested public for designing risk management strategies based on each stakeholders' knowledge (epistemic community) and value system. This strategy can go along with both the risk analysis and the precautionary approach but has been advocated either as an independent path to risk management or more often as a policy-oriented implementation of the precautionary approach. This third strategy is designed to address problems of ambiguity. For managing these risks, the main groups representing different visions of future development should be consulted and, if possible, a consensus among the main actors accomplished.

Over the last few years, advocates of the these strategies have launched a fierce debate over the pros and cons of each of their approaches. There is generally a common agreement that simple risk problems can be managed using the traditional assessment and risk reduction tools. There is, however, a controversy among the professional communities when it comes to distinguishing between the assessment and the resilience camp. One side argues that precautionary strategies to improve the resilience of ecosystems ignore scientific results and lead to arbitrary regulatory decisions. The precautionary statement ``one should be on the safe side'' could be interpreted as a mandate to ban everything that might result in negative side effects. Such a rule would logically apply to any human intervention into the natural environment and would lead to total arbitrariness. The principle has been labeled to be ill-defined, absolutist, to lead to increased risk-taking, to be a value judgment or an ideology, and to be unscientific or to marginalize the role of science. Some analysts claim that by using the precautionary principle there is the risk that science may be held `hostage to interest group politics'. In addition, policy makers could abuse the precautionary principle as a policy strategy to protect their economic interests and to impede world trade.

On the other side of the fence, the advocates of the precautionary approach have argued that precaution does not automatically imply banning substances or activities but a step-by-step diffusion of risky activities or interventions until more knowledge and experience is accumulated. They have accused their critics of ignoring the complexity and uncertainty of most human interventions and relying on data that often turns out to be insufficient for making prudent judgments. In particular, the argument is that all interventions characterised by both high uncertainty (when it comes to measuring the degree of impacts) and the generic possibility of inducing irreversible harm should be (strictly) regulated even if more scientific evidence could demonstrate later that the cautious approach was not warranted. It is better to err on the safe side than to impose unforeseen burdens to future generations.

The third approach of deliberation has found wide acceptance among social scientists and risk analysts from academia but so far has had little impact on the institutional design of risk management. There are, however, isolated examples of community participation in risk decisions, such as in selecting the remedy under the Superfund cleanup program or negotiated rulemaking in the US. In recent years, however, risk policymakers have acknowledged that participation in risk analysis provides many practical advantages because it transforms difficult issues of resolving epistemic uncertainty to topics of negotiation that can be dealt with at the negotiation table. If society participates in the production of policy-relevant scientific knowledge, such `socially robust' knowledge is less likely to be contested than that which is merely reliable. Accordingly, the EU communication on good governance has highlighted the need for more stakeholder involvement and participation in risk management. How to implement this requirement in day-to-day risk management decision is still under dispute. Many scholars have also questioned the value of deliberative approaches in some settings, arguing that when there is trust in the regulator, a top-down form of risk communication (information transfer) may be better than dialog.

An Example

The use of nuclear energy for electric power has long been and remains a particularly controversial source of risk and concern. This is driven partly by perceptual factors and partly by the characteristics of the nuclear fuel cycle.

The cycle begins with, first, the extraction of natural uranium and, then, enrichment of the uranium and its concentration prior to manufacturing the fuel elements; risks of exposure to radioactive material of operating personnel are of prime concern. A nuclear reactor operates with exceedingly high energy density and inventory of radioactive substances (fission products). Multiple and diverse safety systems are provided for reactor control and decay heat removal. Their total failure is highly improbable but may lead to core damage (meltdown) and to release of parts of the core inventory, with long-lasting effects over a large geographic area. For state-of-the-art reactors, an `extremely low frequency, potentially high consequence' risk profile is regarded as typical.

Power plant operations also discharge small quantities of radioactive particles to the environment, which can accumulate in organisms and can pose a slight human cancer risk.

When the fuel in a reactor is spent, the fuel rods are consigned to a reprocessing plant, to interim storage or to a final repository. Any transport of spent fuel rods must be in proof casks, and the transport process itself is another source of risk as the probability that a cask will rupture in an accident that exceeds its design limit is not zero. In reprocessing, the risk is concentrated upon the release of radioactive substances to the environment, while in storage the isolation of the waste from the biosphere needs to be ensured for very long periods (several millennia).

Vast efforts have been made to minimize the probability of events causing harm to public health and the environment, particularly toward reducing or even preventing entirely major radioactive releases, in all stages of the cycle. Future reactors must thus be designed so that, even in the event of rare core-damaging events, off-site emergency measures are not necessary because impacts will not reach beyond the immediate neighborhood. In final storage, several safety barriers are combined in order to exclude groundwater contamination as far as is humanly possible.

Looking at the nuclear fuel cycle, all four risk management strategies are or could be invoked when regulating and managing the risks associated with each step of the cycle. Strategies belonging to the category of simple risks are in place when designing passive safety barriers that should withstand special pressure or thermal emissions. In addition, occupational safety measures for workers in the uranium mine and in other stations of the cycle can be grouped in this category.

Complex risk assessments are needed to model the impact of low-dose ionizing radiation on human health. These assessments include toxicological experiments using test animals and extrapolating the results to humans and extrapolating from high to low dose effects. Additional insights come from epidemiological data, for example, from the results of comparing cancer rates in populations exposed to higher doses of radiation through warfare or accidental exposure with populations that are only exposed to natural background radiation. Combing dose-response models with exposure requires extensive modeling, which relies on an intensive exchange among natural scientists, statisticians, physicians, exposure specialists, and behavioral experts.

Although modeling the effects of low dose radiation to human health results in some uncertainty (particularly addressing interindividual variability and stochastic effects), a resilience-based approach is clearly needed for assessing and managing ecological impacts of large nuclear accidents and the long-term effects of final disposal of radioactive waste for hundreds and thousands of years. Scientists understand in principle the reactions of ecosystems to higher levels of radiation but are far from predicting the concrete biological consequences of large releases of radionuclides in different ecosystems over long time periods. Experiences in contaminated areas such as Hartford in the USA and the neighborhood of Chernobyl seem to indicate that biodiversity is actually increased and biotopes recover faster than many ecologists had expected. At the same time, however, radiation-sensible plants and animals are replaced by others who are less sensible. There is still lots of ignorance and guesswork when it comes to assessing the long-term effects of releasing large quantities of radionuclides in the environment. In terms of management, a combination of risk minimization, ban on using resources from contaminated areas for human purposes, and even cleanup is normally advocated. In the USA, there is also a strong movement toward including major stakeholders and the local population in designing plans for decontamination and partial cleanup. These management strategies constitute a precautionary approach to managing risks. Since the consequences are not yet fully explored and unexpected surprises may occur, the main philosophy is to restrict exposure as much as possible and to avoid irreversible consequences even if these consequences may turn out to be more benign than expected.

Public involvement is even more important when addressing ambiguity. The still-ongoing public controversy does not derive so much from the complexity of nuclear energy, nor from uncertainty: most of the processes and phenomena are largely understood and agreed. Much of the debate in the past was directed toward further reducing uncertainty and explaining complexity rather than addressing the major problem: ambiguity. The controversy is fueled by several ambiguities due to different perceptions of and associations with the risk. To the opponents of nuclear energy, the problem is that a meltdown and catastrophic release cannot be ruled out (catastrophic aversion), and that spent fuel remains active for such a long time period (time aversion). The proponents of nuclear power, on the other hand, are convinced that there are no other reliable options with comparably minimal greenhouse gas emissions. Each position is based on values. Value differences color the interpretation of the data emanating from risk assessments (which is rarely disputed), as well as the way the risk is framed in the debate. Opponents accordingly judge the risks as being intolerable; to proponents, nuclear energy is an optimal means of supplying the world's electricity at minimal risk.

The controversy has led to considerable differences in the decisions of risk managers, even in Europe – where Germany has decided to phase out nuclear generation, France continues to rely on it, and Switzerland seeks the consent of its voters to replace an old reactor with a new one. There is certainly a need for a discursive strategy including different value positions and visions of the future. There is no guarantee for a consensus, but without such a discourse political decision makers will have hard problems to handle this controversy in a democratic and peaceful way.

Political Relevance

The precautionary principle has been adopted in a variety of forms at international, European Union, and national level. It is applied across an increasing number of national jurisdictions, economic sectors, and environmental areas. It has moved from the regulation of industry, technology, and health risk, to the wider governance of science, innovation, and trade. As it has expanded in

scope, so it has grown in profile and authority. In particular, as Article 174(2) in the EC Treaty of 2002, precaution now constitutes a key underlying principle in European Community policymaking. The 2000 Communication on Precaution of the European Commission provides evidence for the high significance that the precautionary principle has gained as a guiding policy of the European Union in areas such as environmental, consumer, and health protection. The document states in the first section: ``Applying the precautionary principle is a key tenet of its policy, and the choices it makes to this end will continue to affect the views it defends internationally, on how this principle should be applied'' (European Commission, 2000: 3). As Elisabeth Fisher (2002) pointed out, the communication specifies also some of the major conditions and requirements for applying the principle. There are two conditions mentioned: ``The measures, although provisional, shall be maintained as long as the scientific data remain incomplete, imprecise or inconclusive and as long as the risk is considered too high to be imposed on society'' (European Commission, 2000: 21). In addition to the presence of remaining uncertainty, the EU communication lists the condition that the risk must be too high to be imposed on society. This relates to the requirement of proportionality that has been stated as one of the major requirements of applying the principle.

In the aftermath of a series of formative public health controversies, economic calamities, and political conflicts (such as those involving BSE and GM crops), precaution is of great salience or importance in may fields including the regulation of ecosystem interventions. Since the application of the precautionary principle has been associated with stricter and more rigid regulations, environmental groups have usually rallied around the precautionary approach, while most industrial and commercial groups have been fighting for the assessment-based approach Again, the issue is not resolved, and the debate has become even more pronounced with the defeat of the European Community in the WTO settlement of hormones in beef. The European Community failed in providing sufficient evidence that the precautionary approach could justify the restriction of imported beef treated with hormones.

It is interesting to note that the assessment-based approach has been widely adopted by the official US regulatory bodies while the precautionary approach has been widely advocated by the EU regulatory bodies. There are, however, also numerous elements of precautionary approaches interspersed into the actual practices of US regulatory agencies, just as there are judgments about magnitudes of risk in the actual practices of regulators in the EU. A strict dichotomy between `precautionary' in Europe and `assessment based' in the US is therefore too simple to describe actual practice.

Summary

Any regulatory regime is faced with the question of how to make regulatory decisions under uncertainty or even ignorance. It may be helpful in this respect to resort to a differentiation that Resnik has proposed:

- *Decisions under certainty*. The outcomes of different choices are known.
- *Decisions under risk*. Probabilities can be assigned to the outcomes of different choices.
- *Decisions under ignorance*. It is not possible to assign probabilities to the outcomes of different choices.

Using precaution for the first two cases seems neither necessary nor prudent given that regulation needs to meet both objectives: ecological protection and securing economic welfare. The legitimate realm of using precaution is in the case of ignorance or other forms of remaining uncertainties (such as system boundaries or truly stochastic events). This is the place where precaution should be applied. The main purpose of precaution in this respect is to avoid irreversible decisions. Where it is clearly impossible to calculate expected values, a precautious approach can help societies to be more resilient against unpleasant surprises and to invest in decreasing vulnerabilities.

Remote Sensing

Ned Horning, American Museum of Natural History, New York, NY, United States

Glossary

Anthromes Human biome that represents ecosystems created or altered by human interactions.
Electromagnetic spectrum All known wavelengths (frequencies) of electromagnetic radiation including short wavelength gamma rays, visible light and long-wavelength radio waves.
Pixel Individual elements of an image that are arranged in a grid of rows and columns.
Radiance Measurement of the intensity of electromagnetic energy. Units for this measurement are typically watts per steradian per square meter ($Wm^{-2}\ sr^{-1}$).
Reflectance Ratio of the intensity of light reflected from a surface divided by the intensity of incident light.

Introduction

Remotely sensed data and methods provide data layers that are used extensively to study relationships between humans and their environments. Understanding fundamental remote sensing concepts will help ecologists make informed decisions regarding the utility and limitations of the broad spectrum of remotely sensed data and their derived products.

The main focus of this article is to introduce remote sensing science and associated datasets of potential relevance to ecology. The article begins with an overview of fundamental remote sensing concepts. This is followed by a section on how remotely sensed data can be used to derive a broad range of biophysical datasets that are useful for ecological mapping and modeling. Several of the more common datasets derived from remotely sensed data are described with comments about how the datasets are produced, their strengths, and limitations. The article concludes with a summary of accuracy and validation.

What Is Remote Sensing?

In general terms, remote sensing is the science and practice of acquiring information about an object without actually coming into contact with it. In terms more appropriate for our purposes remote sensing is a technology for sampling reflected and emitted

electromagnetic (EM) radiation from the Earth's terrestrial and aquatic ecosystems and atmosphere. This is typically done by recording images from airplanes and satellites to help identify or better understand a feature on the Earth's surface. In this article we will discuss a wide set of techniques, often known by the alternative name of Earth Observation (EO). We will only address electromagnetic remote sensing so geomagnetic and acoustic remote sensing techniques (sonar, and seismic sounding) will not be covered.

A simple example of a remote sensing instrument is a photographic or digital camera. A camera records energy in the form of light that is reflected from a surface to form an image. Most photographic cameras record visible light so that when we look at the photograph the image resembles the feature that was photographed. More sophisticated remote sensing instruments are able to record energy outside of the range of visible light. Data from remote sensing instruments can be recorded as images or, in the case of lidar, a collection of point data which are often processed to create images.

Brief History of Remote Sensing

For our purposes we will begin the history of remote sensing with the invention of the photographic camera in the early 19th century. In the 1840s photographs were taken from cameras secured to tethered balloons for purposes of topographic mapping. For the next 100 years or so camera technology improved but the major advances were in the platforms used to hold camera systems. At first people experimented with platforms such as kites, rockets, and even pigeons. A major step forward was made with the invention of the airplane and the next leap occurred when cameras could be mounted on satellites, which provided a very stable and, of course, high altitude platform. Satellites also provide an ideal platform for acquiring systematic data from around the globe which has proved invaluable for large area ecological modeling.

By the 1940s instrument research was also becoming increasingly sophisticated, pushing remote sensing technology beyond visible-spectrum photography into infrared detection and radar systems. Leveraging this research, in 1972 the National Aeronautics and Space Administration (NASA) began the Landsat program with the launch of the Earth Resources Technology Satellite 1 (ERTS 1), which was later renamed Landsat 1. The Landsat program continues and is the longest running program of satellite remote sensing focused on EO. Following the launch of Landsat 1 other satellites were launched carrying different types of instruments such as radar, lidar, and more precise optical sensors. Satellite remote sensing has evolved to the point where most environmental systems (hydrologic, atmospheric, ecosystems) now have dedicated satellite instruments recording information to help us better monitor and manage Earth's environments, and providing valuable data for use in ecological modeling and monitoring. For example, NASA's Earth Observing System (EOS) is a mission that includes the acquisition of satellite-based observations, science, and a data system to support the study of the land surface, biosphere, solid Earth, atmosphere, and oceans. One sensor in particular from the EOS mission that offers a broad range of image products of interest to ecologists is the Moderate Resolution Imaging Spectroradiometer (MODIS). Advances in satellite/instrument packages will continue to be made providing more precise and accurate data that can be used for ecological applications.

Basic Concepts

It is necessary to understand a few basic remote sensing concepts before we begin discussing how remotely sensed imagery can be used in ecology.

Electromagnetic Spectrum

The electromagnetic spectrum (EMS) includes wavelengths of electromagnetic radiation ranging from short wavelength (high frequency) gamma rays to long-wavelength (low frequency) radio waves. We will focus on the region of the spectrum starting in the ultraviolet and continuing through the microwave wavelengths. Optical sensors are used to measure ultraviolet, visible, and infrared wavelengths and microwave sensors are used for the microwave portion of the EMS.

A fundamental physical principal that remote sensing relies on is that different features on the Earth's surface interact with specific wavelengths of the EMS in different ways. When working with optical sensors the most important property used to identify features on the Earth's surface is spectral reflectance; the ratio of the intensity of light reflected from a surface divided by the intensity of incident light. Different features have different spectral reflectance properties and we can use this information to identify individual features. For example, white sand reflects most visible and near-infrared light whereas green vegetation absorbs most red wavelengths and reflects most near-infrared wavelengths. Fig. 1 illustrates the spectral properties of different materials.

Some remote sensing instruments also provide information about how electromagnetic energy interacts with the surface of a feature or within a three-dimensional feature such as a forest. These will be discussed later in this article.

What Is an Image?

The most familiar form of remotely sensed data is an image. An image is made up of individual elements that are arranged in a grid of rows and columns. These elements are called pixels. When zooming into an image, individual pixels can be seen (Fig. 2).

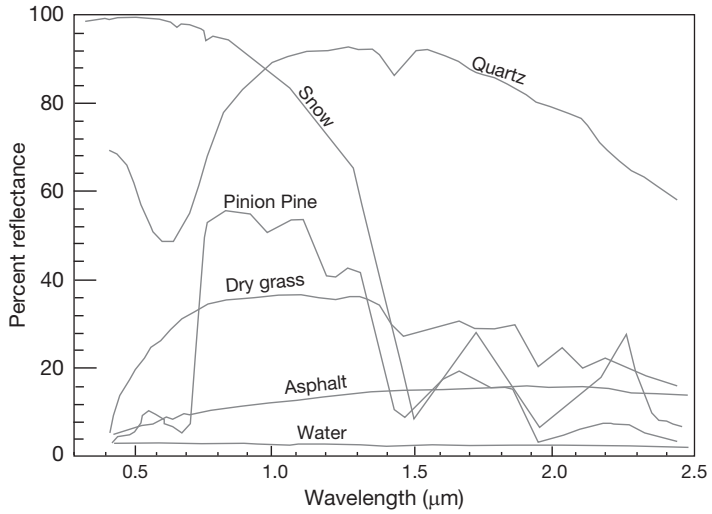

Fig. 1 Spectral signatures for selected features. Materials on the Earth's surface have unique spectral reflectance properties. This figure shows the spectral reflectance curves of six common materials. Many of the methods used in remote sensing are designed to associate the spectral information acquired by a sensor with the spectral qualities of features that are to be identified.

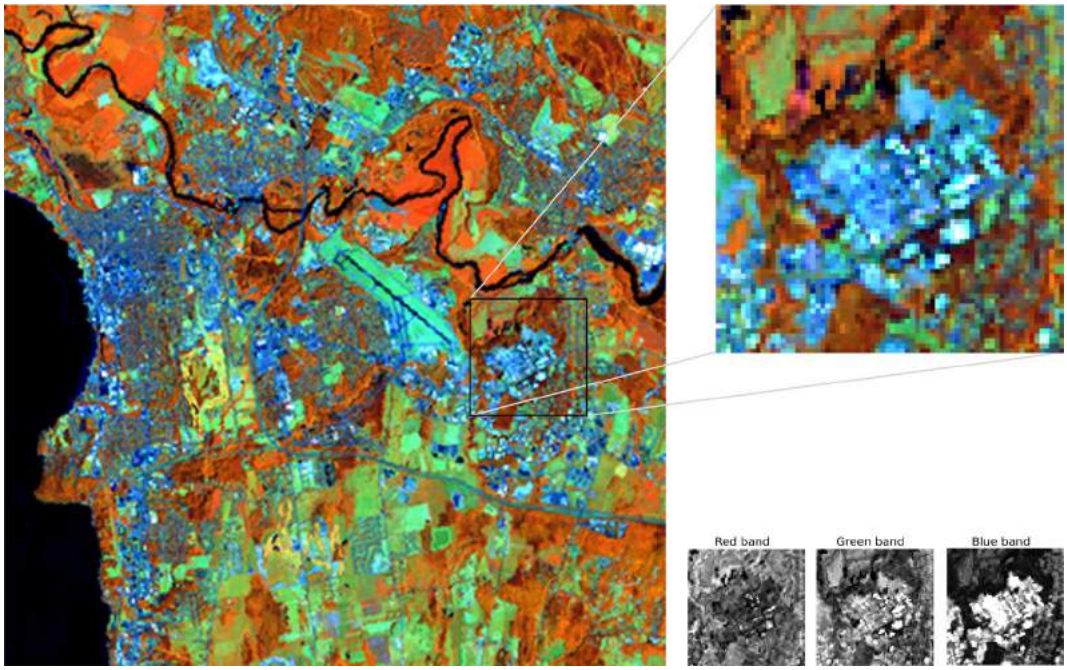

Fig. 2 Zooming to an individual pixel. The image in the top-left is printed at full resolution, it is a Landsat Enhanced Thematic Mapper Plus (ETM+) image acquired over Burlington, Vermont on 21 August 1999. The image in the top-right is a subset of this image that has been magnified by a factor of three. In the magnified image individual pixels (the *square blocks* that make up the image) can be seen. The three *black* and *white images* in the bottom-right represent the three image bands that are used to create the color image. In this case the *red band* is from the ETM+ band 4 (near-infrared), the *green band* is from ETM+ band 5 (mid-infrared), and the *blue band* is from ETM+ band 3 (*red*). These three bands are combined to make the color image.

In addition to rows and columns of pixels, images also have layers. These layers are commonly referred to as "bands" or "channels." Throughout this article we use the term "band" to refer to the layers in an image. These bands also correspond to different wavelengths of the EMS. Remote sensing instruments vary in the number of bands recorded, some only record a single band of data while others record hundreds of bands. A convention has been established to use "hyper-spectral" to describe images with many bands (usually well over 100) and "multispectral" for images with fewer (usually from three to a few dozen) bands.

With most imagery the individual bands are used to record radiance values at different wavelengths. Radiance is a measurement of the intensity of electromagnetic energy. In other words, the sensor is measuring the intensity of light when it hits the detector. The units for this measurement are typically watts per steradian per square meter ($W\ sr^{-1}\ m^{-2}$). It is important to understand that

optical sensors measure radiance and not reflectance. Reflectance, which is the ratio of reflected light over incident light, can be estimated using image processing methods but the physical property recorded by the sensor is radiance (Fig. 3).

Different Platforms and Orbits

For local and detailed information aircraft with on-board and remote pilots are often the platform of choice since it is possible to select which sensors should be mounted for a particular application and it is possible to determine when to fly. Aircraft have the ability to fly low to acquire imagery with a lot of detail. Remotely piloted aircraft, also called drones and unmanned aircraft, are increasingly being used to acquire remotely sensed data to support ecology studies. Regulations constraining use varies dramatically between countries and these constraints can impose a practical limit on how remotely piloted aircraft can be used.

For global and systematic coverage, satellites are the standard remote sensing platform. Most satellite orbits can be classified as either geostationary or polar orbiting. Geostationary satellites orbit the Earth with the same orbital period as the Earth's rotation. In other words, a geostationary satellite orbits around the Earth's rotation axis keeping its position fixed over a specific point on the Earth so it is always viewing the same area. These satellites are commonly used to monitor weather but are too far from the Earth's surface (~38,500 km) for detailed environmental monitoring. More common for Earth remote sensing is a near-polar orbit that provides a near-global view of the Earth over a regular time period, for example, every 16 days in the case of Landsat. It is important to note that with a near-polar orbit the extreme polar regions are not viewed from the satellite. For this reason, when people mention global remotely sensed datasets they often mean the datasets are near-global. Polar and near-polar orbiting satellites fly only several hundred kilometers above the Earth's surface.

A relatively new concept for satellite platforms is to launch several small (often between 1 and 10 kg) satellites called nanosatellites or CubeSats carrying lower-cost sensors. Having a dense constellation of similar satellite sensors orbiting the Earth provides the opportunity for frequent high-resolution data acquisition over the same area.

Passive Versus Active Remote Sensing

Remote sensing instruments are often categorized as having either active or passive sensors. An active sensor generates its own signal which is subsequently measured when reflected back by the Earth's surface. A passive sensor measures solar energy that is either reflected or emitted from features on the Earth's surface. Table 1 lists a number of different active and passive instruments mounted on satellite platforms commonly used for ecological studies.

Although most passive sensors operate in the visible and infrared portions of the EMS, there are also some passive microwave sensors in use that measure a number of parameters such as wind speed, atmospheric and sea surface temperature, soil moisture, rainfall, and atmospheric water vapor.

An advantage of passive sensors is that most rely on the sun's energy to illuminate the target and therefore do not need their own energy source so in general they are simpler instruments. A limitation for most passive optical sensors is that they require daylight to operate, although there are some sensors that record nighttime lights and clouds at night and others that record energy emitted from

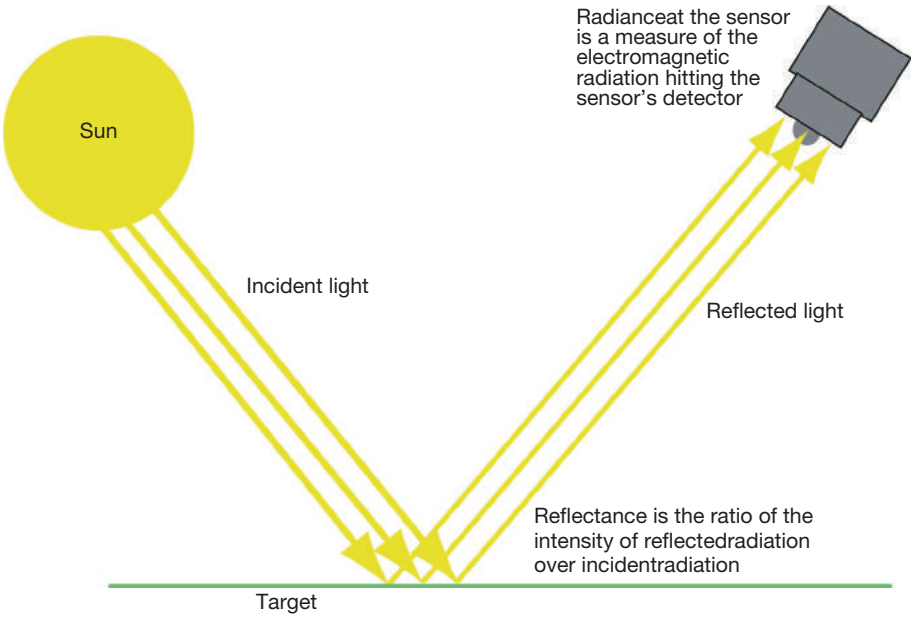

Fig. 3 Reflectance and radiance. Remote sensing detectors measure radiance which is the energy of the radiation hitting the detector. Reflectance, which must be calculated, is the ratio of the intensity of reflected radiation divided by incident radiation.

Table 1 Active and passive satellite-based remote sensing instruments

Sensor name	*Type*	*Wavelength range*	*Resolution*
WorldView-4	Optical	450–920 nm	0.31–1.23 m
SPOT 7	Optical	450–890 nm	1.5–6 m
IRS Resourcesat-2 LISS-III	Optical	520–1700 nm	23.5 m
ALOS AVNIR-2	Optical	420–890 nm	10 m
GeoEye-1	Optical	450–920 nm	0.46–1.84 m
Landsat 8 OLI/TIRS	Optical	430–1251 nm	15–100 m
MODIS	Optical	459–14,385 nm	250–1000 m
Suomi-NPP VIIRS	Optical	410–12,500 nm	400 m
ENVISAT ASAR	Radar	5.7 cm (C band)	30–1000 m
Sentinel-1A and 1B	Radar	5.7 cm (C band)	5–100 m
RADARSAT-2	Radar	5.6 cm (C band)	3–100 m
ALOS-PALSAR-2	Radar	23.5 cm (L band)	0.65–100 m

the Earth's surface. Since most of these sensors operate in the visible and infrared wavelengths, they are adversely affected by weather and cloud cover. Lastly, since sunlight is primarily reflected from the top of a feature, such as a forest, it is not possible to "see" under a canopy to measure vegetation structure. To obtain this kind of information it is necessary to use active sensors.

Active sensors, such as radar and lidar emit their own energy to illuminate a target and are comprised of a signal generator and receiver. They measure the strength of the returned signal and the time delay between when the instrument emits the energy and when it receives the returned pulse. Lidar is an acronym for *li*ght *d*etection *a*nd *r*anging and these systems use lasers that emit light in the visible and near-infrared portions of the electromagnetic spectrum. In a lidar system a single light pulse can reflect off of several features in vertical space such as different layers in a forest. A single emitted pulse will result in a series of returned pulses that are recorded by the detector. These returned pulses can be recorded as a wave (full waveform lidar) or in discrete pieces that correspond to peaks in the returned signal such as the first and last return of the light pulse. The first return corresponds to the top of an object (i.e., top of a tree canopy) and the last return would correspond to the base substrate that the object is resting on (i.e., the ground). This is ideal for measuring the height of features such as trees or buildings. With a full waveform lidar the intensity of multiple returns are recorded which can be useful for characterizing vegetation structure. Although lidar systems are also touted as being able to penetrate a forest canopy it is important to note that laser pulses pass through gaps between leaves and branches and do not actually penetrate through plant material. Lidar systems called imaging lidar are capable of recording a dense collection of points, a point cloud, in three-dimensional space (e.g., height, latitude and longitude) and these can be processed to create images of vegetation or building height, land cover type, terrain elevation, and vegetation structure.

Recent advances in lidar (i.e., multiphoton lidar) make it possible to record a spatial matrix of returns from a single pulse. Multiphoton lidar systems have reduced energy requirements, greater sensor sensitivity and increased data density allowing greater flying heights and faster flight speeds so more area can be covered in a shorter period of time.

Radar is an acronym for *ra*dio *d*etection *a*nd *r*anging. Radar systems operate in the long-wavelength microwave portion of the EMS and thus are largely unaffected by clouds and rain. They can be considered all-weather systems. A radar microwave signal interacts differently with land surface features than shorter wavelength electromagnetic energy detected by optical sensors. For example, a radar signal can penetrate clouds and in some cases can penetrate well into a forest canopy. Radar systems with especially long wavelengths (e.g., P-band systems) can even penetrate dry ground. The ability to penetrate clouds and vegetation makes it possible to map floods through cloudy skies or even under a forest canopy. A radar signal is very sensitive to surface roughness and an object's dielectric constant. Since water can drastically change an object's dielectric constant radar imagery is used to detect changes in soil moisture or vegetation water content. The properties of a detected radar signal also change with varying surface roughness. For example, the ability to detect changes in water surface roughness makes it possible to locate and monitor oil spills in water. This is possible because oil attenuates waves that form on the surface of water bodies so the oiled surface appears smooth while adjacent uncontaminated water has a rougher appearance. Another property of radar is that it can emit and record microwave radiation with different polarizations, usually vertical and horizontal. This feature can be useful when mapping land cover since different land surface features modify the polarization of a radar pulse in unique ways and those differences can be detected with a multipolarization radar instrument. Multiple radar images can be processed to map land surface elevation and detect small changes in elevation over time such as those that occur before a volcanic eruption.

Due to the complex nature of radar remote sensing the skills required to process these data tend to be more difficult to learn than those required for optical image processing. However, most organizations that supply radar imagery provide high-level products than can be used for many applications with moderate training.

What Qualities Determine What Can Be Identified in an Image?

There are different characteristics that affect the detail that can be resolved (seen) in a digital image. These are traditionally referred to as the four types of image resolution. Most people think of "resolution" as being synonymous with spatial resolution but these other "resolution" terms are used in the formal literature.

Spatial resolution which is often simply referred to as "resolution" is the size of a pixel (smallest discrete scene element and image display unit) in ground dimensions. In most cases an image's resolution is labeled with a single number, such as 30 m, which represents the length of a side of a square pixel if it were projected onto the Earth's surface. If the pixel were rectangular (not very common any more), then the length and width of the pixel would be provided.

Spectral characteristics include band width, band placement, and the number of bands. Spectral bandwidth, or spectral resolution as it is often called, refers to the range of wavelengths that are detected in a particular image band. This is effectively a measure of how precisely an image band measures a portion of the electromagnetic spectrum. Band placement defines the portion of the electromagnetic spectrum that is used for a particular image band. For example, one band might detect blue wavelengths and another band might detect thermal wavelengths along the EMS. The properties of the features you are interested in sensing indicate which bands are important. The last spectral variable is the number of bands. The more bands that are available the more precisely spectral properties of a feature can be measured.

Acquisition dynamics has two components. The first is the minimum time a particular feature can be recorded twice, often called the repeat frequency or temporal resolution. Some sensors with a very wide field of view can acquire multiple images of the same area in the same day whereas some sensors have a repeat frequency of several weeks. It should also be reiterated that most remote sensing satellites have a near-polar orbit and are not able to acquire imagery at the poles since their orbit does not go over these areas. The other component is the timing of the acquisitions. Dynamic features such as deciduous forests and events such as flooding often have an optimum time for which they should be imaged. For example, the identification of deciduous vegetation is aided by acquiring imagery during leaf-on and during leaf-off periods. The time of day a satellite acquires an image can also be important for some applications. Many satellites are programmed to acquire images in the morning before clouds build but some acquire imagery in the afternoon or at night. The extent of shadows is also affected by the season and time of image acquisition.

Sensitivity of the sensor is defined by the dynamic range of the sensor as well as the range of digital numbers that can be used to represent the pixel values. Sensors have lower limits below which a signal is not registered and upper limits above which the sensor saturates and is unable to measure increases in radiance. The detail that can be measured between these extremes is determined by the range between the minimum and maximum digital numbers permitted for a particular data type. For example, Landsat TM data values can range from 0 to 255 whereas IKONOS values range from 0 to 2048. This potential range of values is often referred to as quantization or radiometric resolution.

Remotely Sensed Data Sets for Ecological Applications

Remote sensing provides instruments and methods that can be used to derive a broad range of biophysical datasets that are useful for terrestrial and aquatic ecological modeling. In this section several of the more common datasets derived from remotely sensed data will be described with comments about how the datasets are produced, their strengths, and limitations. This is not an exhaustive list but it highlights the diversity of data derived from remote sensing that can be integrated into ecological modeling.

Land Cover

Land cover data are available in image and vector formats with individual types of vegetation assigned to discrete classes. For example, in an image format each vegetation type would be assigned a unique numeric value and in a vector format each polygon would have attribute information that would describe the type of land cover in that polygon. These data are available with a wide range of thematic (classification scheme) and spatial (spatial resolution and extent) qualities.

The specific classification scheme used for a particular land cover dataset can be as simple as forest/nonforest classes or as detailed as a species-level map. One important point related to thematic detail is that the more classes that are used, the lower the per-class accuracy will be. In other words, the classes in a forest/nonforest map will be more accurate than the individual classes in a species-level map. The spatial detail in a land cover dataset is usually a direct result of the type of remotely sensed data on which the classification was based. Using lidar, aerial photography or high-resolution satellite imagery individual tree crowns can be discerned allowing improved capabilities for mapping species-level information.

For the most part land cover maps are created using data from optical sensors and by combining radar and optical data. One area where radar sensors excel is in mapping wetlands and water under forests, such as in flooded forests or vernal pools.

Land cover datasets can be created using manual and/or automated methods. The basic principle of land cover classification is to translate pixel values in a satellite image into meaningful land cover categories. This is often accomplished using automated procedures in which a computer algorithm is used to assign individual pixels or groups of pixels to one of the valid land cover categories. The classification process can also be accomplished using visual interpretation methods where the interpreter uses visual cues such as tone, texture, shape, pattern, and relationship to other objects to identify and group similar land cover types. In general the human brain is better at interpreting the spatial characteristics in an image and automated algorithms are better suited for

processing spectral (the many image bands) information. There are dozens of classification methods in use but not a single "best" approach.

One of the limitations of classified land cover data is that the information is discrete instead of continuous. One way around this is to create a "continuous fields" image dataset for selected types of vegetation. In a continuous fields dataset each pixel value represents the percentage of that pixel covered by a particular land cover type. For example, in a broadleaf tree continuous fields dataset a pixel value of 65 would mean that 65% of that pixel is covered by broadleaf tree species. In addition to different types of land cover it is also possible to create a continuous fields dataset for imperviousness. This is called an impervious surface dataset and it is being used increasingly in ecological modeling particularly when it is necessary to quantify water runoff.

Landscape Metrics

Once a land cover map has been produced it is sometimes desirable to quantify different aspects of patterns in the landscape using assorted landscape metrics for use in ecological models. These metrics provide an objective way to describe patterns commonly described using subjective terms such as "highly fragmented," "small patches," and "heterogeneous landscape." Using software tools it is easy to create these metrics. Some common metrics include:

- Landscape composition
  - Proportion—Area of one cover type compared to the total area
  - Richness—Number of different patch types
  - Evenness—Relative abundance of different patch types
  - Diversity—Composite measure of richness and evenness
- Spatial configuration
  - Patch size and shape
  - Connectivity of patches
  - Dispersed or clumped patches
  - Setting with respect to neighboring patches

Although landscape metrics can be of great value, caution must be exercised when using these metrics. Many of the metrics are very sensitive to image scale and extent of the study area so comparisons across time and space must be done with care.

Vegetation Characteristics

In addition to land cover, there are several vegetation characteristics that can be measured using passive and active remote sensing instruments. These include:

- Phenology
- Primary productivity
- Vegetation health and vigor
- Vegetation structure

Measurements of these characteristics are based on the fact that reflectance, transmittance, and scattering of energy in a canopy is greatly affected by the structure of the vegetation and how the vegetation components (leaves, branches, trunk) interact with the spectrum of energy being used by a particular remote sensing instrument.

Vegetation indices have been used extensively for global studies to monitor changes in vegetation health and cover and have been effective in mapping droughts, desertification, phenology, net primary productivity, and deforestation around the world. The most common vegetation index, the Normalized Difference Vegetation Index (NDVI), is based on the principle that healthy green vegetation absorbs most of the incident red wavelengths of light and reflects most of the near infrared wavelengths. The formula for NDVI is:

$$\mathrm{NDVI} = (\mathrm{NIR} - \mathrm{Red})/(\mathrm{NIR} + \mathrm{Red})$$

where NIR is the radiance or reflectance value from the near-infrared band and Red is the radiance or reflectance value from the red band.

Two other common vegetation indices that use a similar principle as NDVI are the Soil Adjusted Vegetation Index (SAVI), which was developed to reduce the effect of background material (i.e., soil, sand, snow) and the Enhanced Vegetation Index (EVI) which is less sensitive to atmospheric scattering effects. Vegetation index datasets are usually available as temporal composites, such as 10-day or monthly. In a composite product the "best" index values from the composite period are provided for each pixel. Using this approach it is possible to reduce the negative effects of clouds and haze.

Vegetation structure and biomass datasets are often created using data acquired from radar and lidar sensors. Although radar has been used to measure vegetation properties such as biomass, leaf area index, and forest structure most of this has been experimental so data are somewhat limited. This is an area of active research and as new instruments are developed, operational methods using radar instruments may be available in the not too distant future.

Commercial lidar instruments are available for mounting in airplanes that can quickly provide vegetation height information and this can be correlated to tree volume and biomass using allometric tables. Unfortunately using these instruments is expensive and it is often not feasible to cover large areas. Research using airborne and satellite lidar instruments to measure vegetation structure directly is underway and early results look promising.

Topography

Elevation datasets and their derived products (Table 2) are used extensively in ecological applications. Digital elevation data are available as digitized points or contour lines, triangulated irregular networks (TIN), and as gridded surfaces or images.

When using elevation data it is important to know what the elevation values represent. These values can represent the surface of the bare earth, the surface of the features on the earth (i.e., top of the canopy or top of buildings) or somewhere in between.

A commonly used global topographic dataset is the Shuttle Radar Topographic Mission (SRTM) Digital Elevation Model (DEM). The resolution of this dataset is 30 m and it covers land areas between 56 degree south latitude and 60 degree north latitude. The data for the SRTM DEM were collected using an interferometric radar instrument mounted on the Space Shuttle. Over forested areas the elevation value provided by the SRTM dataset represents a point somewhere roughly half-way between the ground surface and the top of the canopy. The exact point depends on the structural characteristics of the forest stand.

Lidar is increasingly being used to collect very detailed elevation data with accuracy on the order of centimeters. Lidar instruments are flown on aircraft and are routinely used for monitoring coastal areas. The accuracy and speed of lidar elevation data collection is unmatched by traditional ground-based methods.

Soil Moisture

Soil moisture is a much sought after dataset for ecological modeling. However, data that meet the needs of a particular application are sometimes not available because existing data spatial resolutions are too coarse, available data do not cover the area of interest, or data do not exist for the required time frame. Relatively new global soil moisture data with a 3–36 km spatial resolution collected from active and passive microwave sensors is available from the Soil Moisture Active Passive (SMAP) NASA mission. People have experimented using data collected from optical remote sensing instruments to map soil moisture but results have been mixed and methods are typically tailored to a specific ecosystem.

Surface Temperature and Precipitation

Although temperature and precipitation data are routinely collected using satellite-based instruments, datasets created using meteorological station data are still often preferred for ecological modeling. In some cases datasets derived from station data are improved by integrating data collected from satellite-based instruments.

Satellite-based rainfall estimates are made using passive microwave, radar, and optical instruments. Rainfall estimate datasets derived from satellite remote sensing are often too coarse (>4 km) for many ecological modeling tasks.

There are many satellite-based instruments that can measure surface temperature including some that produce a global daily and 8-day composite dataset available with a 1 km resolution. Finer resolution data can be acquired using satellite sensors. However, they do not have as frequent repeat cycles as those producing 1 km products.

Table 2 Products commonly derived from digital elevation models (DEM)

Hillshade and perspective views
Viewshed/line of sight
Topographic features
Ridges
Peaks
Channels
Pits
Passes
Plateaus
Hydrologic parameters
Flow direction
Flow accumulation
Predicted watercourses
Watershed boundaries

Atmospheric Properties (Clouds)

Of all the remote sensing-derived atmosphere products (Table 3), the cloud mask is arguably the most frequently used for ecological modeling since it provides a measure of cloud cover. For the MODIS cloud mask product a clear-sky confidence level (high confident clear, probably clear, undecided, cloudy) is assigned to each pixel. This daily dataset is available with 250 m and 1 km spatial resolutions.

Oceans

In the marine environment, remote sensing provides data for a wide variety of environmental variables (Table 4). Optical remote sensing methods are commonly used to map the ocean/land interface and coral reefs. Methods used for these applications are similar to those used for terrestrial land cover mapping except there is greater use of the short wavelength blue bands for coral reef mapping since those wavelengths are better able to penetrate into the water to provide more information on features several meters under the water surface.

Two other common global marine datasets are sea surface temperature, which is derived using methods similar to those used for land temperature, and ocean color which uses optical imagery to determine levels of phytoplankton in the water. Both of these datasets are acquired on a daily basis.

Inland Water

Inland water features include wetlands, streams, and lakes. A mix of optical and microwave remotely sensed data are used to measure and monitor a number of parameters (Table 5) related to inland waters although many of these measurements are only available at local or regional scales and many of the methods require significant field work to correlate actual values with what is recorded by the remote sensing instrument.

Mapping the extent of inland water features is done using a mix of optical and microwave instruments. For example, radar is an ideal technology for locating and mapping standing water, even if it occurs under a forest canopy such as in a flooded forest. Optical sensors are used to measure temperature and identify aquatic vegetation.

Anthropogenic Biomes

Much of human ecology is linked to studying the state and change of anthropogenic biomes or anthromes. Many of the biophysical datasets described above have direct relevance for built and human modified environment. For example, studying the changing urban environment of a city can be done using land cover analysis techniques. One satellite dataset that is largely unique to human activity the Defense Meteorological Satellite Program (DMSP) Operational Linescan System (OLS) sensor nighttime lights. This dataset has been used to create metrics for economic activity and global poverty, population, energy usage, and urban sprawl.

Data Access

Access to remotely sensed data and their derived products has steadily improved over the years as data providers developed more intuitive data browsing and ordering tools. Data licenses for satellite imagery and derived products range from public domain (effectively no restrictions on use) to tightly controlled licenses limiting use to individuals. Initially United States government agencies such as NASA, USGS and NOAA took the lead in providing unrestricted access to remotely sensed data but many other governments such as ESA in Europe, JAXA in Japan and INPE in Brazil have followed that model and offer some of their remote sensing products at no cost. At the other extreme is strict licensing provided by dozens of commercial companies that tend to offer very high-resolution imagery along with services to schedule image acquisitions and provide value added processing. Commercial

Riparian buffer mapping
Flow rates

products nearly always come with well defined licenses that constrain who may legally use those data. Although access to commercial data can be costly it is important to remember you are purchasing the license to use those data and are not purchasing the data itself.

Accuracy Assessment and Validation

When using datasets derived from remote sensing methods, it is important to understand the level of accuracy associated with a particular product. Accuracy figures can refer to the accuracy of the calculated value when compared to the actual biophysical value or it can refer to the positional accuracy. In some cases both figures are provided. Accuracy statistics should be distributed with the dataset. Unfortunately, this is not always the case. In some cases, accuracy statistics for a dataset simply do not exist.

For datasets that represent categorized data, the statistics usually provide per-class and overall accuracy information. This is common practice with land cover datasets. For datasets such as elevation, values are given for horizontal and vertical accuracy. These values are usually given as a probability of being within a specified distance. Other datasets, such as those derived from MODIS data are validated by a team of scientists and in some cases the validation effort is incomplete or ongoing. When using these datasets, it is important to research the most current information available about the dataset's accuracy. This information is often available on the Internet.

Different methods for reporting accuracy exist and this is an active research area. For example, some of the newer accuracy methods provide information about the spatial distribution of error. Methods have also been developed using fuzzy statistics to indicate the severity of the error instead of using the traditional approach of noting a value as either correct or incorrect.

Summary

Remotely sensed and derived data are an invaluable asset for ecological modeling. These data provide broad area and repetitive coverage that is impractical to gather using field methods. This is a very dynamic field and as sensors and processing tools improve, these data will continue to become more plentiful, precise and accurate.

This article provides a brief overview of remote sensing and the types of data that can be derived to support ecological modeling. The intended audience for this article is the consumer, not producer of remote sensing products and it is not a comprehensive treatise on remote sensing. More in depth information about remote sensing and its application to ecological modeling can be found in the recommended reading section for this article.

Resilience

Ali Kharrazi, Advanced Systems Analysis Group, International Institute for Applied Systems Analysis (IIASA), Laxenburg, Austria; Center for the Development of Global Leadership Education, The University of Tokyo, Tokyo, Japan

Introduction

The concept of resilience is increasingly employed across a diverse range of disciplines and has gained critical importance to researchers, practitioners, and policymakers focusing on dynamic socio-ecological systems. The etymology of resilience can be traced to Latin world "resilio," which translates to "jumping back." In the modern view, the word has a common-sense appeal and resonates with the ability of a system to be robust and to recover following a shock or disturbance. The literature surrounding the concept of resilience is highly scattered and contains numerous semantic, theoretical, and qualitative treatments in disciplines ranging from psychology, engineering, sociology, and disaster management. These treatments have increasingly heightened the need for empirical advancements of the concept beyond qualitative, theoretical, and index-based definitions and toward quantitative and systems-level measurements. Toward this end, the discipline of ecology and more specifically ecological modeling have been at the forefront of efforts toward the empirical advancement of the concept of resilience.

With the rise of the nonequilibrium paradigm within the ecological literature, the focus of the concept of resilience has moved away from "engineering resilience," that is, the stability of processes and speed of recovery, to a broader understanding of "ecological resilience," that is, the adaptability of the system and the existence of multiple stable states. Within this framework, the resilience of a system does not necessarily entail a return to an exact status quo ante and shocks or disruptions may lead the system to maintain its critical functions albeit at a different equilibrium. A return to the preshock equilibrium may be more relevant to the inanimate objects, for example, the resilience of buildings to an earthquake, while for socio-ecological systems such as food-webs, given the uncertainty of a changing environment, resilience includes an element of "adaptation." Adaptation is central to the notion that a resilient system exceeds beyond elasticity and that a system's resilience includes multiple basins of attractions. In this avenue, while a system shift from one basin to another basin, it maintains particular core functions even though it may operate under different structures and configurations.

The concept of resilience is predominantly perceived as a positive and desirable system quality in the literature. However, in reality, the specific context of the concept can infer otherwise and systems may be resilient to conditions that are negative and inherently undesirable. For example, the persistence of a eutrophicated lake or an ecological drought are highly resilient systems but inherently undesirable. In these cases, it is essential to examine approaches not to strengthen the resilience of the system but to invest in breaking the system's resilience and lead it toward a more desirable and positive stable equilibrium. Despite its duality of meaning, the concept of resilience is predominately treated as a positive and desirable attribute in the literature.

The wider literature on resilience often portrays the concept as a cost-free attribute without any associated trade-offs. However, within the ecological discipline, the trade-offs of resilience can be categorized as either temporal or spatial. In the first category, resilience has been viewed as the inverse return of time, that is, the required time for a system to return to an equilibrium stability, or as trade-offs between, for example, long-term slow-moving variables such as regeneration and short-term fast-moving variables such resource consumption. In the second category, empirical models arising from the ecological literature have identified trade-offs between spatial and topological configurations defining the resilience of a system.

Models of Resilience

The Adaptive Cycle

The concept of resilience rests on a paradigm emphasizing the ubiquity of change and the need for adaptation for long-term endurance. Based on this paradigm, recent empirically grounded studies have revealed that natural and social systems persist through complex phases of adaptation and renewal. In this avenue, the "adaptive cycle" can heuristically summarize part of this complexity and enhance our ability for resilience thinking.

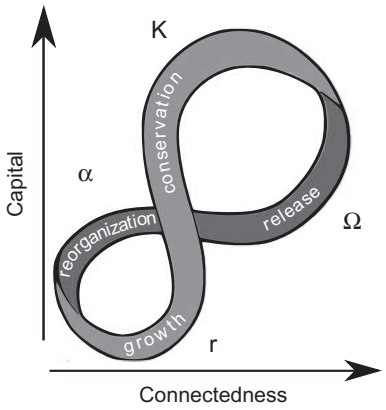

Fig. 1 The four phases of an adaptive cycle.

As illustrated in Fig. 1, the adaptive cycle illustrates a two-dimensional loop-like figure plotted against two axes. The vertical y-axis reflects system complexity and can be measured through an ecological goal function. These goal functions may include, the system's "potential for change" or "accumulation of capital resources," and can reflect the system's capacity to adapt based on alternative future options. Based on this axis, the system, for example, increases its potential by accumulating wealth through novelties that generate returns and following a disturbance depletes its potential to reorganize and adapts to new environmental conditions. The horizontal x-axis reflects the degree of organization or rigidity in a system and can be measured by connectedness. Against the above two-axis, the adaptive cycle depicts a cyclic pattern, inspired from the infinity symbol, which is designated into four phases: new beginnings and growth (r), conservation and status quo ante (K), dissolution and confusion (Ω), and reorganization and innovation (α). These four phases are arranged in two loops, a slow front loop represents the current trajectory while a more rapid back loop represents creative change.

The resilience of a system varies through the adaptive cycle. In the (α) phase the system is described as maintaining low connectedness, necessary for rearranging previously rigid structures, and high resilience, necessary for testing such new rearrangements. On the reverse side in the conservation (K) phase, due to its rigidity and connectedness toward the maximization of resource exploitation, the system maintains lower levels of resilience. The more recent literature on the adaptive cycle, view a resilient system as the ability to successfully navigate all four phases of the adaptive cycle. In this view, a resilient system is able to navigate both the front loop, that is, the long phases of steady growth where available resources are utilized, and also equally important the back loop, that is, the shorter turbulent phases of reorganization and transformation where innovations are sought in the aftermath of a shock or disturbance to the system.

The adaptive cycle maintains high flexibility in its multidimensionality where its axis can be subjective and allow the researcher to devise his/her own worldviews scenarios. A significant strength of the adaptive cycle is its ability in identifying different system trade-offs and to distinguish both positive and negative attractors according to the desired state of the system. This has enabled the application of the adaptive cycle for examining resiliency in various socio-ecological studies.

The Ecological Information-Based Network Approach

The ecological information-based network approach is concerned with the emerging systems-level structure of a network of flows, for example, circulation of material, nutrients, water, or information. The central assumption of this approach is that the resilience of system relies on the topology and magnitude of its flow pathways and is largely defined as a balance between the network configurations of efficiency and redundancy. This approach is applicable to systems that can be depicted as a network web structure, that is, a group of compartments connected by directed and weighted flows depicting the inner exchange and functioning of a system.

While in the long-term, natural systems have been observed to increase their efficiency at the expense of their redundancy, the trade-off between these two system variables may depend on agency behavior, environmental constraints, and shocks or disruptions directed at the system. The efficiency of a system can be defined as the degree of articulation or constraints of flows in a network. In more objective and quantifiable terms, the average mutual information is used to define the network efficiency of a system as:

$$\text{Efficiency} \quad = \quad \sum_{i,j} \frac{T_{ij}}{T_{..}} \log \frac{T_{ij} T_{..}}{T_{i.} T_{.j}} \tag{1}$$

Here, T_{ij} is a flow from agent i to agent j, $T_{i.} = \sum_j T_{ij}$ is the total flow leaving agent i, $T_{.j} = \sum_i T_{ij}$ is the total flow entering agent j and the sum of all flows in the system, $T_{..} = \sum_{ij} T_{ij}$, is known as the total system throughput (TST).

The redundancy of a system, the countering variable to efficiency, can be defined as the degree of freedom or overhead of flows in a network. Network redundancy reflects the diversity of pathways in a system and is critical for a system's flexibility and capacity to

adapt to changing environmental conditions arising from shocks and disruptions. In more objective and quantifiable terms, the conditional entropy is used to define the network redundancy of a system as follows:

$$\text{Redundancy} \quad = -\sum_{i,j} \frac{T_{ij}}{T_{..}} \log \frac{T_{ij}^2}{T_{i.} T_{.j}} \tag{2}$$

Both of these metrics, efficiency and redundancy, are dimensionless and based on units of information depending on the base logarithm used in their calculation, for example, *bits* if the base 2 logarithm is used or *nats* if the natural logarithm is used.

Intuitively, following a disruption, networks with more diverse connections are more flexible in rerouting their flows and maintaining critical functions. Conversely, a more efficient network with a minimal number of well-organized connections can concentrate its capacity for growth and development. This trade-off can be situated in a broader discussion on the phenomenology of ecological growth versus development. As illustrated in Fig. 2, overly redundant networks may be incoherent and lacking the efficiency to grow, while overly efficient networks may be brittle and prone to collapse when subjected to stress—at either extreme of too little efficiency or too little redundancy, the resilience of the system goes to zero. The ratio α is a convenient way to express the degree of which property dominates the system at a given time. Departing from the relative order and invoking the Boltzmann measure of its disorder, the level of a system's Theoretical Resilience can be expressed as:

$$\text{Theoretical resilience} = -\alpha \log(\alpha) \tag{3}$$

From Eq. (3), a maximum value for theoretical resilience is derived as $1/e \approx 0.3704$ (independent of the logarithm's base). Theoretical resilience (Eq. 3) signifies the balance between efficiency and redundancy as a single metric and therefore is useful in exploring and comparing the configurations of heterogeneous networks. Interestingly, empirical investigations have determined that natural networks, for example, ecosystems and food-webs, lie in close proximity to this maximum. Based on these findings, researchers have advanced the idea of bio-mimicry and the need to modify network configurations of various socio-ecological systems toward this normative optimal range for maintaining their resilience. The maximum resilience value, however, should be seen as a theoretical benchmark and a normative balance between redundancy and efficiency of real heterogeneous systems can depend on the environment, stage of development, levels of stresses, and the underlying mechanism forming the network. In this avenue, further research is warranted in evaluating a normative balance for socio-ecological systems that can be grouped based on shared characteristics and local conditions, for example, food-webs, urban networks, and natural resource management.

Statistical Evidence of Resilience

Common system-level properties of resilient systems identified across socio-ecological research include modularity and diversity. By modifying a system and increasing the value of these properties, the system can better withstand an anticipated shock or disruption and increase its resilience and capacity for recovery. Modularity can be related to the degree of the connectivity of a system, whereas

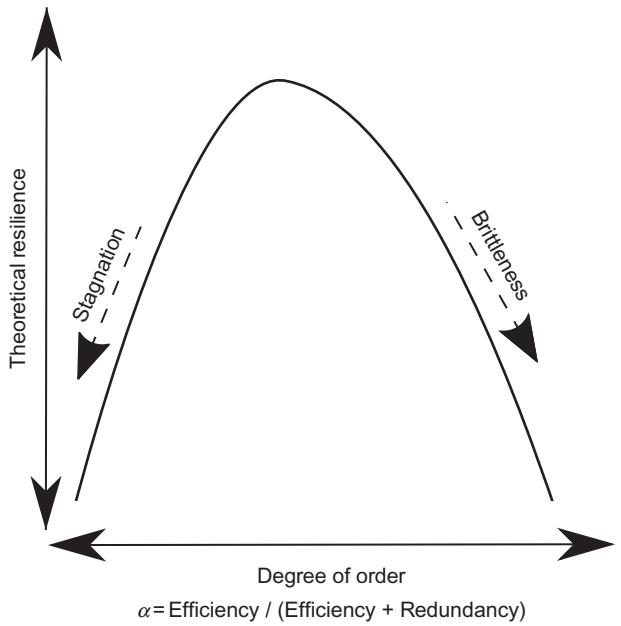

Fig. 2 The conceptual model of the ecological information-based network approach.

diversity relates to the variety among elements of the system. These statistical approaches are highly versatile in their application to increase the resilience of systems to anticipated disturbances or shocks. While individually, modularity and diversity have been employed in the literature, their concurrent use, overlaps, and trade-offs are important research frontiers.

Modularity

Modularity is a system property which measures the degree to which densely connected compartments within a system can be decoupled into separate communities or clusters which interact more among themselves rather than other communities. In a highly interconnected system with low levels of modularity, a shock to one compartment may cascade to other compartment and thus increase the risk of a system-wide collapse. Conversely, in a system with high levels of modularity, a disturbance to one component can be better contained and the disturbance will be less likely to spread to other components. The idea of modularity is widely practiced in the management of various systems, for example, forest firebreaks prevent the spread of fire or port quarantines prevent the spread of epidemics or biological pests. As an important attribute of resilience, modularity has been the subject of increasing research in ecological research. Recent empirical work conducted on food-webs have confirmed that food-webs are more compartmentalized than a null model where species interact with equal probability with other species.

The literature on modularity describes numerous methods for measuring the modularity of a system. Furthermore, in any compartmentalized system, community structures may exist through numerous possible partitions and therefore modularity can be evaluated by seeking a "best fit" for modular partitions. Despite the challenges of a precise mathematical definition, the modularity maximization method is the most widespread in usage and accuracy. In this approach, the modularity of a network partition is evaluated by comparing its number of links against a null network model, that is, an equal number of nodes, links, and degree distribution but with random links among the nodes. From the above definition, a modularity function is defined that can measure the quality of the introduced partitions (P) as a community:

$$P = \frac{1}{T_{..}} \sum_{ij} \left[T_{ij} - \frac{T_{i.} T_{j}}{T_{..}} \right] \delta_{c_i c_j}$$

The expected fraction of links is measured with the assumption that the probability that nodes i and j are connected is $\frac{T_{i.} T_{j}}{T_{..}}$. Here, $T_{i.}$ and $T_{.j}$ are respectively the output and input strengths of nodes i and j, $T_{..}$ is total strengths of the network, and δ is Kronecker's delta where $\delta_{c_i c_j} = 1$ if nodes i and j are in the same community and $\delta_{c_i c_j} = 0$ if otherwise.

Diversity

Diversity is an important characteristic of resilient systems and the concept has been widely used across different disciplines. At its simplest, diversity can be defined as the degree of variation. This may include functional diversity, that is, the degree of the variations of components which maintain similar functions, or response diversity, that is, the degree of the variations of components which exhibit different responses resulting from disruptions. Systems maintaining such diversities can in principle be more flexible when faced with a disruption or shock. For ecologists, diversity is seen as an essential component for ensuring ecosystem resilience and as a long-term survival strategy for natural ecosystems. In ecological studies, for example, abundance, i.e., the proportional abundance of a species or trait, and richness, i.e., the number of species or traits, are important attributes of diversity. While there is no single mathematical definition of diversity in systems, the Shannon–Weaver and Simpson indices are the two most widely used approaches in the literature which combine measures of richness an abundance.

The Shannon–Weaver index is defined as:

$$H = -\sum_{i} p_i \ln (p_i)$$

The Simpson index, more commonly written in its inverse form, is defined as:

$$D = \frac{1}{\sum_i p_i^2}$$

Here, p_i represents the share of category i in the total mix of categories. The higher the value of the H or D, the more diversity is present within a system. The Shannon–Weaver index takes its roots from the information science literature. The Simpson index is also known as Herfindahl index or the Herfindahl–Hirschman index in the economic literature. These two common indices may result in similar measurements of diversity when examining simple systems. However, when examining systems of higher complexity, the choice of index becomes more important, as each index may maintain certain sensitivities, for example, sensitivity to rarity or abundance, in its measurement of diversity.

Summary

The concept of resilience has a common-sense appeal and is increasingly employed within a range of literatures, for example, in psychology, engineering, sociology, and disaster management, each of which maintain numerous semantic and theoretical

definitions. In the wider literature, misconceptions surrounding the concept of resilience include, for example, that resilience does not include an element of adaptability, resilience is an inherently positive and desirable attribute, and that resilience is without trade-offs. Within the discipline of ecology, the emphasis has been toward the empirical advancement of the concept of resilience and toward addressing such misconceptions. Empirical definitions of resilience are more communicable as quantitative measurements and are beneficial in revealing trade-offs in policy and practice. In this avenue, the adaptive cycle, the ecological information-based network approach, and statistical characteristics such modularity and diversity are important and promising directions in advancing resilience research.

The adaptive cycle's strength lies in its flexibility and descriptive trade-offs relevant to the management of a system's resilience. The adaptive cycle, however, does not maintain a strong quantitative approach and it is anticipated that future research can provide new insights in this direction. The ecological information-based approach maintains strong analytical and quantitative definitions and for future research, it is anticipated that more case-study research may reveal normative values in the network efficiency and redundancy of heterogeneous socio-ecological systems. Finally, despite their growing usage in the ecological literature, the influence of modularity and diversity on resilience remains an under-researched area. More specifically, trade-offs and overlaps between modularity and diversity can be considered as important research frontiers.

Socioecological Systems☆

I Petrosillo, R Aretano, and G Zurlini, University of Salento, Lecce, Italy

Socioecological Systems (SESs)

There are no social systems without nature, and few ecosystems without people, such as some large wilderness areas, recognizable for their intactness and for the very low population density. An area must retain at least 70% of its historical habitat extent (500 years ago) and five people per km^2 to be considered a wilderness area, and at global level they are represented by five areas: Amazonia, Congo, New Guinea, the Miombo–Mopane woodlands, and the North American deserts. In the case of oceans, the marine pelagic environments are characterized by some areas free of human influences, even if resource competition due to human exploitation of prey species can cause both nutritional stress and negative behavioral changes in pelagic predators.

Systems where social, economic, ecological, cultural, political, technological, and other components are strongly linked are known as socioecological systems, emphasizing the integrated concept of the 'humans-in-nature' perspective. Socioecological systems (SESs) are truly interconnected and co-evolving across spatial and temporal scales, where the ecological component provides essential services to society such as supply of food, fiber, energy, and drinking water. As a result, socioecological systems have become an emerging focus in scientific and policy arenas.

Landscapes change constantly from natural and anthropogenic drivers, and land use and land cover changes by humans have been identified as a primary effect of humans on natural systems. These changes underlie fragmentation and habitat loss, which are the greatest threats to biodiversity and ecosystem services. The complex interactions between development decisions and ecosystems, and how the consequences of these decisions may then influence human values and subsequent decisions is an important area of research interest.

Given the results of the Millennium Ecosystem Assessment, reciprocal influences among humans and the climate, biota, and ecological goods and services of the world have become both stronger and more widely recognized. In this context there has also been the acknowledgment that in the majority of ecosystems, structure and function are now determined primarily by human interactions, perceptions, and behaviors, so that nowadays it is more appropriate to think of socioecological systems combining approaches from both environmental and social sciences.

The socioecological system theory sprang from the recognition of close interaction between society, in terms of social–economic system, and natural system. For this reason, an interdisciplinary approach is needed: in the past the social–economic approach was distinct from that of ecology; the stereotypical economist might say 'get the price right' without recognizing that price systems require a stable context where social and ecosystem processes behave 'nicely' in a mathematical sense – that is, they are continuous and convex. The stereotypical ecologist might say 'get the indicators precise and right' without recognizing the surprises that nature and people inexorably and continuously generate. These simple approaches are often attractive because they seem to replace inherent uncertainty with the fictitious certainty of ideology or precise numbers. But the theories implicit in these approaches ignore multistable states that characterize SESs.

SESs show a complex and uncertain nature rooted in the complex systems theory that refers to interrelated theories (catastrophe theory, chaos theory, information theory, hierarchy theory, and self-organization theory) that have originated from different scientific disciplines. Despite their traditional scientific disciplinary origins, they have provocative implications across disciplines and fields and, more generally, for the way we understand various types of phenomena as well as the role of learning in planning and policymaking.

In the past, the usual way to study complex phenomena was based on simplifying them through analytical reductionism (describing them as simple systems, machines) or by aggregating and averaging through statistical analysis (describing them as unorganized complex systems). Since an SES is made up of many different parts that interact to form a more complex entity, its dynamic can be explored using an holistic approach because it does not focus on a detailed understanding of parts, but on how key components contribute to the dynamics of the whole system. But complex systems, such as SESs, exist at a threshold between order and chaos, because they are too complex to be treated as machines and too organized to be assumed random and averaged. An example could be the slow erosion of key controlling processes that can abruptly flip an SES into a different state that might be irreversible (the gradual loss of species important for pollination could cause the slump of an economy based on agricultural products).

It is relevant to understand the human sources of ecological change. To do this, we must understand the driving forces motivating human actions. Driving forces are the underlying causes that influence and direct human activities. These forces, either directly or indirectly, result in changes in ecosystems, which can degrade ecosystem capability to provide goods and services. The roots of these forces can be economic, political, sociocultural, and/or legal, and rarely occur in isolation, but rather act in conjunction with others. Direct driving forces, such as mining or agricultural practices, are easily recognizable as they often have an immediately discernible effect. Indirect driving forces are less identifiable; however, they have no less of an impact on ecosystems since they influence people's actions. For example, legislation can encourage people to mine rather than farm an area and influence how they will mine. There are several examples in the world: Britain's solution to rising urban pollution levels in the 1800s was to

☆*Change History:* March 2015. I Petrosillo R Aretano and G Zurlini updated section text and further reading.

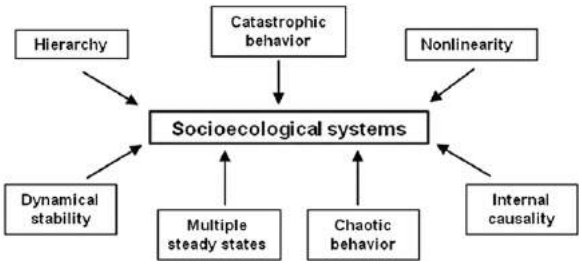

Fig. 1 Characteristics of complex adaptive SESs.

increase the height of factory chimneys. This only postponed the problem in England, while it then introduced problems in Scandinavia. This was only a temporary solution and only at the local scale. The source of the problems, the emissions from industrialization, remained unchanged in quantity or quality. In Europe, the WTO has required the end of European preferential treatment of some banana-producing nations. The opening of trade within the EU could drive land-use changes in other banana-producing countries. The WTO has certainly foreseen this possible outcome. However, it is simply considered a shift of production location based on economic considerations, disregarding both the social and ecological changes that can be driven by such a shift.

Human society is able to choose alternative development scenarios. Initiatives toward development might cause social and ecological changes and bring surprises and uncertainties. It is necessary to plan strategies that enhance system's adaptive capacity to change rather than simply maximize resource consumption. In the case of sweeping surprises, partial solutions, only economic, or social or ecological, bring the loss of benefits coming from the integration among economic, social, and ecological processes. The base of sustainable policies and investments should be turned toward knowledge integration, with the aim to obtain a comprehension based on different viewpoints.

Key Features of SESs

Complex systems theory offers a more sophisticated understanding of the structure and dynamics of both social and ecological systems than the relevant 'normal' scientific disciplines.

The properties of SESs are (Fig. 1):

- *Nonlinearity*. They behave as a system and cannot be understood isolating their components.
- *Hierarchy*. They are hierarchically nested and the 'effect' exercised by a specific level involves a balance of internal (self-control) and external controls involving other hierarchic levels in a mutual causal way. Such interactions cannot be understood by focusing only on one hierarchical level (multiple scales of interest).
- *Internal causality*. This is due to self-organization.
- *Dynamical stability*. There are no equilibrium points for the system.
- *Multiple steady states*. There is not necessarily a unique preferred system state in a given situation, because multiple attractors can be possible in a given situation.
- *Catastrophic behavior*. It is typical of SESs, in terms of (1) bifurcations – moments of unpredictable behavior; (2) flips: sudden discontinuity; and (3) Holling four-box cycle. (exploitation – conservation – release – reorganization).
- *Chaotic behavior*. The human ability to predict the future is always limited.

The complexity of a system is the result of the interaction among a great deal of components that cause new, emergent, and unexpected properties. The analysis of these systems suggests that the possibility for a sustainable development depends on changing perception of human society regarding complex systems. Thus, an essential goal is to change the perception and the way of thinking of social actors, moving their attention from increasing productive capacity to increasing of adaptive capacity. This means that it is necessary to turn social actors' attention to a view where society and nature are coevolving in the biosphere.

SES theory was pioneered in the 1980s by the Resilience Alliance, a voluntary organization of scientists of various disciplines, to explore the SESs' dynamics and their possible evolutions, but there are several scientific schools interested in their study. These theories are based on concepts as adaptive cycles, resilience, adaptability, transformability, and hierarchy (panarchy), and aim to provide knowledge basis to manage complex adaptive systems and to achieve sustainable development in theory and in practice. The knowledge of these aspects should improve natural systems management and their capacity to support human and natural capital.

The novelty of these theories concerns natural, disturbed, and managed ecosystems, identifying which are the key features of ecosystem structures and functions (Table 1):

- Change is episodic, with periods of slow accumulation of natural capital such as biomass, physical structures, nutrients, punctuated by sudden releases and reorganizations of this biotic capital, as the result of internal or external natural disturbances, or human-imposed catastrophes. Rare events, such as hurricanes or the arrivals of invading species, can

Table 1 Key features of socioecological system structures and functions

Change	Change is episodic, with periods of slow accumulation of natural capital punctuated by sudden releases and reorganizations of biotic capital
Spatial attributes	They are neither uniform nor scale invariant. There are several different ranges of scales, each with different attributes of architectural patchiness and texture and each established and sustained by a specific set of abiotic and biotic processes
Stability domain	Ecosystems do not have a single equilibrium and homeostatic controls that keep them near it, rather, multiple equilibria commonly defining different functional states within the same stability domain
Policies and management	Policies and management that apply fixed rules, independently of scale, could lead systems to lose resilience

unpredictably shape system structure at critical times or location, leading to an increase in fragility. In this way, these rare events can modify the future of the systems for long periods, even if irreversible or slowly reversible states can exist; once the system flips into another state, only an explicit external management intervention could allow the system to come back to its previous self-sustaining state, but its full recovery is not assured.

- Spatial attributes are discontinuous at all scales, from the leaf to the landscape to the whole planet. There are several different ranges of scales, each with different attributes of architectural patchiness and texture and each established and sustained by a specific set of abiotic and biotic processes.
- Ecosystems do not have a single equilibrium and homeostatic controls that keep them near it, but rather multiple equilibria commonly defining different functional states within the same stability domain. Normal movements of state variables maintain structure, diversity, and resilience. Stochastic forces and interactions between fast and slow variables mediate the movements of variables among those equilibria.
- Policies and management that apply fixed rules (e.g., maximum sustainable yield), independently of scale, could lead systems to lose resilience, that is, systems break down in the face of disturbances that previously could be absorbed.

How Humans and Environment are Coupled: Examples

There are several examples on how human and environment systems are coupled and how human choices and the consequent environmental effects influence each other. The following are three examples regarding southern Yucatan, Arctic region, and Eastern Europe.

Southeastern Mexico retains parts of the largest continuous expanse of tropical forests in Middle America. One part of the 22 500 km^2 southern Yucatan peninsular region experienced extensive, state-led development beginning in the late 1960s, causing deforestation with consequences on human well-being. In this region, almost all farmers cultivate maize for subsistence and, increasingly, have undertaken commercial chilli production, giving rise to a fragmented landscape of opened and successional forest land. Increasing reliance on commercial chilli production has raised household income but simultaneously driven large swings in this income. This is because chilli is water, pest, and disease sensitive, and the price in the region is highly variable. At the same time, the area is characterized by two main environmental hazards: water stress and hurricanes. The natural land covers, seasonal tropical forests, are adapted to water stress, because they drop foliage during the dry season, while farmers respond to this stress by taking an early dry-season catch crop. On the other hand, severe hurricanes and subsequent dry-season fires knock down large stretches of forest that need a long time to regrow. Hurricanes arrive during the main harvest period, damaging crops, especially chilli, by winds, rain, and floodwater, because a fragmented landscape creates more forest edges exposed to severe winds, damaging near-edge trees. This more open landscape causes less wind protection for crops, with consequences on local economy and human well-being.

Environmental and social changes have had and are expected to have significant effects on coupled human–environment systems in the Arctic. The Arctic Monitoring and Assessment Program have stated that although the Arctic is a relatively clean environment, it continues to suffer from significant pollution hazards, especially with regard to heavy metals and persistent organic pollutants. At the same time, native Arctic peoples have also experienced significant social changes over the past three decades, establishing new relationships between local and national governments, becoming more closely connected to external markets and ways of life, and asserting their identity, rights, and culture in legal and policy forums. Three kinds of stressors interest the Arctic region: (1) climate change with consequences on snow cover, sea ice, and extreme weather events; (2) environmental pollution (potentially toxic organic compounds, acids, metals and radionuclides), some models used in the Scenarios Network for Alaska and Arctic Planning (SNAP) research took into account a steady increase in carbon dioxide emissions from fossil fuels combustion over the first several decades of the 21st century; and (3) societal trends in terms of consumption, governance and regulation, and markets. These represent threats to human health and well-being, indigenous cultures and food security, and human settlements and development. The Arctic region is an example of cross-scale systems interaction, because the decisions taken in different regions affect people living in the Arctic region: global market, climate change, and environmental pollution.

Traditional farming landscapes are an example of socioecological systems, since they are the result of the interaction and co-evolution over centuries between people, which shaped the land through their activities, and the nature that, in turn, gave people a variety of ecosystem services. Many rural communities in Japan, India, China, and Europe are characterized by a well-developed

system of traditional ecological knowledge to assess the quality of the ecosystems goods and services and to sustainably manage natural systems; this resulted in landscapes with high aesthetic, ecological, and cultural values. However, these socioecological systems are rapidly changing due to the social, economic, cultural and institutional changes in the society. In fact, many traditional farming landscapes have come under pressure from by a large number of socio-economic challenges such as the growth of population, economic, industrial and infrastructural development, globalization. These changes have made traditional subsistence agriculture economically unprofitable and unable to meet the increased social demands, leading to landscape changes such as land-use intensification or land abandonment and eroding many valuable cultural and ecological elements as well the linkages between local communities and their ecosystems.

The History as a Basis for the Future of Socioecological Systems

The history of human-dominated socioecological systems is one of successive crises that were either successfully addressed, leading to sustainability, or not, leading to collapse, and the goal of studying history has always been to understand the past in order to understand and deal with the present and the future. The assessment of the vulnerability of modern socioecological systems to future human activities and climate change can be greatly improved by (1) knowing the rates and directions of past trajectories in key processes, such as land cover, soil erosion, and flooding; (2) defining and analyzing how thresholds have been transgressed in the past; and (3) deducing the natural or pre-impact patterns of environmental variability. Therefore, the past provides the means to test the models upon which we depend for future projections and scenarios. The present nature and complexity of socio-ecological systems are heavily contingent on the past; we cannot fully appreciate the present condition without going back decades, centuries, or even millennia.

The complexity theory, with related concepts such as nonlinear change, feedback and regime shifts, suggests that human activities and environmental change should be viewed together as a co-evolutionary and adaptive process. Positive feedback loops may lead to a conditioning of landscapes that makes them more sensitive to new perturbations. Hence, some historical societies, like those on Easter Island, became more prone to collapse through continuing resource depletion and ecological degradation. Others, such as the Akkadian society of Mesopotamia, became increasingly vulnerable to climate perturbations as their dependence on irrigated cultivation increased.

SESs' Management

Environmental management is another field of research and practice integral to any discourse on knowledge and social learning for environmental policy and decision making. A simple definition of environmental management states that it consists of "actual decisions and action concerning policy and practice regarding how resources and the environment are appraised protected, allocated, developed, used, rehabilitated, remediated, and restored." Much of current environmental management focuses on the integration of social and ecological systems, as our understanding of environmental issues has evolved. In this context, environmental decision making has to address the complexity of both ecological systems and interdependent human organizational and institutional systems. Several scholars have set a profound and necessary precedent with their work, explicitly integrating the study of natural resources with human organizations and institutions to focus research and intervention on integrated SESs. In recent decades, efforts to address some of the paradoxes in resource and environmental management have required an evolution in thinking about environmental science and decision making. The result has been a shift from reductionism, command and control science and management, to a more integrated, adaptive, systems-based approach. Integral to this more systemic approach to environmental decision making has been the incorporation of an emerging body of theory often referred to as complex systems theory.

Complex systems theory has offered a more sophisticated understanding of the structure and dynamics of both social and ecological systems than the relevant 'traditional' scientific disciplines. Even this integrated, systemic view of SESs does not explicitly acknowledge the complexity of the process of social learning for decision making within SESs. The integration of planning and governance theory with complex and critical systems thinking, as well as with social learning, points to new opportunities in the study of environmental decision making.

Attempts to extend insights from the field of social learning to the practice and study of resource and environmental management have also contributed to the discourse on social learning for environmental planning and decision making; for example, how public participation in environmental assessment processes provides opportunities for social learning.

Works in the field of environmental management have highlighted the importance of integrating social and ecological systems, highlighting the importance of social learning for the purposes of environmental decision making.

Governance is another main field of practice in which the linkage among knowledge, learning, and intervention in the context of environmental decision making is prevalent. Governance focuses directly on the political side of the decision making. There are several definitions of governance; however, all of these speak to a conception of political economy, and more generally decision making and knowledge for intervention, that is more broad-based, flexible, and evolving than traditional models of public decision making through government intervention.

Complex systems approaches could provide, and are already providing, governance stakeholders with philosophical and methodological underpinnings and practical heuristics to look critically at the interface of learning and intervention. The governance literature highlights the importance of politics and pluralism in decision making.

Existing Socioecological Systems Frameworks

An effective management and understanding of the different aspects of an SES needs the development of an integrated framework that considers the feedback and interactions between and within social, economic and ecological systems. There are several existing socioecological system frameworks that reflect the variety of research fields involved in the study of an SES and that can be applied according to the problem to be studied and the way in which the social-ecological system is conceptualized.

Among them, for example, the DPSIR (Driver-Pressure-State-Impact-Response) conceptual model is one of the framework that shows the cause–effect relationships between environmental and human systems and that has been used for analyzing and assessing the social and ecological problems of systems (above all aquatic systems) subject to anthropogenic influence.

The Millennium Ecosystem Assessment introduced a framework for analyzing SESs connecting drivers, ecosystem services and human well-being. In addition to ecological processes, also social factors such as skills, management regimes, and technology are involved in ecosystem services production. In particular, the framework makes more visible the links between the spatial and temporal provision of ecosystem services (supply) and the beneficiaries where corresponding well-being is appreciated (demand). For this reason the ecosystem service approach is very useful for a better understanding of ecological functioning, social structures, trade-offs and synergies between services, benefits on human well-being, and how these aspects feed back to influence governance and policy and, therefore, SESs and their services. As a consequence, this framework has considerable influence in policy and scientific communities supporting problem solving and proactive management.

A prominent and widely applied framework that focuses attention to socioecological systems is the vulnerability framework that provides the broad classes of components (exposure, sensitivity, resilience) and linkages that comprise a SES's vulnerability to multiple environmental and human changes and hazards. Vulnerability is a highly complex phenomenon with both biophysical (e.g., climatic conditions, natural hazards, topography, land cover) and socio-economic (e.g., demography, poverty, trade, employment, gender, governance) factors that determine its sensitivity to any set of exposures and influence the potential for harm. For this reason, the framework considers linkages to the broader human (social/human capital and endowments) and environmental (natural capital/biophysical endowments such as soils, water, climate, minerals, ecosystems) conditions and processes operating on the SES under study. These conditions can influences the responses (coping, impacts, adjustments, and adaptation). In particular, the social and biophysical responses or coping mechanisms influence and feed back to affect each other, so that a response in the human subsystem could make the biophysical subsystem more or less able to cope, and vice versa.

Another general framework called social-ecological system framework, conceptualizes that each of the individual SESs is composed of four core first-level subsystems: resource systems (e.g., coastal fishery, protected area), resource units (lobsters, wildlife), users (fishers, tourists), governance systems (organizations and rules that govern fishing on that coast, management authority of protected area). Each core subsystem is divided into lower levels made up of multiple second-level variables (e.g., size of a resource system, level of governance,) which are further composed of deeper-level variables. These subsystems are relatively separable but interact and affect each other to produce outcomes at the SES level, which in turn feed back to affect these subsystems and their components, as well other larger or smaller SESs. The framework is useful to identify the multitier hierarchy of variables for analyzing and understanding the functioning of an individual SES and the reasons why certain e.g. management actions and particular policies enhancing sustainability and succeed in one SES and fail in another. This framework has been applied above all for explaining sustainable outcomes in the context of forestry, fishery, and water resources.

SESs and Social Learning

The literature on social learning attempts to make operational many of the complex epistemological issues around the nature of knowledge and the process of learning.

A useful and less theoretical definition underlines that "social learning means more than merely individuals learning in a social situation … (they) envision a community of people with diverse personal interests, but also common interests, who must come together to reach agreement on collective action to solve a mutual problem… it is the process by which changes in the social condition occur – particularly changes in popular awareness and changes in how individuals see their private interests linked with the shared interests of their fellow citizens." Social learning is intended to help improve the quality and wisdom of the decisions when faced with complexity, uncertainty, conflict, and paradox, and the notion has begun to be applied in a variety of complex decision-making contexts, including environmental management and planning. Environmental planning and management are often described as complex and highly uncertain and, from this perspective, management cannot be seen as the search for an optimal solution to a single problem but rather as an ongoing process of adaptation, learning, and negotiation. Thus, to manage complex adaptive systems, it is necessary to create a learning atmosphere, encourage systemic thinking about complex problems, discourage competitive behavior among stakeholders, and focus on 'desirable and feasible change' rather than attempting to achieve absolute consensus on management issues. An example is given by the application of social learning to river basin

management, considered as the capacity of different authorities, experts, interest groups, and the public to manage their river basins effectively. Often, limitations of existing institutions, to consider multiscale, participatory forms of governance for groups involved in river basin management are present. These applications show that social learning processes can improve stakeholders' awareness and participation in environmental deliberation and decision making and therefore contribute to practical change in environmental management as well as institutional change.

Social Adaptive Responses to Ecosystem Change

Despite the lack of theories linking the creation of ecological knowledge from observations and understanding to its incorporation into resources use, Fig. 2 provides a conceptual model of possible responses to a crisis situation. In this context, the term crisis broadly refers to a large perturbation, and it may be human made (resource collapse) or natural (hurricane).

Three generic responses are possible when a crisis occurs:

(1) no effective responses;
(2) response without experience, in which the institution, a government agency or an informal local management institution, responds to a crisis but does not have previously tested policies, with accumulated ecological knowledge, at its disposal; and
(3) response with experience, in which the institution has previous experience with a crisis of that kind and management policy used on previous occasions.

In centralized and bureaucratized management systems, the 'no effective response' is the management reaction that often characterizes brittle or fragile institutions. Such a response allows accumulating up the panarchy (a hierarchy of socioecological systems), creating the conditions for a larger-scale crisis, both political and ecological. Response without experience is a frequently seen reaction to a crisis, and it could lead to institutional learning. This is the case in which the crisis is a true surprise, so that the institutions will have no previous experience with it, or the crisis may have been predictable but be of magnitude that had never been experienced in that area.

The response with experience is possible if the memory of the experience provides a context for the modification of management policy and rules, so that the institution can act adaptively to deal with the crisis.

The more useful management to be applied to SESs is adaptive management, and the more useful assessment is based on the integration of different disciplines.

Adaptive management needs to at least maintain political openness, but usually it needs to create it. Consequently, adaptive management must be a social as well as scientific process. It must focus on the development of new institutions and institutional strategies just as much as it must focus upon scientific hypotheses and experimental frameworks. Adaptive management attempts to use a scientific approach, accompanied by collegial hypotheses testing to build understanding, but this process also aims to enhance institutional flexibility and encourage the formation of the new institutions that are required to use this understanding on a day-to-day basis.

Adaptive management approach needs the definition of SESs' boundaries encompassing multiple spatial scales of socioecological processes and engaging a variety of stakeholders to ensure that management interventions and policy strategies could reflect many different socioecological values and viewpoints. Moreover, since institutions, policies and goals are established over a particular time, they need to be continuously monitored, assessed, and re-evaluated or adapted, as circumstances change, knowledge about the SES is increased and learning takes place.

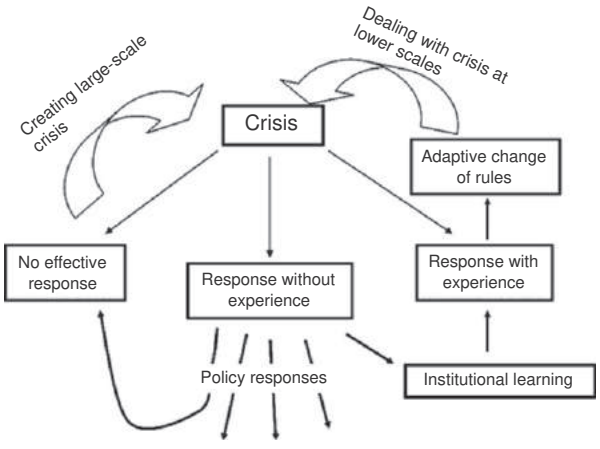

Fig. 2 Three generic responses to resources and environmental crisis. Most responses fall into categories of (1) no effective response, which can lead to larger-scale surprises; (2) reacting with no memory or experience; or (3) responding through learning.

Conclusions

The SES theory recognizes that human dimension shapes and is shaped by environment, so that social and ecological systems are interconnected and coevolving across scales. Since both social and ecological systems are dynamical, the associated policies, including economy that represents the main driver, have to be dynamical; governance systems based on policies that try to control few ecological processes (command and control) do not allow the sustaining of the capacity to deal with change, producing fragile SESs.

A central aspect in dealing with SESs is that they are characterized by cross-scale interactions, both temporal and spatial, and the same is applicable to their governance, because decisions taken at one place in the past and in the present can affect people currently or in the future living elsewhere. The approach used to dealing with SESs assigns surplus value to a social system that clears the limits of sociological approach. In this perspective, social system includes also economic, institutional, and management aspects, by setting the rules. This gains in importance because, according to the 'tragedy of the commons,' the prediction is that in the absence of rules governing who can use natural resources (open access), individual users pursue their own interests, as in the case of ecosystem goods and services.

Since systems are uncertain and complex, the management needs to be flexible and adaptive, recognizing that it is impossible to control so many variables. Strategically, the only way to manage SESs is to adopt a systematic process for continually improving management policies and practices by learning from the outcomes of operational programs, by evaluating alternative hypotheses about the system being managed.

The Sustainable Development Goals

Massimo Gigliotti, University of Siena, Siena, Italy
Guido Schmidt-Traub, UN Sustainable Development Solutions Network, Paris, France
Simone Bastianoni, University of Siena, Siena, Italy

A Plan for the Future

The Sustainable Development Goals (SDGs) were approved by all 193 countries participating at the 70th General Assembly of the United Nations, held in New York on 25th September 2015. The goals are the "2030 Agenda for Sustainable Development". They define a universal, holistic set of objectives to help countries move towards the three dimensions of sustainable development—economic development, social inclusion and environmental sustainability—in a climate of peace, justice, and international collaboration. After more than a year of deliberations, the Open Working Group proposed a set of 17 SDGs and 169 accompanying targets that form a basis for the post-2015 intergovernmental process (UN-SG, 2014).

The previous Millennium Development Goals (2000–15) were eight purely social goals aimed at developing countries. During the 15 years of their application, great improvements were made in national data gathering, however annual statistical information was slow in becoming available—often three or more years after the reference year—and the databases were sometimes incomplete or noncomparable across countries, making the indicators useless for decision-making (UN, 2015). There was also insufficient investment to strengthen statistical capacity and ensure real-time monitoring of those goals. To achieve the Sustainable Development Goals, more investment in independent, impartial national statistical capacity is required. Annual reporting must offer high-quality data from all countries, disaggregated and comparable across countries and time (IEAG, 2014). This should ensure a constant flow of information, useful for implementing policies in line with reality and the new goals.

The 17 Sustainable Development Goals

The 17 SDGs address the three pillars of sustainability: economic development, social inclusion, and environmental sustainability. The targets for each goal articulate the aims and link the goals where possible (UN, 2014) (Fig. 1).

Fig. 1 The framework of the 17 SDGs. Source: http://www.un.org/sustainabledevelopment/sustainable-development-goals/.

SDG1: End Poverty in All Its Forms Everywhere

Since 1990, extreme poverty has halved from 1.9 billion people below the poverty line of $2 a day to nearly 800 million people in 2015, against a corresponding rise in the global population (especially in countries with high rates of extreme poverty) from 5.2 to 7 billion. Despite this remarkable result, one in five people still live in absolute poverty and many others risk slipping back into it.

SDG2: End Hunger, Achieve Food Security and Improved Nutrition and Promote Sustainable Agriculture

Last century, intensive agriculture caused food insecurity and loss of soil fertility. The world wastes 1.3 billion tons of food every year, while 1 billion people are hungry and another billion are undernourished. At the same time, almost 2 billion people are overweight or obese.

A profound change in agriculture is needed to end malnutrition, account for an additional 2 billion people by 2050, and to meet the rising per capita demand for meat and other high-protein diets that require plant feed.

Climate change is raising average temperatures, changing precipitation patterns, and increasing the likelihood and severity of extreme weather events. On current trends climate change will therefore have a major adverse impact on agricultural productivity in most regions. It will also likely increase mass migration.

SDG3: Ensure Healthy Lives and Promote Well-Being for All at All Ages

Between 2000 and 2015, maternal and infant/under-five mortality rates fell by 37% and 44%, respectively. Significant progress was made against severe infectious diseases such as tuberculosis, malaria and polio and against the spread of HIV. However, much effort is still needed to eradicate these diseases. Research and investment are needed to address the possibility of new pandemics caused by high population density, climate change and antibiotic resistance.

SDG4: Ensure Inclusive Quality Education for All and Promote Lifelong Learning

In 2015, enrolment in primary education in developing countries reached 91%, but there are still 57 million children left out of school. Quality education is fundamental for many of the SDGs. Education gives people tools to rise out of poverty and helps reduce inequalities and achieve gender equality. Greater efforts are required to achieve the goal of global literacy with gender equality not only in primary education but at all levels.

SDG5: Achieve Gender Equality and Empower All Women and Girls

Significant progress has been made towards gender equality and the emancipation of women in recent decades, however in the period 2005–16, 19% of women aged 15 to 49 years in 87 countries reported suffering physical or sexual violence from a partner in the last 12 months.

Even today many women receive lower salaries than their male counterparts, even in developed countries. In many countries, although women represent more than 30% of the political electorate, female managerial representation remains low in the private sector. Strengthening female empowerment will fuel more equitable and sustainable economies and societies.

SDG6: Ensure Access to Water and Sanitation for All

Between 1990 and 2015, the percentage of the global population with access to safe drinking water increased from 76% to 91%, corresponding to 2.6 billion people, but almost 700 million people are still without access to improved water sources. Water scarcity affects more than 40% of the global population and is rising rapidly. Water availability is fundamental for a healthy life, but each day nearly 1000 children die from preventable water sanitation-related gastrointestinal diseases.

Finally, 70% of all freshwater withdrawals are used for irrigation. Hydropower is the major renewable source of energy, representing 16% of total electricity production worldwide in 2011. Floods and drought are two opposite problems related to the availability of water that will increase in many parts of the world due to climate change.

SDG7: Ensure Access to Affordable, Reliable, Sustainable, Modern Energy for All

Modern societies need energy for every aspect of work: production of food, goods, services, transport, trade, recreation, and fun. A radical transition from the use of fossil fuels to renewable sources such as solar, wind, hydroelectric, biomass, geothermal, and wave energy is needed as soon as possible, also to mitigate the effects of climate change.

In addition to the change in production upstream of the energy process, it is also necessary to spread awareness about energy saving and the negative effects of wasting energy. It is often not necessary to produce more energy if what is already produced is used more efficiently.

SDG8: Promote Inclusive and Sustainable Economic Growth, Employment and Decent Work for All

Duly paid work is the only universal tool that can allow people to rise above absolute poverty and therefore escape hunger, enjoy good physical and mental health, and contribute to the economic development of their country.

The opportunity for decent work would strengthen the basic social contract, the democratic foundations of which are threatened. Providing quality work for everyone will remain a major challenge for all nations, since every year 30 million new people are looking for jobs.

SDG9: Build Resilient Infrastructure, Promote Sustainable Industrialization and Foster Innovation

Industrial development that is socially inclusive and attentive to environmental protection will be the main source of income for millions of people in developed and developing countries. Energy efficiency and substantial reductions in resource use can be achieved through technological innovation.

Infrastructure is necessary to transport sustainable energy and to exploit technological progress in many other sectors, such as agricultural production, education, transport, and information.

SDG10: Reduce Inequality Within and Between Countries

In the period 2008–14, 40% of the world's poor saw an increase in their income or consumer opportunities. Although the international community has achieved significant results in the reduction in income disparities between nations, inequality within countries has increased. Less than one hundred people hold the same amount of wealth as is the bottom 50% of the world population. It is now widely believed that economic growth is only possible when the three dimensions of sustainability (economic, social, and environmental) are considered.

SDG11: Make Cities Inclusive, Safe, Resilient, and Sustainable

Cities have been the engines of civilizations and cultures since historic times. Businesses, centers of learning, social development, ideas, and innovations thrive in cities. However, the population explosion over the last 200 years has led to rapid urbanization, and many cities have been unable to build adequate infrastructure and provide social service to support their growing populations.

The lack of adequate housing and infrastructure has led to the spread of slums and road congestion. In 2015, 54% of the world's population (4 billion people) lived in cities and it is expected that by 2030 there will be a total of 5 billion people living in urban

areas. The challenges that cities have to face in order to restore social prosperity include reduction of poverty and pollution, construction of infrastructure and implementation of services required by today's and tomorrow's citizens.

SDG12: Ensure Sustainable Consumption and Production Patterns

Globally, the Material Footprint, which indicates the flows of mineral and organic resources withdrawn from the environment to produce assets, increased from 48.5 billion tons in 2000 to 69.3 billion tons in 2010. If the global population reaches 9.6 billion by 2050, the equivalent of three planets will be needed to support current lifestyles unless technologies change profoundly to dematerialize consumption and production patterns.

Sustainable production and consumption require the promotion of energy efficiency and the reduction of waste. Their implementation would create jobs, reduce negative environmental, social and economic impacts, and improve the competitiveness of nations. The circular economy aims to "do more and better by consuming less" but requires a considerable effort and a systemic approach involving all actors in production chains, as well as much commitment and awareness on the part of consumers, who are empowered to make informed purchases through information labels.

SDG13: Take Urgent Action to Combat Climate Change and Its Impacts

Climate change has now begun to show its first effects in every country in the world. If we do not take measures to curtail emissions of greenhouse gases, global average temperatures could exceed 3–4°C this century. In some parts of the world the increase may be significantly greater. Climate migrants could number 1 billion.

Climate change is a global challenge that goes beyond national borders and must therefore be tackled by international concerted action. Countries adopted the Paris Agreement at COP21 and pledged to work together to maintain the increase in global average temperature below 2°C and possibly below 1.5°C.

SDG14: Conserve and Sustainably Use the Oceans, Seas, and Marine Resources

Through phytoplankton, the oceans are the lungs of planet Earth. They also sequester carbon, but this acidifies seawater and endangers coral reefs, hot-spots of biodiversity. Sixteen percent of marine ecosystems are at risk or seriously at risk of coastal eutrophication, while overfishing has reduced food production, damaged ecosystems, and decreased biodiversity.

Seas and oceans are heavily polluted by chemicals, excess organic matter and urban waste such as plastics. The latter form huge plastic islands trapped in the ocean gyres. Protecting marine resources means supporting island populations, biodiversity and the health of the planet.

SDG15: Sustainably Manage Forests, Combat Desertification, Halt and Reverse Land Degradation, Halt Biodiversity Loss

Terrestrial ecosystems support most of our development, from raw materials to food production. Forests make up 30% of the Earth's surface, provide oxygen and shelter for many land species, and constitute and important stock of carbon. In the period 2010–15, the annual loss of forested land was less than half that in 1990 but 12 million hectares of forest per year are lost and biodiversity continues to decline at alarming rates. At today's technologies, a growing human population will require more cultivated fields but this cannot be allowed at the expense of forested land, also considering advancing desertification due to climate change. Water resources and many new drugs and unknown active ingredients depend on the conservation of forest ecosystems.

SDG16: Promote Just, Peaceful and Inclusive Societies

Wars and conflicts breed inequality and poverty. Effective institutions and access to justice for all are the best way to prevent future conflicts. On a global level, the number of victims of voluntary homicide in 2015 stood between 4.6 and 6.8 per 100,000 people, and many forms of violence against children persist. Racial, religious and sexual intolerance continue to be a problem. Corruption, theft and tax evasion cost the world community $1.25 billion per year that could be used to raise people out of absolute poverty.

SDG17: Revitalize the Global Partnership for Sustainable Development

Some sustainable development challenges can be addressed thorough efforts of individual nations. Others will require concerted international action. Some solutions start bottom-up, from individual behavior, while others must be managed by policy makers at various levels (from local to international). To achieve sustainable development, every part of society must be involved: governments, the private sector, and civil society. International mobilization is necessary if industrialized countries are to help poorer nations fight extreme poverty and prevent them from repeating today's models of resource depletion. Long-term investments are needed in the fields of sustainable energy, infrastructure, transport and ICT. In 2014, official development aid reached 135 billion dollars, the highest ever recorded. Together it is possible to achieve the Sustainable Development Goals through greater investments and policy coordination centered on the 2030 Agenda.

Monitoring Systems at Different Spatial Scales

The goals and targets form a common context for all institutions, public or private, that choose to implement the SDGs as strategic objectives. They are available on the United Nations website: https://sustainabledevelopment.un.org/?menu=1300. The United Nations proposes a set of 232 SDG indicators (A/RES/71/313), but institutions can choose the ones they judge most appropriate (on the basis of the targets) for tracking their progress towards sustainable development (SDSN, 2015).

However, the goals also describe a global agenda which includes cross-border issues that can only be successfully addressed through close international cooperation, which in turn requires national responsibility and monitoring. The SDGs cannot be approached unless national efforts are complemented by an effective global monitoring framework.

These four levels of monitoring—national, regional, global, and thematic (UN-SG, 2014)—are illustrated in Fig. 2 (SDSN, 2015).

National Monitoring

The most important level of monitoring is the national one. Nations should implement the SDG monitoring framework in their government agendas, selecting indicators to suit their national needs and priorities. Indicators must be specific, measurable over time, disaggregated and processed by official National Statistics Offices. Nonofficial indicators can be elements of further interest to add richness to national monitoring.

Global Monitoring

Global monitoring is necessary to ensure global coordination and to achieve cross-border goals in thematic areas of supranational interest (e.g., climate change, poverty, inequalities). A dialogue between states is necessary to determine which areas will need more assistance and international aid.

Series of common indicators are chosen by international organizations, ranging from the United Nations to other institutions working in thematic spheres, for example the Food and Agriculture Organization (FAO) and the World Health Organization (WHO).

Regional Monitoring

Regional monitoring can be seen as a subset of the national and global levels (Fig. 2). It may affect political or geographical regions such as the European Union, OECD countries, Southeast Asia and the Pacific and Caribbean islands. It can offer an opportunity for countries linked by common issues to share knowledge and to collaborate in the implementation of joint projects for regional priorities such as shared watersheds, regional conflicts and regional infrastructure. Thus, indicators for regional monitoring may extend beyond the scope of the Global Monitoring Indicators and may include some metrics not considered under Complementary National Indicators.

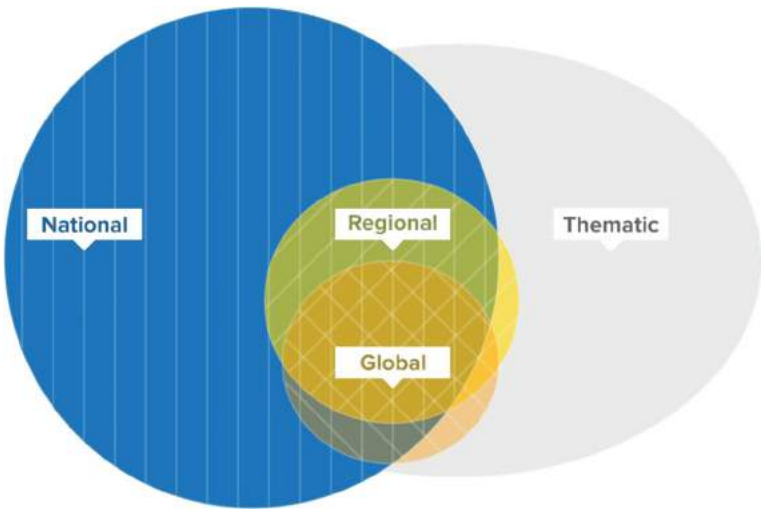

Fig. 2 Schematic illustration of indicators for national, regional, global and thematic monitoring. Source: Sustainable Development Solution Network (2015). Indicators and monitoring framework for the Sustainable Development Goals. Launching a data revolution.

Thematic Monitoring

Many challenges for mankind concern thematic areas like health, agriculture, education, nutrition, the water-energy-food nexus, consumption, and production. Partnerships between countries are the key to shared solutions to a given issue through common knowledge. Specific monitoring indicators should be developed by specialized international organizations for each issue and accountable thematic communities built to track countries across the globe. These indicators are often complementary to official national indicators, and tend to focus better on the issues.

International Institutions

The UN Secretary-General launched the Sustainable Development Solution Network (SDSN) in 2012. Its task is to mobilize global scientific and technological expertise to promote practical solutions towards sustainable development, including implementation of SDGs, involving policy-makers, the private sector and all citizens.

The SDSN is involved in implementation of the SDG framework and publishes an annual report on the progress towards achieving the goals. This report draws on official UN indicators for the SDGs and fills data gaps using other official or unofficial metrics.

The 2017 SDG Index and Dashboards Report published in collaboration with the Bertelsmann Stiftung presents data for 157 countries using some 89 indicators across the 17 SDGs. Countries' distance from the targets is calculated for each indicator, SDG, and the sum of all 17 goals. The using average performance across the 17 goals, the report presents a ranking of all countries.

The report contains an analysis of the international "spillovers" in achieving the SDGs. Major cases of SDG-related spillovers and misuse of the global commons are identified and measured (Bertelsmann Stiftung & SDSN, 2017).

System Sustainability

Federico M Pulselli, University of Siena, Siena, Italy

Sustainability

Sustainability is a word that is used—sometimes overused—in many fields to indicate many things. Sometimes it refers to the environmental sphere and sometimes it has to do with the human sphere, considering its social, economic, financial and political aspects at macro and micro levels. It is therefore difficult to arrive at a univocal definition of the concept, although a strong scientific basis for it can be found in the literature that has evolved in the last 30–40 years.

Nature is the quintessence of sustainability; a translation of the concept for humans would define a virtuous path for evolution of the human system. Sustainability is important for humans and their actions for many reasons, not least the survival of our species. Learning from nature can enable us to translate its winning strategies into virtuous behavior and avoid mistakes and risks for the future.

The first step to characterize sustainability consists in the identification of its biophysical foundations as necessary condition to limit the elusive aspects of the concept (Pulselli *et al.*, 2008).

Time

If we look at a pianist, we see that he plays a chord by striking keys on the piano. When he removes his hands from the keys, the chord dies. If the pianist presses a special pedal, a mechanism enables the chord to continue to vibrate even after the fingers have been removed. The pedal maintains the notes for a while and its name is "sustain." Time is therefore intrinsic to the meaning of sustainability. Something that exists or survives in time is sustainable. This essence of the term "sustainability" and the adjective "sustainable" is important to avoid misuse. It also characterizes the difference between the expressions "carrying capacity" and "sustainable development" because the verb "to carry" means to hold, contain or support something, whereas "to sustain" means to maintain in time. So if we consider time as a crucial element of sustainability it means that we view the dynamics of ecosystems and human activity not as a simple sequence of changes of state and modifications, but as evolution. This helps clarify which actions are virtuous and which should be avoided in order to maintain a system indefinitely in time.

Biophysical Limits

Nature has been surviving for about 4 billion years, during which time biological evolution proceeded through winning strategies under the inevitable condition of limited resources. Nature diversifies: biodiversity is a strong general attribute for survival. Nature exploits the most abundant and reliable energy source, solar energy, finding ways of using it to feed vital mechanisms. Nature optimizes resources and disposes of wastes and degraded energy (e.g., by closure of cycles and dissipation of heat into space). Nature has not only been successful in surviving in time but also in thriving and flourishing within geobiophysical constraints (Jørgensen *et al.*, 2015). Human activities, which are always fed by resource extraction and consumption and generate flows of degraded energy and matter, should be consistent with the finite and constrained ability of the planet to regenerate resources and absorb wastes.

Relations

Thermodynamics gives us the tools to understand these constraints. For instance, its fundamental laws define the limits to overall availability and our capacity to exploit energy: the law of conservation of energy (first law of thermodynamics) states that energy cannot be created or destroyed, and the law of energy dissipation (second law of thermodynamics) states that every activity or conversion degrades energy to heat which is unable to do work. Biological systems are open systems (they exchange matter and energy with their environment) that involve extremely ordered structures and evolve in the direction of increasing order by processing the flow of energy and resources they capture from the environment. They discharge their wastes as degraded energy (heat) and matter (e.g., emissions, pollutants). A continuous process of transformations, cycles and feedbacks demonstrates the importance of relationships for living systems and the dependence of these systems on the context in which they live. This is valid for a cell, a tree, a human being, an ecosystem, but also for a city, a production process, an urban or regional system. All these systems survive by exploiting flows of energy and matter, releasing wastes, emissions and heat into their surroundings (see, among others, Schrödinger, 1944; Prigogine, 1954; Tiezzi, 2003).

Time, biophysical limits and relations are three cornerstones of the concept of sustainability. A system or project cannot be called sustainable if it does not rest on these foundations: it must be durable, it must develop within the limits imposed by natural

 doi:10.1016/B978-0-12-409548-9.10610-4

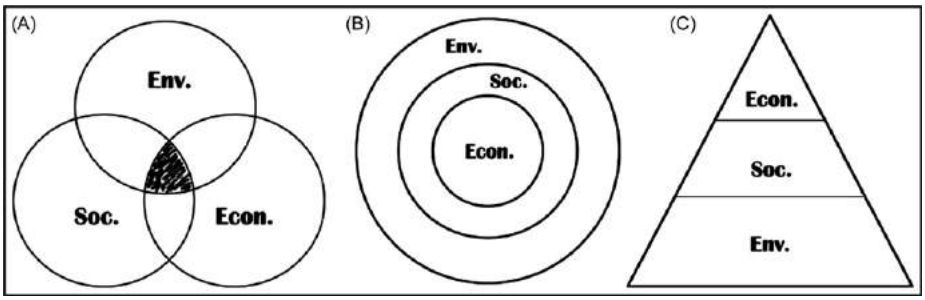

Fig. 1 Representations of sustainability. The usual representation of sustainability shows the *different (A–C)* contributions and interactions between the environmental (Env.), social (Soc.) and economic (Econ.) spheres of human life.

laws (such as the laws of thermodynamics) and it must maintain relationships with other systems and the surrounding environment. Without considering these pillars, the use of the word sustainable is misleading, inappropriate, or even false.

Representing Sustainability

Human development involves three spheres: economic, social and environmental. According to Barbier (1987), sustainable development is defined by simultaneous interaction of the three intersecting spheres. The intersection is where sustainable development can occur, suggesting that converging goals from the different spheres must be achieved together (**Fig. 1**A). This view, however, places the three circles on the same level, and excluding their intersection, it considers the ecological, social and economic elements of sustainability to be interchangeable or substitutable (which amounts to the condition of weak sustainability). An alternative interpretation is that of concentric circles, which implies an environmental basis for the social sphere that contains the economic expression of society (**Fig. 1**B). Another view depicts sustainability as a pyramid, highlighting the relative sizes of the three spheres (**Fig. 1**C). These rather conventional ways of representing the concept of sustainability underline the need for an organic view of human presence and activity on the planet. Study of the relationship between the human species and the Earth system is urgently needed. Researchers have been proposing ideas in this field for several decades, highlighting the risk and consequences of reaching or passing critical points or thresholds. This was one of the aims of the well-known and influential report entitled "The Limits to Growth" (Meadows *et al.*, 1972), which took an organic, comprehensive and global view of the planet.

System Sustainability

The basic concept of system is expressed by the well-known adage of systems science: "the whole is greater than the sum of its parts." This can be explained by the fact that a system, namely "things that stay together," consists of components that cooperate with each other, giving rise to emerging novelties and new properties. For instance, a human being has a body made of 10^{14} cells. Every cell has biochemical, metabolic and anabolic characteristics and properties determined by genetic and environmental conditions but they do not explain the characteristics and properties of the organism as a whole (knowledge, feelings, emotions, pain, etc.). Similarly, an ecosystem is composed of organisms linked in a complex cooperative synergistic relationship that results in properties like adaptation, evolution, self-organization, resistance, flexibility and ultimately beauty (Jørgensen *et al.*, 2015).

According to Jørgensen (2012), "systems with emerging properties cannot be described by listing the components and their properties, but it is necessary to capture, understand and describe the emerging system properties." A fundamental overview of general systems theory was proposed by Von Bertalanffy (1969). Since then many authors have investigated the question which is relevant to our life on the planet and especially sustainability. In a comprehensive survey of the systems approach, Capra (1996) suggested that the essential properties of an organism or living system are properties of the whole system, which no single component has per se. These properties emerge from interactions and relations among the parts of the system. There have been major advances and novelties in many areas of systems science. Ecology, for example, is an area permeated by the systems view. According to Capra, if we consider the world as an integrated system rather than a series of separate components, we take a holistic or even ecological view in keeping with the term "ecological," namely something characterized by relations among its parts and included in a larger context. One fundamental contribution to the advancement of ecology was by Eugene Odum. In a major paper, he emphasized the role of ecology as a discipline that connects and advanced various ideas about the concept of sustainability: "[…] cell level science will contribute very little to the well-being or survival of human civilization if our understanding of supraindividual levels of organization is so inadequate that we can find no solutions to population over-growth, social disorder, pollution, and other forms of societal and environmental cancer. […] It is in the properties of the large-scale, integrated system that hold solutions to most of the long-range problems of society" (Odum, 1977). The paper is actually a precursor of sustainability science because it also traces the link between ecology on the one hand, and social sciences, technology, politics and economics on the other. Jørgensen (2012) subsequently published a textbook on Systems Ecology that deals with

thermodynamics- and biochemistry-based foundations, ecological laws, ecosystem properties and ultimately environmental management. He stresses the need for a holistic view to problem solving and touches on the progressive emergence of meta-disciplines, particularly ecological modeling and ecological engineering, that tend to unify different approaches. Another interesting example of adoption of a systems approach can be found in systems chemistry, that is "the study of complex systems, or networks, of molecules [to] investigate how interactions between members propagate through networks allowing complex behavior to emerge" (Nitschke, 2009).

The concept of sustainability can only be considered from a systemic viewpoint. The study of human sustainable development is concerned with relations between the individual and collective expressions of humankind and the multiplicity of contexts in which the human action develops. The context can be physical, environmental, social, economic, political, institutional, urban, legal and so forth. Pulselli *et al.* (2016) derive at least three key points from this: (a) the organic picture of reality (i.e., what should be sustainable?) requires a transdisciplinary approach in order to encompass the many dimensions of the context in which we live; (b) the purpose (i.e., why should we be sustainable?) is to create and maintain the conditions for durably living better and in harmony with nature and other individuals; and (c) the critical assessment of how we can reach these conditions (i.e., how can we be sustainable?) demands new frameworks in which to evaluate progress toward the desired change. Sustainability therefore connotes a system within its context. By adapting a statement from Jørgensen (2012), originally referring to ecosystems, we can say that if we can understand how ecosystems (as well as human systems) work as systems, we will be able to develop an ecosystem (as well as sustainability) theory that can be used to predict the effects on an ecosystem (as well as a human system) of well-defined changes of forcing function.

Various approaches and methodologies have been developed in recent years to implement a systemic view. Regarding system sustainability, attempts have been made to identify, categorize, quantify and manage the relationships between human life and activity and the context(s) in which they develop, with particular emphasis on environmental context.

An important approach is that of ecosystem service (ES) identification and evaluation. Ecosystem services are the portion of ecosystem functions that directly or indirectly contributes to human welfare. Ecosystem functions occur independently of humans, however humans exploit the existence of ecosystems and their dynamics. These services are usually classified in four categories: provisioning services (e.g., food, water, timber, fiber), regulating services (regarding climate, floods, disease, wastes, water quality etc.), cultural services (that provide recreational, esthetic and spiritual benefits) and supporting services (e.g., soil formation, photosynthesis, nutrient cycling) (see MA, 2005, and the corresponding entry in this encyclopedia). The benefits people obtain from these ecological services can be assessed in economic terms, and the results are surprising. As Costanza *et al.* (1997) demonstrated, at global level, nature provides humans with more resources, and more efficiently, than does world economic infrastructure (which is designed to do just that). Assessment of ecosystem services is therefore a way to estimate and express the importance of ecological dynamics for human life and its sustainability.

Sustainability research has always paid great attention to the determination of thresholds. These are measured or estimated levels of an entity or parameter, beyond which conditions may change unexpectedly, unpredictably and/or irreversibly. An important approach to human activity thresholds at global level is the so-called planetary boundaries framework that aims to identify a safe global operating space for the survival and prosperity of humanity (see Rockström *et al.*, 2009, and the corresponding entry in this encyclopedia). The approach measures selected control variables to determine the risk of dangerous consequences for human well-being in nine Earth processes: climate change, biogeochemical flows, biodiversity loss, land system changes, ocean acidification, stratospheric ozone depletion, freshwater use, atmospheric aerosol loading and chemical pollution. Research in this field is demonstrating that the first four processes involve risk factors for humanity. A major aspect of this approach is the concept of the Earth as an integrated system to be considered, preserved and managed as a whole. The approach is also inspiring research in other fields, such as legislation. For example, a multidisciplinary group of researchers are promoting a systemic legal framework applicable to the Earth as a whole, with a set of assessment and regulatory tools that can be condensed into a safe operating space treaty (SOS Treaty). The treaty is proposed as a new global guideline for legal framework researchers because the Earth is still formally an unidentified legal object (Magalhães *et al.*, 2016).

A further system sustainability approach is the so-called food-energy-water nexus. Used in many studies by various organizations (e.g., the Food and Agriculture Organization of the United Nations, FAO), it offers a way to first identify and then solve problems that a large portion of the world population is facing. By combining different fields of investigation and action it confirms the importance of seeing the world in which we live as a set of cooperative interrelated units and systems. In this case, study of the three sectors—food, energy and water—, to which the climatic system is often added, helps us recognize the many links between them and the fact that problems in one may trigger serious crises in the others. The three-sided approach highlights the main conditions for achieving essential tasks, such as poverty reduction, human well-being and sustainable development at global level, that depend on the context in which human development occurs.

The Sustainable Development Goals, promoted by the United Nations in 2015, are an enlargement of this view. Countries adopted these goals "to end poverty, protect the planet, and ensure prosperity for all as part of a new sustainable development agenda. Each goal has specific targets to be achieved by 2030" (for an overview, see UN, 2015). The set of goals is so wide that it offers an encompassing vision of the human condition on the planet. It includes the following 17 items: no poverty, zero hunger, good health and well-being, quality education, gender equality, clean water and sanitation, affordable and clean energy, decent work and economic growth, industry, innovation and infrastructure, reduced inequalities, sustainable cities and communities, responsible consumption and production, climate action, life below water, life on land, peace, justice and strong institutions and

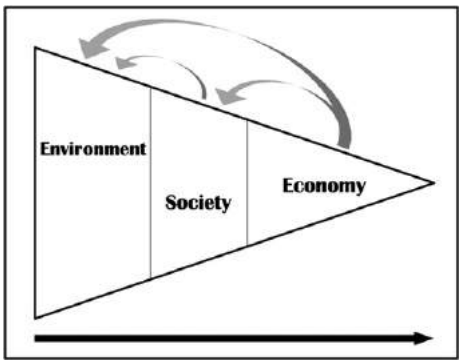

Fig. 2 A less usual representation of sustainability with a more logical/consequential series of stages ordered from left to right.

partnerships for the goals. Again all these aspects are linked and the set works as a system. The challenge is that the purpose of system sustainability is only achieved if the goals are largely achieved together at the same time.

Problems do not observe disciplinary or geographical boundaries but arise almost everywhere, in many ways and with different dimensions and scales. The approaches outlined above can help solve these problems by adopting a systemic view that facilitates understanding of the connections between different components of a given system and identification of emerging properties and problems of the system.

Less Usual Representation of Sustainability and a Possible Interpretative Framework

The scientific community recognizes the environmental, social and economic spheres as components of the concept of sustainability. However, we have seen that they cannot be considered interchangeable.

Fig. 1C shows the relationships between the three spheres of sustainability in the form of a pyramid: the base of the pyramid represents natural assets, crucial inputs into the system; the middle section represents society with its organization and structure, and can be viewed as the state of the system; the point of the pyramid is the real economy that produces the system's output. The pyramid can be considered an evolution of the concentric-circles representation (**Fig. 1**B) that also combines the environmental, social and economic spheres.

Pulselli *et al.* (2015) proposed a slightly different version of this three-stage approach in order to represent sustainability and facilitate investigation. This less usual representation of sustainability rotates the pyramid 90 degree clockwise to capture the succession of the stages (**Fig. 2**) from left to right. "A flow of material and energy inputs generated by the available stock of Natural Capital feeds (is captured by) the system. These resources are necessary for the elements of the system (i.e., society and its organizational units) to operate (act, live, survive); the level of organization of the society influences the degree of utility/satisfaction derived from processing/using/consuming resources. An organized society is supposed to be able to achieve better economic results, providing outputs from its productive processes" (Pulselli *et al.*, 2015).

This version of the scheme aims to represent the physical, relational and thermodynamic order (environment-society-economy) of the succession of stages. It offers a more logical/consequential approach to combining and evaluating different indicators, starting from the economy's dependence on societal organization and environmental resources and including feedback produced by the socioeconomic system.

A general systemic approach emerging from this new version of the sustainability scheme could be the Input-State-Output (I-S-O) framework, useful for assessing system sustainability. In Sustainability section, we saw that living biological systems (including human-driven ones like cities and production processes) are fed by a continuous flow of energy and matter that is processed internally (e.g., self-organization) to give useful outputs (in terms of services, feedback flows, products, etc.). These vital evolutionary steps are therefore simplified by this linear but organic scheme (**Fig. 3**) that also helps select suitable methods and tools for quantifying phenomena. Here different combinations of indicators can be used to count inputs of energy and matter into a system, describe organizational state and quantify outputs. The I-S-O framework orientates the use of well-defined triads of systems indicators representing links between the three spheres of sustainability. This process, consisting of a succession of stages in a series, must be viewed as the integrated way in which the system works. Nevertheless, identifying the three stages makes it possible to select corresponding indicators and compose multidimensional data, often expressed in different units, without losing information. Indeed, the framework can be investigated using a diagram with three axes representing the input, state and output indicators, and the information gained by different indicators is not lost in final aggregations. This framework represents relationships between indicators and helps classify the systems in question in terms of their sustainability.

The choice of indicators is crucial for implementing this method. If we consider the correspondence between the I-S-O scheme and the environmental-social-economic spheres of sustainability, we can use physical measures for input, social indicators for state and economic parameters for output. Thus the triads are composed of groups of indicators/measures representative of each dimension: measures of resource flows (such as ecological footprint, emergy flow, gross emission of CO_2 equivalent, or more

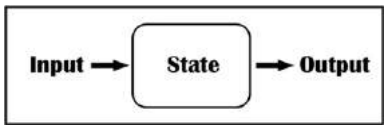

Fig. 3 The Input-State-Output (I-S-O) framework.

generically, energy, matter and pollutant flows) to represent the environmental contribution to the system; measures representative of the state or health of a society or its inequality level (such as employment level or an index of income distribution); economic measures representative of output (such as GDP or value added, or the welfare/happiness of a population).

Each triad gives different information, depending on the indicators chosen. The point representing combination of the three indicator values can be identified in the 3D space enclosed by the three axes. Every system can therefore be identified by a point on the three-axis diagram and its position can be discussed in a static way, determining, for example, the main components that characterize the results obtained (environmental, social or economic), or in a dynamic way, when a time series of indicators is available, signaling development trajectories for that system.

According to the authors, "this application is a rational solution for the study of system sustainability, because it incorporates consistency with traditional sectors proposed in sustainability research and is feasible because it is limited to small number of (already available) data. [The proposal also] maintains the informative capacity of every aspect of system behavior, but it also provides a synthetic picture of the reality. […] This new way of considering these fundamental aspects of our life can be the basis for assessment of long term system sustainability and helps identify the contradictions, hypocrisies, and nonsustainable nature of many of our current behaviors" (Pulselli *et al.*, 2015).

Conclusion

System sustainability designates a condition that characterizes a given system. A system is sustainable if it has durable prospects with respect to constraints and preserves relations. Sustainability is a property of the whole system with all its elements, actors, connections and properties. The concept of sustainability applies especially to human systems, for which a multidimensional/systemic approach makes it possible to consider man-driven systems and actions within their context and limits. Humanity is continuously faced with major problems regarding the health of the planet and ecosystems as life supporting systems, relationships between nations and populations, and ultimately the survival of the species. Improving our capacity to measure/observe the world in which we live and widening the set of investigation tools in this field are urgent tasks. Instruments that enable holistic understanding of the environmental, social and economic view of human life are the most suitable for achieving sustainable systems. In particular, we need investigation and management tools for the environmental and social sphere that complement the primacy of the economic dimension. We have seen that systemic approaches, methods, interpretation proposals and solutions proposed in the last 30 years aim to make the multidimensionality of our world more explicit. To conclude this survey, it is worth mentioning two books which are fundamental references for a systemic view of sustainability. The first is "A prosperous way down" (Odum and Odum, 2001), an innovative contribution that anticipated more modern tendencies like the so-called de-growth movements and the EU Beyond GDP initiative. The importance of the book lies in the fact that it associates relevant aspects of natural and physical phenomena and energy-based dynamics with economic, social, political and demographic problems. The second is "Flourishing within limits to growth. Following nature's way" (Jørgensen *et al.*, 2015): inspired by "Limits to growth" (Meadows *et al.*, 1972), it acknowledges the existence of constraints and limits, but stresses that like ecosystems, human systems must find a way to flourish while observing these limits, seeking wealth but preserving the environment and quality of life.

Tragedy of the Ecological Commons

E Ostrom, Indiana University, Bloomington, IN, USA

Hardin's Theoretical Assumptions

Garrett Hardin mobilized the energies of many ecologists when he wrote `The tragedy of the commons'. Hardin envisioned `a pasture open to all' in which every herder received direct benefits from adding animals to graze and suffered only delayed costs from his own and others' overgrazing. Given that the benefits of putting an additional animal on the commons accrue to the herder while the costs of overgrazing are shared by all, Hardin predicts that all herders will continue to add animals until they destroy the pasture. Therein lies the `tragedy of the commons'.

To derive his conclusions to his metaphorical theory, Hardin made the following five assumptions: (1) no governance arrangements were present related to the resource system; (2) no human investments were made to improve the productivity of the ecological resource (the pasture); (3) the animals grazing on the pasture were the private property of each pastoralist; (4) a large number of herders and their animals were involved leading to adverse effects on the pasture's long-term productivity; and (5) the herders made decisions totally independently without any communication, local organization, or established norms. When this set of assumptions is posited in a one-shot or finitely repeated game-theoretical analysis, the conclusion of substantial overharvesting is theoretically correct. Thus, Hardin's conclusion is correct given his assumptions.

It is also important to recognize that Hardin's theory is empirically predictive in settings meeting the assumptions that relatively anonymous individuals independently make decisions taking into account only their own individual and immediate payoffs. Researchers have repeatedly generated a `tragedy of the commons' in experimental laboratories when subjects face a common-pool resource setting and make independent and anonymous decisions. Making one small change, however, in the structure of laboratory experiments – a change that is not predicted by game theory to make any difference in outcomes – has repeatedly had a major impact on harvesting behavior and outcomes. Allowing subjects to engage in face-to-face communication between decision rounds significantly changes behavior so that subjects approach optimal harvesting levels rather than overharvesting the commons. In face-to-face discussions, subjects tend to discuss the situation in which they find themselves, compare options, decide what they should all do, and then build norms to encourage conformance.

In settings where there is a large group, no one communicates, and where no rights to the resource exist, the theory that Hardin proposed is supported by considerable empirical evidence. There are many settings in the world where the tragedy of the commons has occurred and continues to occur – ocean fisheries and the atmosphere being the most obvious. The global ocean has lost a vast majority of its large predatory fishes. Large mobile fishing fleets do not coordinate fishing efforts but rather act more like pirates to keep shifting where they fish in order to sell to global markets. The agricultural and forestry practices of advanced industrial countries have also led to immense carbon loss from soils.

Contrary to Hardin's sweeping conclusions that all resources not owned by government or a private owner were severely threatened, however, an outpouring of research efforts has occurred since his famous article to study ecological commons in the field. The possibility that the users would find ways to organize themselves was not considered by Hardin. He thought that the users were trapped in the structure in which they found themselves. The possibility of resource users organizing to get out of the tragedy was also not mentioned in basic economic textbooks on environmental problems until recently.

More recent empirical and theoretical research shows that successful governance of common-pool resources has been achieved by a variety of community, government, and private arrangements. No simple governance system is successful in all settings. The robust resource governance systems documented in recent research do not resemble the textbook versions of either a hierarchical government or a strictly private-for-profit firm.

Design Principles for Common-Property Institutions

After reading a large volume of case studies and finding an immense array of specific rules used to govern ecological resources successfully, it appeared more reasonable to identify underlying design principles that characterized robust common-property institutions than the specific rules crafted to fit the immense variety of ecological resources. No claim was made that those crafting long-lasting institutions were self-consciously using the design principle that characterized their hard work. Rather, those systems that were robust could be characterized as meeting a large number of these principles and those systems that failed were not so structured.

The design principles have now been independently examined by a number of researchers conducting field research in a diversity of different settings. The design principles help one understand indigenous inshore fishery institutions in both Canada and Japan. Their relevance has been established for analyzing the European institutions that managed common land in northwest

 doi:10.1016/B978-0-444-63768-0.00634-X

Table 1 Design principles derived from studies of long-enduring institutions for governing sustainable resources

1. Clearly defined boundaries
   The boundaries of the resource system (e.g., pasture, irrigation system, or fishery) and the individuals or households with rights to harvest resource units are clearly defined.
2. *Proportional equivalence between benefits and costs*
   Rules specifying the amount of resource products that a user is allocated are related to local conditions and to rules requiring labor, materials, and/or money inputs.
3. *Collective-choice arrangements*
   Many of the individuals affected by harvesting and protection rules are included in the group who can modify these rules.
4. *Monitoring*
   Monitors, who actively audit biophysical conditions and user behavior, are at least partially accountable to the users and/or are the users themselves.
5. *Graduated sanctions*
   Users who violate rules-in-use are likely to receive graduated sanctions (depending on the seriousness and context of the offense) from other users, from officials accountable to these users, or from both.
6. *Conflict-resolution mechanisms*
   Users and their officials have rapid access to low-cost, local arenas to resolve conflict among users or between users and officials.
7. *Minimal recognition of rights to organize*
   The rights of users to devise their own institutions are not challenged by external governmental authorities, and users have long-term tenure rights to the resource.
   For resources that are parts of larger systems:
8. *Nested enterprises*
   Appropriation, provision, monitoring, enforcement, conflict resolution, and governance activities are organized in multiple layers of nested enterprises.

Based on Ostrom, E., 1990. Governing the Commons: The Evolution of Institutions for Collective Action. New York: Cambridge University Press.

Europe from 1500 to 1850 as well as for building robust rural regimes in Australia. Given the consistent evidence of their relevance, let us briefly review the eight design principles listed in **Table 1**.

Boundary rules enable a group of users to determine their own membership – including those who agree to use specified rules in harvesting from an ecological resource and excluding those who do not agree to these rules (Design Principle 1). This enables participants to know who is in and who is out of a defined set of relationships and thus, with whom to cooperate. Contemporary developments in evolutionary theory applied to cultural systems and processes of adaptation help to explain how these design principles work to help groups sustain and build their cooperation over long periods of time.

If a group of users is going to harvest from an ecological system in the long run, they must devise rules related to how much, when, and how different products are to be harvested and they need to assess the costs of operating a system on users. The second design principle is that the local rules-in-use allocate benefits proportional to required inputs and are crafted to take local conditions into account. Well-tailored rules help to account for the perseverance of the resource itself.

The third design principle is that most of the individuals affected by a resource regime may participate in making and modifying their rules. Resource regimes that use this principle are more able to tailor rules to local circumstances. They are also able to devise rules that are considered fair by participants. More individuals are willing to abide by these rules because they participated in their design and because they meet shared concepts of fairness.

Few long-surviving resource regimes rely entirely on trust and reciprocity alone. Most long-surviving resource regimes select their own monitors or guards, who are accountable to the users or are users themselves, and who keep an eye on resource conditions as well as on user behavior (Design Principle 4). Further, these monitors use graduated sanctions that depend on the seriousness and context of the offense (Design Principle 5). By creating official positions for local monitors, the community legitimates a position. In some systems, users rotate into this position so everyone has a chance to be a participant as well as a monitor. In other systems, all participants contribute resources to pay the monitors.

The operation of these principles is bolstered by a sixth principle that points to the importance of access to rapid, low-cost, local arenas to resolve conflicts fairly among users or between users and officials. Situations always exist in which participants can interpret a rule differently even when they have jointly made the rules. By devising simple, local mechanisms to get conflicts aired immediately and resolutions that are generally known in the community, the number of conflicts can be reduced. If individuals are going to follow rules over a long period of time, some mechanism for discussing and resolving what is or is not a rule infraction is necessary to the continuance of rule conformance itself.

The capability of local users to develop an ever more effective regime over time is affected by whether they have at least minimal recognition by a national or local government of the right to organize (Design Principle 7). Users frequently devise their own rules without creating formal, governmental jurisdictions for this purpose. So long as external governmental officials give at least minimal recognition to the legitimacy of such rules, the fishers themselves may be able to enforce the rules. But if external governmental officials presume that only they can make authoritative rules, then it is difficult for local users to sustain a self-organized regime.

When an ecological system is large, an eighth design principle tends to characterize successful systems – the presence of governance activities organized in multiple layers of nested enterprises. The rules appropriate for allocating water among major

branches of an irrigation system, for example, may not be appropriate for allocating water among farmers along a single distributory channel. Consequently, among long-enduring self-governed regimes, smaller-scale organizations tend to be nested in ever larger organizations.

All economic and political organizations are vulnerable to threats, and self-organized resource-governance regimes are no exception. Even institutions that are characterized by the design principles fail. Both exogenous and endogenous factors challenge their long-term viability. Major migration (out of or into an area) is always a threat that may or may not be countered effectively. Out-migration may simply endanger the viability of a regime due to loss of those who contribute needed resources. In-migration may bring new participants who do not trust others and do not rapidly learn social norms that have been established over a long period of time. Since collective action is largely based on mutual trust, some self-organized resource regimes that are in areas of rapid settlement have disintegrated within relatively short times.

Garrett Hardin brought the challenge of governing ecological resources sustainably to the world's attention. Significant progress has been made since his classic article. What we have learned is that we should not continue to strive for simple solutions to the problem of governing diverse ecological commons – such as the two extremes posited by Hardin. Social–ecological systems are complex, and the problems of overharvesting and misuse are rarely cured by some simple solution. Holling, Berkes, and Folke identified the structure of the problems involved:

> The answers are not simple because we have just begun to develop the concepts, technology and methods that can address the generic nature of the problems. Characteristically, these problems tend to be systems problems, where aspects of behaviour are complex and unpredictable and where causes, while at times simple (when finally understood), are always multiple. They are non-linear in nature, cross-scale in time and in space, and have an evolutionary character. This is true for both natural and social systems. In fact, they are one system, with critical feedbacks across temporal and spatial scales. Therefore interdisciplinary and integrated modes of inquiry are needed for understanding. Furthermore, understanding (but not necessarily complete explanation) of the combined system of humans and nature is needed to formulate policies. (Berkes and Folke, 1998, p. 352).

Given the complex structure of ecological systems, we have learned that simple solutions are frequently counterproductive for fostering sustainable ecological systems. The conceptual structure of these problems needs to be characterized as a rugged landscape with many peaks and valleys. We need to go beyond the simple solutions that Hardin offered – privatize or nationalize – to recognize the complexity and understand how diverse institutional arrangements affect the incentives and likely actions of multiple actors using a variety of governance arrangements.

Urban Metabolism

Yan Zhang, Beijing Normal University, Beijing, China

Introduction

The complex environmental issues caused by humanity's huge and growing urban resource consumption and pollutant discharge has become an increasingly prominent problem. Facing this dilemma, researchers have looked for ways to understand the components of the problem to guide their search for solutions. For more than 50 years, some have wondered whether the flows of energy and materials through cities mimic the processes in natural systems (ecosystems and organisms) and whether the theoretical insights gained from natural systems can provide insights into urban systems. If so, this would let urban managers mitigate the environmental problems of these hybrid artificial–natural systems. This raises the question of what urban managers could do to better mimic the metabolism of natural systems, which are highly efficient and sustainable.

In this context, the concept of urban metabolism was proposed more than 50 years ago to provide a framework and research perspective for understanding cities, and a suite of methods for performing the analysis. By quantifying the material and energy flows that occur through resource exploitation, transformation into goods and services, and the associated pollutant emission, urban metabolism research integrates the natural system (the environment) that supports all human systems with the human (socioeconomic) system to holistically analyze all aspects of resource utilization and pollutant production. This will let managers identify and relieve environmental issues that arise during urban development.

During the evolution of this research, the scales of analysis have expanded from considerations of individual households and cities to regional, national, and even global scales. Simultaneously, researchers have diversified their approaches to understanding urban metabolic processes and their driving forces from the perspectives of political ecology, human ecology, urban ecology, and other disciplines. However, because of their different perspectives, researchers from different disciplines produce different understandings.

Definitions

Since the late 1800s, researchers have tried to comprehend the connotations of material and urban metabolisms from the perspectives of sociology and political economics. Karl Marx first discussed the concept of materials metabolism in his book *Capital*, in which he used the concept of metabolism to describe the exchanges of materials and energy between nature and society. In 1925, Ernest Burgess, a sociologist who considered the division and evolution of labor, proposed that these processes represented manifestations of an urban metabolism, and proposed the phrase "urban metabolism" to describe them. In 1965, Abel Wolman, a water treatment expert, first developed this concept. He adopted an engineering perspective, and applied it to a case study of how urban development affected the environment and vice versa. He treated cities as organisms with equivalents to metabolic processes, and defined urban metabolism as the inputs of materials and energy into the system and its emission of wastes.

Since Wolman's early research, many scholars have developed new interpretations and extensions of urban metabolism. They have mainly focused on processes, on interactions and relationships among the system's components, on assessing the metabolism's environmental impacts, and on seeking opportunities for improvement. Newman's and Kennedy's researches have been typical. Newman combined an urban metabolism model with a consideration of social factors (e.g., the health of residents, employment rates, education) to expand urban metabolism's scope to include human factors. Kennedy considered urban metabolism to be the sum of a city's energy production and waste elimination technologies and socioeconomic development processes.

These definitions of urban metabolism emphasized the socioeconomic system's human and technological metabolic processes and treated natural systems as just another kind of fuel or support for these processes. Researchers did not integrate natural processes into the urban metabolism or consider natural systems as distinct components of the system. In the present article, a more inclusive description that accounts for the natural environment that supports all socioeconomic systems is given. From this perspective, a city can be seen as a "superorganism," and its internal mechanisms and interactions with its environment can be modeled by analogy with a natural ecosystem. This analogy can then be used to define and quantify the interactions between the system's human and natural components. Urban metabolism is the set of processes that meet the production and living requirements of a city and its inhabitants. Thus, the inputs, outputs, transformations, and cycling of materials and energy through the system can be analyzed, including all socioeconomic (technological) and natural metabolic processes, with the goal of improving our understanding of the system's environmental, sociological, and economic characteristics. Achieving this goal lets urban planners, designers, and managers seek opportunities and measures for improvement.

Of course, the analogy should not be taken too far; cities are not organisms. Bohle noted that this analogy must be constrained by the natural laws that govern social structures and processes. Fischer-Kowalski noted that "metabolism" is a way to emphasize the flows of materials and energy and the associated processes. The purpose of the analogy is to improve our understanding, not to

propose a precise parallel for systems that are not truly equal; for example, cities do not reproduce nor do they "die." In urban metabolic research, researchers must remember the limitations of the analogy to avoid being misled.

Historical Background

Urban metabolism research can be divided into three periods.

During the first period, Wolman built a black box input–output model (i.e., one in which the internal processes of the system were not examined) based on a virtual city with a population of thousands rather than millions, during its early development. Few researchers were interested in this approach until the early 1970s, when the practical research began with studies of Miami, Tokyo, Brussels, and Hong Kong. These studies mostly used material and energy flow analysis. During this period, researchers began to consider the technological and biological metabolisms of a city, although this approach was overlooked for a long time by subsequent researchers. Meanwhile, the theoretical research evolved. E.P. Odum modeled an urban system's heterotrophic characteristics (i.e., assumed the system functioned in a manner similar to that of consumers in an ecosystem, without producers such as plants providing the energy and materials that are consumed), thereby laying the foundation for future quantitative analysis. The systems ecologist H.T. Odum analyzed the relationships between humans and their environment in terms of energy, and used metabolic energy to represent the metabolic processes involved in producing and consuming organic matter (i.e., photosynthesis and respiration, respectively) in socioeconomic systems. Based on this approach, he proposed the concept of "emergy."

During the second period (from 1981 to 2000), researchers developed new methods, and standardization of their results became a problem. It became difficult to reliably combine or compare results from different studies, and this problem continues to constrain urban metabolism research. However, the new concepts of hierarchies among the components of a system and of urban parasitism to account for nonreciprocal relationships within the system have strengthened urban metabolism theory; in turn, this has strengthened model development. Akiyama noted that black box models and subsystem models are both legitimate approaches, but for different purposes. Newman extended input–output metabolic models to account for the dynamics and livability of communities, and established a dynamic model that better combined the social and economic perspectives on urban systems. Girardet focused on the link between urban metabolism and sustainability based on the differences between linear (one-way) and circular (recycling) flows. He proposed a sustainable circular metabolic model, thereby laying a foundation for research based on the methods of industrial ecology.

During the third phase of urban metabolism research (since c. 2000), journals, conferences, collaborative projects, and reports emerged in large numbers. Simulation models progressed rapidly, reflected in further application of circular metabolic flows, dynamic metabolic models, and the establishment and development of network models. Network models go beyond traditional black box models to deeply analyze the system's internal structure, transformation processes, and interactions among the system's components. Unfortunately, most researchers still ignored or greatly simplified interactions with the city's external environment. However, researchers have developed dynamic models that account for changes over time. Examples include dynamic models for built environments, dynamic evaluation and simulation models for metropolitan subprocesses, and dynamic models for urban water. Although different kinds of models have been developed, it has been difficult to make these models spatially explicit using tools such as geographic information systems to support urban planning, which requires network models to support real-world planning. This has been due mostly to a lack of spatially explicit data to use as inputs for the network models.

Throughout the evolution of urban metabolism research, scholars have tried to understand urban metabolism from different perspectives. Political ecology uses the theoretical categories from political economics to study the conversion of materials and energy and the effects on the social environment caused by decision-making processes such as urban development and resource exploitation. Human ecology and social ecology analyze how social paradigm shifts influence the flows of materials and energy from the perspective of historical changes, and analyze how changing social institutions can transform an urban metabolism.

Urban ecology researchers have proposed three paradigms to guide their research, intending to explore the relationship between humans and nature and promote sustainable urban development. These paradigms are "Ecology in the city," "Ecology of the city," and "Ecology for the city," "Ecology in the city" resembles ecology's narrow scope, and focuses on the city's natural elements, including the structure and distribution of animal and plant resources and their service functions, and treats socio-economic activities as external stressors. "Ecology of the city" focuses on flows of materials and energy through socioeconomic systems and their ecological and environmental impacts; because cities represent highly concentrated human activity, the research focuses on these intense socioeconomic activities, and considers the natural environment as an external constraint on these activities. "Ecology for the city" combines aspects of the other paradigms by focusing on the complex hybrid socioeconomic and natural ecosystem, and treats the natural environment and human activities as equally important, thereby requiring that development decisions account for both aspects of urban development.

"Four in One" Methodology of Urban Metabolism

Based on the description of urban metabolism concepts, researchers should describe metabolic pathologies (i.e., problems with an urban system's functioning), diagnosis of urban metabolic disorders, the etiology of these disorders, and treatments. To do so, a

"four in one" methodology is proposed, which combines process analysis with accounting evaluations, model development, and efforts to find optimal regulation mechanisms (Fig. 1).

Process Analysis

Process analysis evolved from studies of linear input and output processes to studies of cyclical processes that convert the output from one system component to the input for another component, and then to network analysis methods that improve on "black box" models by uniting these flows into an overall model of the network that reveals the system's inner details (Fig. 2).

By identifying the different actors within a metabolism, network analysis can focus on the production processes of different areas, industries, or sectors. As a result, it can examine activities that drive flows of materials and energy and their environmental impacts. Thus, it can study the metabolism of industrial parks, industries, communities, and families, among others. By identifying the metabolism's components, network analysis can trace the flows of energy and key materials (e.g., chemical elements such as carbon or nitrogen; materials such as water) between materials (analogous to metabolites) and their environmental impacts.

Before conducting this analysis, it's necessary to define the system's boundary and its main metabolic pathways, as well as external areas that support the system by providing energy or materials. Researchers can then analyze the main actors that create flows along these pathways, including flows between the system and its external environment. The interactions among actors along multiple pathways define the network's structure and a complex network of flows. This model can then be used to track the inputs, outputs, transformations, and cycling of materials and energy. That is the subject of the second step in the "four in one" model.

Accounting and Assessment

The main accounting methods in urban metabolism research are material flow analysis, emergy analysis, and the ecological footprint method. Material flow analysis analyzes the flows of materials, thereby tracing the input, storage, transformation, and output processes. It focuses on classification of the material flows and on developing a balance sheet that accounts for all flows. It then characterizes the environmental impact of the metabolic processes by applying a suitable weight to each material. Emergy analysis attempts to quantitatively express all flows in a consistent set of units (typically solar emjoules, sej). This approach can convert different kinds of flow (materials, energy, and money) into units that can be directly compared, thereby allowing a comparison of very different kinds of flows. The ecological footprint method converts the environmental impacts of each flow into area units to reveal the area required to supply all inputs required for the system's survival. The analysis is based on a matrix that links consumption with land use, and can therefore analyze the relationship between a unit of land's capacity to provide one or more resources and the pressure exerted on that land by the consumption activities it supports; that is, it

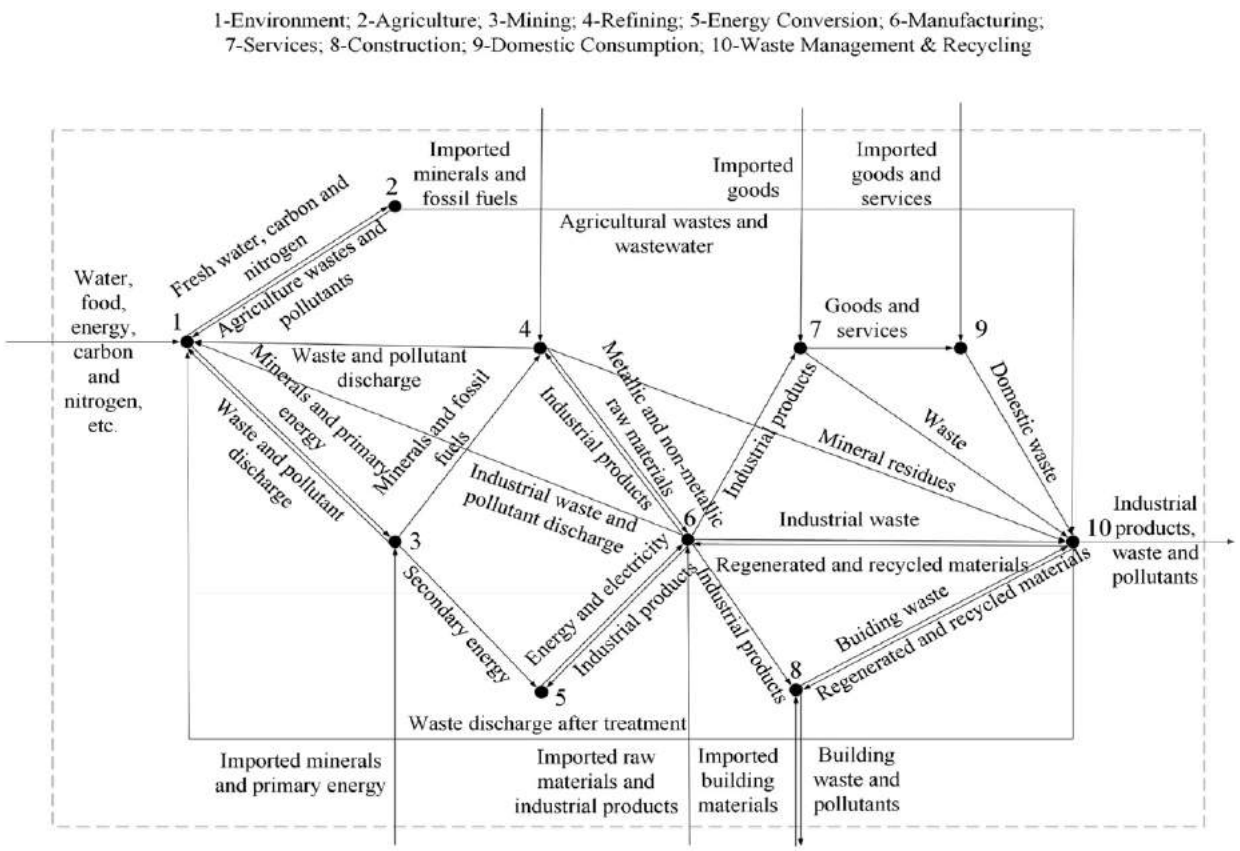

Fig. 2 Illustration of the concept of network process analysis.

represents the system's pressure on the environment and the environment's ability to sustain that pressure. **Table 1** compares the different accounting methods.

The main assessment method is life-cycle assessment, which provides a cradle-to-grave accounting of the direct and indirect energy consumption and material flows involved in the production of a product or delivery of a service. The result quantifies the environmental load of the metabolic processes at each stage of a product's or service's life cycle. Some researchers have used this analysis to compare the indicators used in metabolic accounting (e.g., direct material consumption, demand for materials, pollutant emissions) with economic parameters, the population size, or the land area. They then constructed a system of evaluation indices that include aspects of metabolic efficiency, intensity, density, and influence. However, there is uncertainty in how to divide the life-cycle stages, choose impact categories, determine characterization factors, and standardize the data.

Model Simulation

Ecological dynamics models, input–output analysis models, and ecological network models simulate the evolution of metabolic processes, the factors that influence them, and the system's internal operating mechanisms. Ecological dynamics models are an important tool for simulating flows of materials and energy in an urban metabolism because rapid advances in computer technology have made such complex simulations feasible. These models combine system dynamics methods with material accounting and emergy indicators by analyzing the system's composition and structure and the causal mechanisms responsible for flows through the system. A model of the evolution of the system's ecological thermodynamic properties and processes can be constructed, and will allow prediction of long-term dynamic changes in the system's metabolic processes. Input–output models can be used to account for all inputs into and outputs from a system. As this accounting becomes increasingly precise, it allows the development of input–output tables for the actors in the urban metabolic processes, and therefore allows simulation of the direct and indirect effects of the actors. Because flows may be measured in many units (e.g., energy, money, mass), and because some of these flows are difficult to quantify, monetary flows often serve as proxies for these different units. The main difficulty is how to convert economic data (i.e., monetary input–output tables) into physical tables that represent the quantity of a material implied by the monetary value. Ecological network models can simulate the system's direct and indirect effects on its environment, producing data on the integrated flows within the system; based on these flows, it can reveal trophic levels (e.g., consumers vs.

Table 1 Comparison of the accounting methods

Method	*Merits*	*Drawbacks*
Material flow analysis	Measures the inflows and outflows throughout a product's or service's entire life cycle within the urban system. Hidden flows can be identified to reveal the pressures on the environment. This method reflects the intensity and scale of urban activities, and can be used to compare cities	Adding the weight of different materials directly increases the substitution of resources, as it implies the possibility that any resource can be replaced by one or more other resources, and ignores the quality differences among materials. Because some materials flow through a system in many forms, it is difficult to obtain enough data for comprehensive analysis
Emergy analysis	Ensures that the flows of energy that underlie the creation and flow of all materials is accounted for along with the flows of materials, and accounts for differences in the quality of the materials or energy	Determining appropriate transformity values for specific objects or flows is a difficult problem that has not yet been solved
Ecological footprint analysis	Combines the demand created by socioeconomic development with the supply from the ecological environment, thereby revealing an ecological deficit or surplus	Treating land as a single homogeneous source of supply neglects the diversity of functions that land provides. The criteria for selecting areas that supply ecological resources are not unified, and incomplete accounting for the resources provided by natural systems and of the wastes eliminated by natural systems result in underestimation of the true values

Table 2 Comparison of the main urban metabolism simulation methods

Model	*Merits*	*Drawbacks*
Ecological dynamics model	Uses causal feedback relationships to analyze an urban metabolic system's operation and evolution, and combines social, economic, and natural elements to simulate the system's evolution	Quantitatively unifying flow processes for multiple ecological elements is difficult because there is no unified accounting method. In addition, researchers have mostly focused on simulating metabolic processes for a single element. Simulations that combine many elements have difficulty tracking all elements
Input–output analysis model	Combines economic elements with flows of materials and energy to construct an environmental input–output table that refines the description of the actors in urban metabolic processes	To conduct analyses at a given scale, it's necessary to obtain data from broader scales (e.g., the province or country in which a city is located) to account for flows into the city from these larger regions. It's difficult to combine material and energy flows with input–output tables, as it's unclear how to account for exchanges among sectors or locations (due to the limited material and energy data that is available) using an economic (monetary flow) matrix, leading to only an approximate simulation
Ecological network analysis	Combines the methods of flow, utility, and path analysis to quantitatively simulate the system's structure and function and the relationships among its components	The lack of flows among a system's subnetworks makes it difficult to refine the sectors within the network, and the ecological connotations are not yet fully understood

producers) within the system and the hierarchy of ecological relationships among the actors (e.g., competition vs. mutualism). Table 2 summarizes the merits and drawbacks of these methods.

Optimization and Regulation

To optimize a city's urban metabolic processes (i.e., maximize their efficiency or minimize their environmental impact), it's necessary to determine which factors most strongly regulate the metabolism and how to modify them. That is, researchers must identify the key driving factors to provide a basis for urban planning and management to account for those factors. The factor decomposition method and the structural decomposition method are generally adopted to identify socioeconomic factors (such as industrial and urban transformation plans, the industrial structure, the technology level, the scale and structure of final demand, income levels, population size and structure, lifestyle changes). Simultaneously, researchers should pay attention to ecological factors such as urban heat island effects, differences in roof albedo, and urban forests that influence the metabolism. Moreover, the urban form, density, and infrastructure, as well as changes in land use, influence the metabolic flows and stocks of energy and materials, and should also be considered. Based on this analysis, researchers can develop and compare scenarios using scenario analysis, factor decomposition, and multiobjective optimization to identify the possible impact of key driving factors, and define development scenarios based on the results to guide subsequent regulation of the urban metabolism. Table 3 shows the merits and drawbacks of these methods.

Table 3 Comparison of the main urban metabolism optimization and regulation methods

Model	*Merits*	*Drawbacks*
Factor decomposition	Analyzes varieties of factors that affect a variable's development (e.g., economic structure, population, energy intensity, technology level). Based on aggregated data, which is usually easy to obtain	The aggregated data is comprehensive and additive, but cannot reflect processes at more detailed scales
Structural decomposition	Since it is based on the input–output model, it can perform detailed analysis of changes in the economic structure, including changes in the production structure, final demand (structure and scale), and technology	Decomposition is based on an input–output model which includes coefficients that represent pollutant emissions or resource consumption per unit GDP. Because the structure depends on the equation's components, the effect of other factors may be neglected
Scenario analysis	Uses a small amount of data to predict alternative outcomes, and to design future scenarios that can improve perceptions of future possibilities, and support strategic planning	Depends too much on the current situation; when hypothetical scenarios are inconsistent with future developments, the results can be misleading. Can only predict some future points rather than continuous dynamic trends
Multiobjective optimization	Considers the overall objectives from socioeconomic and environmental perspectives, constructs a utility function based on constraints to coordinate multiple objectives, and thereby provides an optimal solution	When the objective has an optional range, this objective is treated as constraint to reduce the number of objectives, leading to less-certain predictions

Applications

Cities are open systems (i.e., they exchange materials and energy with their environment) and show considerable internal variation. Thus, studies of urban metabolic processes must cross multiple scales. Because metabolic activities within an urban area require support from the external environment, researchers must fully consider the environment's resource supply and ability to accept urban waste at larger scales (e.g., urban agglomeration, megacity, regional, national, or global scales). This will reveal the roles of a city within larger systems that have their own metabolic processes. However, these larger-scale studies failed to account for differences between communities and industries because they were based on coarse-resolution (aggregated) data. Therefore, it is also essential to perform analyses at a smaller scale, such as community or household scales, because data from those scales is aggregated to provide the basis for research at larger scales.

Analysis of Water Metabolic Process in Beijing

Using ecological network analysis, Zhang and her colleagues constructed a simple network model of an urban water metabolic system, and used the model to analyze Beijing's water metabolic processes. Using the trophic levels of natural ecosystems as a reference, they defined the compartments that participate in the water metabolism as producers (the ecological environment and the artificial rainwater collection system), consumers (the industrial, agricultural, and domestic sectors), and reducers (the wastewater recycling system), and determined the water flows among the system's components. They then developed a conceptual model of the urban water metabolism (**Fig. 3**). Because each component may play different roles at different times, changes in the roles of these components produce dynamic changes within a network rather than simple linear changes in the relationships between pairs of components.

Based on this analysis, they established an ecological network model of Beijing's water metabolism (**Fig. 4**). They used network throughflow analysis to determine the flows among the components, and measured both the indirect and direct flows. Using a network utility matrix, which quantifies the utility each node in the network receives from its interaction with other nodes, they determined the relationships and degrees of mutualism among the system's six compartments (**Table 4**). The capacity of producers to provide water for Beijing decreased from 2003 to 2007, and consumer demand for water decreased due to decreasing industrial and agricultural demand; the recycling capacity of reducers also improved, decreasing the discharge pressure on the environment. From 2003 to 2007, the main changes in the ecological relationships among the components of Beijing's water metabolic system mostly occurred between the local environment, the agricultural sector, and the industrial sector. The ecological relationships between the industrial sector and the local environment changed from exploitation to competition and back again, while the ecological relationship between the agricultural and industrial sectors changed from competition to exploitation and back again. Although Beijing's mutualism indices remained generally stable, the ecological relationships among compartments changed greatly. To ensure that water supplies stabilize or improve, the authors proposed that the system's rainwater collection and recycling components must continue to improve, and that water consumption by the industrial, agricultural, and domestic sectors must continue to decrease, perhaps by increasing reuse and recycling of water. In addition, measures must be taken to allow recharge of water resources.

Analysis of Energy Metabolic Processes in the Jing-Jin-Ji Urban Agglomeration

Zhang and her colleagues combined multiregional input–output tables with ecological network analysis to develop an analytical method, and used the Beijing–Tianjin–Hebei (Jing-Jin-Ji) urban agglomeration as a case study to illustrate how to define a network model and simulate the energy flows (e_{ij}) among the three regions and their sectors. They quantified the indirect flows and the distribution of ecological relationships among the metabolic actors. The flows began with the Agriculture and Industrial sectors, which process resources from the Earth into materials that they deliver to downstream sectors. The flows continued with the Industrial sector, which provides materials to the Construction sector to produce infrastructure (e.g., buildings, roads). Next, the Transportation, Storage, and Postal Services sector and the Other Services sector used products from upstream sectors to provide services to residents. The first component of this model was based on a multiregional input–output table, which the authors used

Table 4 Beijing's integral utility (**U**) matrix for the city's water metabolic system in 2007, and the corresponding sign (sgn) matrix

U_{2007}							$sgn(U_{2007})$						
	1	2	3	4	5	6		1	2	3	4	5	6
1	0.748	0.038	0.038	0.160	0.120	0.153	1	+	−	−	−	+	+
2	0.230	0.930	0.001	0.049	0.327	0.255	2	+	+	+	−	−	+
3	0.274	0.022	0.982	0.059	0.007	0.004	3	+	−	+	−	−	−
4	0.374	0.019	0.019	0.920	0.060	0.076	4	+	−	−	+	+	+
5	0.360	0.080	0.040	0.077	0.671	0.276	5	+	+	−	−	+	−
6	0.394	0.112	0.061	0.084	0.509	0.587	6	−	+	+	+	+	+

Utilities are calculated based on the flow between the nodes in the first column of the table to the nodes in the first row of the table. Nodes: 1, ecological environment; 2, rainwater collection system; 3, industrial sector; 4, agricultural sector; 5, domestic sector; 6, wastewater regeneration system.

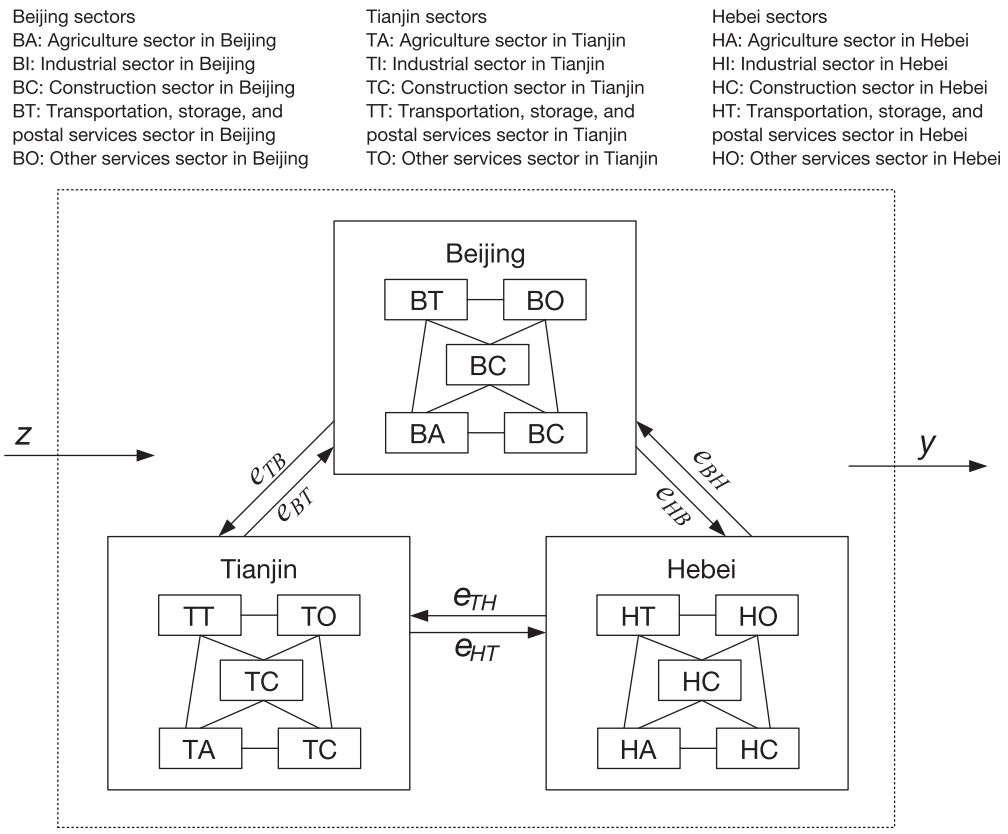

Fig. 5 The network models for the Jing-Jin-Ji urban agglomeration. Abbreviations: e_{ij}, energy flow from sector j to sector i; z and y represent flows into the system from the external environment and from the system to the external environment, respectively. From Zhang, Y., Zheng, H., Yang, Z., Li, Y., Liu, G., Su, M. and Yin, X. (2016). to establish a steady-state network model for the relationships among Beijing, Tianjin, Hebei, and their external environment as well as the relationships among the five sectors within each region (Fig. 5).

Hebei had the largest embodied energy consumption in 2007, followed by Beijing (Fig. 6). In all three regions, energy consumption by the Industrial sector was largest, but with different trends from 2002 to 2007. The consumption by most sectors in Tianjin and Hebei increased; only Tianjin's and Hebei's Agriculture sectors, Tianjin's Other Services sector, and Hebei's Construction sector showed decreased energy consumption. Beijing showed the largest number of sectors with decreased consumption (five sectors); Hebei and Tianjin each had two sectors that decreased. The ecological roles of Hebei (producer) and Beijing (consumer) did not change. However, Tianjin changed from a secondary consumer to a primary consumer. Based on the ecological relationships among the regions and sectors, they found that although the government's plans for the Jing-Jin-Ji agglomeration were intended to increase the efficiency of the interactions among sectors within and between the three regions, this goal has not been achieved. Exploitation relationships (in which one region benefited at the expense of another) and control relationships (in

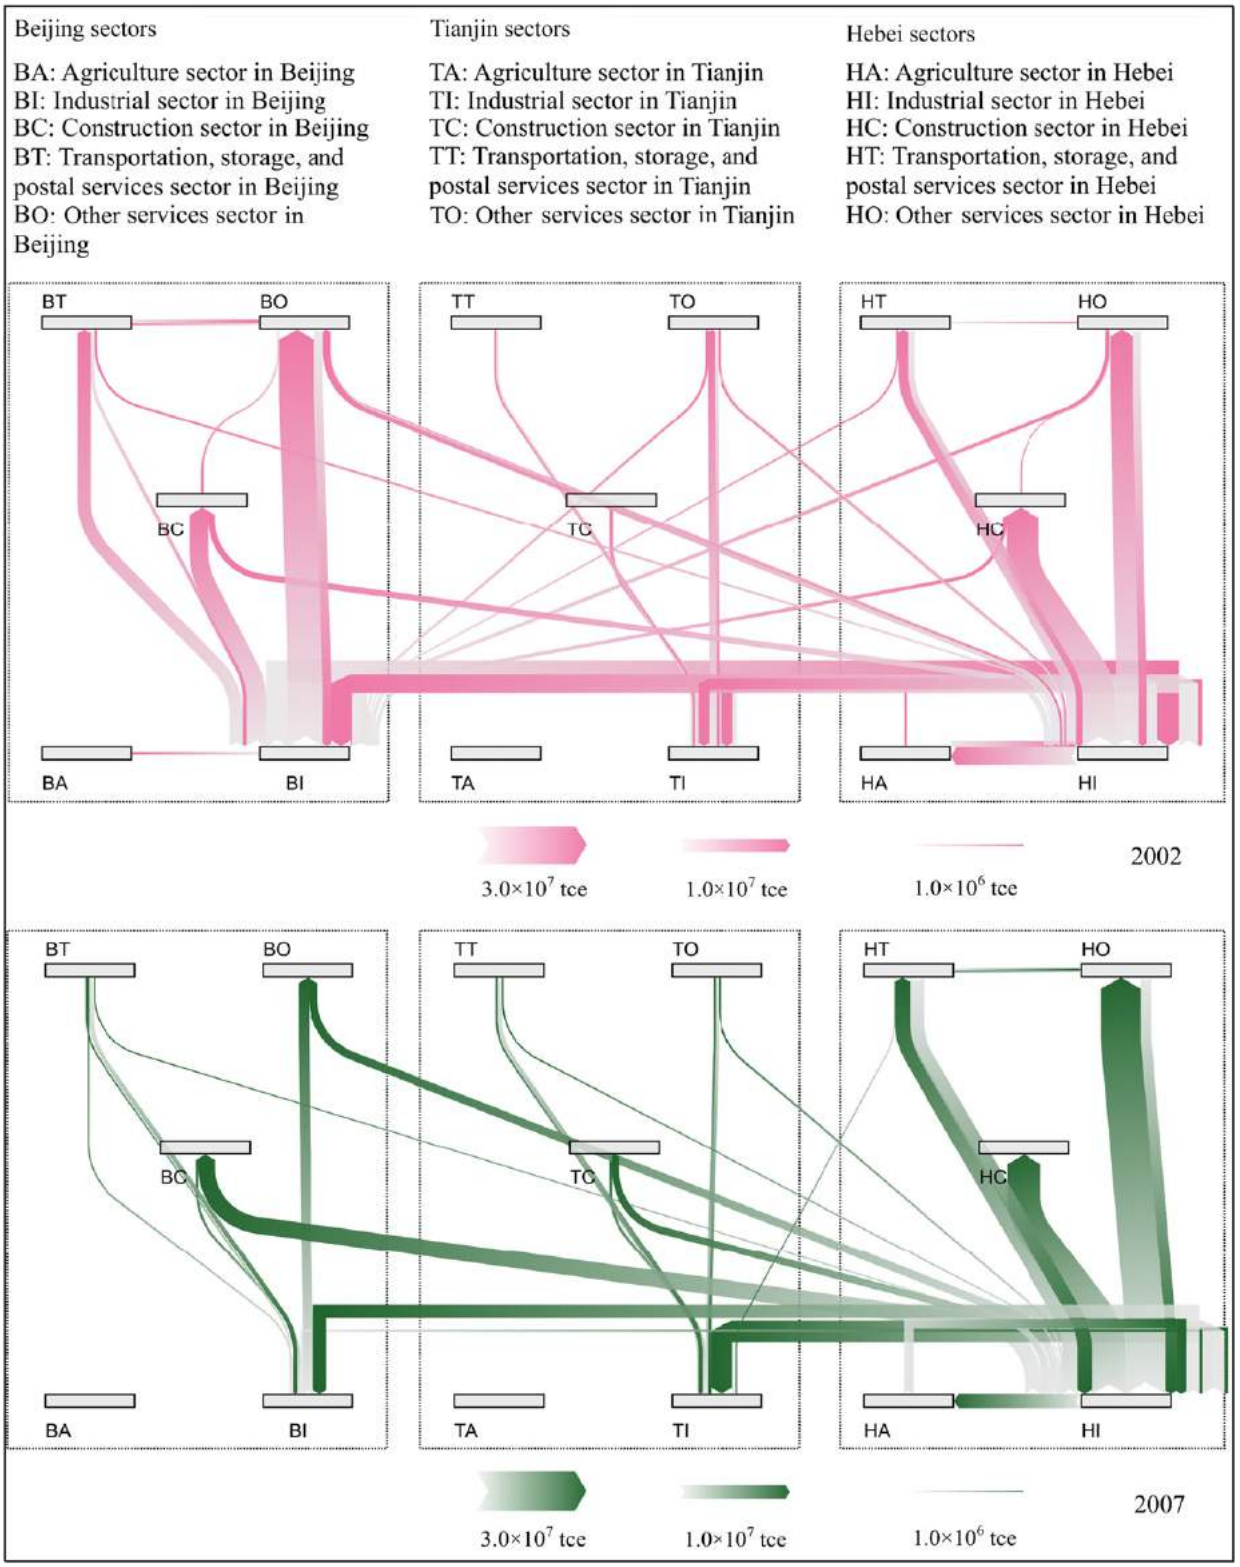

Fig. 6 The total embodied energy flows among sectors in the Jing-Jin-Ji agglomeration that were greater than 1.0×10^6 tonnes coal equivalent (tce) in 2002 and 2007 (1.0×10^6 tce). From Zhang, Y., Zheng, H., Yang, Z., Li, Y., Liu, G., Su, M. and Yin, X. (2016). Urban energy flow processes in the Beijing–Tianjin–Hebei (Jing-Jin-Ji) urban agglomeration: Combining multi-regional input–output tables with ecological network analysis. *Journal of Cleaner Production* **114**, 243–256.

which one region controlled the flows from another) dominated the three regions throughout the study, followed by competition relationships (in which both regions suffer from their relationship), revealing a strong need to reduce competition and encourage the development of more mutualisms (in which both regions benefit from their relationship). The low number of mutualisms suggests that the agglomeration program has much room for improvement. Planners should examine the sectors in each region to determine whether there are ways to transform competition into exploitation and exploitation into mutualism.

Urban Design Based on an Analysis of Metabolic Processes

Existing multiple-scale analyses have been primarily theoretical, with an emphasis on the rules that govern the system, and application of such research to actual planning exercises has been rare. Examples include the redesign of the Toronto Port Lands and the urban redesign after Hurricane Katrina struck New Orleans.

The graduate students of the Civil Engineering Department of the University of Toronto applied urban metabolism concepts at a neighborhood scale to redesign the Toronto Port Lands. They divided the neighborhood into water, transport, building, energy, and open space components, and used their experience with green construction design, alternative energy sources, and sustainable transport to design a closed-loop recycling infrastructure that reduced the inputs of resources and outputs of wastes from their study system.

Fernández's team from the MIT Construction School conducted a successful case study of redesign after Hurricane Katrina struck New Orleans. They developed software that let them use material-flow analysis to account for the inputs and outputs of materials and energy, the durability of the housing stock, the costs of different building types, energy consumption rates, waste generation rates, data on population and employment, housing needs, and growth priorities. Based on this analysis, they proposed goals for rebuilding the city and making it more resistant to hurricane damage and more green. They hope to increase New Orleans' resource-utilization efficiency in a way that provides a model for other cities, while rebuilding the city in a way that balances the needs of the many stakeholders and applies scientific rigor to urban design. Using this tool, New Orleans' urban planners can model the overall green city or target specific neighborhoods, and can make better-informed decisions about rebuilding strategies.

The Future of Urban Metabolism Research

The theory, methods, and models of urban metabolism research have been greatly improved through long-term research and development. However, many problems must still be solved. The lack of a unified methodology is slowing research on urban metabolism. Therefore, it is necessary to establish a more unified approach and to standardize data classification and inventory to ensure that each study provides the basic data required for analysis and evaluation, while also facilitating comparisons among studies.

In addition, data that is aggregated at urban or regional scales cannot yet associate metabolic processes with specific locations, activities, or humans. For example, data on industrial and commercial water and energy use is often difficult to obtain at sufficient resolution to let researchers map the data to specific land uses. This also greatly limits the ability to decompose large-scale data at a spatial resolution sufficient to support real-world planning and design. Micro-scale studies at the level of families, communities, industrial parks, and businesses would provide data with sufficient resolution to support larger-scale studies and real-world plans.

In the future, geographical information system technology, remote sensing data, and information network technology should be combined to acquire sufficient spatially explicit data to study material and energy flows at scales sufficiently small to support planning, since planning usually occurs at these smaller scales. Problems with metabolic flows can be identified by means of bottom-up analysis at the scale of individuals and communities using segmentation models, and can be used to guide efforts to reduce the size of the flows. Such analyses would support the implementation of green buildings, community-greening landscape designs, and changes in family consumption patterns. It would also permit the formation of a closed-loop design in which all or most materials and energy are recycled at the micro scale, which would promote the development of a circular economy on an urban scale, regional scale, or even global scale by closing open loops that are identified at smaller scales.

Many theories and methods have been developed to promote urban metabolic research, but the problems identified in this section have limited the application of urban metabolic methods. Therefore, in future research, it will be increasingly necessary to use ideas from systems engineering and other disciplines, using a multidisciplinary approach, to establish a more comprehensive and unified knowledge system capable of meeting the needs of decision-makers and land managers, as well as to meet the needs of different stakeholders.

Introduction

Urbanization is a global multidimensional process that manifests itself through rapidly changing human population densities and changing land cover. The growth of cities is due to a combination of four forces: natural growth, rural to urban migration, massive migration due to extreme events, and redefinitions of administrative boundaries. Half of the world's population today lives in urban areas, a proportion expected to increase by 2/3 within 50 years. Today, over 300 cities have a population of more than 10^6 and 19 megacities exceed 10^7. As urbanization is accelerating, the growth of cities forms large urban landscapes, particularly in developing countries. (Urban landscape is here defined as an area with human agglomerations with $>50\%$ of the surface built, surrounded by other areas with 30–50% built, and overall a population density of >10 ind. ha^{-1}.) For example, during the last 20 years in China, clusters of cities have emerged forming at least five mega-urban landscapes. These large and densely urbanized regions have each between 9 and 43 large cities located in close proximity and a population ranging from 27 to 75 million people. This rapid urbanization represents both a challenge and an opportunity to ensure basic human welfare and a viable global environment. The opportunity lies in that urban landscapes also are the very places where knowledge, innovations, human and financial resources for finding solutions to global environmental problems are likely to be found.

Since urbanization is a process operating at multiple scales, factors influencing environmental change in urban landscapes often originate far beyond city, regional, or even national boundaries. Fluctuation in global trade, civil unrest in other countries, health pandemics, natural disasters, and possibly climate change and political decisions are all factors driving social–ecological transformations of the urban landscape.

Mismatches between spatial and temporal scales of ecological process on the one hand, and social scales of monitoring and decision making on the other have not only limited our understanding of ecological processes in urban landscapes, they have also limited the integration of urban ecological knowledge into urban planning. In ecology there is now a growing understanding that human processes and cultures are fundamental for sustainable management of ecosystems, and in urban planning it is becoming more and more evident that urban management needs to operate at an ecosystem scale rather than within the traditional boundaries of the city.

Although studies of ecological patterns and processes in urban areas have shown a rapid increase during the last decade, there are still significant research gaps that constrain our general understanding of the effects of urbanization processes. The vast majority of studies so far have been short term (one to two seasons), conducted in cities in Northern Europe or the US, have lacked experimental approaches, focused on either birds or plants, while other taxa are rarely represented and have only included portions of a rural–urban gradient. Most significantly, we nearly completely lack studies in rapidly growing urban landscapes in tropical developing countries that are rich in biodiversity and are just beginning to address the complexity of human settlements in the tropics.

Of further significance is that urban landscapes provide important large-scale probing experiments of the effects of global change on ecosystems, since, for example, significant warming and increased nitrogen deposition already are prevalent and because they provide extreme, visible, and measurable examples of human domination of ecosystem processes. Urban landscapes may be viewed as numerous large-scale experiments producing novel types of plant and animal communities and novel types of interactions among species, and as such deserve the full attention of not only evolutionary biologists and ecologists but also of students of social–ecological interactions.

Urbanization and Plant and Animal Communities

Urbanization is today viewed to endanger more species and to be more geographically ubiquitous than any other human activity (Fig. 1). For example, urban sprawl is rapidly transforming critical habitats of global biodiversity value, for example, in the Atlantic Forest Region of Brazil, the Cape of South Africa, and coastal Central America. Urbanization is also viewed as a driving force for increased homogenization of fauna and flora. In the urban core in Northern Hemisphere cities, a similar set of species is recorded that is, often cosmopolitan plant and animal species tolerant of anthropogenic impacts. For example, the composition of communities of wildlife species found in cities across the US is remarkably similar despite large variation in climate and geographical features. A common pattern among cities is that they often show a high turnover of species with losses of native species and gains of non-natives over time. For example, it is documented that New York has lost 578 native plant species while it gained 411, and Adelaide lost 89 while it gained 613 new plant species over a period of 166 years. Although cities may be species rich,

 doi:10.1016/B978-0-444-63768-0.00364-4

Fig. 1 Cape Town, South Africa with more than 3 million residents is located in the Cape Floristic Region, an area with the highest density of plant species in the world with more than 9600 plants species of which 70% are endemic. Through initiatives like Working for Wetlands and Cape Flats Nature, successful efforts are taken to address the large challenge of conserving precious biodiversity in fragmented natural habitats in an urban setting where poverty is widespread. These initiatives focus on building bridges between people and nature and demonstrating benefits from conservation for the surrounding communities, particularly areas where incomes are low and living conditions are poor, and encouraging local leadership for conservation action.

frequently having higher species diversity than surrounding natural habitats, this is often due to a high influx of non-native species and formation of new communities of plants and animals. A trend of increasing non-native species from the suburbs to the urban core is well documented for plants, birds, mammals, and insects. For example, in Berlin the proportion of novel species increased from 28% in the outer suburbs to 50% in the built-up center of the city. In New York, the abundance and biomass of earthworms increased tenfold when comparing rural and urban forests, mainly due to increased numbers of introduced species in urban areas. Over broad geographical scales urbanization seems to have an effect of convergence in species composition with loss of native species and invasion of exotics. Nevertheless, a remarkable amount of native species diversity is known to exist in and around large cities, such as Singapore, Rio de Janeiro, Calcutta, New Dehli, and Stockholm.

Interestingly, the number of plant species in urban areas often correlates with the human population size. Species number often increases with log number of human inhabitants, and that relationship is stronger than the correlation with city area. The age of the city also affects species richness; large, older cities have more plant species than large, younger cities. Also of interest is that diversity may correlate with measures of economic wealth. For example, in Phoenix, USA, measures of plant and avian diversity in urban neighborhoods and parks show a significant positive correlation with measures of median family income levels.

In general, urban landscapes present novel ecological conditions, such as rapid rate of change, chronic disturbances, and complex interactions between patterns and processes. Organisms that have survived in urbanized areas have been able to do so for at least two reasons: (1) they evolved rapidly and adjusted genetically or (2) they were largely preadapted to this environment and required little or no genetic adjustment. There are several documented cases of rapid evolution in urban areas, involving, for example, tolerance to toxic substances and heavy metals in plants, such as lead tolerance in urban roadside *Plantago lanceolata*. Among insects there are many cases of rapid evolution in urban areas, notable example being the famous case of industrial melanism among Lepidoptera in UK, a phenomenon also documented from areas in USA, Canada, and elsewhere in Europe. Also of interest is that specific urban and rural races have been identified within well-studied *Drosophila* species.

In **Table 1** we have summarized some of the effects of urbanization including abiotic and biotic changes. Human activities may cause increased deposition of nutrients such as nitrogen and phosphorus and emission of toxic chemicals which influence urban soil processes. Decomposition rates in urban soils are often negatively affected by pollution and toxic chemicals, but positively affected by increased soil temperature. Decomposition rates may therefore often be higher in urban than in rural soils. However, urban litter tends to have higher C:N ratios and therefore also tends to be more recalcitrant than rural litter. Urbanization affects in complex ways both directly and indirectly C-pools and N-transformation rates and contrasting dynamics in urban and rural soils is an area where much more research is needed.

Biotic changes influencing ecosystem functioning are listed in **Table 1**. There are a number of reasons why new human-imposed scales for ecological processes are found within urban areas. First, compared with ecosystems in rural areas, urban systems are highly patchy and the spatial patch structure is characterized by a high point-to-point variation and degree of isolation between patches. Second, disturbances such as fire and flooding are suppressed in urban areas, and human-induced disturbances are more prevalent as well as intense human management of urban habitats. Third, because of the `heat-island' effect, that is, higher mean temperatures in cities than in the surroundings, cities in temperate climates have significantly longer vegetation growth periods. Fourth, ecological successions are altered, suppressed, or truncated in urban green areas, and the diversity and structure of communities of plants and animals may show fundamental differences from those of nonurban areas. In general, with increasing urbanization there is a trend toward dominance of generalist species with high reproductive capacity and short generation times.

Table 1 Ecological effects of urbanization

Physical and chemical environment	*Population and community characteristics*	*Ecosystem structure and function*
Air pollution increases	Altered reproductive rates	Altered disturbance regimes
Hydrological changes	Genetic drift, changes in selection	Altered succession
Local climate change	Social and behavioral changes	Altered decomposition rates
Soil changes	High species turn over, increase of exotic species	Altered nutrient retention
Water changes	Loss of K-species and gain of r-species	Habitat fragmentation
	Increased dominance of generalist species	Changes in trophic structure, domination of omnivores

Urban Habitats and Gradient Analyses

Urban habitats are extremely diverse and examples include parks, cemeteries, vacant lots, streams and lakes, gardens and yards, campus areas, golf courses, bridges, air ports, and landfills. These habitats are highly dynamic, influenced by both biophysical and ecological drivers on the one hand and social and economic drivers on the other. Urban landscapes often represent cases of extreme habitat fragmentation. Habitat patches in the urban core are more or less strongly isolated from each other by a matrix of built environment making dispersal risky and difficult at least for poorly dispersing organisms. There are numerous studies analyzing effects of isolation of urban habitats and, for example, in urban gardens in UK, the best predictor of species richness of ground arthropods was found to be the proportion of green areas within a 1 km radius of the sampling site. Analyses of the distribution of plant species in vegetation fragments in Birmingham, UK showed a positive correlation between the density of patches available to a species and the proportion of these patches that was occupied. For many plant species the rate of occupancy increased with site age, area, and similarity of adjacent habitats. Similarly, for urban amphibian assemblages in Melbourne, Australia, an increase in species richness was associated with pond size and a decrease with increasing isolation. Habitat quality also influenced species composition. The importance of isolation is likely to increase over time and, for example, in Boston an isolated urban park lost 25% of its plant diversity over 100 years. To what extent greenways and corridors increase connectivity and contribute to maintain viable populations in urban green areas is poorly understood. But greenways may, in multiple ways, provide a chain of different habitats permeating the urban environment and be of benefit for many organisms. Apart from preventing local extinction and facilitating re-colonization, increased habitat connectivity is important to maintaining vital biological interactions, for example, plant–pollinator interactions and plant–seed disperser interactions. Although most of the studies in urban landscapes address the continuous loss of green areas due to urban growth and expansion, this is not the case in all cities. For example, in Shanghai the proportion of green areas has increased in parallel with urban expansion and the total area expanded from less than 9 km^2 in 1975 to more than 250 km^2 in 2005.

Gradient analyses have a long tradition in ecology and go back to the pioneering work by Whittaker in the late 1960s. Gradient analyses have also been a rather common way of disentangling the complexity of urban habitats and have been used to investigate how urbanization changes ecological patterns and processes across landscapes, for example, in invertebrate, plant, and bird community composition, leaf litter decomposition and nutrient cycling, and the structure of landscape elements. Almost all the gradients that have been used for urban studies have been one dimensional in the sense that they only describe physical features of the gradient such as proportion of impervious surface, while the characteristics of the human population occupying a particular portion of the landscape often have been neglected. Because urbanization is an exceedingly complex amalgamation of factors, by using only a single axis the interpretation of the underlying processes has often been severely constrained. It has been suggested that a more comprehensive gradient analysis should include not only physical geography, demography, rates of ecological processes, and energy, but also history of land use, socioeconomic analyses, and patterns of management.

Variation in species densities across an urban gradient suggests that some individual species disappear with urbanization, whereas other species invade in response to the environmental changes associated with development. At least for birds, species richness has often been found to peak at intermediate levels of urbanization and decrease with either more or less development. Some species are classified as urban avoiders with their highest densities at the most natural sites, whereas many species seem to be able to adapt to suburban environments, with densities peaking at intermediate levels of development. Some species are urban exploiters whose highest densities are found at the urban core (see **Fig. 2**).

A multitude of factors are likely to influence this pattern of extinction and colonization, of which changes in predation rates have been suggested to be among the most important. Predation on artificial nests has often been found to be higher in urban parks than in neighboring woodlands and the abundance of predators such as corvids, rats, and house mice are often more in urban parks compared to the rural end of the gradient. However, there are also studies showing no correlation or a declining predation pressure along the urban–rural gradient. Observed patterns of extinction and invasion in urban landscapes may also be linked to gaps in the spectrum of body masses exhibited in the community and there are documented cases that body mass patterns are correlated with invasion and extinction in other human-transformed ecosystems.

In cities, ownership and management of urban habitats is extremely diverse and complex. In addition to land managed by government, municipalities, churches, and foundations, there is also land managed by local user groups that often covers substantial tracts. For example, domestic gardens cover 23% of the land area of Sheffield, and as much as 27% of the city of

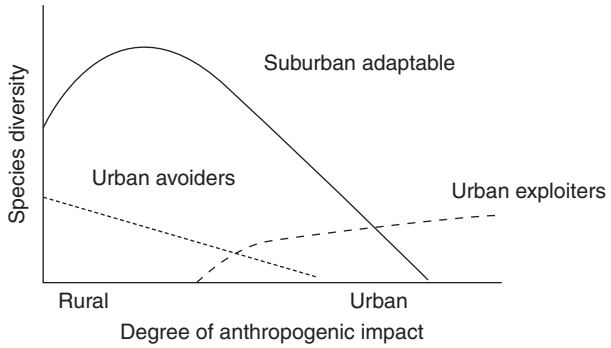

Fig. 2 Plants and animals may respond differently to increasing human impact. Urban avoiders are large-bodied species or species linked to late successional stages. These species might be very sensitive and show a decline already at moderate human impacts. Suburban adaptable speceis may, to various degrees, utilize human modifications of the landscape; the majority of plant and animal species likely belong to this group. Urban exploiters directly benefit from human presence for food, reproduction or protection, and may often be cosmopolitan, generalist species. Terminology after Blair, R.B., 1996. Land use and avian species diversity along an urban gradient. Ecological Applications 6 (2), 506–519.

Leicester. Lands appropriated for allotment areas, domestic gardens, and golf courses were found to cover nearly 18% of the total green space of greater Stockholm, Sweden, representing well over twice the area covered by nature-protected areas. While the numbers of ecological studies of urban green areas are limited, there is evidence that different types of urban green areas used for purposes other than biodiversity conservation play an important role in sustaining urban biodiversity. For example, in many cities of Asia, educational institutions sometimes harbor the largest and last remaining green areas in extensively urban developed settings. These campus areas can be extremely significant for biodiversity. A good example is the university campuses of Pune city, India, which harbor up to half the plant, bird, and butterfly species of the region despite the fact that these campuses only cover some 5% of the land area. Another illustrative case is the Musahi Institute of Technology in Yokohama, Japan, where a former community-managed forest now restored for student education, has revived interest in reducing the loss of biodiversity-rich forests in semiurban areas of Japan. Ecological studies also show that domestic gardens sometimes hold a rich flora of plants, including rare and threatened ones. Thompson and colleagues found that the private gardens in Sheffield, UK, contained twice as many plant species as any other habitat assessed. These gardens also supported surprisingly high numbers of invertebrates and this regardless of whether garden plants were native or alien. Even such a controversial land use as golf courses can contribute with important biodiversity functions in cities when courses are wisely managed and well designed. For example, golf courses contribute to sustain urban woodlands in many cities of Japan, and in some larger cities of Sweden they may harbor significant populations of species of both amphibians and macro-invertebrates, which are declining in rural areas.

Also, smaller habitat parcels in urban settings can provide high-quality habitats. One illustrative example of this is allotment areas, common in many city-regions in developed countries. For example, while allotment areas only cover some 0.3% of the land in greater Stockholm, they tend to be extremely biodiversity rich. In Stockholm city one allotment garden was found to contain 447 different plant species in an area of 400 m^2.

Urban Systems and Ecosystem Services

The concept of ecosystem services has proved to be useful in describing human benefits from urban ecosystems. For example, urban vegetation may significantly reduce air pollution, mitigate the urban heat island effect, reduce noise, and enhance recreational and cultural values, of importance for urban citizen's well-being (**Table 2**).

The scale of importance for generation of these services is often much larger than a city, for example, for reduction of air pollutants and water regulation, while for some, such as recreational and educational services, generation often occur within city boundaries. In most cases, these services tend to be overlooked by urban planners and decision makers, despite the fact that the potential of generation of ecosystem services can be quite substantial. In a study made within Stockholm County, it was assessed that this region's ecosystems potentially could accumulate about 41% of the CO_2 generated by traffic and about 17% of total anthropogenic CO_2. In the Chicago region, trees were found to remove some 5500 t of air pollutants per year, providing a substantial improvement in air quality. It was also found that the present value of long-term benefits from the trees of the Chicago region was more than twice the present value of costs related to planting. Moreover, wetlands in urban settings can substantially lower the amount of money spent on sewage treatment costs and in many cities large-scale experiments are taking place where wetlands are being used to treat sewage water. It has been estimated that up to as much as 96% of the nitrogen and 97% of the phosphorus can be retained in wetlands through the assimilation of wetland plants and animals. Green spaces of cities also provide ample opportunity for recreation. In a study on the response of persons put under stress, it was shown that when subjects of the experiment were exposed to natural environments the stress level decreased, whereas during exposure to built-up urban environments the stress levels remained high or even increased.

Table 2 Examples of services generated by urban ecosystems

Local climate regulation
Water purification and waste treatment
Biological control
Pollination
Cultural services
Esthetic and recreational
Educational

A major challenge in urban areas is how to sustain the capacity to generate ecosystem services. This capacity is mainly but not exclusively related to the diversity of `functional groups' of species in a system, like organisms that pollinate, graze, predate, fix nitrogen, spread seeds, decompose, generate soils, modify water flows, open up patches for reorganization, and contribute to the colonization of such patches. In urban areas, such functional groups may be substantially reduced in size or show changes in the composition due to high species turnover, both of which may increase vulnerability in maintaining ecosystem services. To what extent exotic species contribute to reduce or enhance the flow of ecosystem services is virtually unknown for any urban area. But, since introduced species make up a large proportion of the urban biota, it is important to know not only to what extent introduced species are detrimental, but also to what degree some of the introduced species may enhance local diversity and maintain important functional roles. For urban ecology to significantly contribute to improving management of urban habitats and the maintenance of ecosystem services, the following research questions are particularly urgent to address:

- To what extent are urban ecosystems sinks for many animal and plant species and what are the effects of species loss on ecosystem functions?
- To what extent do novel species play important functional roles in urban ecosystems by replacing role of extinct native species and enhancing ecosystem functions and services?
- What is the importance of source–sink dynamics and matrix permeability for maintenance of urban biodiversity and important ecosystem services?
- How do we develop management systems that match the spatial and temporal scales of ecological processes?

Urban Restoration

Designed, replicated urban restoration experiments could substantially advance our knowledge and understanding of processes of importance for generating urban ecosystem services, for example, through better understanding of population and community responses to disturbances, patterns of self-organization and succession, assembly rules, and through identifying components that contribute to resilience or vulnerability. Urban restoration also represents an interesting opportunity for ecologists to work in partnership with landscape architects, urban designers, and architects and help in designing urban environments based on ecological knowledge but merged with the functional and esthetic design of urban space.

The majority of urban restoration projects deal with transforming brown areas (abandoned industrial lots or air fields, landfills, etc.) to functioning green areas, such as Fresh Kills landfill on Staten Island, New York, or the Olympic Park in Beijing. Other large-scale restoration projects involve, for example, substantial wetland restoration such as Kristianstad, Sweden, and New Orleans, USA. In New Orleans, coastal wetlands have eroded substantially during the last 50 years and restoring wetlands is viewed as one important measure to reduce vulnerability to hurricanes. Important lessons of urban restoration projects so far are that restoring ecological functions in urban areas is possible but time consuming and that there are often significant effects on many ecosystem services even after one or two seasons. Although the costs are initially high, these could be offset by increases in property values and increased investments in development in areas surrounding the restoration site.

Urban Landscapes as Arenas for Adaptive Management

In cities that experience rapid social and environmental transformation, it is critical to develop a capacity to respond to potential surprises. One important aspect of such capacity building is to facilitate for a wider integration of local people and interest groups in the use and management of urban green areas. There are several reasons for a wider integration of local people in urban ecosystem management. First, governments cannot entirely rest on protected area management to safeguard the native flora and fauna found in city-regions. As cities expand, there will be an increased lack of natural lands for the establishment of protected areas. Studies also show that many urban nature reserves are unable to sustain native species in the long run. In addition, protected area management is financially costly to most local governments. In London, for example, parts of the protected green belt have been severely degraded due to lack of money and this has resulted in urban residents avoiding these areas for various activities. Second, much of the flora and fauna depend on well-functioning habitats provided by privately owned lands. In the US, for example, almost two-thirds of all the endangered and threatened species depend on private lands for their continued existence. Also, urban homeowners with gardens have been engaged to support declining pollinator populations in Great Britain through the deliberate planting of certain nectar providing plants in their yards. They have also helped sustain urban frog populations during their period of main rural declines through a massive establishment of garden ponds. Homeowners in Britain are also involved in programs for monitoring trends in the population status of birds. Third, a number of international treaties that have been signed by national governments around the world, including local Agenda 21, the Convention of Biological Diversity, and the Malawi-principles, strive toward a decentralization of biodiversity management down to local people. Recently, the Millennium Ecosystem Assessment (MA 2005) concluded that a wider cooperation among people within different sectors in society is necessary for more efficient land use that contributes to the support of ecosystem services.

One approach increasingly used to achieve collaborative partnership in urban ecosystem management is `adaptive co-management'. The approach rests on the notion of the sharing of resource management responsibility and authority between users of ecosystems and government agencies. This typically involves local people and interest groups, scientists and local authorities, with the potential to promote information exchange to effectively deal with and respond to change and issues that often transcend locality. Adaptive co-management emphasizes `learning-by-doing' in ecosystem management, where management objectives are treated as `experiments' from which people can learn by testing and evaluating different management policies. This form of ecosystem management avoids set prescriptions of management that may be superimposed on a particular place, situation, or context. Such designs have the potential to lower overall costs of management, most notably costs incurred for describing and monitoring the ecosystem, designing regulations, coordinating users and enforcing regulations, and depend on the self-interest of participants. Co-management arenas could, for example, also serve as platforms for designed experiments and urban restoration as discussed above and improve ecological functions and designs in cities.

Linking Humans and Nature in the Urban Landscape

Urban landscapes are not only ecological experiments but also long-term experiments in social, economic, and cultural transformations shaped by cultures, property rights, and access rights. Since cities are places where knowledge, human and financial resources are concentrated, rapid urban transformations can likely be more readily monitored and observed than similar processes in more rural areas. Studies of transformations in urban landscapes may therefore well provide the ground for a better understanding of socio-economic drivers of changes also in other ecosystems. After decades of mutual neglect and artificial divide between nature on the one hand, and cities with their respective urban processes on the other hand, the conservation community has started to shift its perception to include cities as a component of natural landscapes. Just as it is now increasingly recognized that in protected nature reserves, conservation will not be successful as long as it is at the expense of human aspirations, urban planners increasingly acknowledge that functioning natural systems such as watersheds, mangroves, and wetlands are indispensable for reducing vulnerabilities to natural disasters and building long-term resilience.

In New Orleans for example, it has been argued that population growth and urban economic growth is necessary for meeting the costs of building a viable defense against the grave environmental problems of massive coastal erosion. In the New York Metropolitan region, sustainable management of the Catskills, the land around the upland water reservoirs supplying New York City with drinking water, has been chosen as an important complement to building water treatment plants.

The urban landscape provides a public space for the cross-fertilization of minds and various disciplines, enabling a new perspective on man in nature, one that could place human well-being at the core, break the artificial and largely culturally biased divide between the pristine and the human-dominated ecosystems, and contribute to the creation of a new language, with signs, concepts, words, tools, and institutions that would gather rather than divide, broker conflicts rather than create them, and establish responsible environmental stewardship at the heart of public interest.

The Water-Energy-Food-Ecosystems (WEFE) Nexus

Giovanni Bidoglio, Davy Vanham, Faycal Bouraoui, and Stefano Barchiesi, European Commission, Joint Research Centre, 21027 Ispra (VA), Italy

Water in the Nexus

The last few years have witnessed an increasing attention to water beyond its environmental role and looked at water crises as a major global risk to social and economic stability. An example is the report on Global Risks released by the World Economic Forum (WEF, 2018) or the World Bank report "High and Dry" (World Bank, 2016), which predicts that some regions in the world could see their growth rates decline by as much as 6% of GDP by 2050 as a result of water-related losses. Indeed, demand for water from agriculture could increase by 50%, for urban uses by 50% to 70%. According to FAO (2018), feeding a global population expected to reach 9 billion people by 2050 will require a 60% increase in food production. Global energy consumption is projected to grow up to 50% by 2035 (IEA, 2010). However, constraints on water can challenge not only the physical, economic and environmental reliability of future projects, but also that of today's existing operations. The Californian "almond case" is a striking example of this challenge (Le Monde, 2015). In California, which is heavily affected by drought since a few years, the 900 tons of yearly production of almonds uses the same amount of water necessary to quench the thirst of the inhabitants of Los Angeles, San Diego and San Francisco, which, together, represent two thirds of the entire Californian population, while almond production represents just 2% of the State's GDP. In Poland, the summer of 2015 experienced a heatwave that drained the rivers supplying water to cool power plants resulting in problems of electricity supply (Reuters, 2016). In 2015, the European Parliament released a report on the implementation of current EU water legislation and confirmed that there are still implementation gaps with missing economic benefits estimated in the order of 2.8 billion euro per year (EPRS, 2015). One of the reasons is that the goals of water protection policies and related policies, particularly energy and agriculture, are occasionally incoherent or even in conflict.

Constraints to water supply/availability can then occur naturally, or be human-induced, as a result of growing competition among water using sectors. The examples above show that securing resilience of global energy and food systems needs to build on better and nontransient fairness of water allocation strategies across the energy and the food sectors, especially in light of the expected growing of pressures in the coming decades also associated to climate change. What we need is to overcome stakeholders' view of resources as individual assets by developing an understanding of the broader system. This points to the interdependency of policies and introduces the notion of Water-Energy-Food Nexus.

From Concept to Implementation

The Water-Energy-Food Nexus is a cross-sectoral perspective which requires that response options go beyond traditional sectoral approaches. It means that the three sectors or securities—water security, energy security and food security (Sustainable Development Goals or SDGs 6, 7 and 2)—are inextricably linked and that actions in one area have impacts in one or both of the others. However, a fourth leg that we should consider in the Nexus is that of ecosystems, as they are central in providing and sustaining these three securities, through the services they deliver to the human being and society. Exploitation of water, agricultural and energy resources should not undermine the provision of these services, especially considering that they are often at the basis of the only resources available to poor people in different parts of the world. Fig. 1 shows these interlinkages. At the same time, some of the impacted ecosystem services may support combinations of both built and natural infrastructure that in turn provide water services or can be considered solutions to water resources management challenges from sedimentation in reservoirs to water purification (Baker et al., 2015; UNEP, 2014). The Nexus is about understanding and managing often-competing interests, while ensuring the integrity of ecosystems.

According to FAO (2002), food security is defined as "availability and access to sufficient, safe and nutritious (nutrition security) food to meet the dietary needs and food preferences for an active and healthy life." Food is defined as a human right. The end products for food security encompass edible agricultural crops, livestock products (meat, dairy and eggs), freshwater fish (wild and aquaculture), wild foods (e.g., berries, mushrooms, fruits, nuts, game and bushmeat, insects), but also marine fish and seafood. The International Energy Agency (IEA) defines energy security as "the uninterrupted availability of energy sources at an affordable price." The UN defines it as "the access to clean, reliable and affordable energy services for cooking and heating, lighting, communications

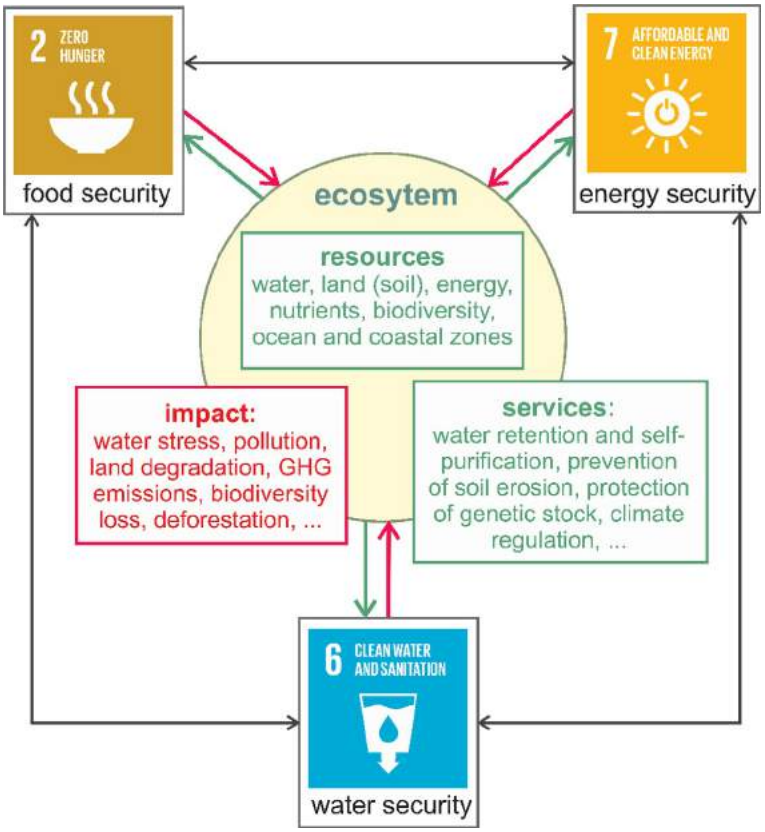

Fig. 1 Schematic representation of the WEFE Nexus.

and productive uses (end products)." Primary energy is generated by means of fossil energy, nuclear energy and renewable energy. Water security is defined as "access to safe drinking water and sanitation," both of which have recently become a human right (UN, 2010). One of the most frequently resources required for realizing the nexus, that is, minimizing tradeoffs and maximizing synergies across resource securities, is water. Fig. 2 shows the links between available water resources (green and blue) and food security, energy security and water security. Interlinkages are many and consequently possible tradeoffs too. The nexus between energy and food security is, for example, very visible in the amount of energy required for food security, which is about one third (32%) of global energy end consumption (from farm to fork) (FAO, 2011). The primary production of crops, livestock and fisheries accounts for 6.6% of global energy end consumption.

Generally, national governments and international organizations have separate departments/ministries dealing with water, energy, and agriculture. They often define and implement policies for each sector separately (SEI, 2014). The same is true for research on these issues: expertise on energy, water and food systems is clustered in separate groups, with often limited interaction (SEI, 2014). It is on this basis that the cross-institutional planning of water resources referred to as integrated river basin management is often conducted. The Nexus approach recognizes that water, energy, food and ecosystems are closely linked, through global, basin and local resource use and impact cycles. In developing an effectively integrated nexus approach it is important to recognize that many activities take place at the very bottom of the grassroots, at the level of, for example, households, farmers. An array of options and measures adapted to the specificity of local conditions need then to be developed.

Terminology in the Nexus Communication

The Nexus is often accounted for in different terminologies or even defined in different ways, but addressing the same concept. Different authors use the terminology FEW (Food-Energy-Water) Nexus, especially in the United States (Chini et al., 2017). Others mix the components in a different order, for example, the EFW Nexus (Owen et al., 2018; Liu et al., 2018), as often referred to by energy experts, putting the E first. Other authors define the Nexus in a variety of combinations, like the Land-Water-Energy Nexus (Silalertruksa and Gheewala, 2018), the Water-Land-Food Nexus (Rulli et al., 2016), the Land-Water-Energy-Food Nexus (Siciliano et al., 2017), the Water-Land-Energy-Food-Climate (WLEFC) Nexus (Munaretto and Witmer, 2017; Sušnik et al., 2018) or many others. These terminologies try to describe the complexity of the Nexus, however they often differ from the original definition (Hoff, 2011) by including elements like land or climate that are not securities, but resources or impacts.

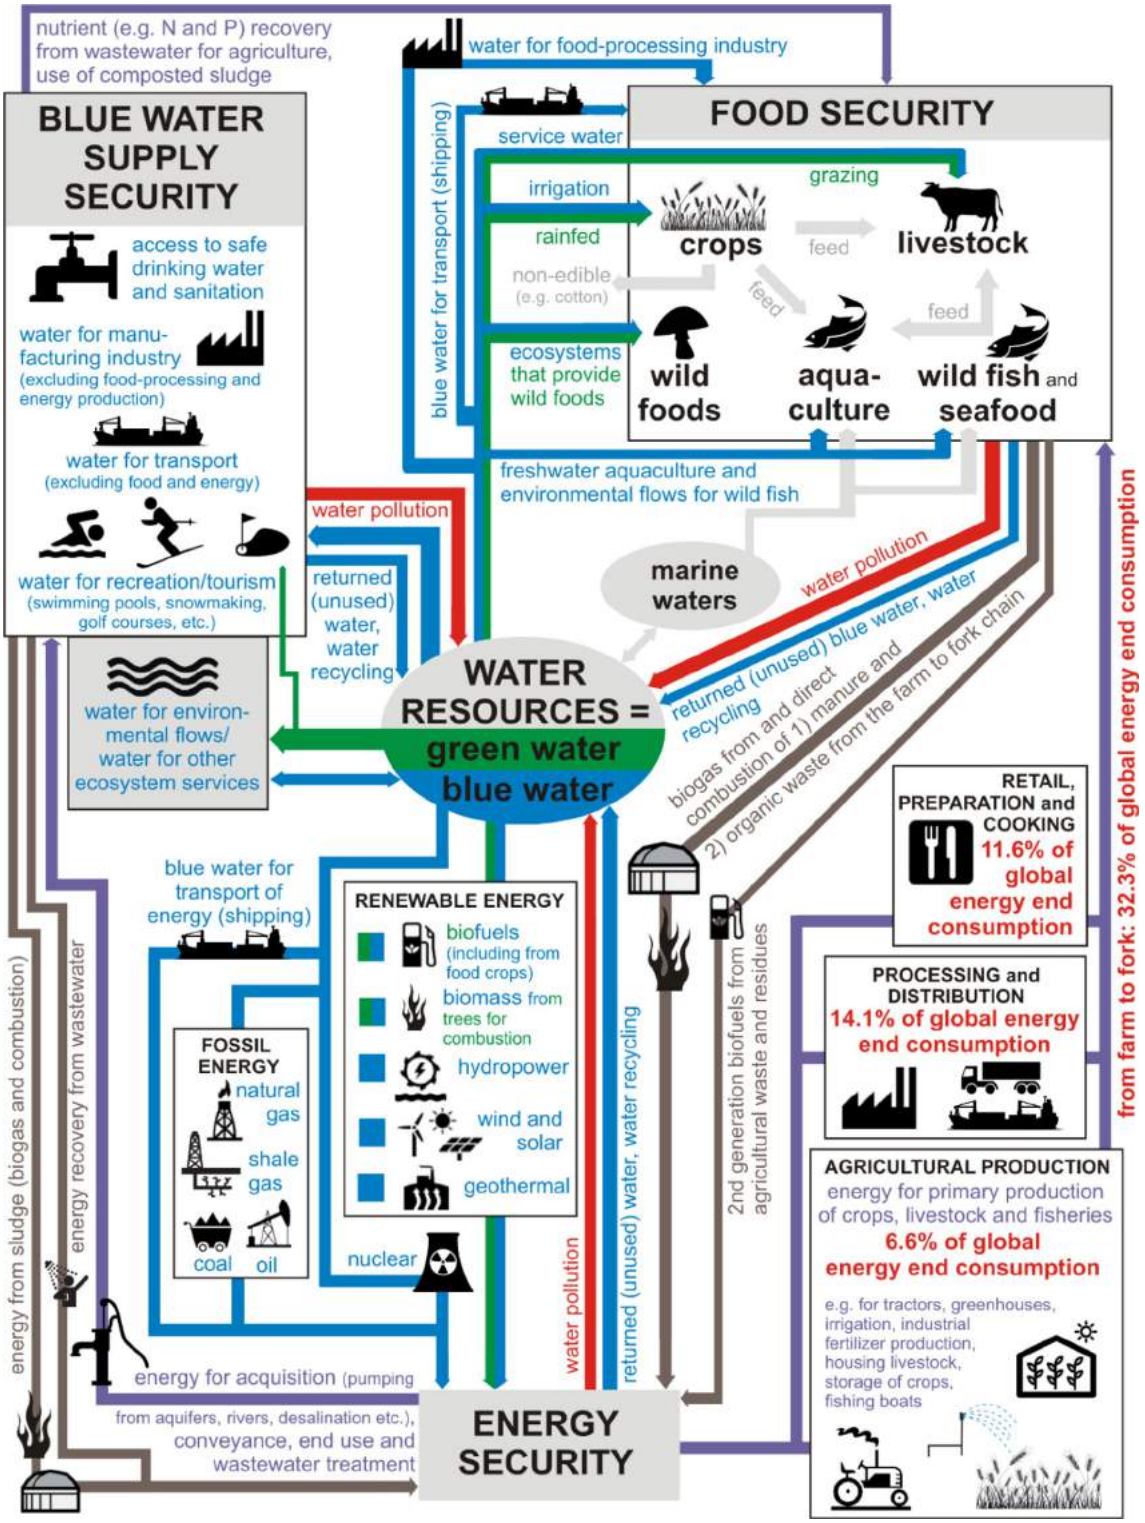

Fig. 2 The WEFE Nexus for blue and green water, as presented in Vanham (2016).

Exploring WEFE Interdependencies

Water, energy and food resources are linked through many interactions: we need water for power generation (hydropower, cooling, biofuels, etc.), while at the same time large amounts of energy are required to pump, treat and desalinate water, and both water and energy use are required for food production and distribution. Using water to irrigate crops can increase food production, but also

reduce river flows and hydropower potential as well as affect water quality and ecosystem health and services. Growing bioenergy crops under irrigated agriculture can increase overall water withdrawals and also affect food security. Converting surface irrigation into high efficiency pressurized irrigation may save water, but also result in higher energy use.

The modernization of the irrigation sector that took place in Spain in the years 1950–2007 offers a paradoxical example of the energy-water interdependency (Tarjuelo et al., 2015; González-Cebollada, 2015). During this period, water consumption by agriculture has quadrupled, due to a shift of cropping patterns with greater water needs, also influenced by subsidies. Efforts mostly focused on irrigation efficiency (from 67% to 82.5%) resulting in a 19-fold increase in energy consumption, which has led to an increase in water costs. Irrigation systems modernized in a climate of strong public support without giving much thought to the significant energy dependence they would introduce may then represent a barrier to economic sustainability for certain crops and irrigation regions.

Hydro-economic interdependencies exist also between distant global geographies via trade, especially of agricultural and manufactured goods (Vanham and Bidoglio, 2014). This makes local consumption dependent on foreign water resources and increases virtual water exports from other regions.

The Water-Energy-Food-Ecosystems (WEFE) Nexus highlights the need of a joint management of bundles of resources, rather than of individual resources, if we want to achieve sustainable development (Biggs et al., 2015). The Sustainable Development Goals (*SDGs*) of the 2030 Agenda set by the United Nations promote a crosscutting understanding of the interdependencies of the goals and targets as opposed to their individual consideration. It follows that the implementation of the Nexus helps meet the SDG commitments. Indeed, accounting for tradeoffs and synergies of the WEFE Nexus contributes to the achievement of a number of interdependent SDGs. The WEFE Nexus directly addresses a number of SDGs: SDG 6 (clean water), SDG 7 (clean energy) and SDG 2 (zero hunger), while the last E of WEFE refers to other SDGs like 14 (life below water) and 15 (life on land). Resilient communities better prepared to react and recover from water resources crises are those that have identified crucial interdependencies and built relationships between the water-using sectors.

Ecosystems as Fourth Pillar of the Nexus

Aquatic ecosystems offer a wide array of benefits to human society, such as water retention and self-purification, the prevention of soil erosion, the protection of genetic stock. Preserving these services guarantees the maintenance and improvement of water quality and quantity, increases the resilience of ecosystems to natural and man-made alterations making floods less severe, food and energy production more reliable (Russi et al., 2013; UNWWAP, 2018). Ecosystems have then to be considered as water using sectors on an equal ground as food and energy production. The practical instrument for achieving these interdependent goals is the deployment of green–blue infrastructure, or "natural infrastructure." This refers to the network of green (land) and blue (water) spaces that provide services to people, can help decision makers and infrastructure managers address interconnected challenges facing water, energy and food systems. The value of ecosystems is explicited in the EU policy-making process (e.g., Water Framework Directive, Common Agricultural Policy, EU Biodiversity Strategy) by promoting nature-based solutions (NBS). The EU has promoted a Green Infrastructure Strategy to become an integral part of spatial planning and territorial development whenever it offers a better alternative, or is complementary, to standard gray choices (EC, 2013). This is reflected in certain research projects on NBS in the urban environment (EC, 2015; GrowGreen, 2018), another key scale for Nexus implementation considering that cities are where global and local resource constraints meet. The potential of nature-based solutions to address water management across the agricultural sector, sustainable cities, disaster risk reduction and improving water quality is also addressed by the 2018 UN World Water Development Report (UNWWAP, 2018).

What makes natural infrastructure particularly attractive is its multifunctionality, that is its ability to perform several functions and provide several benefits on the same spatial area. The challenge is to build on the knowledge gained from the traditional and local sustainable water management practices, link the green–blue infrastructure or "natural capital" part to ecosystem services and their role in river basin management plans, including investment in these natural solutions instead of purely technical ones. While in some cases planners may directly compare the advantages of "green versus gray" water infrastructure solutions, greater emphasis should be placed on understanding how green solutions can be integrated within an overall system of water management, composed of appropriately sited and designed elements of both green and gray water infrastructure (UNEP, 2014). Any methodology for developing combined portfolios consisting of green and gray alternatives, or mutually supportive green and gray elements, should therefore provide meaningful evaluation of all water infrastructure options, including in monetary terms to the extent possible. This then leads to the development of adequately informed strategies for investing in natural infrastructure. For these to be incorporated into broader infrastructure packages, appropriate mechanisms for investment are however needed that can unlock financing for ecosystem management that also supports empowerment of stakeholders to participate in and enable implementation of these options (Bennett et al,. 2016). Forms of investment in natural infrastructure are sustainable dam management for the Nexus, certifiable standards for watershed stewardship, and public–private partnerships for Payments for Ecosystem Services (PES). These are established instruments, not without hurdles, to direct private and public investments to sustain provisioning services in ecosystems and watersheds (Bennett and Carroll, 2014). As an example, a water conservation project along the Cauca River near the city of Cali in Colombia pooled money from downstream water users to pay upstream stakeholders who have the ability to impact water quantity and quality and to implement projects and practices addressing the interdependent, downstream's needs for food, energy and water (Madre Agua Water Fund, 2018). Ozment et al. (2015) examine reasons and ways to include natural infrastructure

in the Nexus along with challenges that have prevented increased investments and recommendations for moving forward. For example, they present recent studies that estimate that the global community invests about 12.3 billion $ per year to protect, manage and restore natural infrastructure to secure water resources. Yet, the energy and agriculture sectors collectively contributed less than 1% of all natural infrastructure investments in 2013. Partnerships are still needed that proactively identify more opportunities to invest in green–blue infrastructure, leverage new sources of financing, and reform policy and standards to broaden investments.

In Search of Appropriate WEFE Nexus Indicators

By their nature, water, energy, food and ecosystems require integrated and transdisciplinary approaches for addressing the peculiarity of their interlinked temporal and spatial variabilities. However, integration goes beyond these pillars and should include social, political and governance aspects. In addition, the Nexus approach should consider tradeoffs, not only across sectors, but also among different users of the same sectors (Sønderberg Petersen and Larsen, 2016). Moreover, solutions valid in a place do not necessarily apply under different bio-geographical and socio-economic conditions (Liu et al., 2017). In this context, data and appropriate methodologies are needed to inform on these complex interlinkages, in the present situation and also under different future scenarios, to help policy makers in decision making. Most of the existing WEFE Nexus analyses have been performed at large scale ranging from global, to regional and national (Martinez-Hernandez et al., 2017), however at very coarse resolution. As international and regional decisions have significant impact at the local level, the local specificities need to be considered when designing efficient management strategies (Aarnoudse and Leentvaar, 2015). However, the local scale is rarely addressed even though it is the relevant scale at which policy implementation is usually taking place and where synergies between the food, water and energy can be enhanced (Martinez-Hernandez et al., 2017). As stressed by Mohtar (2016), it is at the local scale that also the SDG targets deliver their benefits. Different assessment levels are then needed to address the WEFE Nexus.

Addressing the WEFE Nexus or the achievement of the associated SDGs requires a holistic approach and a systems view (Bazilian et al., 2011; UNECE, 2015; de Strasser et al., 2016). Endo et al. (2017) classified the tools used in Nexus studies in two broad categories including qualitative and quantitative approaches. Qualitative approaches are used to identify the priorities and understand the types of environmental, economic and societal tradeoffs. Quantitative methods are used to assess baselines and carry out scenario analyses for the evaluation of the impact of alternative proposed interventions. Examples of how an assessment of the four pillar Nexus can be operationalized are offered by Tesfaye et al. (2016) and Karabulut et al. (2016). These authors investigated spatially explicit tradeoffs and co-benefits for two large transboundary river basins, the Blue Nile basin in Ethiopia and the Danube River basin in Europe. A wide range of the facets of the water-food nexus have been analyzed in a series of multi-disciplinary papers edited by Laio et al. (2017). A coupled simulation and optimization tool with which stakeholders can define their own objectives was proposed by Karnib (2017). A systematic review of Nexus-specific methods by Albrecht et al. (2018) shows that mixed-methods and interdisciplinary approaches are needed that incorporate social and political dimensions of water, energy and food. Dai et al. (2018) found that fewer approaches are designed to support governance and implementation of water-energy nexus technical solutions. In general, most of the published Nexus studies are considering two sectors, rarely the three components of the WEF, leaving repeatedly ecosystems outside the analysis (Martiner-Hernadez et al., 2017). Moreover, our understanding and representation of the interactions and tradeoffs are often limited by data availability, collection and management thus failing to encompass a comprehensive overview of the interlinkages between the pillars of the Nexus.

Nexus Solutions for Sustainable Development

Already today different control variables within the planetary boundary framework show human-made disruptions (Steffen et al., 2015). Climate change and global socio-economic developments like population increase, rapid urbanization, changing diets and economic growth are among drivers that will increase the demands for energy, food and water. Can we afford continuing in this way? Certainly not if we consider that about 78% of the world's total active workforce is water-dependent globally (WWAP, 2016).

These considerations place the Water-Energy-Food-Ecosystems Nexus at the core of resilience strategies (Smith, 2016). To implement the Nexus we need actions for the development of a multilevel governance, the investment in human and social infrastructure, the enrollment of technologies across water-using sectors, and the leveraging of public–private cooperation. Governance deals with the ability of institutions to manage water use through different sectors and propose policies that are socially acceptable and can address competition through an analysis of tradeoffs. To this end, rules and regulations are necessary, but not sufficient if not integrated with constructive engagement of social actors, as good WEFE Nexus practices that work in a place do not necessarily apply to different social, economic and geographical conditions. The organizational model must accommodate creation and diffusion of technology tools that span multiple applications and innovate solutions across water-using sectors. This will require creating incentives for public–private partnerships to cultivate the innovative operational models, policies, strategies and technologies.

The circular economy dynamics based on reuse and recycling offers the framework for conserving and saving water, energy and materials by ensuring the balance between supply and demand from the different sectors. If supply decreases, we have to find ways

of reducing demand or decrease losses. Opportunities exist especially in the field of efficient irrigation techniques, sustainable water pumping, crop refinement techniques, water efficient appliances and processes, technologies for aquifer storage as well as water treatment and reuse. The IGN Group and the Ellen McArthur Foundation released a report addressing the concept of circular economy in relation to the water sector (IGN, 2017). For the investigated countries, circular water economy has the potential to save 412 billion m^3 of water a year, which is equivalent to 11% of annual global water demand, or almost the entire water consumption in the United States. Of course, this does not equally applies everywhere. The concept of circular economy is very much different from regions to regions in the world. The report shows that effects are different, for example, from California to the Emirates. In addition, circular economy measures can look appealing when viewed in isolation. However, circular economy requires a system approach to be developed not only for water, but also for its nexus with energy and materials.

Policy, science and technology can bring about change, but this change takes place in a specific local ecological, economic and cultural context. In order to provide water, food and energy security to a growing and urbanizing global population, within global planetary boundaries with limited resources availability (Rockstrom et al., 2009; Steffen et al., 2015), solutions need to come from all stages within supply chains (Fig. 3), that is, from the production to the consumption side (Godfray et al., 2010; Foley et al., 2011).

Production side solutions may include (Godfray et al., 2010; Foley et al., 2011):

- The sustainable intensification of agriculture (Garnett et al., 2013). In order to close yield gaps, nutrient management and integrated land and water management on existing agricultural lands (rainfed and irrigated) are key to this development (Mueller et al., 2012). Often the increase in water productivity is referred to as "more crop per drop." In the wider context of the Nexus, the expression "more biomass per drop" (apart from crops also fish, livestock, fiber, tree biomass ...) is more appropriate.
- Production processes along the supply chain need to become more resource-efficient, energy-efficient, circular and sustainable. For instance, installation of new hydropower plants in existing water infrastructures is an attractive Nexus solution in that it can save construction costs and minimize environmental and social impacts. Moreover, it may contribute to the reduction of the global footprint of these infrastructures. Examples of how hydropower can be incorporated in existing hydraulic infrastructures where electricity generation was not a primary objective are municipal and agricultural water systems, for example, for wastewater treatment and irrigation canals, hydraulic circulation systems for cooling and heating of plants, and hydropower dams themselves where there are ship navigation locks or fish passages that need dissipation of energy (Marence et al., 2018). Existing infrastructure in the water sector has a high potential for additional renewable energy production from solar as well, for example, the installation of photovoltaic (PV) systems on the face of existing dams and the coverage of irrigation canals with solar PV systems (Szabó et al., 2018).

Demand side solutions may include:

- Consumer behavior in water use, energy consumption, food consumption and (food) waste generation. In the EU, for instance, citizens can decrease their current food-related water footprint by 24% when shifting to a healthy diet and by 40% when shifting to a vegetarian diet (Vanham et al., 2013). EU consumers waste on average 123 kg of food per person annually, of which 80% is avoidable (Vanham et al., 2015). A reduction in food waste as envisaged by SDG target 12.3 would have an influential impact on the Nexus.
- Some scholars also state that family planning to lower per capita fertility should be part of the solution (Potts, 2014; Speidel et al., 2009). Especially in Africa a population explosion is projected for the next few decades (UN, 2014). There are consequently more frequent calls to address environmental problems by advocating further reductions in human fertility (Bradshaw and Brook, 2014), including in the second notice of "World Scientists' Warning to Humanity" (Ripple et al., 2017).

It is clear that the provision of water, energy and food security for people within a geographical region relates to the consumption side of this geographical region and not the production side. Trade between regions is thus essential to provide these three securities. Sustainability does not mean self-sufficiency.

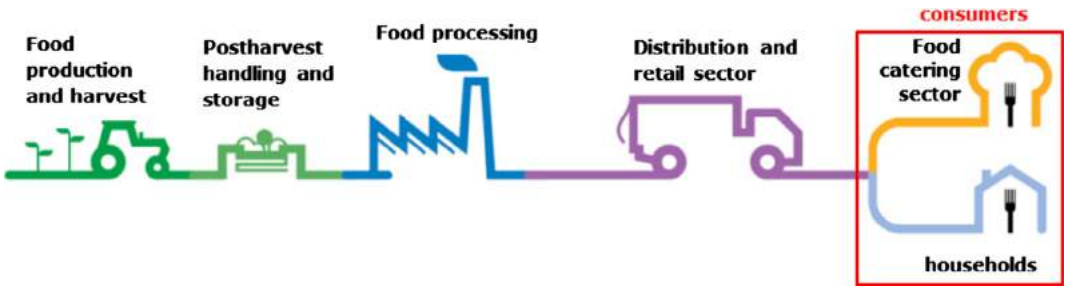

Fig. 3 Graphical representation of the food supply chain. Solutions to address the Nexus need to come from all stages within supply chains. Different processes can take place in different geographical regions.

Agroforestry☆

Steven M Newman, BioDiversity International Ltd, Faversham, Kent, United Kingdom

Glossary

Agroforestry A collective name for land use systems and technologies where woody perennials (trees, shrubs, palms, bamboos, etc.) are deliberately used on the same land management unit as agricultural crops and/or animals, either in some form of spatial arrangement or temporal sequence. In agroforestry systems, there are both ecological and economic interactions between the different components.
Forest farming It refers to growing crops or raising livestock in a natural or created forest.
Forest gardens It presents an attempt to grow mainly perennial crops and tree in a diverse multilayered garden.
Intercropping The simultaneous growing of more than one crop species on the same land area within a year, for example, the intercropping of beans in a field of maize.
Interculture Refers to the intercropping in plantations of tree crops in both temperate and tropical environments.
Permaculture A concatenation of the words permanent and agriculture and refers to the conscious design of diverse perennial based cropping systems so as to reduce agrochemical inputs (mainly artificial fertilizers and pesticides) and make the best use of local landscape features, for example, to allow rainwater harvesting.
Riparian strips Strips of trees or crops planted in linear arrangements next to water courses with a view to producing environmental benefits, for example, reducing nitrate pollution from arable crop fields.
Silvopastoral systems Are agroforestry systems where livestock are a major output. They can include forest grazing and grassed orchard systems.
Silvoarable systems Are agroforestry systems where arable crops are grown with trees.
Swidden Refers to shifting cultivation and is where woody vegetation is partially cleared for a short period to allow for the growing of crops. When crops begin to exhaust the soil, the plot is allowed to return to fallow for a period of time. This fallow can then be partially cleared to start the cycle again. Swidden does not have to involve the use of fire as in the case of "slash and burn" agriculture.

Introduction

One of the definitions for agroforestry developed by the International Centre for Agroforestry (now World Agroforestry Centre) was:

> a collective name for land use systems and technologies where woody perennials (trees, shrubs, palms, bamboos, etc.) are deliberately used on the same land management unit as agricultural crops and/or animals, either in some form of spatial arrangement or temporal sequence. In agroforestry systems, there are both ecological and economic interactions between the different components.

This definition is useful in that it shows that woody perennials (which include fruit trees) are key and not just forest trees. It shows that there must be a mixture of animals/crops and woody perennials so shade trees used in coffee or tea production is not

☆*Change History:* February 2018. Steven M. Newman has updated the text throughout the article.

This is an update of P.K.R. Nair, A.M. Gordon, and M. Rosa Mosquera-Losada, Agroforestry, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, Pages 101–110.

Table 1 Common reasons for deliberately designing agroforestry systems as an alternative to monocultures

Type of reason	*Indicator*
Environmental	Soil organic matter
	Reduced nitrate leaching
	Greater species diversity of wildlife
Agronomic	Greater yield per unit area
	Greater yield per unit labor
Economic	Greater return on investment
	Increased asset value if plot is sold
	Lower insurance costs

agroforestry. The phrase "deliberately used" is also important as this excludes relic systems such as most hedgerows around crop fields in the United Kingdom where the manager is not deliberately using the hedges as happened in the past. The economical and ecological interactions are the main challenge for agroforesters as the goal is to improve profit or other measures of effectiveness and knowledge of these is central to optimization. Table 1 below gives a sample of possible reasons why a grower may deliberately opt for agroforestry compared to monocultures.

The only problem with the definition is the term agricultural crops as agroforestry now encompasses all kinds of crops such as medicinal, horticultural and energy crops.

Scale

Agroforestry can be designed and carried out at a wide range of scales from a small oasis containing a single tree to a landscape scale covering a watershed, district or country. For the manager the boundary of the scale could be set by his/her control or the effects of the trees. It is known for instance that the effect of a windbreak may extend beyond the crop field that it is meant to protect. A rule of thumb is that the distance is three to five times the height of the tree. Recent research on volatile organic compounds arising from trees means (Slowik et al., 2010) that effect boundaries could be far larger than this. In addition it is now known that trees can affect rainfall patterns (Ong et al., 2015). The limit of both these effects is still the subject of research. Some of the largest agroforestry investments have been attempts to control desertification or reduce sand dune migration. In India and China these projects have covered hundreds of square kilometers.

History

The start of agroforestry can be hypothesized to have occurred in prehistoric times when a hunter gatherer realized that by planting browse resistant tree seeds in wild grasslands; more wild animals could be attracted. In the forest situation the same hunter gatherer may notice that if a tree is felled then other nutritious herbaceous vegetation follows. If that tree is burnt the floristic composition of this vegetation may be different. It is clear that agroforestry was well established as a practice at the birth of agriculture, which is currently thought to be more than 5000 year ago in China and other countries in Asia.

The first examples of agroforestry in the literature where contrived beneficial interactions between trees and crops in Europe are outlined in Sylva a book written by Evelyn (1679). He stated that:

> The walnut delights in a dry sound and rich land; . . . in cornfields. . . . Burgundy abounds with them, where they stand in the midst of goodly wheat lands, at sixty and an hundred feet distance; and it is far from hurting the crop, that they look on them as a great preserver, by keeping the grounds warm, nor do the roots hinder the plough.

Scientific agroforestry where agronomists have quantified the yield advantages and sought to characterize the biological basis for the advantage have only occurred very recently however. Newman (1986) was the first time that it was demonstrated that it is possible to obtain a full yield of an orchard crop (pear) and a full yield of a vegetable crop (radish) on the same area of land. This has been called multilayered cropping or three dimensional agriculture in principle imitating a rain forest.

In summary agroforestry is an old practice and a new science. More on the history of agroforestry in temperate areas can be found in Gordon and Newman (1997).

Relevance and Subtypes

Agroforestry is relevant to all countries where woody perennials can grow. It is relevant to a range of "starting points" including; forests, rangelands, crop fields, orchards, gardens, tree crop/timber plantations and bare land. It is equally relevant in tropical and nontropical climates. Agroforestry subtypes can classified as the following based on the work of Newman and Gordon (1997)

1. Silvoarable: Crops and trees including swidden and other sequential systems
2. Silvopastoral: Animals and trees including forest grazing
3. Orchard/plantation intercropping: for example, crops in fruit/nut orchards or timber plantations (sometimes called interculture)
4. Forest farming/forest gardens, for example, growing crops in forests or creating a garden with a high density of trees
5. Environmental systems such as wind breaks or tree strips acting as pollution traps on river banks (riparian strips)

Permaculture is a concatenation of the words permanent and agriculture and if it contains woody perennials rather than herbaceous perennials could be a form of agroforestry. Key ideas held by the Permaculture movement are that rainfall harvesting using natural topography can be used to improve sustainability based on the "Keyline System" ideas of Yeomans (1958) and the idea that if humans/animals derived caloric staples and other foods from woody perennials there would be les soil erosion and other negative environmental effects than relying on grasses, for example, wheat/rice/barley etc. outlined by Russel Smith (1929). Unfortunately there are still very few yield and scientific studies of Permaculture in the peer reviewed literature.

Examples

The most widespread traditional agroforestry system in Europe is The *Dehesa* system of the Iberian peninsula covering an area of 2 million ha with widely spaced oak trees (grown for acorns for animal and sometimes human consumption), with cereal and fodder intercrops (Joffre et al., 1988). The trees are commonly planted on the square in fields at a density of over 50 stems per hectare. In the southern part of the range, dehesas can include oak trees grown for cork. The Dehesa system can therefore involve silvoarable or silvopastoral practices.

In Asia silvoarable systems with *Paulownia* spp. are also planted at spacings of 5 $\times$ 10 m to 5 $\times$ 40 m and the extent was reported at 1.3 million ha (Zhu et al., 1991). In India poplar grown as alley cropping systems is very common and has been very successful commercially (Newman, 1997). Recent travels by the author to upland areas East Africa and India show a very interesting example where farmer have looked at neighbors using *Grevillea robusta* as a shade tree in tea or coffee plantations. They have used this tree as part of silvopastoral systems and silvoarable systems using square panting, row planting and boundary planting. The extent of this must be now approaching 1 million ha. Farmers appear to prefer multipurpose trees that can provide timber and other products, for example, fruit or fodder. Deciduous trees also offer the best potential in minimizing negative effects on understory crops.

Benefits

When outlining claimed benefits of agroforestry it is important to ask "compared to what?"

The following entities serve to illustrate this

(a) Compared to nonwoody annual crops on their own
(b) Compared to a forest or timber plantation
(c) Compared to an orchard or tree crop plantation with no herbaceous component
(d) Compared to a pasture or rangeland with no woody component

A list of the most widely claimed benefits are given below compared to entities in square brackets, with reflections outlined in brackets.

1. Increased yield [a, b, c, d] (see section on measuring success)
2. Increased biodiversity [a, b, c, d] (specific taxa)
3. More profitable in the long term [a, b, c, d] (may reduce asset value of arable land due to reduced flexibility)
4. Reduced need for artificial fertilizers, for example, N and P [a, b, c, d] (mixtures of herbaceous crops can also achieve this)
5. Can reduce soil erosion and water pollution [a, b, c, d] (perennial herbaceous crops can also achieve this)
6. Can reduce runoff and potential flooding [a, c, d] (perennial herbaceous crops can also achieve this)
7. Reduced need for fungicides and insecticides [a, c, d] (mixtures of herbaceous crops can also achieve this)
8. More resilient to changing climate in terms of productivity and profit [a, b, c, d]
9. More carbon sequestration in the living biomass and soil organic carbon [a, c, d]
10. Can "attract" rainfall [a, c, d] by a variety of mechanisms
11. Animals suffer less from temperature extremes and can self-medicate [d]
12. Reduced animal feed requirement leading to cost and carbon footprint reduction [d]
13. Greater amenity and social benefits including health improvement poverty reduction [a, b, c, d]

Challenges and Future Research Needs

1. The benefits outlined above are not derived from a simple addition of any tree. Benefits are only obtained from specific species combinations planted at specific densities and spatial arrangements (number of rows in a block/strip and rectangularity). The challenge is to find the right configuration and this requires research and development in many cases.

2. The biological basis of many benefits depends on the age/size of the tree so the management of the system can be complicated.
3. Trees can be expensive to establish, protect from livestock, and to remove (including stump and roots) after productive life.
4. Mechanization can be difficult but is getting less so given the fact that trees can be designed/pruned/planted to allow access of machines and robots.
5. Extension services and policy makers find it difficult to facilitate agroforestry
6. Some existing policies and practices (e.g., corruption linked to felling licenses and timber transportation) limit use of timber trees by farmers.
7. Farmers may not have the skills and attitude to make money from trees especially timber trees.
8. Farmers and advisors may have a lot of misconceptions about trees and their effects on livestock/crop operations.

The Measurement of Success in the Optimization of Agroforestry

There are the broad categories of measures of effectiveness in agroforestry; agronomic, economic or environmental. Agronomic advantages can also be subdivided into three categories of combined yield main crop yield and feedstock yield (Newman, 1990), related to three questions that a manager may ask respectively:

1. I would like to manage two entities, is it better to combine them as agroforestry or treat them as separate entities on different parts of the farm?
2. I am mainly interested in one entity could the addition of another entity via agroforestry help?
3. I am interested in a product, blend or feedstock is it better to combine them as agroforestry or treat them as separate entities on different parts of the farm?

For combined yield, one of the commonly used terms for evaluating combined yield is that of land equivalent ratio (LER) (Mead and Willey, 1980).

$$LER = \frac{Y_A}{S_A} + \frac{Y_B}{S_B}$$

Y_A and Y_B are the yields of two crops A and B in intercropping (in the case of agroforestry a crop and a tree species), S_A and S_B are the yields of the same two crops in monoculture under identical conditions, and L_A and L_B are the partial LER values for the two species. If we imagine an agroforestry system where species A (the crop species) normally produces 10 tons of wheat per hectare per year, species B (the tree species) normally produces 10 tons of walnuts per hectare per year, and the two are grown together in a 50:50 mix, with each occupying half of a 1 ha site. If 5 ton of grain and 5 tons of nuts is obtained then LER = 5/10 + 5/10 or 1. This shows no advantage. If it was 7/10 plus 5/10 then the LER would be 1.2 or in other words 20% more land would be required to obtain the same yield from monocultures. Newman (1986) obtained LER values of over 2.0 for agroforestry involving pear and radish. In other words twice the land area would be required if pear and radish were grown separately as monocultures.

Main crop yield is simpler. If the farmer sees the wheat as the main crop he will only tolerate the presence of walnut if 10 tons per hectare or more of wheat can be obtained.

For feedstock yield the farmer may be interested in the straw or nut tree pruning to produce energy from biomass. If the total biomass of straw and prunings is higher than the biomass obtained from the highest yielding sole crop then there is an advantage. The same approach is relevant to fodder or blended flour to make bread.

Economic analysis could be a comparison of profit or return on capital under a range of scenarios. If the return from the tree takes a number of years then some form of discounted cash flow analysis may be required. Income stability could also be a key measure. Agroforestry is a method of not "having all your eggs in one basket."

Environmental analysis requires that an environmental variable is selected such as soil loss due to erosion, ammonia pollution reduced from livestock, or carbon footprint reduced.

The Ecological Basis of Yield Advantage in Agroforestry

This is a very complicated area and is asking the question why is the effect of mixing in the woody perennials not negative, competing for resources used by the crop or other entity? Newman (1982) presented a simple theoretical framework of three mechanisms; partitioning, synthesis and modulation. Partitioning is where the tree is using phosphate or other resources at a different time in the year to the crop (temporal partitioning) or at a different layer in the soil (spatial partitioning). Synthesis is where the tree is producing a chemical change in the environment of the other entity that could help to reduce pests or disease for example. Modulation is where the tree is producing a physical change in the environment of the other entity that could help to reduce the damaging effect of wind or to provide a physical support for example. Recent research is showing that trees in agroforestry could improve water availability and "attract rainfall" for instance (Ong et al., 2015). This is an example of modulation.

Scientific Approaches to Optimization

The ecological combining ability of the system can be helped by an understanding of what interactions are happening above (e.g., light availability) and below ground (e.g., water and nutrient availability). The two environments can be separated for analysis using barriers in trenches or plastic pots (phytometers as outlined in Newman (1984)). Genotypes can be selected to optimize production, for example, an understorey can be selected that is shade tolerant or an overstorey can be selected that is columnar in form to reduce shade.

Management Approaches to Optimization

The spatial arrangement of trees can be manipulated to optimize effects as can the planting sequence. Special low cost techniques can be used to protect trees from damage by livestock. Tree pruning can be used to reduce shade and in fruit/nut trees different rootstocks can be used optimize precocity, tree form and regularity of bearing.

Anthropogenic Landscapes

Maria Rita Pasimeni, Donatella Valente, Teodoro Semeraro, Irene Petrosillo, and Giovanni Zurlini, University of Salento, Lecce, Italy

Anthropogenic Landscapes: A Scientific and Social Challenge

Anthropogenic activities like modifying natural landscapes for economic purposes or changing management practices on human-dominated lands have transformed a large proportion of Earth's surface. Human actions have almost completely transformed, eroded, and fragmented preexisting natural landscapes, leaving only a limited number of natural areas, in an often heavily anthropogenic matrix. Nowadays, this phenomenon has reached critical thresholds, since residual areas of natural landscapes are increasingly rare and dispersed in many parts of the world. Human actions, mostly associated with agricultural expansion and intensification, conversion of perennial habitats to cultivation fields, farming practices such as fire and crop rotation, urban sprawl, industrial development, road infrastructure, or any other substitution or conversion of an original natural landscape with an anthropogenic type, lead to anthropogenic landscapes.

Recent and novel approaches applied in the study of anthropogenic landscapes move from the traditional separation of social and ecological components to a social-ecological landscape (SEL) approach, considering SEL as a whole coevolving and historically interdependent system of humans-in-nature. In this respect, addressing SELs represents a more pragmatic basis for envisioning how the anthropogenic landscapes work and how we would like them to be, as SELs represent the spatially explicit integration of social–political and ecological scales in the geographical world, recognizing the primary role of humans as a driving force in intentionally shaping and modifying systems' compositions and processes.

Natural and semi-natural ecosystems and landscapes provide a mix of ecosystem goods and services, both private and public, to human society now and in the future; these are referred to as natural capital provided by multifunctional landscapes. Nowadays, landscapes are disrupted, impaired, or reengineered by many human activities, in ways that can exceed the rate, severity, and spatial extent of even the largest natural disturbance. In this context, land-use/land-cover changes refer to the way in which man uses the territory and its resources, creating patterns that can alter natural processes, and they represent the most tangible effects. The landscape mosaic is altered by the direct human use, which inevitably has profound effects on the ecosystem's structures and functions with its activities—that is, agriculture, mineral extraction, and urban, industrial, and tourism settlements, with consequences on the availability of goods and ecosystem services.

In this perspective, man is an integral part of SELs, posing difficult challenges to address a new era of epochal changes that need to be addressed, the Anthropocene, to define strategies and behaviors toward sustainability and a renewed balance between the humankind and the environment. The beginning of this new era indicates the current ability of man to act, in a quantitatively significant manner, on the drivers of SEL dynamics, by heavily affecting the stock of natural resources with direct and indirect impacts on economy, society, and landscapes. Therefore, a single species, namely man, acts as a prevailing force, by directing SEL dynamics and evolution, trying to adapt the environment to its own needs.

SELs are characterized by a large number of components that interact in a nonlinear way and exhibit intrinsic uncertainties and adaptive properties through time. SELs generally show a nonstationary and complex behavior, with their usual phase state fluctuating around some averages. They are commonly assumed to respond smoothly to gradual change in climate, habitat fragmentation, or resource exploitation. Such a condition, however, can be sporadically interrupted by an abrupt shift to a radically different regime. For these reasons, such systems should be conceived as complex adaptive landscapes: complex refers to the multiple variables that generate a nonlinear and unpredictable behavior in the medium and long term; adaptive means that their dynamism can evolve in space and time by adapting the composition and configuration of the elements and functions to the changing conditions that arise. Complex adaptive landscapes are deemed to exhibit alternative stable organizations with multiple stable states of the same ecological phase. These multiple states can be visited several times during the landscape evolutionary trajectory, and represent the phase attractor. If the structure of the SEL becomes radically different, a phase transition takes place; transitions between different stable states are due to changes in the interactions of structuring variables and processes characterizing SELs.

The acceleration that human activities have generated in the formation and transformation of landscapes adds uncertainty to that already present in SELs. In addition, each complex adaptive landscape is characterized by a strong dependence on the set of driving forces acting on it, and by all historical events that have determined landscape properties and its ability to respond to future shocks. Therefore, the current state of anthropogenic landscapes can be fully understood only in the context of state variable change trajectory, where traditional ecological knowledge pays a crucial role, and landscape ecology is fundamental to face the difficulty in managing anthropogenic landscapes in a dynamic and increasingly accelerated context.

Landscape Ecology Is Central for Anthropogenic Landscapes Studies

Landscape ecology is considered to be a holistic and transdisciplinary science for landscape study, appraisal, history, planning and management, conservation, and restoration dealing with the interrelation between human society and its

 doi:10.1016/B978-0-12-409548-9.10602-5

living space. Several authors have, over time, provided a definition of landscape ecology, as shown by the following examples:

- It considers the development and dynamics of space heterogeneity, interactions in space and time, changes in heterogeneous landscapes, spatial heterogeneity influences on biotic and abiotic processes, and, last but not least, land management issues.
- It tries to understand the development and pattern dynamics of ecological phenomena, the role of disorder in ecosystems, and the spatial and temporal scales of ecological events.
- It highlights the relationship of reciprocal pattern-process influence as well as the need to study its relationships in space.
- It studies the localization, spatial distribution, and shape of landscape elements in different degrees of naturalness in order to understand their structure, processes, and dynamics.

The aspects arising from these definitions concern the quantification of the elements that constitute the landscape mosaic and the description of their spatial distribution in order to appreciate the reciprocal relationships and constraints with biotic and abiotic processes as well as the spatial pattern configuration. It also recognizes the central role of the scale concept in spatial and temporal analysis of SELs as an effective tool for addressing the relationships between their spatial heterogeneity, processes and time dynamics.

Patch-Mosaic

Spatial structure or pattern refers both to the composition of the elements, namely their quality and abundance (what and how much is there?), and to their spatial configuration (how is it arranged?). The pattern is the result of: (1) the spatial and temporal heterogeneity of abiotic conditions (i.e., climatic, regional-scale morphology, and local soil composition); (2) the biotic interactions among communities, including humans; and (3) the dynamics of the system due to evolutionary processes and the regime of natural and/or anthropic disturbance. The study of the landscape pattern is usually based on the concept of patches and is framed in the theoretical and methodological context of the matrix-corridor-patch landscape model or fragmentation pattern. The patch-matrix model is based on a substantially schematic and rather static view of the landscape that views individual areas as "islands" of habitat that are connected by habitat corridors such that all areas together constitute a regional habitat network. With that model, the "contents" of the network are described by landscape descriptions of patches and corridors, while the "context" of conservation areas refers to the nature of the surrounding landscapes. At the landscape level, the context, which could be envisioned as a "buffer" around a site, may or may not help to maintain ecosystem functioning within a protected area (PA), allowing animal and plant dispersal and gene flow that is essential for population maintenance. The patch is defined as a surface area relatively homogeneous, differing from its environment in nature or appearance at a given scale. The patch structure has important implications for the supported processes and communities as well as its role in the mosaic: for example, its form is the expression of ongoing processes within and between adjacent patches. Being spatially and functionally connected to all other surrounding elements of the landscapes, the patch is actually the result of spatial and temporal processes taking place inside and outside. The set of patches constitutes, at a given scale, the landscape mosaic. The mosaic is the physical basis on which structures are organized, relations are created, and processes are established, and thus is to be considered functional and not just the structure of the landscape. The composition and configuration of a landscape mosaic has such influence on the dynamics of ecological systems that the same landscape, in the presence of a different configuration of patch arrangement, can have different properties.

The development of tools and indices to quantify the heterogeneity of the mosaic has contributed to the development of hundreds of quantitative measurements of the landscape patterns to describe different aspects of spatial heterogeneity. However, the matrix-patch-corridor model limitations have led to the development of alternative analytical techniques beyond the simple geometric evaluation of the patch as a basic element in the landscape mosaic survey, by adopting a multiple scale perspective, able to appreciate complex landscape properties such as multiscale connectivity or fragmentation. The novelty of this approach is that the landscape components become meaningful only when considering the context in which they are placed.

Scales

Scale refers to the spatial and temporal dimension of an object or process. The pattern and dynamics of a landscape mosaic are deeply influenced by the spatial and temporal scales adopted in the analysis. Two fundamental components of the scale are the extent and the grain. The extent defines the upper resolution limit of a study, and the entire area examined during an investigation or the entire time period studied represents it. Grain represents the lower-resolution, fine or coarse limit of the survey—that is, in spatial terms, the smallest entity that can evaluate in the landscape, while in temporal terms it corresponds to the smallest time window selected in the survey.

Spatial and temporal scales are related to each other. The ability to predict ecological phenomena characterizing SELs actually depends on the identification of the appropriate spatial and temporal scales. In practice, the extent and the grain are often established and/or determined by the data characteristics (i.e., aerial photo scale or sample rate) or processing techniques rather than being derived from the ecological property of the system in examination.

The description of a mosaic cannot disregard the scale constraints imposed in the analysis since ecological systems are scalar entities. The proper identification of the landscape patterns is a scalar problem, since the pattern is the result of processes and

structures that are in turn scale-dependent. The quantitative analysis of a landscape mosaic is based on the use of metrics describing patch composition and configuration properties.

In SELs, as complex adaptive landscapes, there is no a priori single scale for a survey able to take into account the number and variability of features characterizing SELs. Therefore, an appropriate approach should be based on their evaluation at multiple scales in order to identify scalar intervals of invariance of their properties. In other words, there is the need to identify scalar domains of a phenomenon/process and intervals along the spectrum of levels within which the pattern-process relationships are well defined and vary in a predictable manner. In addition to the focal point of the survey, multiscale analysis shows the valuable information of both the levels immediately higher and lower with respect to the focal point. In scalar terms, this means extending the survey to larger and smaller extents or grains in the surroundings of the focal point.

Disturbance

Anthropogenic disturbances are typically imposed by groups of people who are organized at different levels (i.e., from household to global) in a panarchy, with differing views as to which system states are desirable or which ecosystem services are to be exploited. Land-use change depends on individual and social responses to changing economic conditions, mediated by institutional factors, such as markets and policies, and increasingly influenced by global markets. There may be circumstances where landscapes do not change due to social and cultural drivers like new reserves based on nature or cultural values. Yet climate change and weather extremes could occasionally trigger further change, resulting in ecological surprises. The difficulty of controlling or predicting the biophysical effects of all those forces has resulted in failed attempts to closely manage and regulate the dynamics of ecosystems. The usual state of affairs in living systems like SELs is one of systems fluctuating around some trend or stable average; however, this condition is sporadically interrupted by an abrupt shift to a radically different regime. Disturbance can be deemed as an event causing departure of a living system from the normal range of conditions typical of its basin of attraction. The apparent paradox that disruption of the existing order (i.e., disorder) and persistence (i.e., order, stability) always coexist in living systems such as SELs is addressed by the concept of resilience, defined as the amount of disturbance a system can absorb without shifting into an alternative state and losing function and services. Many disturbances can have a strong climate forcing; nevertheless, the relative importance of different drivers varies among systems and can even vary through time within the same system. To understand the disturbance regime of biophysical systems like SELs and reveal possible regularities, we must consider the variable frequency of forcing due to the physical environment and its historical role in shaping biophysical systems.

New Methodological Approaches to Analyze Anthropogenic Landscapes

In the context of landscape ecology, emerging methodological approaches are represented by retrospective analysis, remote sensing application in SELs, and multiscale disturbance approach to value SELs transformations.

Retrospective Analysis to Value SEL Transformations

Land-use change represents a primary human effect on natural systems, causing fragmentation and habitat loss, which are the greatest threats to biodiversity and Ecosystem Services (ESs). Since human land use is a major force in driving landscape change, landscape dynamics can be better addressed in the context of SELs, as complex adaptive landscapes, integrating phenomena across multiple scales of space, time, and organizational complexity.

The most direct way to quantify composition dynamics is to analyze land cover area change using retrospective analyses. Retrospective analysis is needed to understand the present system conditions in the context of a trajectory of change that encompasses system past, disturbance regimes, and cross-scale interactions and constraints in a hierarchy of systems, in addition to endogenous self-organizational processes. Retrospective analysis is useful, as it links the present-day system status with its past dynamics and enables the identification of possible evolutionary trajectories to reveal continuity, turnover, directions, or degree of changes. By providing a means for analyzing short- and long-term system dynamics and for assessing the complex structure of the multiscale relationships in SELs, retrospective observational studies are valuable as they can address the role and nature of feedback mechanisms and scale-dependent interactions in systems.

Such system-level properties differ in three important ways from traditional ecological indicators. First, they need to be addressed by holistic measures describing, as far as possible, the entire system, not just specific subsystems or components. Second, as any important aspects of SELs may not be directly observable, they must be inferred only indirectly using surrogates, whose relationships between systems' properties may be dynamic, complex, and multidimensional. As a system evolves and adapts in time, the components and functions sustaining particular system properties change, so that a surrogate is useful only in a particular context or time frame. Third, some features of a complex landscapes (i.e., landscape resilience) focus on properties that underlie SEL capacity to provide ecosystem goods and services, whereas other indicators often address only the current state of the system component or service.

As an example, a retrospective analysis has been used to evaluate the effectiveness of conservation policy by studying decades of aerial photographs of a natural PA, Torre Guaceto in the Apulia region. In particular, the Italian government designated this PA as

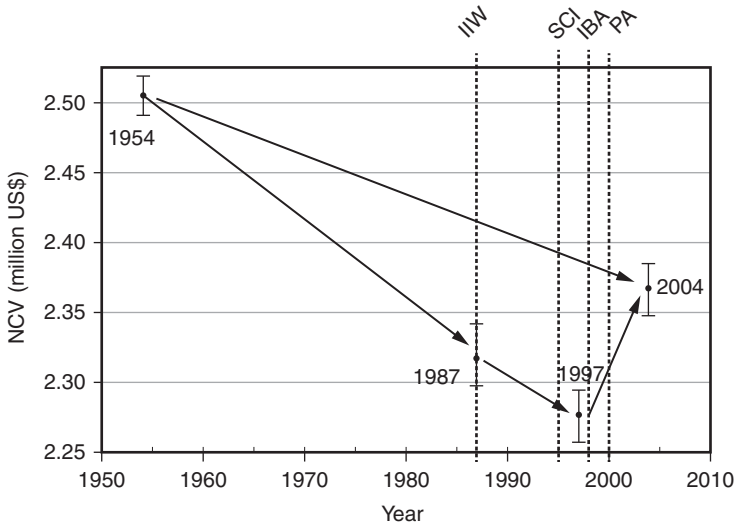

Fig. 1 Retrospective analyses: temporal changes of natural capital value (NCV) in a Mediterranean protected area, highlighting the different temporal recognitions of its natural value (*IIW*: International Important Wetland; *SCI*: Site of Community Importance; *IBA*: Important Bird Area; *PA*: institution of the natural Protected Area). *Bars* represent the NCV variability range due to an estimated 2 m average digitalization error.

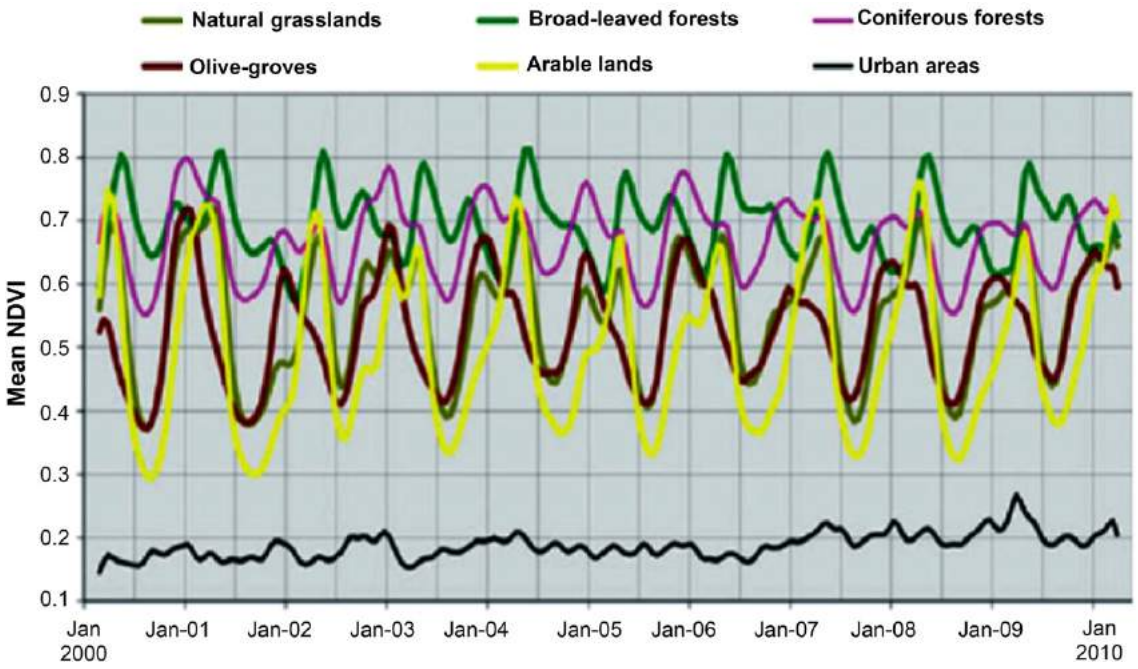

Fig. 2 Mean Normalized Difference Vegetation Index (NDVI) time trajectories computed on 148 16-days NDVI maximum values composite images acquired by the two MODIS platform TERRA and AQUA with a spatial resolution of 250 m (MOD13Q1 v.005 and MYD13Q1 v.005) for a Mediterranean region.

an International Important Mediterranean Wetland (IIW) under the Ramsar Convention in 1971, a Site of Community Importance (SCI) under Natura 2000 in 1995, an Important Bird Area (IBA) in 1998 under the European Birds Directive, and an institution of the natural PA in 2000. However, the findings suggest that only the PA measure has had a noticeable impact, improving the conservation value of the area.

The research assessed the effectiveness of each of these recognitions in conserving the area by calculating changes to its natural capital value (NCV). This concept places a monetary value on tangible commercial services that come from the natural environment—such as clean water and food production—and noncommercial services including aesthetic benefits, recreation, and climate regulation. The specific contribution of this example is to show that those coefficients could play a role as operational surrogates to evaluate the recent temporal dynamics of the overall flux of natural capital in the study area.

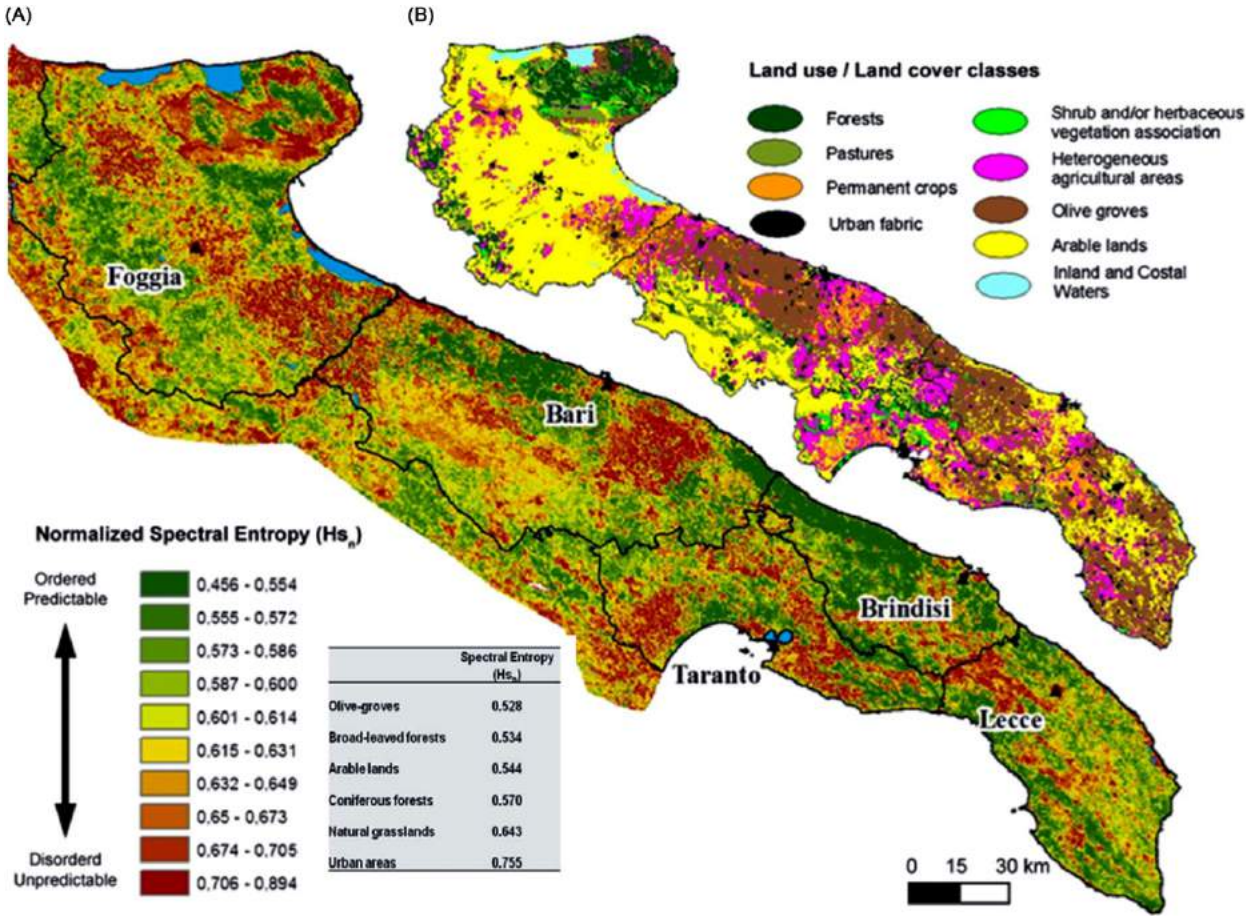

Fig. 3 Map of normalized spectral entropy (Hsn) (A) and map of major LULC classes (B) for a Mediterranean region. Hsn is based on the same composite images used for Fig. 2. The LULC categories are derived from a CORINE land cover map of the year 2006.

Overall, the temporal change of NCV decreased from 1954 to 1997. The IIW and SCI designations had no apparent impact on conserving the area and the researchers were unable to assess the impact of the IBA accreditation due to gaps in the data. However, there was an increase in NCV from 1997 to 2004, which the authors attribute to the PA official designation (Fig. 1).

Designations are, therefore, not so effective in themselves, and local management by means of regulations, ecological monitoring, and environmental education and communication activities seem to be more effective in supporting natural capital conservation and enhancement.

Remote Sensing and Landscape Ecology

Remote sensing is a primary source of information and it has become a proven tool for scientists to monitor environmental phenomena synoptically and globally, to understand major disturbance events and their historical regimes at regional and global scales. It has provided valuable indices to describe and quantify natural and human-related land-cover transformations and processes.

Vegetation indices are broadly recognized as a spatially explicit robust indicator to gauge social–ecological processes such as habitat-land use conversion (i.e., urban sprawling) or crop rotation. Vegetation indices are spectral transformation of two or more bands of satellite images designed to enhance vegetation proprieties and canopy structure. For example, the Normalized Difference Vegetation Index (NDVI) is widely used to identify and assess the impact of disturbances such as drought, fire, flood, frost, or other human-driven disturbances. NDVI is used to quantify the photosynthetic capacity of plant canopies, and it is calculated from these individual measurements as follows:

$$\mathrm{NDVI} = (\mathrm{NIR} - \mathrm{RED})/(\mathrm{NIR} + \mathrm{RED})$$

where RED and NIR are the spectral reflectance measurements acquired in the red (visible) and near-infrared regions, respectively.

Furthermore, NDVI-related indices can also supply data on potential species richness in many parts of the world, and may help monitor ecosystem services (ESs) like carbon sequestration, water cycling and regulation, and soil fertility.

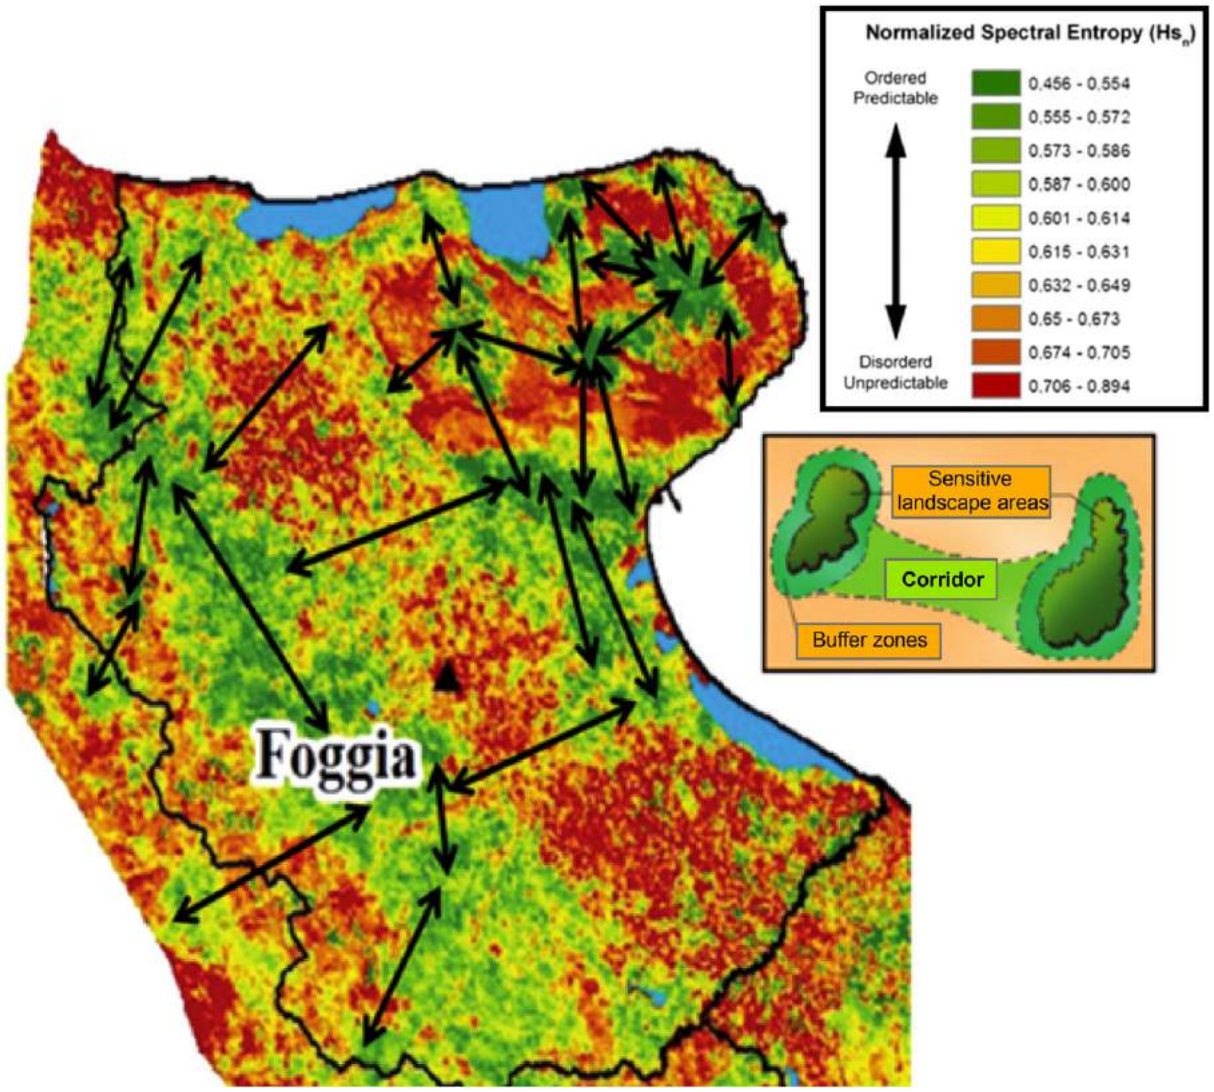

Fig. 4 Example of connectivity network based on a predictability map of a Mediterranean area. *Arrows* search to connect the most predictable areas indicating which areas could be transformed in more predictable by a proper change of their management or type of land cover to foster the overall network.

Time series of vegetation indices are an essential reservoir of past SEL, information as they keep track of the disturbances that occurred. They must be deeply investigated since they can reveal a great deal about the magnitude of disturbance and the timing of return to the usual functionality of systems.

An example of NDVI time series (2000 – 10) for primary land use/land cover (LULC) categories for a Mediterranean region (Fig. 2) demonstrates the differences in the inter-annual periodicities of NDVI related to both human controls (arable lands and olive groves) and natural balancing feedback loops (natural grasslands, broad-leaved forests, coniferous forests), whereas urban areas show a disordered behavior.

In the context of landscape ecology, entropy-based indices like Shannon's H or contagion are among the most commonly used metrics to analyze time series in order to represent the dynamics of landscape composition and configuration diversity, because they are capable of reflecting changes in the level of human impacts and disturbance regimes, species diversity and habitat use, or biodiversity level estimates from remotely sensed images.

The normalized spectral entropy (Hsn), for example, is an entropy-related index able to describe the degree of order and predictability (i.e., regularity) within an ecological time-series based on its power spectrum. This index has been suggested as a holistic indicator for system-level properties able to characterize heterogeneity in time and pointing to the system's self-organization strength. Spectral entropy (Hsn) of NDVI time series can be of practical help in mapping predictability of SELs—for example, the predictability map of invariant structures as provided by NDVI (Fig. 3). It can be calculated on the trajectories for each pixel of the map for 10-year series of 16-day maximum NDVI composite images (Fig. 2). In such an example, distinctive spatial patterns are shown at 250 m resolution with greener zones meaning higher predictability (1-Hsn), that is, more regular

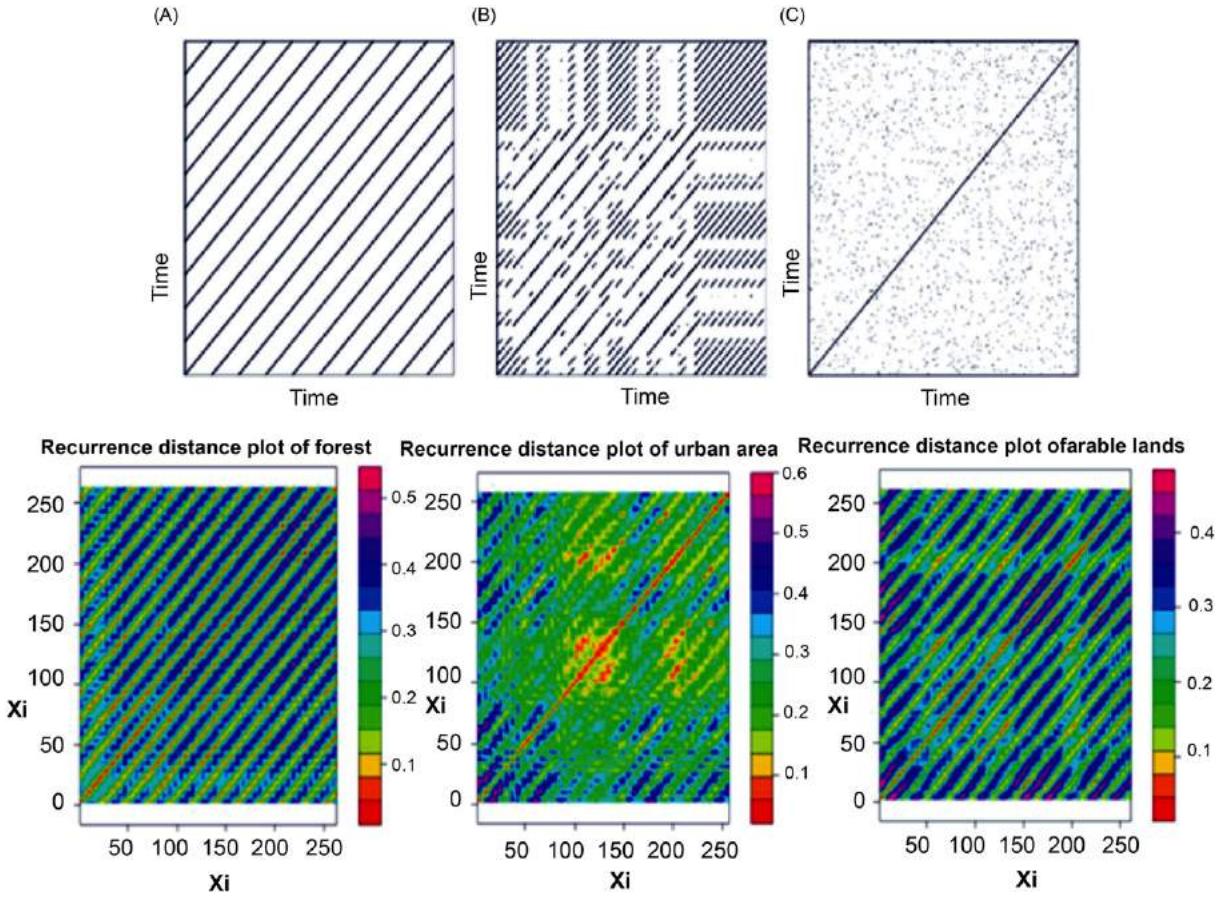

Fig. 5 Recurrence plots of three prototypical systems (top) (A) a periodic motion with one frequency (very predictable), (B) of a chaotic system (unpredictable), and (C) of uniformly distributed noise, and recurrence plots (bottom) of forest, urban areas, and arable lands for a Mediterranean region (2000–12). Marwan, N., Romano, M.C., Thiel, M., Kurths, J., 2007. Recurrence plots for the analysis of complex systems. Physics Reports 438, 237–329.

time series, while reddish areas are more unpredictable. Low spectral entropy refers to locations with less complex temporal pattern, that is, with more stable cyclical developments. Clear coherent regions of predictability and unpredictability emerge, as well as gradients of transition between the two. Large predictability geographic regions arise in the map of the Mediterranean region (e.g., olive groves, large farmlands), whereas unpredictability regions tend to be associated with heterogeneous cultivation areas.

Once one obtains a predictability map of invariant structures, one can think of applying different modeling tools to derive, under uncertainty, what could possibly be an effective corridor network and a suitable fragmentation for the future (Fig. 4). So it could be discovered that along with classical *green* and *blue* ways, other elements in the landscape could be identified and considered crucial based on their predictability for the maintenance of the overall connectivity in the face of climate change. Consequently they could be converted in persistent through planning and management efforts. Time series of natural or human dominated processes can have a distinct recurrent behavior, that is, periodicities (as seasonal or Milankovich cycles), but also irregular cyclicities (as El Niño Southern Oscillation). Moreover, the recurrence of states is a fundamental property of deterministic dynamical systems and is typical for nonlinear or chaotic systems.

Operatively, recurrence analysis reveals all the times when the phase space trajectory of the dynamical system visits roughly the same area in the phase space and therefore it recurs. Such cyclic patterns provide useful indications on the resilience capacity of a SEL in a retrospective way, exploring the ability of the system to absorb disturbances occurred in the past. One promising method of nonlinear time series analysis is the recurrence quantification analysis. The recurrence plot (RP) depicts the collection of pairs of times at which the trajectory is at the same place. It is a visualization (or a graph) of a square matrix, in which the matrix elements correspond to those times at which a state of a dynamical system recurs (columns and rows then correspond to a certain pair of times).

Let us consider the RPs of three prototypical systems (Fig. 5, top), namely of a periodic motion on a circle (Fig. 5A), of a chaotic system (Fig. 5B), and of uniformly distributed, independent noise (Fig. 5C). In all systems recurrences can be observed, but the patterns of the plots are rather different. Long and noninterrupted diagonals reflect the periodic motion. The vertical distance between these lines corresponds to the period of the oscillation.

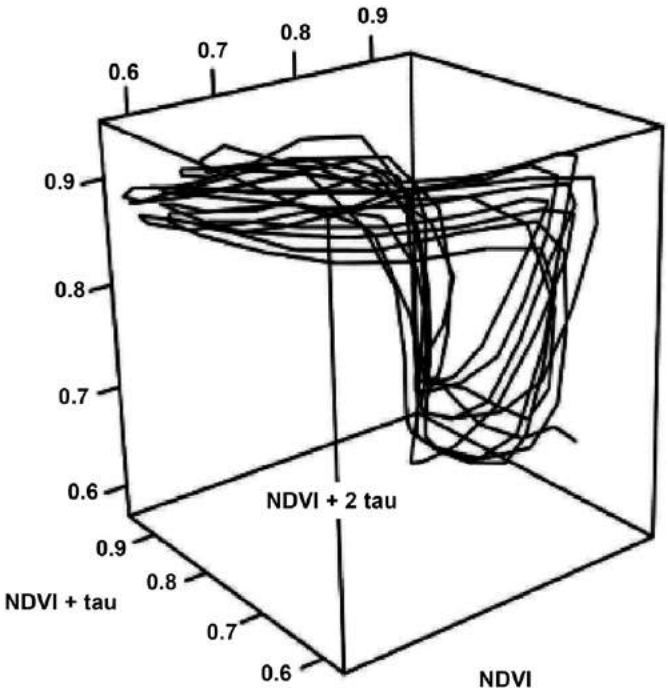

Fig. 6 Three-dimensional reconstruction of Normalized Difference Vegetation Index signal in phase space for the land cover class of forest (2000–12) by the method of time delays, with phase space trajectories visiting approximately the same area all the time (cf. Fig. 5).

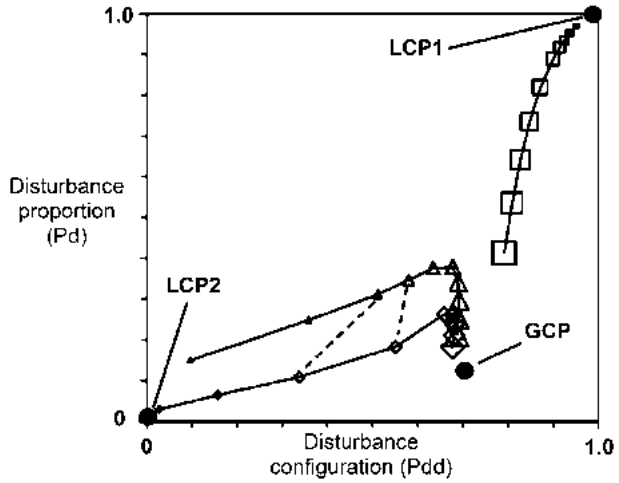

Fig. 7 The conceptual model is illustrated by three disturbance profiles in a pattern space defined by the local proportion and contagion of disturbance. Each disturbance profile connects the observed patterns across measurement extent (scale), and the size of the symbols indicates the relative extent. In addition to the global convergence point (GCP), there are two local convergence points for an extent equal to the size of one pixel that is either disturbed (LCP1) or undisturbed (LCP2). The *dotted lines* illustrate a cross-scale mismatch.

The RPs of NDVI for a Mediterranean region (Fig. 6, below) show that space trajectories can visit roughly the same area in the phase space all the times, that is, ES dynamics for forest are fairly spatiotemporally predictable, thus the probability that such a state will persist is rather high (resilience is high).

Arable lands are less predictable despite the action of self-correcting balancing feedback loops (i.e., drought-irrigation, soil impoverishment-fertilization). Urban areas, on the contrary, show a chaotic behavior (Fig. 5, below).

Nonlinear analysis of spatial-temporal dynamics of SELs helps gauge the capacity of any SEL to activate balancing feedback loops to adjust its responses to drivers. Adaptability is a fundamental component of resilience and captures the capacity of any SEL to learn, combine experience and knowledge, and activate balancing feedback loops to adjust its responses to changing external drivers and internal processes, and continue developing within the current stability domain or basin of attraction (i.e., Forest in Fig. 6); whereas resilience is the probability that such state will persist. Moreover, looking at phase space trajectories of time series

can help to look at possible impeding regime shifts. The three-dimensional reconstruction of NDVI signal in phase space for Forest (2000–12) (Fig. 6) shows that phase space trajectories have been visiting for 12 years approximately the same area all the times showing a high adaptability.

Multiscale Disturbance Approach

The effects of land-use intensity on local biodiversity and ecological functioning in SELs depend on spatial scales much larger than a single field or land use. This demands a landscape perspective, which takes into account the spatial arrangement of surrounding land-use types at multiple scales. So, a central question in landscape ecology is how patterns and processes change with the scale of observation. A scale domain has been defined as an interval in scale space within which landscape patterns and/or pattern-process relationships are stable or predictable. Knowledge of scale domains is important because inferences made within one domain do not necessarily occur in another domain. Therefore, spatial patterns at multiple observation scales provide a framework to improve the understanding of pattern-related phenomena.

Taking into account the scales and patterns of human land uses as source/sink disturbance systems, a conceptual model has been advanced that describes a framework to characterize and interpret the spatial patterns of disturbances along a continuum of scales in a panarchy of nested jurisdictional SELs like regions, provinces, and counties.

The conceptual model considers a pattern space defined by the proportion of composition (Pd: disturbed pixel) and configuration (Pdd: contagion between disturbed pixel) of disturbance (Fig. 7). Therefore, considering a binary map showing pixels of disturbed and undisturbed locations, multiscale disturbance patterns can be measured and mapped using an overlapping pixel-level moving window whereby scale is varied by changing the size of the window. Within a given window, composition is expressed as the probability of disturbance, and is estimated by the proportion of pixels that are disturbed (Pd). Configuration is measured within the same given window by the adjacency of disturbance, given by the probability that a disturbed pixel is adjacent, by the four-neighbor rule, to another disturbed pixel (Pdd), so that it is a measure of contagion.

In that pattern space, there is a global convergence point (GCP), which is the [Pd, Pdd] value corresponding exactly to the extent of the entire study area. For smaller extents, the observed [Pd, Pdd] departs from the GCP if the local pattern is different from the global pattern, where local is defined by a particular location and extent. At a given location, the trajectory away from the GCP is the disturbance profile, which describes the scaling of pattern at that location. A multiscale domain is a set of geographic locations with similar disturbance profiles. Whereas classical scale domains are identified by local invariance of pattern in pattern space, multiscale domains are identified by local invariance of the scaling of pattern in geographic space. This conceptual model made it possible to exploit the local sensitivity of pattern metrics such as proportion and contagion, by incorporating their geographic variance into the definition of a multiscale domain. The conceptual model has a high potential for the prediction and management of disturbance-related processes such as the spread of invasive species across landscapes.

Conclusions

To face the challenge of managing anthropogenic landscapes in a dynamic and increasingly accelerated context, an effective transdisciplinary integration has to be achieved by embodying the complexities of SELs into traditional landscape ecology analyses. In this context, the role of landscape ecology is to assess the impact of landscape heterogeneity combined with the impact of anthropogenic disturbances on ecosystem processes and the related delivery of ESs at multiple scales. In particular, there is a need to consider the complexities of anthropogenic landscapes in terms of order and disorder, where order implies causality, well-defined boundaries, and predictable outcomes, while disorder implies uncertain causality, shifting boundaries, and often unpredictable outcomes. The new methodological approaches can be used to increase spatially explicit anticipatory capability in environmental science and natural resource management, based on how the SELs have responded to stress in the past.

Such strategies could involve the design and management of landscape elements and structure through the strategic placement of managed land uses and natural ecosystems, so the services of natural ecosystems (i.e., pest control, pollination, reduced land erosion) can be maintained and even enhanced across the landscape. Additionally, these strategies should also consider landscape pattern design for the deliberate placement and confinement of local contagious disturbances that humans can manage at certain scale ranges to control, for instance, biological invasions, and to mitigate cross-scale impacts on ecosystem service flow.

These advancements should contribute greatly to strategies to foster SEL resilience in general and sustainable anthropogenic landscapes management in particular, and for the spatially explicit adaptive comanagement of ecosystem services.

Buffer Zones☆

Jesper S Schou and Emilie W Hansen, University of Copenhagen, Copenhagen, Denmark
Peter Schaarup, Danish Forest and Nature Agency, Copenhagen, Denmark

Introduction

Buffer zones may serve a wide range of purposes covering from environmental to socioeconomic and military issues, but here the focus is on the use of buffer zones for environmental protection purposes. Basically, an environmental buffer zone serves the purpose of changing an environmental pressure and, thus, effect occurring in a recipient adjacent to the zone. Therefore, buffer zones are closely connected to environmental problems of a site-specific nature.

Usually, the designation of a buffer zone in itself does not lead to changes in environmental pressures although a number of studies indicate that buffer zones may represent biologically valuable habitats (e.g. Douglas *et al.*, 2009; Musters *et al.*, 2009). Therefore, an important part of defining buffer zones is to establish the specific regulation of activities within the zone. Thus, the designation of buffer zones can be structured into tree initial steps:

- define the policy target;
- establish the criteria for designation the zone; and
- define regulation within the zone

To support the policy choices an *ex ante* evaluation of different options should be performed, and the implementation should be followed by an *ex post* evaluation to evaluate the fulfillment of the policy target. Establishment of buffer zones in this article is seen as a policy strategy applied to realize a pre-specified environmental objective; thus, focus here is on issues 2 and 3.

Designating the Zone

The criteria for designating the zone are of cause closely connected to the policy target. Knowing the policy target, the first step is to establish which areas that should be targeted to the buffer zones. This may lead to two types of buffer zones: zones changing the pressures on a location inside or adjacent to the zone, or zones changing pressures within the zone. In the first situation it is generally also useful to define the area outside the zone to which the pressures should be changed. An example of the first type of buffer zone may be a riparian buffer zone alongside a stream serving to reduce the erosion and loss of nutrients and pesticides to the stream (see **Fig. 1**) or buffer zones along highways to reduce traffic noise in domestic areas. An example of the former type of zone could be a buffer zone along the coastline where domestic settlements are prohibited in order to secure the landscape.

As apparent from the examples the specific location of the zone is of importance. The simplest way to designate the zone is to appoint an area within a certain distance of the targeted location. However, natural conditions such as soil types, slopes, and the dominant wind direction (in case of airborne pollution) may be relevant to take into consideration when designating the zones. This implies that more complex criteria for designating the zone may be efficient. One example could be to design a buffer zone dependent on the wind direction frequency if the aim is to reduce ammonia depositions to specific nature locations. Another example could be varying the width of riparian buffer zones depending upon the erosion potential of the adjacent fields.

Regulation Within the Zone

The regulation applied within the buffer zone can either be mandatory, flexible, or voluntary. In the case of a mandatory regulation, this will typically consist of prohibition or restrictions on the activities within the zone. This implies that land owners within the zone are subject to limitations in the property rights or – more far reaching – are obliged to carry out certain nature preservation activities. One example is the National Danish Nature Protection Act that requires land use to be unchanged within designated locations characterized by specific nature types.

The term 'flexible regulation' refers to policy measures regulating environmental pressures through the market by application of taxes of tradable quotas. This regulation is difficult to target locally, and is thus, not likely to be a general feasible option within buffer zones.

In the case of voluntary regulation, the landowners are given the opportunity to engage in environment-friendly schemes within the designated buffer zones. The scheme may either provide the landowners with the opportunity to enter subsidy

payments targeted at reducing environmental pressures within the buffer zone, for example, reduced pesticide use, or simply provision of advisory services targeted to landowners within the zone.

Mandatory, flexible, and voluntary regulation can of course also be applied in various combinations. One example could be ammonia buffer zones where farmers are faced with a mandatory requirement of reducing ammonia emissions to a pre-specified level, but at the same time are eligible to apply for subsidies to implementing ammonia abatement technologies.

Types of Buffer Zones and Their Function

Table 1 lists the most common types of environmental buffer zones described by their design and functions found in the international literature.

Recent Developments

Buffer zones have drawn attention both in research and in administrative organizations and NGOs. From the organizational side Cooper *et al.* (2009) reviews the use of buffer zones and other relevant measures for providing public goods from agriculture, and Dairynz (2012) describes the key benefits of managing waterways for the farm, the water quality and for the broader environment.

Turning to the research contributions, effects of riparian buffer strips on farmland biodiversity and ecological functions have received large attention. For example Cole *et al.* (2015) investigates the role of riparian buffer strips for the conservation of insect pollinators in intensive grassland systems and find that fenced riparian buffer strips have the potential to provide resources for insect pollinators. McCracken *et al.* (2012) investigated the connection between fencing off the margins of lowland grassland fields and the diversity of invertebrate species and find that fencing watercourses may increase the abundance of key groups of invertebrates. In both studies, the width of the buffer zones was found to be of importance. Brudvig *et al.* (2009) look at habitat corridors as important feature of reserves and demonstrate that corridors by increasing species richness inside target patches benefit biodiversity in surrounding non-target habitat. Musters *et al.* (2009) analyses the effect of taking field margins out of intensive cultivation and find that the plant species richness and species composition of the field margins changed over a four year period. The question if riparian ecosystems are particularly vulnerable to climate change are discussed by Capon *et al.* (2013) who find that the need for planned adaptation of and for riparian ecosystems is likely to be increased under a changing climate. Last, Douglas *et al.* (2009) investigated the effect of the height of the vegetation on margin areas for farmland birds and find that more frequent cutting and increased accessibility to the areas are likely to benefit a range of bird species.

At the more aggregated level Carswell *et al.* (2015) examines the potential trade-offs between carbon sequestration and biodiversity when selecting non-forested lands in New Zealand for natural forest regeneration. Further, a number for studies evaluate economic aspects of buffer zones. Roberts *et al.* (2009) estimates the annualized costs of establishing and maintaining riparian buffer strips on all agricultural land adjoining a waterway in Tennessee's Harpeth River watershed, and Laurén *et al.* (2007) investigates the interaction between the harvested stock in the buffer strips and the income for the landowner. The results further indicate that cost-effective water protection can be achieved when the dimension of buffer zone and the intensity of thinning are optimized. Last, using a newly developed indicator of the pesticide risk for aquatic biocenosis in

Table 1 Types of environmental buffer zones and their function

Type	*Design considerations and functional principles*
Riparian buffer zones	Zones with restrictions on land use or cropping technology on fields alongside rivers, streams, and lakes. Restrictions may imply a mandatory requirement of permanent grassland or no tilt from harvest until, e.g., April 1st. Primary function is to reduce erosion and nutrient losses. Secondary functions are to serve as habitats and establish connectivity between habitats.
Landscape buffer zones	Zones with restrictions on land use and mandatory rules of the future management. Primary function is to prevent new pressures within the zone and secure scenic views through the zone, e.g., by keeping the area free of domestic settlements or forest.
Wildlife buffer zones	Zones adjacent to or within appointed habitats with restrictions on land use or other human activities. Primary function is to reduce external pressures on the wildlife and secondary function is to improve the habitat and establish connectivity between habitats. Alternatively wildlife buffer zones can appoint areas where regulation of specific wildlife species is approved. An example could be a zone where predators such as wolfs feeding on domestic husbandry may be trapped or shot. Primary function is to secure domestic husbandry inside the zone and protect the predators outside the zone.
Ammonia buffer zones	Buffer zones where ammonia emissions are specifically regulated around specific habitats. The regulation designated to the buffer zones can either apply to future changes in husbandry production, e.g., establishment of new stables in the zone, or to existing and future husbandry production. The primary function is to reduce the local contribution to eutrophication of the appointed habitats. A secondary effect is likely to be reallocation of livestock production to outside the zone.
Pesticide free buffer zones	Zones where in use of pesticides in general or specific active substances are prohibited. The zones are typically located along field margins adjacent to hedgerows, streams, and similar landscape elements. Primary function is to increase the conditions for wildlife by increasing the production of forage such as weeds and insects. Further, the pesticide free buffer zones will reduce the external pressures on the adjacent habitats due to reduced wind drift.

surface water bodies' in application with an economic sector model alternative designs for an environmental policy programme is evaluated by Sieber *et al.* (2010). Results show that 3 m buffer strips perform best in a cost efficiency test due to low costs from changing agricultural land use.

Case Study – Ammonia Buffer Zones in Denmark

On 1 January 2007 a new integrated environmental accreditation scheme for all livestock farms was passed in Denmark. According to this scheme all farms with more than 75 animal units (one animal unit correspond to the nitrate production of one jersey cow) have to be approved based on their extra loss of nutrients when applying for an increase of the number of animal units. The integrated approach means that all environmental emissions have to be considered in the application including ammonia emissions from the stables and manure containers.

The general accreditation rule is that all the ammonia emissions from the new stables have to be generally reduced with more than 15% compared to the best available stable system. This general rule is supplemented by an individual regulation regarding the contribution of ammonia emission from the farms (if these are adjacent, i.e., situated within a buffer zone around) to the following types of nitrogen vulnerable areas: (1) raised bogs; (2) lobelia lakes; (3) moors larger than 10 ha and all moors in NATURA 2000 areas; (4) uncultivated, dry meadows larger than 2.5 ha and all uncultivated, dry meadows in NATURA 2000 areas; and (5) nitrogen vulnerable lakes in NATURA 2000 areas. Around these areas the regulation is divided into three parts:

- *Buffer zone I*. If just one of new or modified stable or manure container of the farm is situated less than 300 m from the vulnerable area no increased emission is approved.
- *Buffer zone II*. If just one of new or modified stable or manure container of the farm is situated less than 100 m from the nitrogen vulnerable area, a standardized emission calculation has to be carried out. The total contribution of ammonia deposition from the new or modified stables in the vulnerable area may not exceed 0.7 kg N per m^2. In order to take the cumulating aspects into account the maximum accepted increase in the ammonia deposition descends if another farm with more than 75 animal units is situated close to the nitrogen vulnerable area; if only one farm is situated closer than 1000 m from the new or modified stables then the contribution of ammonia from the new or modified stables in the vulnerable area may not exceed 0.5 kg N per m^2. If two or more farms with more than 75 animal units are situated closer than 1000 m from the new or modified stables, the threshold is 0.3 kg N per m^2.
- *Outside the buffer zones*. No individual regulation of the ammonia emissions from the farms under environmental approval.

The nitrogen vulnerable areas were pointed out by a national committee (the so-called Wilhjelm-udvalget). Afterwards the areas were adopted as part of the third Aquatic Action Plan, and the regulation related to the ammonia buffer zones was implemented as part of the new law on environmental approval of livestock farms as the primary basis for the individual regulation of ammonia emissions.

The scope for making this gradual regulation with two buffer zones is to make a differentiated incitement for the farms to locate new or extended stables at a proper distance from the vulnerable areas. Further, buffer zones are considered as a cost-effective way to focus the regulation in areas where the environmental effect is significant. Furthermore, one of the scopes is to ease the

administrative costs because only in buffer zone II the more complicated and costly calculations of emissions are needed. Furthermore, in order to reduce the administrative burdens and to ensure the quality of the applications all environmental calculations (including ammonia emission calculations) and other information needed for the application for an integrated environmental approval are integrated in a new internet-based digital application system (www.husdyrgodkendelse.dk).

Classical and Augmentative Biological Control

RG Van Driesche and K Abell, University of Massachusetts, Amherst, MA, USA

Glossary

augmentative biological control Programs based on the release of commercially reared parasitoids or predators for pest control in crops.

classical biological control Programs of importation of natural enemies from an invasive pest's homeland for the permanent, area-wide suppression of the pest; may be directed against either economic pests of crops or ecological pests of natural areas; may target pest insects, mites, or weeds.

hyperparasitoid A parasitoid that attacks another species that is itself a parasitoid; these species may be detrimental to insect biological control programs.

inoculative biological control A form of augmentative biological control in which the goal is to establish reproducing populations of natural enemies at the start of the crop.

inundative biological control A form of augmentative biological control in which natural enemies are released in large numbers throughout the cropping period, with no expectation that the released biological control agents will establish; pest control is expected from the individuals actually released, not their progeny.

insectaries Rearing facilities in which parasitoids and predators are mass produced, usually for sale as agents for augmentative biological control programs.

natural control The level of control produced by natural enemies that occur naturally in the crop without any active management by people.

nontarget impact Mortality or population or range decreases that may occur to beneficial or native species as a consequence of the use of natural enemies in biological control programs.

parasitoids Insects that develop in or on a host, consuming and killing it; parasitoid larvae require one host to complete development; adult females can also kill hosts through host feeding.

predators Organisms that attack and eat other organisms. Predators typically kill and consume many prey during their development as larvae and as adults.

quarantine A secure importation facility designed to prevent the unintentional release of natural enemy species into new geographic regions after their discovery during foreign exploration.

Definition and Scope of Biological Control

Biological control is a form of pest control that uses living organisms (parasitoids, predators, or herbivorous arthropods) to suppress a pest's density to lower levels. There are four kinds of biological control, two of which – classical biological control and augmentative biological control – are discussed in this article and two others – conservation biological control and biopesticides.

Classical biological control is the deliberate importation and release of new species of natural enemies with the intention of suppressing the densities of a target weed or insect permanently over the whole of its range in the country receiving the natural enemies. Target pests are typically invasive species and the introduced natural enemies are those specialized agents that attack it in its native range. Classical biological control is a major tool in reducing impacts of invasive species, both in crops and natural areas.

Augmentative biological control is pest suppression in greenhouses or outdoor crops through the purchase and release of commercially reared natural enemies. This approach is used against pest insects and mites, but not against weeds. Natural enemies used include both predators and parasitoids. The value of this approach depends on efficacy and cost of the natural enemy. This approach is most effective in greenhouse crops.

Biological control has important advantages compared to other methods of pest control. Classical biological control is often cheaper and less polluting than use of pesticides, because pest control is relatively permanent and does not require annual retreatment. Initial costs of classical biological control are high, for discovery, importation, testing, and initial release of new natural enemies. However, costs drop to low or even zero levels in later years, while the benefits of the pest control achieved continue to accrue for years. For augmentation biological control, results are temporary and costs reoccur annually, as with pesticides. Augmentative biological control may be either more or less expensive than other approaches depending on details such as the cost of natural enemy production by commercial insectaries that sell beneficial organisms, and efficacy of other control tactics. Both of these types of biological control are harmless to people and vertebrates, giving the approach a distinct advantage over pesticides, which must be actively managed for safe use to mitigate harm to humans and other nontarget organisms. Risks of both augmentative and classical biological control to nontarget insects or, for weed biocontrol projects, to plants can exist, but these risks can be managed to low levels by careful screening of species being considered for release in new areas. Biological control as a scientific endeavor has a history of about 125 years of effective use (beginning in the 1880s), over which time new information, techniques, and technologies have increased our ability to use biological control agents with increasingly greater understanding and effectiveness.

 doi:10.1016/B978-0-444-63768-0.00039-1

Classical Biological Control

Ecological Justification

People routinely move species, such as crops and ornamental plants, across natural barriers such as mountain ranges or oceans that would otherwise limit their spread. These plants may carry with them small, unrecognized infestations of pest insects. In some cases the plants themselves may spread and become invasive. Both invasive plants and insects often escape their specialized natural enemies when they cross geographic barriers and establish in new locations. Local natural enemies, unfavorable habitats or climates, or, for insects only, lack of a susceptible local plant, prevent many invaders from establishing or reaching high densities. However, for some invasive species, local climates and hosts are favorable and local natural enemies are generalists that have limited impact. Those species increase to densities from 10 to 10 000 times greater than their numbers in the native range. Such high-density invasive species cause great economic and ecological damage and are the targets of classical biological control. By introducing more effective natural enemies, classical biological control seeks to lower the invader's density, which then allows the invaded community to return fully or partially back to its preinvasion condition. Two examples follow that illustrate the process and how such projects produce economic and ecological benefits.

Pink Hibiscus Mealybug

Pink hibiscus mealybug (*Maconellicoccus hirsutus* Green) (Fig. 1) invaded the Caribbean nation of Grenada in *c.* 1993, where it infested young shoots, flowers, and fruits of a wide range of plants, particularly those in the family Malvaceae. Among the important plants affected were ornamental hibiscus (*Hibiscus rosa-sinensis* L.), soursop (*Annona muricata* L.), cotton (*Gossypium hirsutum* L.), cocoa (*Theobroma cacao* L.), and citrus (*Citrus* spp.). The mealybug reached high densities and began to spread rapidly to other islands and adjacent mainland areas. Mealybugs caused immediate losses to the tourist industry by reducing beauty of ornamental plants around hotels. Losses also occurred in several major crops and inter-island trade was affected through the quarantines (albeit ineffective ones) enacted to prevent spread to other islands. Grenada and the islands of Trinidad and Tobago

Fig. 1 Pink hibiscus mealybug (*Maconellicoccus hirsutus* Green) invaded the Caribbean region in the 1990s and rapidly became an important pest on a wide range of woody plants. Photo Courtesy of Dale Meyerdirk, USDA; Forestryimages.org.

suffered an estimated $US10–18 million in losses in the first year following the mealybug invasion. In contrast, Puerto Rico, where effective parasitoids were rapidly introduced almost immediately after an invasive population was discovered, suffered almost no economic losses.

Control of this pest was greatly facilitated by previous successful control of the same species in Egypt in the 1920s, where it had invaded, presumably from India. Several predatory coccinellids, including the mealybug destroyer, *Cryptolaemus montrouzieri* Mulsant, and the encyrtid parasitoid *Anagyrus kamali* Moursi, were introduced into Egypt. In the Caribbean, both *C. montrouzieri* and *A. kamali* were also introduced, as well as another encyrtid parasitoid, *Gyranusoidea indica* Shafee, Alam, and Agarwal. The predatory coccinellid had little or no effect, even though *C. montrouzieri* did establish. Costly releases of *C. montrouzieri* were somewhat useful as a stop gap measure to reduce extremely high populations on limited areas of high value plants but could not provide control over wide areas. In contrast, region-wide control was rapid and complete following the release of several parasitoids, mainly *A. kamali*.

To gauge the specificity of *A. kamali*, nine species of mealybugs were assessed. Of the species tested, *A. kamali* parasitized only two nontarget species, but development in these species was not successful. This parasitoid was, therefore, judged to be relatively specific and beneficial. In contrast, *C. montrouzieri*, which was also introduced to Grenada (but not to most other locations invaded later), is a known generalist predator.

This project provided rapid, permanent, and complete control of an invasive economic pest in many Caribbean nations and the United States. Because the pest had been controlled previously in Egypt, the natural enemy likely to be effective was already known. Because the introduced parasitoid was specific to mealybugs, it was safe to nontarget insects in other groups and host range tests showed it unlikely even to affect other mealybugs.

Waterhyacinth

Waterhyacinth (*Eichhornia crassipes* [Mart.] Solm) (**Fig. 2**) is both a plant used in ornamental fish ponds and the world's most damaging aquatic weed. Its beautiful lavender flowers have led people to take it far from its native range in the Amazon basin of South America. Wherever waterhyancinth has been introduced into subtropical or tropical climates, it has escaped into the wild. There it forms gigantic mats that clog rivers and cover over bays and ponds, causing great ecological damage and harming economic activities such as fishing, transportation, and hydropower. Among the many places invaded by waterhyacinth is Lake Victoria in East Africa. It was first recorded there in 1980 and by the mid-1990s some 12 000 ha of weed mats were clogging bays and inlets around the lake. Economic losses were caused to fisheries (the mats impede the launching of boats and the use of nets) and to water and hydroelectric power works. Ecologically, the weed threatened one of evolution's greatest products – a radiation of some 200–400 species of endemic cichlid fishes. These fish, often separated by mating habits based on female color preference, were threatened by hybridization among species induced by low light under weed mats, where color-based visual-recognition mating systems could not be sustained.

Control efforts recommended to the governments of the affected countries (Uganda, Kenya, and Tanzania) included herbiciding the mats, use of harvester boats to cut the mats, and release of specialized herbivorous insects. Two weevils, *Neochetina eichhorniae* Warner and *N. bruchi* Hustache, known to be specialists on waterhyacinth from earlier work in Florida, were chosen for release. In 1995, Uganda was first to release biological control insects against the weed, followed by the other two countries in 1997. On the Ugandan shore, weed mats began to show damage from herbivory by late 1998. By 1999 some 75% of the mats had died and sunk into the lake.

This project illustrates the power of classical biological control to provide control of invasive species damaging large natural systems without the recurrent costs of mechanical control or the pollution of pesticides.

Fig. 2 Waterhyacinth (*Eichhornia crassipes* [Mart.] solms) has invaded water bodies throughout the tropics and subtropics, causing great ecological and economic damage. Photo Courtesy of Chris Evans; Forestryimages.org.

Description of the Process

Regardless of the target pest, a similar series of steps are followed in any classical biological control project.

Choice of the target pest

Species chosen as targets of importation biological control should be ones for which there is broad social agreement that they are pests and need to be reduced in density. Targets should be species that are strongly regulated by natural enemies in their native ranges and these species should be missing in the areas invaded by the pest. Nontarget risk to native plants can be minimized if species selected as targets do not have closely related (same genus) species in the recipient country.

Pest identification and taxonomy

Correct identification of the target pest is essential. Mistakes at this stage will cause project delays or failure. If the pest is an unknown species, its nearest relatives need to be identified, as this can provide clues to the pest's native range. Molecular markers are now commonly used to identify populations of both pests and natural enemies with increased precision. Such identification for pests allows exact origins of an invader population to be identified, often within very large native ranges. Markers for natural enemies allow biotypes or cryptic species to be recognized and facilitates identification of recovered specimens after release.

Identification of the native range

The region where the pest evolved needs to be identified as it is the best place in which to search for specialized natural enemies that have evolved with the pest. This can be done based on several criteria, including the center of the geographic range of the pest, the area where the principal host plant of the pest evolved, regions where the pest is recorded to occur, but remains at low densities, and regions with the largest numbers of species closely related to the pest.

Surveys to collect natural enemies

Natural enemy collection, or foreign exploration, needs to be done extensively over the range of locations, habitats, and seasons where the pest is found naturally. Surveys of natural enemies in the invaded area are unlikely to locate effective natural enemies, but are needed to identify any natural enemies that may already be present because of their own invasion of the region.

Importation to quarantine

Promising natural enemies collected in surveys need to be shipped to quarantine laboratories, where they can be colonized and maintained on the pest for further study to evaluate their host ranges and make a judgment as to their safety for introduction into the proposed recipient country.

Host specificity and biology studies

To promote selection of safe species for importation, the biology and degree of host specificity of each candidate biological control agent needs to be determined through a mixture of literature records, field observations in the area of origin, and laboratory host range studies (feeding and oviposition evaluations with species potentially at risk) in quarantine before release into a new area is approved.

Release and colonization in the field

Releases need to be made at numerous locations where the target pest is present, and over extended periods of time until efficient means to establish the natural enemies in the invaded area are discovered or until it is clear the agents are unable to establish. Once established, natural enemies disperse naturally or are redistributed artificially throughout the range of the pest.

Evaluation of efficacy

Field experiments in the invaded area comparing pest density in plots having and lacking the introduced natural enemy are needed to measure the degree to which the natural enemy is able to reduce the density of the pest (for insect targets) or, for weeds, how much the natural enemies lower a variety of plant performance and population measures such as percent cover, biomasss, seed set, etc.

Documentation of benefits

Economic and ecological consequences of the project need to be recorded and published.

Extent of Successful Use

Following introductions of natural enemies, pest densities may be reduced, in some cases by 90%–99% or more. This has been achieved for a variety of pest insects, including caterpillars, sawflies, aphids, scales, whiteflies, and mealybugs. Over the last 125 years, more than 1200 insect biological control projects have been attempted. Of these, 60% have resulted in a reduction of the pest's density. In 17% of cases, control was complete and no further effort was needed. Introductions of specialized herbivores have been made for over 133 species of invasive plants and, of these, 41 species (31%) have been completely controlled.

Economics

Importation of biological control agents is a government activity for the common good. Funds for such work are typically provided by governments, but may in some cases come from grower organizations representing particular crops in a region. Costs of projects are concentrated at the beginning of the work, as costs to search for and study new candidate natural enemies are high. Use of proven biological control agents in newly invaded locations as the pest spreads is cheaper, as much of the initial work will not have to be repeated and known natural enemies can quickly be introduced. Benefits of successful projects accrue indefinitely into the future and benefit-to-cost ratios of past projects have averaged 17:1, with some projects having much higher ratios, of 100 or even 200:1. In successful programs, control is permanent and does not require continued annual investments to sustain the benefits, in contrast to other forms of pest control (e.g., pesticide applications). This makes the method particularly attractive for use to protect natural areas and to protect crops in countries with resource-poor farmers. Biological control also promotes good environmental stewardship of farmlands in developed countries.

Safety of Natural Enemy Importations

Insects may be released as natural enemies of either invasive plants or invasive insects. Both biological weed control and biological insect control show a very high level of safety to vertebrate and human health. There are three safety issues when insects (herbivores, predators, or parasitoids) are imported to a new region: (1) identification of unwanted contaminants in foreign shipments; (2) recognition of organisms that, by virtue of their biology, may be damaging to other biological control agents; and (3) potential damage to nontarget species (e.g., native insects or plants) in the area of release by natural enemies with broad host ranges.

The first two of these safety concerns are addressed by the use of quarantine facilities, which are designed to prevent the accidental release of new species into the environment following importation. In quarantine, desired natural enemies are separated from all other materials, including miscellaneous insects that might have been accidentally included in the package by the collector, extraneous plant material, or soil. A taxonomist then confirms the species identification of the organism and ensures that all individuals collected are the same species. Voucher specimens are deposited with an entomological museum for future reference. Natural enemy identification will either indicate the name of the organism or that it is a species not yet described. New species can usually be placed in a known genus, for which some biological information will exist. A sample of the natural enemies are also submitted to a pathologist to determine if they carry any microbial or nematode infections. If they do, they will either be destroyed or, if possible, treated with antibiotics to eliminate the infection. This group of field-collected, healthy individuals will then be bred in the laboratory on the target host. This eliminates any undesirable parasitoids (for herbivores attacking weeds) or hyperparasitoids (for insect agents) that might exist in the collected material that, if established, would damage the biological control project by reducing the efficacy of imported natural enemies. For insect parasitoids, rearing for one generation on the target host excludes the possibility that a hyperparasitoid has been obtained by mistake.

The potential for attack on nontarget species after release is minimized by estimating the host range of the natural enemy proposed for release and reviewing that information in light of the fauna or flora in the recipient country. Estimation of an agent's host range is based on (1) literature records of species known to be attacked by the agent in the region from which it is collected, (2) negative evidence in the literaure, that is, any species of interest that occur with the agent in its home range but which are not attacked, and (3) data from laboratory tests. Most evidence comes from laboratory host range tests. For herbivorous insects released for weed biological control, these laboratory tests include studies of both the adult's oviposition preferences and the feeding preferences of the immature stages and, in some cases, adults. For immature stages, tests also include an assessment of a test plant species' suitability to support growth and development. Similar tests can be applied to the study of parasitoids, that is, both oviposition preferences and survival of the immature stages on a given host. For predators, feeding preferences of both adults and larvae must be measured.

Historically, estimation of host ranges of herbivorous insects used against weeds began early (in the 1920s), evolving from testing only local crops, to a phylogenetically based attempt to define the limits of the host range by testing plants in the same genus as the target weed, then the same tribe, etc. This process has been highly successful in avoiding the introduction of insects whose host ranges are wider than initially thought. Cases of attack of introduced herbivores on nontarget plants have largely been limited to other species in the same genus and have largely been well predicted. Of 117 species introduced into North America, Hawaii, or the Caribbean for biological weed control, only one species (the lacebug *Teleonemia scrupulosa*, introduced into Hawaii in 1902 against the shrub *Lantana camara* L.) has attacked nontarget plants that were not either in the same genus as the target weed, or a very closely related genus.

Estimation of host ranges of parasitoids and predators introduced for biological control of insects began in the 1990s, in response to changing views on the ecological and conservation value of native nontarget insects. Techniques for making estimates of arthropod natural enemy safety are less well developed than for herbivorous biological control agents. A few cases of harm from parasitoids or predacious insects to nontarget insects have been reported. Importation of generalist species that have broad host ranges should be avoided because of such potential to harm native insects.

Laws explicit to biological control importations exist principally in New Zealand and Australia. Laws in the United States regulate importation of herbivorous insects used against weeds, but do not currently regulate importation of parasitoids or predators.

Augmentative Biological Control

History and Scope

Methods have been developed to rear a variety of species of predators and parasitoids at commercial levels. Augmentative biological control is based on the user purchasing and releasing the natural enemies needed for his crop. This approach to pest control began in greenhouse-grown tomatoes with *Encarsia formosa* Gahan, a parasitoid of the greenhouse whitefly (*Trialeurodes vaporariorum* [Westwood]), which was first reared commercially by English growers in the 1920s. Modern augmentative biological control began in the 1970s when Dutch greenhouse tomato growers revived *E. formosa* rearing as a commercial activity because whiteflies in their greenhouses had developed pesticide resistance. From 1970 to 2006, the number of commercial insectaries producing parasitoids and predators for pest control grew to several dozen firms, which collectively produce about 100 species of natural enemies for use in greenhouses or related facilities. *Encarsia formosa* and the predatory mite *Phytoseiulus persimilis* Athias-Henriot make up most of the sales. Natural enemy releases are used in greenhouses, plant conservatories, mushroom houses, and animal holding buildings such as dairies, hog rearing facilities, poultry barns, and zoos.

Outdoor releases of several species of predators and parasitoids developed independently of the indoor applications described above and mainly focused on egg parasitoids in the genus *Trichogramma* (Hymenoptera: Trichogrammatidae). These parasitoids are released to suppress pest weevils and caterpillars in cotton, corn and sugarcane, especially in China, Russia, and tropical sugar-producing countries. Predators of mealybugs for release on citrus crops in parts of California have been reared by a growers' cooperative since 1926. Several species of predatory phytoseiid mites are released for control of pest spider mites in strawberries, outdoor foliage plant production, and other high value crops.

There are two approaches to augmentative biological control: inoculative and inundative releases. Most indoor releases of natural enemies are inoculative, consisting of a small release early in the crop cycle that is intended to suppress the pest after the natural enemy's numbers have increased naturally through reproduction in the crop. Cost of this approach is minimized because smaller numbers of the natural enemy are needed. In contrast, inundative biological control consists of frequent, large releases throughout the crop cycle, with control coming from the attacks of the released individuals. Little reproduction in the crop is expected. Because much higher numbers are released, only natural enemies with very low production costs are economical for use in this way. This is the approach behind *Trichogramma* releases, given that these parasitoids can be reared very inexpensively.

How Insectaries Turn Natural Enemies into Mass Market Products

To profitably market a natural enemy, an insectary must succeed in a series of activities.

Find a suitable natural enemy

Augmentative biological control starts with the discovery of a natural enemy that research suggests may be effective. The natural enemy must attack an important pest efficiently, be easily reared under mass production conditions, able to survive shipping, and be competitive in price with other forms of pest control available to growers.

Develop a mass rearing system

Some species, such as the whitefly parasitoid *E. formosa*, can be reared cheaply using their natural host on a living plant. In other cases, costs of production or the scale of production are improved by switching to an alternative rearing species other than the target pest. Most *Trichogramma* wasp species are grown on the eggs of moths that feed on stored grain, rather than on eggs of the target moths themselves, because colonies of grain-feeding moths can be reared much more cheaply.

Develop efficient harvest, storage, and shipping methods

Mass reared predators and parasitoids must be released within days of production. Shipping to customers must be rapid (1–3 days) and avoid delays at international borders. Longer delays invariably kill natural enemies due to heat, desiccation, continued development, or starvation.

Provide clear release instructions

The customer must release the natural enemy using the right rate and the correct procedure. Effective rates are discovered by controlled trials in universities and government laboratories, and by experience of growers using products in accordance with advice from producers.

Extent of Successful Use

Indoor crops

The use of augmentative biological control has become widespread in greenhouses in Northern Europe and Canada that produce vegetables, with over 5000 ha using *E. formosa* for whitefly control and over 7000 acres using *P. persimilis* for spider mite control. These amounts, however, still represent only a small percentage of the world's protected culture. Biological control is used much less often in Southern Europe and Japan, areas with extensive greenhouse vegetable production, because of differences in climate

and greenhouse construction. Development of methods effective in warm climates, however, is underway. Similarly, use of biological control is very limited in greenhouses producing bedding plants or floral crops, the major focus of greenhouse production in the United States.

Outdoor crops

The scientific use of augmentative natural enemy releases in outdoor crops is best established in Northern Europe for control of European corn borer (*Ostrinia nubilalis* [Hübner]) in corn. Use is greatest in Germany and France, with about 11 000 acres being protected annually in Germany with *Trichogramma* releases. This is, however, only a small fraction of the total corn acreage in Europe, and use of biological control is concentrated principally where pesticide use is not allowed because of concern for health of people living near corn fields and is supported by a government subsidy. Natural enemy releases for mite control has been successful in strawberries in California, Florida, and the northeastern United States, and in outdoor shade houses used for production of foliage plants in Florida. In Mexico, Russia, China, and other countries, large-scale releases of *Trichogramma* spp. have been made for a variety of moth and beetle pests of corn, sorghum, and cotton, but the efficacy of these releases has not been well demonstrated. In some instances, these activities have been state-supported and their actual economic value for pest control is not clear.

Safety of Augmentative Biological Control

Release of parasitoids and predators replaces pesticide application and thus enhances human safety. For workers in insectaries, handling of large quantities of insects or mites is an allergy risk. Where problems arise, risk can be reduced through air exchange or filtration to reduce concentrations of airborne particles and use of gloves and long sleeved shirts to reduce skin contact with arthropod body fragments. Risk to native species posed by releases of non-native natural enemies can be of concern in some instances. Generalist, non-native species released in large numbers may establish outdoors if climates are permissive and attack or suppress populations of native species, or reduce densities of native natural enemies through competition for resources. Consequently, some governments, such as those of Hawaii, Australia, and New Zealand, restrict importation of natural enemies used in augmentative biological control. Importation of North American green lacewing species (Neuroptera: Chrysopidae, *Chrysopa* spp.) (used in greenhouses as predators of aphids) might, for example, lead to the establishment of such species in the wild, increasing competition with the endemic native lacewings in Hawaii, which have conservation value as unique native wildlife.

Conclusion

Classical biological control is the dominant form of biological control, being suitable for use on thousands to millions of acres of land and is a critical tool in controlling the ecological and economic damage caused by invasive pests. It is a government-supported activity for the public good and is based in ecology and population dynamics. It has an excellent, but not perfect, safety record, and methods exist for predicting risks to native species, allowing them to be minimized by choice of agents released. Augmentative biological control, in contrast, is a commercial activity with a narrow scope. It is suitable for providing crop protection for limited periods of time. Its costs recur with each crop and must be paid by the end user. The range of natural enemies reared commercially is a small subset of those that occur naturally, being limited by economics of production and market size, such that only species that generate profits can be offered for sale. Both methods improve human and ecological health by replacing pesticide use.

Ecological Engineering: Design Principles☆

Susan Bolton, University of Washington, Seattle, WA, United States

Introduction

Engineering is the application of science through design to create systems to benefit humans. Design is the essence of engineering. Engineering has its basis in math and physics, but subfields are based on a particular science. For example, chemical engineering is based on chemistry, mechanical engineering on mechanics, and electrical engineering on electricity. The concepts of ecological engineering were introduced in the United States in the 1960s by H.T. Odum. Ecological engineering, as the name implies, is an engineering subfield that is based on ecology. Ecology includes aspects of all of the sciences that study living or nonliving components in an ecosystem, for example, biology, botany, geology, hydrology, soil science, zoology, and specifically addresses the interactions among the living and nonliving components of the ecosystem. Historically ecologists have viewed many engineering projects as destructive of natural systems making ecological engineering a contradiction in terms. Likewise, engineers often have little appreciation for ecological knowledge, which is usually less precise and mathematical than traditional engineering science.

Ecology is the study of the interrelationships between biotic (living or previously living, e.g., plants, animals, carcasses) and abiotic (never living, e.g., water, sediment, chemicals, temperature) components of the environment. Ecological engineering incorporates elements of the sciences used in ecology to create engineered designs that reflect and incorporate ecological processes. The goal is to provide for human welfare with engineering projects while also protecting the goods and services that are provided by a natural environment. These goods and services include production of oxygen, air and water purification, carbon storage, flood control, regeneration of soil and soil fertility, pollination of food crops, waste decomposition and protection from ultraviolet rays. Recognizing that all social and economic systems depend on a functioning ecological system implies that ecological engineers acknowledge the values of sustainability and protection of natural systems even as they design systems for the benefit of humans. These concepts define an engineering discipline based on ecological science with an explicit recognition that the values of sustainability and protection of natural systems are incorporated in designs for the benefit of humans and the environment.

Increasingly, natural scientists with no training in design methods are engaged in applied science as they address and try to solve environmental problems such as wetland loss, river and water quality degradation, and soil contamination. Engineers are addressing similar questions with more formal design procedures but with little training in the relevant scientific areas. This can create a variety of unintended consequences that can diminish the ecosystem's ability to provide the goods and services upon which all life on earth depends. Ecological engineering uses ecological knowledge and theory and standard engineering design procedures to address environmental problems. Standard design procedures allow for the collection of information on which design criteria are successful and which are not. Documentation of the design process allows for others to learn from either design errors or less than perfect designs and contributes to improved future designs. Numerous authors have discussed design principles for ecological engineering all of which derive from the overarching principles of thermodynamics and evolution.

Overarching Principles

Thermodynamics and Conservation of Mass and Energy

Ecological engineering principles are constrained by the laws of conservation of mass and energy and the laws of thermodynamics, just as chemical, mechanical, or electrical engineering principles are constrained by these laws. Ecosystems are open systems that require a continual input of energy to maintain their structure and function. Two of the most inviolable principles of ecological science can be described as energy flow and material recycling.

Energy flow

Energy inputs, driven by solar radiation, are required to maintain structure and function in the face of the physical tendency toward disorder (the increase of entropy). Traditionally engineered systems use human and hydrocarbon-based energy to maintain order (keep the system intact and functioning). Ecosystems use photosynthesis, driven by solar energy, as their energy source. Biological energy flow can be measured by rates of production (biomass accumulation) and respiration (energy used for production). Physical energy flow can be measured by the mobilization, transport and deposition of organic and inorganic materials by the kinetic and potential energy of fluids or solids such as water, wind, and sediment. Both biological energy and physical energy are constrained by

☆*Change History*: February 2018. Susan Bolton updated the keywords, updated abstract, added content on ecosystem services and issues related to climate change to Section 2.2.2, added an example of project types to Section 3, added newer references, and added web site links.

This is an update of S. Bolton, Design Principles, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 898–902.

conservation of mass and energy laws. Ecology, as the interaction of biotic and abiotic processes looks at the interactions of both types of energy. Some energy is lost at each transformation so while total entropy increases in accordance with the second law of thermodynamics, order is locally increased. This has been described as the self-organization feature of ecosystems or exergy.

Emergy, an accounting system developed by H.T. Odum can be used to put all natural and human production into common units based on solar radiation. Emergy measures the inputs to make a product or service. It is a measure of energy used in the past and thus is different from a measure of current energy use. This provides a way to evaluate the costs of ecological goods and services in the same units as the costs of human production of goods and services. Ecological engineering designs seek to maximize the use of renewable energy (e.g., solar radiation) and minimize the use of nonrenewable energy.

Material recycling

Nutrient and material (re)cycling is another major ecological principle. Material is conserved by the continual reuse of materials and the transfer of those materials between organic and inorganic states through biogeochemical cycles. Organic and inorganic materials cycle through the system appearing in different locations and forms through time. Waste disposal is seldom an issue in a functioning ecosystem as the output from one system is used as input to another. Natural biogeochemical cycles mobilize, transport, and store material in the atmosphere, biosphere, hydrosphere, and lithosphere. Producers, consumers, and decomposers transfer organic matter and nutrients among themselves and the storage compartments. Many traditional human engineering designs lead to the accumulation of waste materials that cannot be reused by the original process and can contaminate other processes. Ecological engineering designs seek to minimize waste production and to utilize wastes (material not related to the primary function of the design) as inputs for other processes. One example of this is using ecological processes to clean up waste products such as using wetlands to treat wastewater or phytoremediation to clean up soil contamination.

Natural Selection and Evolution

Self-organization

In traditional engineering design, one seeks to maintain the independence of functional requirements. Functional requirements are the specific functions that the design feature is to provide. The engineer selects specific physical elements (design features) to meet each functional requirement. In the final design, each functional requirement has one solution and does not rely on other design features. That is, modification of any one design parameter affects only one functional requirement. There is no interaction or coupling of design features to multiple functional requirements. This is exemplified by the concept of modularity in software design where individual modules can be swapped in and out of programs without affecting program stability or performance.

Engineering designs seek tight tolerances and rigid, stable systems that do not change. Nothing is left to nature; everything is preplanned. In the event of system or component failure identical back-up systems or components may be built to provide redundancy. The traditional engineering approach of maintaining independence between subsystems ignores the interrelationships and complexity of ecosystems.

Nature does not build things the way humans do. There is no external plan, design engineer, or architect that creates steps to achieve an envisioned final product. It is the flow of energy and material through an open system that allows for self-organization. Ecosystems are complexly coupled, that is, everything is connected to everything else. Ecosystem structure and function can be maintained through many different pathways that can operate under varying conditions, that is, wide tolerances. For example, accumulation of biomass can be accomplished by a wide array of plant and animal species. The actual species that live in a given ecosystem are adapted to the abiotic and biotic environment of the system. The loss of one species, either through succession or extinction, does not destroy the ecosystem. Other species continue the flow of energy and the cycling of nutrients and materials. In other words, there is redundancy of function but not necessarily of structure.

One measure of self-organization is the amount of information that is required to predict the final outcome. Higher levels of self-organization require large amounts of information to predict the final composition. To predict what an office building will look like when finished requires the blueprint and some drawings; to predict which organisms will provide structure and function to an ecosystem at any given time is almost impossible except in general terms. Self-organization also gives ecosystems properties of robustness, persistence, the ability to self-repair, and flexibility in the face of changing environmental conditions. Because of the interactions among system components, biotic and abiotic, changes in one component can ripple through the system and change many other components.

Self-organization is visible as an ecosystem goes through successional stages. It derives from the overarching actions of natural selection and evolution through which organisms have adapted to certain physical, chemical, and biological environments over time. For example, bare rock exposed by glacial retreat will pass through a series of plant and animal communities composed of different combinations of species over time as it develops into a forest. The general progress of this succession is understood, but predicting the exact composition of each step and the duration of each step is not. The exact composition is an emergent property of the interaction between the biotic and abiotic components of the ecosystem.

This ability of self-organization is taken advantage of by ecological engineers. Ecological engineering designs work with nature and allow nature to do some of the "engineering." That is, rather than fully proscribing only one satisfactory end result, the ecological engineered design recognizes that more than one final state may meet the functional requirements of the design.

Engineering designs that ignore the self-organization properties of ecosystems require continued inputs of human-based energy and dollars (to buy materials and energy) to keep the system in the designed state (the desired, predicted outcome). Allowing nature to finalize the outcome of the design uses solar energy to organize the system and ensures some flexibility in the face of changing conditions.

Ecological engineers can take advantage of ecosystem self-organization in various ways. For example, a wetland or streambank restoration project may plant a variety of species that are water tolerant. But rather than insisting that the original mix is the best and inputting labor and energy to maintain the original composition of species, the system is allowed to mature without interference, resulting in a set of species that is most suited to the conditions at a given site. The species most able to survive and reproduce in that particular environment will spread and grow. In a stream restoration effort, material necessary to create lost habitat complexity and diversity, such as large organic debris or sediment can be provided to the system and then be distributed by natural stream forces rather than anchoring it in place. By incorporating natural process into ecological engineering designs, ecological engineers reduce the use of nonrenewable energy and nonrecyclable material input and allow the self-organization capacity of the ecosystem to determine what is most suitable in a given location using natural goods and services.

Disturbance and thresholds

Ecosystems have a history of disturbance that influences the current composition of the ecosystem. Self-organization capacity in concert with natural selection and evolution result in an ecosystem that reflects past conditions and disturbances. Some organisms are more successful in relative stable conditions; some can only compete successfully in dynamic and ever-changing conditions. Disturbances (e.g., fires, floods, tides, seasons, plate tectonics) periodically introduce forces that reset ecosystem structure at varying temporal and spatial scales. If a disturbance occurs that creates a large change in the abiotic or biotic environment, an ecosystem can cross a threshold which makes it unable to recover to its previous state. Examples include loss of soil fertility that cannot be restored, changes in water table levels that lead to desertification or wetland development, loss of a keystone species, and introduction on new diseases or species.

Human-managed systems typically lose structural and functional diversity (fewer species providing fewer goods and services) and become more spatially uniform over time, for example, agricultural fields, managed forests, urbanization. The alteration of natural disturbance cycles (e.g., fire suppression and flood control) disrupts the patch dynamics of ecosystems and generally reduces habitat complexity and thus biodiversity. As uniformity increases, resistance to disturbances decreases. For example, spatially extensive monocrops, whether mountain forests, urban trees, or agricultural crops can be destroyed by a single virulent disease vector. Monocrops tend to be genetically similar, do not have the variability to resist diseases and diseases spread rapidly to adjacent identical, susceptible plants.

This homogenization of human-managed systems highlights the differences between engineering resilience and ecological resilience. Designing for traditional engineering resilience seeks stability and permanence; systems with high engineering resilience return to a stable equilibrium point quickly after a disturbance. Ecosystems do not exist around a stationary equilibrium point. Ecological resilience is a measure of how large a disturbance an ecosystem can absorb and maintain its original structure and function. Major disturbances, whether chronic or instantaneous, such as volcanic eruptions, glacial advances or retreats, overfishing, or sea level rises and falls may cause an ecosystem to cross a threshold. The ecological resilience of ecosystems can be exceeded by a major disturbance. This typically results in a dramatic change in species composition and the start of a new self-organization process perhaps with different abiotic conditions.

Ecological engineering recognizes the stochastic nature (unpredictability) of disturbances in space and time and seeks designs that tolerate multiple states while still meeting the design purpose, thus benefiting humans and protecting the environment. Ecological engineers recognize the hubris in the thinking that ecosystems need to be managed constantly or extensively to provide goods and services. Ecological engineering designs take into account the variability in time and space of processes and species composition across the landscape. This awareness of the stochastic nature of ecosystems is vital for meeting the challenges of climate change and maintenance of ecosystem services. By including no and low-regret options in project designs that produce ecosystem services, benefits to humans can be provided irrespective of climate trajectories.

Ecological engineering recognizes the four categories of ecosystem services (supporting, provisioning, regulating, and cultural) and seeks to include such services in their designs and projects. This includes taking into consideration the concepts of natural capital in addition to standard economic analyses.

Traditional engineering design incorporates factors of safety in design parameters. Risk analysis estimates the probability of failure of the design, and energy and material are used to enable the structure to resist failure that can result in harm to humans or infrastructure. This is called fail-safe design. The risks are known and are more or less predictable. Efficiency, constancy, and predictability are guiding principles for traditional engineering. Ecological engineers recognize that over time the forces of nature can overcome any affordable design. Persistence, change, and unpredictability are hallmarks of ecological theory. Ecosystems are complex systems with many variables and risk may come more from unknown (or unrecognized) sources than from known sources. That is, the probability of occurrence of the risk is unknown or in some cases, the risk itself is unknown. For this reason, ecological engineering strives for safe-fail design, that is, when the design fails, the failure takes place such that extensive harm to humans, infrastructure, and the ecosystem is minimized. When considering design alternatives, ecological engineers choose the one that has the best worst-case outcome.

Common Steps for Ecological Engineering Design

There is no cookbook available for ecological engineering design. The emergent properties of ecosystems do not lend themselves to a constant set of variables such as exists for chemistry (periodic table of elements) or mechanics (design table properties for steel or concrete). Each setting for ecological engineering design will have a unique history and set of interactions.

Ecological engineers are aware of and take advantage of the processes that are active in natural systems. This awareness comes from a thorough understanding of ecological theories that describe the ecosystem of interest to the designer. The naturally occurring ecosystem processes are partners in design, not obstacles to overcome and dominate. Important aspects of ecosystems that need to be accounted for in design include disturbance, diversity, heterogeneity, change, and self-organization at multiple scales in space and time. Using a standard design procedure allows for the documentation of responses and allows ecological engineering to be used to test ecological theories. Importance of the following components and depth of analyses will vary by environment and design objectives.

Following the steps below provides the relevant ecological information that is needed to create an ecologically engineered design. The final design, grounded in the information gathered below, adheres to the traits listed in **Table 1** under ecological engineering.

1. Identify the biotic and abiotic factors that drive the ecosystem of interest.
   a. These factors control organisms and pathways through which energy flows and materials cycle.
   b. The design should not impair these factors.
2. Identify the types of disturbance, whether chronic or intermittent, biotic or abiotic, that are present in the system.
   a. The design should be ecologically resilient to these disturbances.
   b. The design should be safe-fail.
   c. The design should maintain spatial and temporal heterogeneity in the system.
3. Identify the goods and services being produced by the ecosystem.
   a. Production of goods and services should be maintained or enhanced.
   b. Inputs of human produced materials should not exceed assimilation capacity.
   c. Any wastes that are produced should be usable in another design.
   d. Energy needs of the design should minimize the use of nonrenewable sources.
   e. Extraction of renewable resources should be less than the rate of renewal.
4. Use the naturally occurring forces of nature to help with design and maintenance.
   a. Working at cross-purposes with nature is frustrating and expensive in the best case and disastrous and counterproductive in the worst case.
5. Recognize that implementation of any design will create some disturbance to the preexisting conditions.
   a. No design is perfect. Accurate appraisal of potential problems allows for minimization and/or mitigation of the impacts.
6. Keep complete and accurate documentation of design process, parameters, and outcome.
   a. Documentation of preexisting conditions, design process, and monitoring of outcome provides the means to improve designs in the future.

Ecological engineering designs can be applied to a variety of ecosystem problems, such as:

- Phytoremediation and wastewater treatment wetlands can be used to reduce or solve pollution problems. In this case, the design seeks to replicate or take advantage of ecosystem properties.

Table 1 Concepts and characteristics of traditional versus ecological engineering designs

Traditional engineering	*Ecological engineering*
Efficiency of function	Persistence of function
Seeks stability	Accepts inevitability of change
Resists disturbance	Absorbs and recovers from disturbance
One equilibrium point	Multiple, nonstable equilibria
Redundancy of structure	Redundancy of function
Single acceptable outcome	More than one acceptable outcome
Spatially and temporally uniform	Spatially and temporally diverse
Tries to control natural forces	Works with natural forces
Predictability	Unpredictability
Fail-safe	Safe-fail
Tight tolerances	Wide tolerances
Heavy reliance on nonrenewable energy and material	Maximum use of renewable energy and energy and material
Rigid boundaries and edges	Flexible boundaries and edges
Unconcerned by production of waste materials from the design	Minimizes production of waste and seeks to use the waste in another design or process
Deductive	Inductive
Engineering resilience	Ecological resilience

- Forest restoration or wetland mitigation can be used to reduce resource degradation problems. Here the design seeks to copy or reproduce ecosystem structure and function and to provide ecosystem services.
- Mine land restoration or lake restoration seeks to hasten the recovery of an ecosystem following major disturbance. Here the design seeks to uses the self-organization properties of ecosystems to recreate the predisturbance system. The design is mindful that some disturbances, such as fires and hurricanes are natural, and ecosystems have recovered from them before human management or intervention was possible or even considered.
- Extraction or use of ecosystem goods and services are done such that production of those goods and services is not decreased. Here the design seeks to meet sustainability criteria and decrease the use of nonrenewable energy.
- Coastal and riverine projects involved in adaptation to climate change and other human activities seek to maintain ecosystem services and natural capital.

Ecological Engineering: Overview

SE Jørgensen, Copenhagen University, Copenhagen, Denmark

What Is Ecological Engineering?

The most used definition of ecological engineering employs the following formulation: ecological engineering is defined as the design of sustainable natural and artificial ecosystems that integrate human society with its natural environment for the benefit of both. It requires, on the one hand, that we understand nature and ensure a sustainable development of natural resources and ecosystems and, on the other hand, that we make use (but not abuse) of natural resources to the benefit of the human society. Thus, our inevitable interactions with nature must be made under the comprehensive consideration of the sustainability and balance of nature.

H. T. Odum was among the first to define ecological engineering as the ``environmental manipulation by man using small amounts of supplementary energy to control systems in which the main energy drives are coming from natural sources.'' Odum further developed the concept of ecological engineering as follows: ecological engineering, the engineering of new ecosystems designs, is a field that uses systems that are mainly self-organizing.

Straskraba has defined ecological engineering (or ecotechnology, as he called it) more broadly, as being the use of technological means for ecosystem management, based on a deep ecological understanding, in order to minimize the costs of measures and their harm to the environment. For the purposes of this report, ecological engineering and ecotechnology may be considered synonymous.

Ecological engineering is engineering, in the sense that it involves the design of man-made or natural ecosystems or parts of ecosystems. Like all engineering disciplines, it is based on basic science, in this case ecology and systems ecology. The biological species are the components applied in ecological engineering. Thus, ecological engineering represents therefore a clear application of ecosystem theory.

Ecotechnic is another often applied word but one that also encompasses the development of all types of `soft' technology applied in society, in addition to ecotechnology or ecological engineering. These types of technology are often based on ecological principles (e.g., all types of cleaner technology), particularly if they are applied to solve an environmental problem. The use of ecological principles in the development of technology is denoted as industrial ecology.

Recently, UNEP and UNESCO have introduced two other terms relevant to this discussion:

1. *Phytoremediation*. The use of plants in ecological engineering (e.g., using wetlands to treat wastewater pollutants, or for removing toxic substance from contaminated soil).
2. *Ecohydrology*. The use of a combination of ecological and hydrological principles to obtain ecologically sound environmental management.

Both phytoremidiation and ecohydrology are subdisciplines within the discipline ecological engineering or ecotechnology, which is an often used synonym for ecological engineering.

Further, ecological engineering should not be confused with bioengineering or biotechnology. Biotechnology involves the manipulation of the genetic structure of cells to produce new organisms capable of performing certain functions. Ecotechnology does not involve manipulation at the genetic level, but rather at several steps higher in the ecological hierarchy. The manipulation takes place on an assemblage of species and/or their abiotic environment, as a self-designing system that can adapt to changes brought about by outside forces, whether controlled by humans or by natural forcing functions.

Ecological engineering is also not the same thing as environmental engineering, the latter is involved in cleaning processes to prevent pollution problems. It involves the use of settling tanks, filters, scrubbers, and man-made components that have nothing to do with the biological and ecological components applied in ecological engineering, even though the use of environmental engineering is directed to reducing man-made forcing functions on ecosystems. As mentioned above, the term ecotechnic may be considered to include a part of environmental technology, namely the part based on ecological principles such as recirculation. The tool boxes of ecological engineering and environmental engineering are completely different; where ecological engineering uses ecosystems, communities, organisms and their immediate abiotic environment, and environmental engineering uses chemical and biotechnological unit processes such as filtration, precipitation, and biological decomposition by aeration.

All applications of technologies are based on quantification. Because ecosystems are very complex systems, the quantification of their reactions to impacts or manipulations is also complex. Fortunately, ecological modeling represents a well-developed tool to survey ecosystems, their reactions, and the linkage of their components. Ecological modeling is able to synthesize our knowledge about an ecosystem, making it possible to quantify, to a certain degree, any changes in ecosystems resulting from the use of both environmental engineering and ecological engineering. Ecological engineering may also be used directly to design

 doi:10.1016/B978-0-444-63768-0.00042-1

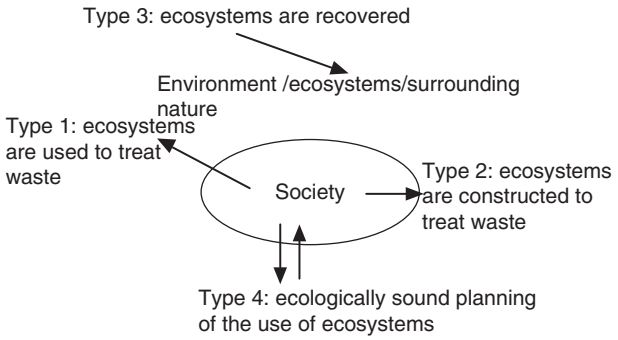

Fig. 1 An illustration of the four types of ecological engineering. Reproduced by permission of Elsevier.

constructed ecosystems. Consequently, ecological modeling and ecological engineering are two closely cooperating fields. Research in ecological engineering was originally addressed in the *Journal of Ecological Modelling*, which was initially named *Ecological Modelling – International Journal on Ecological Modelling and Engineering and Systems Ecology* to emphasize the close relationship between the three fields of ecological modeling, ecological engineering, and systems ecology. *Ecological Engineering* was launched as an independent journal in 1992, with the name of *Ecological Modelling* being changed to *Ecological Modelling – An International Journal on Ecological Modelling and Systems Ecology*. At the same time, the journal *Ecological Engineering* has successfully covered the field of ecological engineering, which has grown rapidly during the 1990s due to increasing acknowledgment of the need to use technologies other than environmental technology in efforts to solve pollution problems. This development does not imply that ecological modeling and ecological engineering are moving in different directions. On the contrary, ecological engineering has increasingly been using models to perform designs of constructed ecosystems, or to quantify the results of applying specific ecological engineering methods for comparison to alternative, applicable methods.

In addition, the relationship between ecological engineering and systems ecology is very clear. Ecological principles are used widely in practical application of ecological engineering methods. Mitsch and Jørgensen have provided 19 principles that can be used as a checklist to assess if an ecological engineering project follows ecological principles, that is, to determine if a project is ecologically sound.

Classification of Ecotechnology

Ecological engineering may be based on one or more of the following four classes of ecotechnology:

1. Ecosystems are used to reduce or solve a pollution problem that otherwise would be (more) harmful to other ecosystems. A typical example is the use of wetlands for wastewater treatment.
2. Ecosystems are imitated or copied to reduce or solve a pollution problem, leading to constructed ecosystems. Examples are fishponds and constructed wetlands for treating wastewater or diffuse pollution sources.
3. The recovery of ecosystems after significant disturbances. Examples are coal mine reclamation and restoration of lakes and rivers.
4. The use of ecosystems for the benefit of humanity without destroying the ecological balance (i.e., the utilization of ecosystems on an ecologically sound basis). Typical examples are the use of integrated agriculture and development of organic agriculture; this type of ecotechnology finds wide application in the ecological management of renewable resources.

The rationale behind these four classes of ecotechnology is illustrated in **Fig. 1**. It is noted that ecotechnology or ecological engineering operates in the environment and its ecosystems. As already mentioned, it is this domain that ecological engineering employs as its toolbox.

Illustrative examples of all four classes of ecological engineering may be found in situations where ecological engineering is applied to replace environmental engineering, mainly because the ecological engineering methods offer an ecologically more-acceptable solution, and where ecological engineering is the only method that can offer a proper solution to a problem. Examples are provided in **Table 1**,where alternative environmental technological solutions are also indicated. This does not imply that ecological engineering can replace environmental engineering. On the contrary, the two technologies should work hand-in-hand to solve environmental management problems, better than they could do if applied individually. This is illustrated in type 1 ecological engineering (application of ecosystems to reduce or solve pollution problems) by wetlands utilized to reduce diffuse nutrient loads to lakes. This problem cannot be solved by environmental technology. Sludge treatment can be solved by environmental technology, namely by incineration. However, the ecological engineering solution (i.e., sludge disposal on agricultural land, which involves utilization of the organic material and nutrients in the sludge) is a much sounder method from an ecological perspective. **Fig. 2** gives an example, where both ecological engineering and environmental technology are applied to solve an environmental problem.

Table 1 Ecological engineering examples (alternative environmental engineering methods are given)

Type of ecological engineering	Example of ecological engineering		
	Without environmental eng. alternative	With environmental eng. alternative	Environment engineering alternative
1	Wetlands utilized to reduce diffuse pollution	Sludge disposal on agricultural land	Sludge incineration
2	Constructed wetland to reduce diffuse pollution	Root zone plant	Traditional wastewater treatment
3	Recovery of lakes	Recovery of contaminated land *in situ*	Transport and treatment of contaminated soil
4	Agroforestry	Ecologically sound planning of harvest rates of resources	

Reproduced by permission of Elsevier.

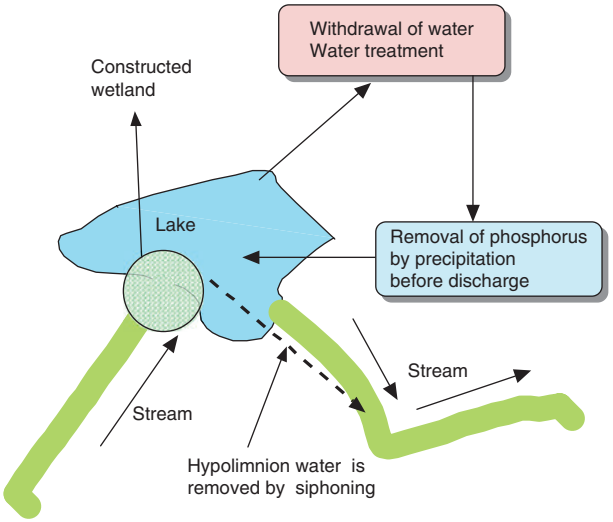

Fig. 2 Control of lake eutrophication, illustrating a combination of (1) chemical precipitation for phosphorus removal from wastewater (environmental technology); (2) a wetland to remove nutrients from the inflow (type 1 or 2 ecotechnology); and (3) siphoning of nutrient-rich hypolimnetic water downstream (type 3 ecotechnology). The eutrophication abatement may also be combined in this case with biomanipulation. Reproduced by permission of Elsevier.

The application of constructed wetlands to cope with diffuse pollution is a good example of type 2 ecological engineering. Again, this problem cannot be solved by environmental technology. The application of root zone plants for treating small quantities of wastewater is an example of type 2 ecological engineering, in which the environmental engineering alternative (a mechanical–biological–chemical treatment) cannot compete, when the waste volume is low and/or the area costs are moderate, mainly because it would involve excessive costs, relative to the quantity of wastewater (sewage system, pumping stations, etc.). A solution requiring fewer resources always will be a more ecologically sound solution.

Although recovery of land contaminated by toxic chemicals is possible using environmental technology, it will require transportation of the soil to a soil treatment plant, where biological biodegradation of the contaminants would take place. Ecological engineering will propose an *in situ* treatment with adapted microorganisms or plants. The latter method will be much more cost-effective, and the pollution related to transporting the soil will be omitted. Restoration of lakes by biomanipulation, installation of an impoundment, sediment removal or coverage, siphoning of hypolimnetic water (rich in nutrients) downstream, or by several other proposed ecological engineering techniques are examples of type 3 ecological engineering. It is difficult to obtain the same results using environmental engineering, because this requires activities in the lake and/or the vicinity of the lake.

Type 4 ecological engineering is based, to a great extent, on pollution prevention by utilization of ecosystems on an ecologically sound basis. Although it is very difficult to find environmental engineering alternatives in this case, it is clear that a prudent harvest rate of renewable resources (whether, e.g., timber or fish) is the best long-term strategy from an ecological and economic perspective. Ecologically sound landscape planning is another example of the use of type 4 ecological engineering.

Constructed subsurface wetlands may also be used to treat dairy farm wastewater, mine water pollutants, textile wastewater, and pulp mill wastewater.

Forestry Management

HH Shugart, University of Virginia, Charlottesville, VA, USA

Introduction

Trees are very long-lived organisms with high potential birth rates. Thus, estimating the basic birth and death parameters of tree populations is intrinsically difficult over the time duration of most ecological studies. The sizes of trees from seedling to mature tree vary over five orders of magnitude. Trees grow large enough to alter aspects of their environment as they mature. This individual–environment feedback is not usually included in traditional ecological population models. Tree interactions obtaining essential resources of light, water, and nutrients involve tree geometry in vertically for light, spatially for nutrients and water, and volumetrically for interactions among tree crowns such as crown pruning (where the branches of a tree abrade the buds from limbs of neighbor trees and change the shapes of competing trees). These geometrical aspects of tree populations are omitted in the mathematical structures of most ecological population models which, at least until recently, considered only the time dimension. Tree populations represent a modeling departure from traditional population models. Significantly, forestry models from their origins have always attempted to predict a combined response of the sizes of trees and the number of trees on a given area.

Tree population models have deep historical roots that are often not appreciated by modern population ecologists, perhaps in part because the origins of many of these forestry-based approaches are in applied fields and are focused on practical, regional results rather than the development of a general theory. For this reason, it is useful to discuss forestry models from their beginnings through the evolution to the modern approaches.

Yield Tables: Empirical Forestry Models

Throughout Europe in medieval times there was a substantial clearing of forests followed by even more extensive deforestation regionally. With the progressive reduction of forests, class conflicts over the products of forests intensified and this manifested itself in laws against poaching of animals, thieving of wood, and proscriptions against public use of forests, in general. In the mid-eighteenth century, a forest management concept called `Nachhalttigkeit' or sustainability was developed by the Germans. From about 1800, this new forestry practice spread over Europe, particularly Northern Europe. This was essentially a transition from the earlier, exploitive extraction of materials from forests to a more `trees as a crop' agricultural management of forest tracts. Nachhaltigkeit involved detailed determination of how to best manage forests to produce wood and other goods. Essential to this objective was manipulating density by spacing trees on a given site, either by planting trees or by thinning a naturally regenerated stand of trees following a timber harvest or a natural disturbance. Additionally, one needed to determine how long one should wait before harvesting a stand of trees and then planting a new stand. This spacing/length-of-rotation problem had long been solved for crop plants through experimentation and observation. To produce trees as long-lived crops, elaborate long-term data collection started on the height; size in diameter; amount of wood; and size of crowns in forest stands of different densities at sites with different environmental conditions. Eventually, a forest modeling concept called the `yield table' approach developed and became the signature of modern forestry (see **Fig. 1**).

Nowadays, some of the historical forest data sets used in yield tables have grown to 250+ years of continual record. It was found that on a given kind of site (same soils, same rainfall, etc.) trees grew to the same height at a given age, regardless of density of trees. At low densities, one might find trees with large diameters and crowns and on an equivalent high-density location the trees would have small diameters and crowns – but the heights of the trees would be the same in both cases. In a yield table, decades and sometimes centuries of forest stand data are arranged by the height the trees at a given location reach at a given age, usually the typical age of tree harvest. The tree height at this standard age is called a `site index' and is used to signify the overall quality of a location for growing trees. Site index is clearly defined in terms of the basic data that goes into a yield table and it can be directly determined by measuring the heights of trees on even-aged stands at the reference age.

Associating site index with actual plots of land is a learned skill and an art at the same time. A capable site surveyor can judge site index by reconnaissance of land in a particular region and can make a good wage practicing this trade. Along with such arcane practices as axe-throwing, log-rolling, and tree-felling, forestry schools have regular intercollegiate competitions of judging site indices among their students as part of `Forestry Field Day' celebrations. At the edge of virtually all universities with a college of forestry, one will find plat of trees planted at different densities for field teaching on the calibration of yield tables. The yield table concept is the quantitative basis of modern forestry.

 doi:10.1016/B978-0-444-63768-0.00670-3

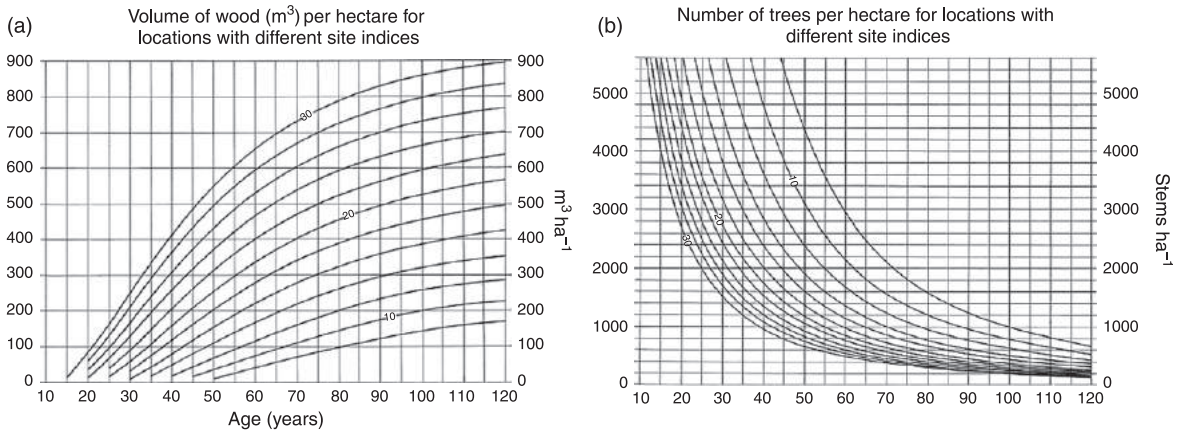

Fig. 1 Sections of stand yield tables for Switzerland. The site index is the height of the dominant trees in even-aged stands of spruce (*Picea abies*) at an age of 50 years. Note that this data set covers 120 years of measurement. The amount of wood (a) in a forests increases with age and slows in its rate of increase over time. Sites with higher site indices have more wood at any given time. The thinning of trees (due to suppressed trees being eliminated by more vigorously growing taller trees) slows over time (b) but is stronger in locations with higher site indices. Reproduced from Erragstafeln: Fichte. Eidgenössische Anstalt für das forstliche Versuchswesen, Birmensdorf ZH, with permission from Swiss National Forest Inventory.

Beyond Yield Tables

In the twentieth century, yield table methodologies had become the standard for forestry applications and were essential part to any forestry curriculum. Considerable effort went into enriching the data sets and perfecting the basic concepts of yield tables for forestry production. For example, since the product of a forest plantation is not always wood but is often boards of a given dimension, allowing a forest to grow more wood (as predicted by a yield table) does not necessarily produce more boards. As another example, under certain spacing, the trunks of trees have different degrees of taper which also affect the lengths of standard boards to be sawn from the harvested wood. These sorts of complexities were determined and calibrated into the predictions from yield tables.

In the mid- to late-1950s several developments conspired to generate difficulties for yield table projections. The dependency on extensive long-term data sets to calibrate yield tables manifested itself as a problem. Some of the long data sets in Europe were initiated before the end of the so-called `Little Ice Age' around the 1850s and thus were collected over intervals of significant climate applications. The warmer and often dryer conditions that prevailed in the decades of 1930s and the 1950s represented a similar problem for shorter calibrations of other yield tables. The fundamental assumption in yield tables, that the expected height of a canopy tree in a stand of a reference age could be used as a constant to encapsulate the quality of a site for growing trees, was undermined by these climate variations.

At the same time and particularly in the US, foresters were experimenting with developments that would change the growth rates of trees – using genetic selection to develop faster-growing commercial tree species or fertilizing forest for faster growth. Increased air pollutants and changes in the chemistry of rainfall (`acid rain') were seen as potentially slowing tree growth. The possibility of metrification in the US meant that the complex calculations to calibrate merchantable-dimension boards in English units would need to be recalibrated for metric units. In the western states of the US, the end of harvest of previously uncut forests of Douglas fir (*Pseudotsuga menziesii*) and the interests in developing plantation forestry for this species poised the immediate question of how does one develop a yield table for a condition for which there is no long-term data record. Japanese foresters faced a similar problem with their plantation forestry practice at home and in foreign countries. In tropical and subtropical locations, where the forests have relatively little softwood timber, planting of exotic North American species, notably Monterey pine, *Pinus radiata*, gave local foresters a need to develop planting strategies with no data to calibrate yield tables. Worldwide, the realization that forests do more than just produce wood called for a simultaneous management of forests for water quality, wildlife, flood control, landslide protection, and recreation, all implied a broader approach than the wood production emphasis of yield table forestry. This soon was seen as need for a better capability to manage complex, natural forests with a mixture of tree ages and species. There was a considerable impetus to develop new approaches to projecting forest dynamics beyond the yield table approach.

In the late 1950s and early 1960s, the need for forest prediction beyond the capabilities of empirical yield tables led to a proliferation of forest modeling approaches, notably in the US and Japan. This modeling revolution in the late 1960s and 1970s occurred independently at different locations with different emphases on theory development, computer simulation, and advanced statistics. These developments, intended to re-analyze the intensive data archives behind the yield tables and extend insights of a century of forestry empirical-model predictions, coincided with a fascination with the potential for high-speed computers. Many of the resulting models depend strongly on digital computation and have become more widespread as the power of computers has increased over the past 50 years.

Each of these different foci on the modeling of forests contributed different points of view as to how to predict the dynamics of forest ecosystems and are discussed in the sections below. In the case of forestry models, three significant intellectual centers for this development were

1. a Japanese group of forest scientists who emphasized the theoretical underpinnings for forest dynamics;
2. one US center focused on the statistics needed to parametrize coupled differential equations for biomass, number of trees, and size of the average tree in forest plantations. This group was strongly oriented to understand the dynamics of Loblolly pine (*Pinus teada*) plantations;
3. a second US group developing digital computer simulation models that incorporated the three-dimensional geometry of interactions among growing trees, initially emphasizing Douglas fir and spruce forests. The approach was to develop what is referred to today as individual-based or agent-based models.

Each of these groups produced different insights on the population dynamics of forests and has evolved in relative independence until the present day.

At about the same time that new alternatives to yield tables were being developed in forestry, ecologists were developing a parallel interest in the use of dynamic models to predict forest dynamics. This culminated in a major international research program called the International Biological Programme (IBP) intended to foster a comparative understanding of ecosystem dynamics across the globe. The focus was on the productivity and element processing of natural ecosystems and constitutes a fourth independent thrust to develop forest ecosystem models. The models developed in this program tended to emphasize fundamental processes (productivity, decomposition, element uptake by ecosystems). These models represent a relatively significant departure for the forestry modeling tradition in assuming these processes can be represented over a homogeneous forested area. The IBP models are in many cases the predecessors of ecological models currently applied to compute the carbon dynamics to predict the responses of the global carbon cycle.

Japanese Theoretical Approaches to Forest Population Modeling

While the German traditional approach to yield table development were based on the normalization of data based on tree heights, Japanese foresters focused on the statistical interrelations among all of the dimensions of trees. They developed a geometrical theory for the dynamics of forest stands using allometric equations. These equations express one measurable dimension of an organism as another dimension raised to a fractional power times a constant ($x_1 = cx_2^z$, where x_1 and x_2 are different measurements of a tree and c and z are constants). At the beginning of the twentieth century, the British mathematical ecologist, D'Arcy Wentworth Thompson, had written extensively about these and other more complex underlying mathematical formulations describing the shapes of plants and animals. The Japanese compilation of these data for trees was extensive. Significantly, K. Shinozaki and his colleagues developed a basic theory (in 1964) to explain some of these regularities in form.

Shinozaki's `pipe model' posited that a tree is a great collection of pipes – notably the xylem cells, tubes that transmit water from roots through the trunks and branches to the leaves. In the pipe model, the cross-sectional area of the tree's transport systems (the `pipes') should be conserved at different levels of the tree. A given area of leaves required a certain cross-sectional area of xylem tubes through all the parts of the tree that supplied it. As a tree grows taller, more and more length of pipes is needed to provide the same cross-sectional area. Thus, the cost to the tree of supporting a given area of canopy leaves (requiring a given cross-sectional area of pipes) increases as the tree grows. The exponent in an allometric equation typically has values near one-third when relating a linear dimension such as tree's diameter to volume-related measurements such as tree biomass and a value near two-thirds when relating area measurements such as cross-sectional area of a tree trunk to tree mass.

In 1963, the Japanese forester, K. Yoda, and several of his colleagues extended the classic allometric concept for individual organisms to entire forest stands. The motivation was to investigate one of the basic premises in yield tables – the regularities in the average size of trees in even-aged forest stands as a function of the density of trees. In self-thinning stands (stands in which some trees die from competition as other, more vigorous trees grow), the average biomass of a tree is a constant times the density of trees raised to the $-3/2$ power (Fig. 2). This $-3/2$ power law or self-thinning law has been found in a wide variety of ecosystems in which organisms (corals, grasses, trees) compete for space. Its application is restricted to even-aged systems that have been initiated with a competing cohort of individuals.

Models Coupling Mass and Numbers Equations for Forest Dynamics

At about the same time that foresters in Japan were developing their theoretical concepts, J. L. Clutter and a group of colleagues and students at the University of Georgia were developing an alternative approach with the same underlying concept as that of the Japanese–connecting the size of an average tree to the number of trees in an even-aged forest stand. The Georgian approach was to conceive stand dynamics as being modeled by two differential or difference equations, one equation for the change of numbers over time and the other for the change in the size of the average tree over time. These two equations were coupled to one another by statistically estimated terms. For example, if the weaker trees that die as the stand trees are smaller than average, then tree death increases the average tree size and a part of the average-size equation would have a term that expresses this effect. The terms in each equation that coupled numbers to size (and vice versa) were estimated statistically from the same sort of data that is used in yield

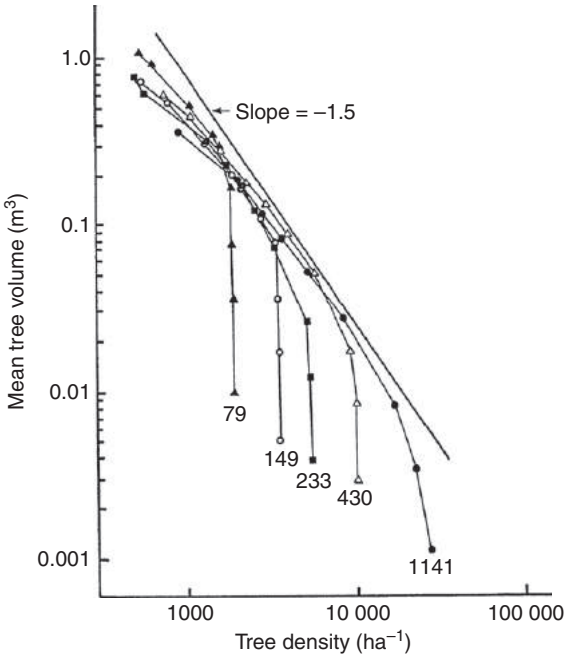

Fig. 2 An example of a $-3/2$ law stand-thinning concept. Forest stands planted at different densities converge to a limit described by a line with a slope of $-3/2$ (or -1.5). Data are for Loblolly pine plantations with different initial planting densities (79 trees ha^{-1}; 149 trees ha^{-1}; 233 trees ha^{-1}; 430 trees ha^{-1}; 1141 trees ha^{-1}). The points represent stand inventory starting in 1935 when the experimental forest was established at the Duke University Experimental Forest near Durham, New Hampshire. As trees increase in size, numbers are reduced in these even-aged stands. Reproduced from Peet, R.K., Christensen, N.L., 1987. Competition and tree death. BioScience 37, 586–595, with permission from American Institute of Biological Science.

tables in some cases. In other cases, the need for information on how to couple the number and mass equations suggested new experiments or new data collections. The advantage of the method was that if genetics or forest fertilization made the trees grow faster, this effect could be directly added to the average tree mass equation. The estimation of the parameters in the coupled equations could be improved as more field data were obtained. Thus, the models were expected to improve over time.

Today, this approach and its descendents dominate plantation forestry, particularly for Loblolly pine (*Pinus taeda*), the principal commercial tree species in the US. The method works best on forests in which the trees do not vary greatly from one another in size (hence, the average tree does not have large associated variability).

Individual-Based Forest Models

The power of digital computation in the middle of the 1960s on what today would be considered primitive computers, inspired the development of a new class of models that simulated the behavior of large complex systems by modeling the dynamics of the individuals in the systems. These included models of forests based on the changes in each individual tree in a simulated forest stand. In these models two implicit assumptions associated with traditional ecological population modeling are not necessary:

1. The assumption that the unique features of individuals are sufficiently unimportant to the degree that individuals are assumed to be identical. This allows the simulation of the numbers of individuals in the population without consideration of sizes or ages of the members of the populations.
2. The assumption that the population is `perfectly mixed' so that there are no local spatial interactions of any important magnitude.

Individual-based models of forests spring from a rejection of these assumptions. Trees vary greatly in size over their life span. Trees are sessile (so that spatial location matters and every individual in a population does not affect all the other members). This may be one of the reasons that tree-based forest models are among the earliest and most widely elaborated of the individual-based genre of models.

These models were developed by quantitatively oriented foresters in the mid-1960s and focused strongly on production forestry. The earliest such model was developed by R. M. Newnham for even-aged Douglas fir forests. This was followed by similar developments at several schools of forestry in North America. These models were implemented on a digital computer programmed to alter the sizes of trees on a map of the positions of each tree in a forest. When a tree died it was erased from the computer map. Three-dimensional spatial interactions among individual trees were explicitly represented and these initial models are as complex and as detailed as their descendants today.

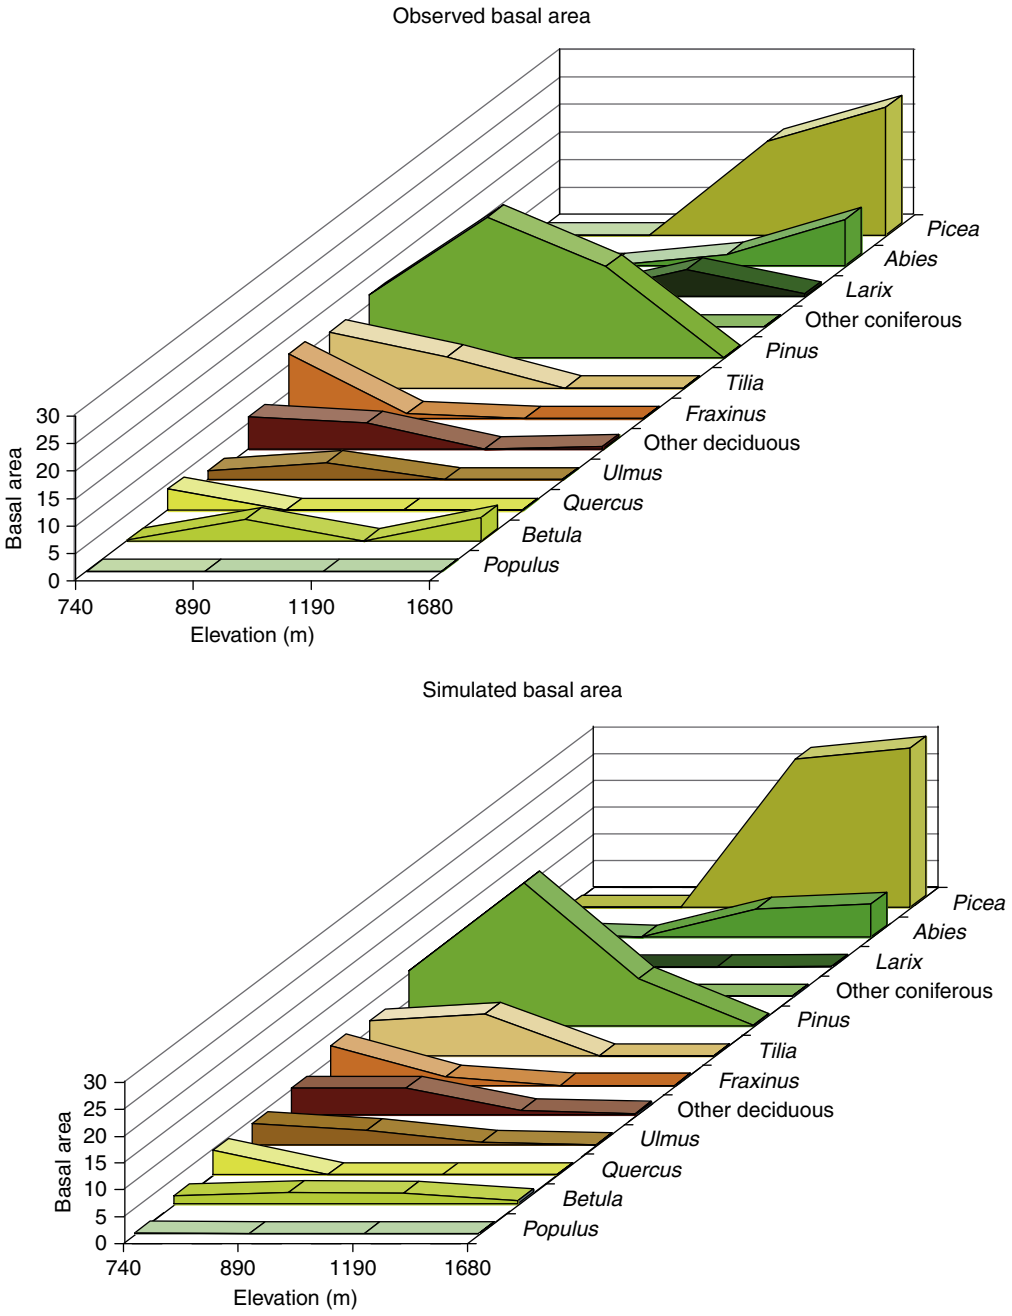

Fig. 3 A comparison of observed and simulated basal area (m^2 ha^{-1}) at four elevations (740, 890, 1190, and 1680 m) along the North Slope of Changbai Mountain (42.2° N, 128.0° E), Northeastern China using the gap model, FAREAST. In this simulation the basal area (m^2 of the sum of stem cross-sections of living trees per ha of forest) measure on the mountain at different elevations is compared to the forest vegetation simulated by the FAREAST gap model for these elevations. Such a model test provides insight in the capability of the model to simulate forest composition expected for different climate conditions. Modified from Yan, X., Shugart, H.H., 2005. A forest gap model to simulate dynamics and patterns of Eastern Eurasian forests. Journal of Biogeography 32, 1641–1648.

These dynamic mapping techniques initially were applied to even-aged plantations but applications in more complex forests soon followed. After these first modeling efforts, individual-based tree models tended to feature simplifications of these initial models. The early individual-tree based simulators took what was known from yield tables and other data sets and developed a more flexible, quantitative methodology for prediction. One significant simplification of this class of models was to simulate only the vertical (shading) relations on a small plot dominated by a single large canopy tree. The resultant `gap models' found wide application in forest ecology of natural, mixed-aged, and mixed-species stands.

Gap models feature relatively simple protocols for estimating the model parameters and synthesize information on the performance of individual trees (growth rates, establishment requirements, and height/diameter relations) to directly estimate model parameters. The simple rules for interactions among individuals (e.g., shading and competition for limiting resources) and equally simple rules for birth, death, and growth of individuals in these models have both positive and negative consequences. The positive aspects largely relate to the ease of estimating model parameters for a large number of species. The negative aspects relate to the lack of physiological mechanism in the description of growth and environmental response. Much of the current research in the subsequent development of gap models relates to overcoming these limitations (**Fig. 3**).

Future Developments

The impetus of the need to predict future forest condition in the face of change that has driven the development of model forestry models should be an even stronger force in the future. Concerns over the responses of forests to climate change have increased the world interest in predicting future forests. Our rather poor appreciation of the potential direct effects of CO_2 in the atmosphere (effects involving the rates of photosynthesis and other plant functions) in addition to the concern over greenhouse-gas-generated climate change will continue to create a need to scale up basic plant physiology to longer timescale and larger spatial-scale consequences. Today's research challenges involve the incorporation of these novel effects and the rich problem of designing ways to test our model predictions. An important application of gap models in this direction was developed by Moorcroft and several of his colleagues. They formulated a gap model for Amazonian rainforest using a postulated relationship between growth rate, photosynthesis, and wood density. This gap model was used to obtain the parameters for a statistical model of the size distribution of trees across the Amazon Basin (based on an extension of the Japanese approaches to forest dynamics modeling pioneered by Kohyama in 1993). This was then driven by a photosynthesis/production model to incorporate the effects of temperature and moisture. The resultant model called the ecosystem demography (ED) model represents a synthesis of the Japanese and individual-based approaches to forestry modeling with process models of the sort initially championed in the IBP.

Integrated Farming Systems

David W Archer, Jose G Franco, Jonathan J Halvorson, and Krishna P Pokharel, USDA Agricultural Research Service, Northern Great Plains Research Laboratory, Mandan, ND, Unites States

Glossary

Alley cropping Planting rows of trees or shrubs with grain or forage crops planted between the tree rows. Alley cropping is sometimes called hedgerow intercropping, and is a type of intercropping with larger spaces between rows that allows for managing the crops separately.

Cover crop A crop planted during a fallow period to provide ecosystem benefits. These may include soil cover to reduce soil erosion, inputs to soil organic carbon, weed suppression, nutrient retention, and pollinator benefits.

Crop rotation A sequence of crops on a field in succeeding growing seasons or years, often in a consistent and repeating pattern. For, example in a corn-soybean rotation, corn would be grown in the first year, soybean in the second year, and corn in the third year. However, in a dynamic crop rotation, crop choices may be selected each year or growing season based on environmental or economic criteria, without following a consistent pattern.

Economies of scale The cost advantages enjoyed by firms that are larger in size. Among the reasons economies of scale may occur on a farm are the ability to spread equipment and machinery costs over more units of production, use of larger equipment which reduces labor use per unit of production, and the ability to negotiate better prices on product sales and volume discounts on purchased inputs.

Economies of scope The cost advantages enjoyed by firms that have multiple enterprises. These occur through interactions among the enterprises that increase efficiency of producing and marketing multiple products rather than a single product.

Ecosystem services The direct and indirect benefits humans obtain from ecosystems. The four major categories of ecosystems services are provisioning services, supporting services, regulating services, and cultural services.

Green manure crop Plants left in the field to serve as a soil amendment. Typically these are cover crops and are often incorporated into the soil using tillage.

Intercropping Growing two or more crops in the same field at the same time. The crops are often grown in alternating rows or mixed within rows.

Mixed crop-livestock farming Integrated farming systems that include both crops and livestock. Also called integrated crop-livestock systems.

Monocropping Growing the same crop on a field every growing season or year without rotating to another crop.

Definition

Integrated farming has been defined in numerous ways, and could be envisioned as encompassing a range of agricultural systems arrayed along a continuum of possible organizational structures, and spatial and temporal scales (Bell and Moore, 2012). Some common definitions include the agricultural production system with multiple enterprises that interact in space and /or time to get benefits through a synergistic resource transfer among enterprises (Hendrickson et al., 2008). An emphasis in these systems is managing interactions so that waste from one component becomes an input for another component of the system, reducing the need for purchasing and applying expensive and potentially polluting inputs, such as fuel, fertilizers and pesticides, reducing leakages to the environment, and increasing overall production or income. The key factors in integrated farming systems are the inter-dependence among enterprises within the system, synergetic transfer of resources among enterprises and the flexibility in the system to be sustainable in the long run (Hendrickson et al., 2008; Vereijken, 1989). Integrated farming systems are often assumed to include both crop and livestock enterprises, called mixed crop-livestock farming or integrated crop-livestock systems. However, integrated farming systems may broadly include systems where only multiple crop components interact. These include crop rotational systems, use of annual and perennial cover crops, green manure crops, or intercropping to reduce the need for purchased inputs by fixing or retaining nutrients and reducing weed, disease, and pest pressures.

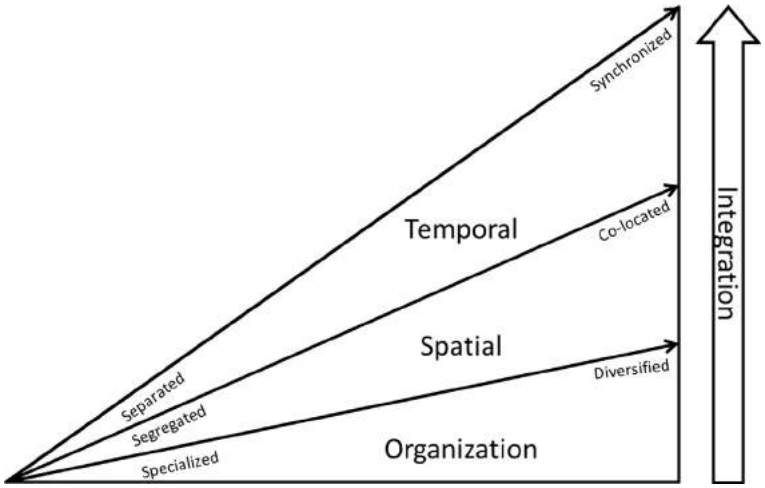

Fig. 1 Continuum of farming system integration in three interacting dimensions: temporal, spatial, and organization.

Following Bell and Moore (2012), we describe integrated farming systems using the three interacting dimensions; organization, space, and time (Fig. 1). However, we envision a continuum for each rather than discrete classes, emphasizing the wide range of systems that occur. The organization scale is represented by the number of enterprises ranging from specialized ($n = 1$) to diversified interactions ($n =$ many). The spatial integration scale is represented by the operating distance between enterprises and ranges from segregated to co-located. Within the continuum of spatial scales, two broad scale categories that have been identified are integration within a single farm unit and regional integration among multiple farms (Russelle et al., 2007). However, there are ranges of integration within these categories. The temporal integration scale refers to the separation in time between cooperating enterprises and ranges from uncoordinated independence to synchronized. Temporal separation includes sequencing of enterprises that can occur over multiple years or even decades, also known as phase farming. Sequencing enterprises also includes the traditional idea of crop rotation, with different crops grown each cropping season or year. With synchronized enterprises, multiple enterprises occupy the same unit of land at the same time, or within the same growing season. For example, using grazing animals within a growing crop, or grazing crop residues after grain crop harvest. In this representation, the most closely integrated farms are those with many enterprises that are co-located and synchronized temporally. Two additional integration dimensions of ownership and management have also been described (Sumberg, 2003), where ownership describes the degree to which assets are in the hands of a single entity, and management describes the degree to which management control is in the hands of a single entity. Integration tends to decrease when assets or management control are distributed across multiple entities. Informal integration among multiple farms or more organized farm cooperatives are instances where integration can cross multiple ownership and management entities. Contracts between specialist crop and livestock producers for the transfer of manures and, to a lesser extent, feed can be a mechanism to increase the adoption rate of integrated farming (Wilkins, 2008).

History

Evidence for the development of agriculture, including both crop and livestock domestication, has been uncovered in various parts of the world dating back some 10–12 thousand years, and has been termed the "Neolithic Revolution". The gradual and sporadic evolution from reliance on nomadic hunting and gathering to practices that promoted greater food security is thought to have been influenced by several factors including environmental limitations/opportunities or socio-economic drivers. Larger and more dependable supplies of food together with their requisite investments of time and labor ultimately resulted in the development of permanent settlements, higher population growth with concomitant increases in societal complexity, and the emergence of new technology. At some point there was a transition from coincidental husbandry of animals dependent on natural resources (e.g. pasture) to purposeful integration of animals and crops such that temporal, spatial and organizational synergies between under-utilized resources or waste products such as crop residues and animal manure were realized (Hilimire, 2011).

In integrated farming systems of the past, animals were used directly for food or to provide other services such as power (draught animals) or transportation (horses). In addition, animals were employed indirectly to provide services such as weed and pest control, fertilization, or pollination; or food items such as milk, eggs or honey. Animals were also a source of materials such as manure or leather that could be sold directly or converted to a value-add product, returning cash to the enterprise (Devendra and Thomas, 2002). The emergence of new technologies, along with the availability of abundant and cheap natural resources, characterized the industrial revolution of the18th and 19th centuries. Important technologies that led to changes in agriculture included mechanical transportation and power technologies. A particular watershed development was the development and

adoption of the tractor in the 1920s that heralded a decline in the use of animals for farm labor (Hilimire, 2011). This reduced the need for individual farms to raise both livestock and crops, and reduced the need for production of forage crops. Transportation technologies also allowed for regional specialization in agricultural production as goods could be cheaply transported over larger distances. Additional technological developments included synthetic fertilizers and pesticides. These further reduced the need for individual farms to raise both livestock and crops, and reduced the need for crop rotations and legumes for nitrogen fixation, as fertilizers could be used to meet crop nutrient needs, and pesticides could be used to manage weed and insect pests. Continued technological developments, including the development of high yielding, pest-resistant, and herbicide tolerant crops further contributed to feasibility and desirability of specialized and intensified agricultural practices that accompanied global patterns of development and have come to be termed "conventional".

The resultant patterns of increasing specialization and decreasing integrated mixed farming systems have varied widely, perhaps reflecting transitions between alternative sets of divergent competing paradigms that are thought to define and differentiate conventional from non-conventional or "alternative: agriculture (Beus and Dunlap, 1990). Although many of the methods and approaches characteristic of conventional agriculture are of ancient origin (Merrill, 1983), conventional agriculture has come to be associated with intensively managed, specialized management systems that evolved primarily in an attempt to increase production efficiency and economic returns. Often, the goals of increasing production or reducing the risk of crop failure were achieved by focusing management efforts on a single or just a few factors selected to produce the greatest increases in crop growth or yield. Emphasis on increasing productivity through management of a critical limiting resource such as water or nitrogen, guided the development of management strategies and technology, and resulted in significant increases in productivity, but did so at the expense of other ecosystem services. Ecosystem services can be classified into four major categories; provisioning, regulating, supporting, or cultural services and are those indirect and direct benefits to humans obtained from ecosystems (Millennium Ecosystem Assessment, 2005). For this discussion we focus on provisioning services such as food, forage, fiber and fuel; supporting services such as biodiversity, soil fertility and nutrient cycling; and regulating services such as habitat for wildlife, insects, and pollinators, and the regulation of water quality, greenhouse gas emissions, carbon sequestration, and soil loss due to erosion. Primary focus on management practices that focused on provisioning, and were highly responsive to market demand and other economic pressures, favored economies of scale and tend to favor specialize farming systems (Peyraud et al., 2014).

Organic farms are examples of farms that are typically integrated, with producers utilizing crop rotations, cover crops, and integration of crops and livestock to eliminate the need for synthetic fertilizers and pesticides. Organic farming has increased steadily in the U.S. over the last 25 years. This is associated with increased demand for organic products and resulting persistent price premiums for organic crops that improve the profitability of organic systems. Even among farms that are not certified organic, there has been resurgence in interest in integrated farming in the U.S. This is reflected in recent interest and emphasis on soil health, and practices that can build soil health, such as reduced tillage and diversified crop rotations, with a particular emphasis on the use of cover crops. Increased use of cover crops has encouraged producers to consider bringing livestock to farms that have specialized in crop production only.

Drivers

Several types of drivers influence the adoption of integrated farming systems including economic, environmental, and social (Hendrickson et al., 2008). Economic drivers include production complementarities, risk, and management requirements.

Integrated farming systems have economic benefits through economies of scope. Economies of scope occur when it is cheaper to produce two or more products simultaneously than producing them separately. Integrated crop-livestock systems reduce production costs due to complementarities in production such as use of grain screenings or crop residues for animal feed and subsequent application of livestock manure to land as fertilizer. The benefits of economies of scope tend to be more pronounced for small farms than for large farms, so there are stronger incentives for integration in small farms.

Farmers are generally risk averse and favor practices that reduce risk exposure. Integrated farming systems may reduce economic risk through diversification of production across multiple enterprises, when economic returns for these enterprises are imperfectly correlated. Integrated systems, however, increase management complexity due to the need to understand and coordinate multiple enterprises. This can be an important barrier to the adoption of these systems, and exemplifies the concept of bounded rationality (Simon, 1957). Productivity and economic performance can be reduced if administrative decisions are limited by managers' ability to process and act on complex information. Thus, if integrated systems are more complex, this can decrease productivity and create incentives against integration (Chavas, 2008).

While integrated agricultural systems have many benefits, there is a current trend toward specialized and large scale farms, reducing the number of farmers and increasing total assets through mergers and consolidations. This is particularly apparent in developed countries where the benefits gained through economies of scope decrease with increased farm size. Large farms may benefit from specialization, which is associated with economies of scale. Economies of scale exist if the per unit cost decreases with an increased farms size by spreading incremental cost over more production units. Specialized and large scale farms characteristically use technology intensive production systems. Intensive use of technology in agriculture may lead to a transition from within-farm integration to among-farm integration, and favor large agribusinesses that reduce cost through economies of scale and through higher market power and market access. Policy makers and large agribusinesses may prefer large systems as it reduces the number of stakeholders they must deal with and reduces transaction costs (Russelle et al., 2007).

With regard to environmental drivers, two main drivers for integration in North America are environmental concerns associated with excess nutrients produced by intensive livestock production, and high energy inputs for mono-cropping system (Russelle et al., 2007). Integrated farming systems are relatively self-sufficient, requiring less purchased fertilizer, herbicide, and pesticide inputs. This occurs since integrated systems utilize outputs from one enterprise as inputs to other enterprises, often use legumes in rotation reducing the need for purchased nitrogen, and include diverse crop rotations that help reduce weed, insect, and disease pressures. These reductions in purchased inputs also help to diminish production costs for integrated systems. Improved energy efficiency, realized with integrated systems, results from reductions in the use of purchased inputs, particularly applied nitrogen fertilizers, but, in some cases from lower tillage use as a result of less fuel needed to power equipment.

Integrated farming systems are thought to enhance a wide range of environmental services due to the higher level of diversity in these systems compared to specialized monocropping systems, and, in turn, reduced adverse environmental impacts. Examples of environmental services positively impacted by integrated systems include reduced soil erosion, increased soil organic carbon, improved soil biological function, reduced irrigation water use, and improved water quality (Sanderson et al., 2013). As a result, these systems are considered to be better for public health (Vereijken, 1989). This is a significant social driver and may be economically beneficial for producers since consumers are willing to pay price premiums for high quality goods that are perceived to be more beneficial due to growing awareness and concern for health, environment, social responsibility, and animal welfare, particularly in developed countries (USDA-ERS). In addition to the offsite effects, improved environmental services on integrated farms include increased soil fertility, and enhanced water quantity and quality, resulting in higher crop and livestock productivity, and increasing profitability in the long run. While the economic impacts from these farm resource conservation benefits may not be apparent in the short-term, they are important for maintaining long-term sustainability (Russelle et al., 2007).

Integrated Farming Examples

Integrated farming is a common practice in developing countries where farmland acreage, and access to manufactured fertilizers and agrochemicals are limited. In many developing countries land holdings are typically less than 1 ha. In comparison, average U.S. farm size in 2011 was 95 ha (234 ac) of cropland, but the median was just 18 ha (45 ac), indicating a large number of small farms. However, there were also many large farms with half of the cropland accounted for by farms 445 ha (1100 ac) or greater, and the size of this 'midpoint farm' had nearly doubled since 1982 (MacDonald et al., 2013). For the purposes of this chapter, we define small-scale systems as farms less than 40 ha (100 ac) in size, large-scale systems as farms between 40 ha and 800 ha (100–2000 ac), and very large-scale systems as farms larger than 800 ha (2000 ac). The examples given here are not meant to encompass all types of integrated approaches, but rather to highlight a few practices that are more common to or increasing in popularity within the farm scale in question.

Out of necessity, small-scale farms lend themselves to integrated practices that rely heavily on synergistic relationships between system components while maximizing production per unit of land. In developed countries, the local foods movement has, in part, driven a more deliberate approach to integrated farming in small-scale systems that attempt to mimic natural ecosystem processes. Small-scale systems, more so than large-scale, utilize manual harvesting and weeding in their operations. This allows for more flexibility with regards to the type of and extent to which integrated practices can be applied. At this scale, intercropping, cover-cropping, crop rotations, crop-livestock integration, and other cultural practices such as soil solarization, whereby solar energy is trapped underneath transparent plastic to kill weed seeds and harmful soil organisms and soil-borne pathogens, and the use of on- and off-farm sources of livestock manure and other soil amendments are all feasible. For example, low-input and organic systems, in particular, rely more heavily on approaches such as intercropping at various spatial and temporal scales and cover cropping to introduce biodiversity into the system.

Intercropping has long been used by small farmers around the world to satisfy dietary needs, spread labor requirements, reduce crop failure risks and produce more food per unit of land. Prior to the 1940's when mechanization, low-cost fertilizers and pesticides, and improvements in plant breeding were not yet available, intercropping was also practiced in the United States and Europe. Intercropping is the practice of growing two or more crops simultaneously so that positive plant interactions can be exploited and available resources can be utilized more completely and efficiently. In many instances, it is also a method used to reduce weed and insect pest pressure, and the spread and severity of disease. There are several types of intercropping, which include mixed intercropping where crops are completely mixed, strip intercropping where crops are arranged in alternate rows, alley cropping where crops are sown between tree rows in orchard or timber systems, and relay cropping where one crop is planted in the same field of another crop that has completed its growth. The goal of this approach is to reduce labor and the need for external inputs such as fertilizers and pesticides. Although not inclusive of all intercropping systems used around the world, examples of some common intercropping systems include cassava- or banana-based systems intercropped with coffee, cocoa, rubber, or cowpea in the tropics, maize-based intercropping with sweet potato, common bean, cowpea, or legume trees in Africa, rice-based systems intercropped with melon or maize in Asia, and the traditional three sisters system utilized by native cultures in North America, which consisted of maize-squash-beans. Companion crops in these types of systems are selected based complementarity of growth forms and their function within the system, such as a nitrogen-fixation by legumes, and on harvest timing compatibility. While not necessarily unique to small-scale systems, intercropping is not as widely practiced in large-scale systems due to management complexities and mechanization considerations. With large-scale farms, intercropping must be specifically designed to allow for

mechanization. Often, this means selecting crops that mature at similar times, and thus can be harvested at the same time. Also, this means selecting crops that can be easily separated at or after harvest, or utilized together as for food, seed, feed or forage. Also intercropping at the large scale often includes a legume to provide nitrogen fixing benefits. Some large-scale intercropping examples that exhibit these characteristics include canola/field pea, canola/spring wheat/field pea, winter wheat/hairy vetch, and oat/field pea.

The adoption of cover crops has become increasingly popular regardless of farm type or farm size. Annual crop rotations and cropping systems that integrate cover crops can provide a number of ecosystem services. Multi-species cover crop mixtures are often promoted as a way of introducing diversity and redundancy into the system to be more resilient to abiotic stressors. The functional diversity concept from ecology is often easiest applied to cover crops as species representing broad categories of plant types are often included. Examples of functional group categories include warm-season grasses, warm-season legumes, cool-season legumes, warm-season broadleaf plants, and cool-season broadleaf plants. Species are selected based on site-specific problems and priorities. For instance, cover crops such as radish and turnip are used as a biological method of aerating soil in no-till cropping systems and as method of increasing biological activity and nutrient cycling. Phacelia, buckwheat, and mustard are examples of crops used in mixtures in areas where pollinator resources are a priority due to floral qualities that attract pollinators. Grass cover crops such as rye, wheat, and millet are popular for their ability to compete with weeds and reduce weed pressure. Crops with deep rooting characteristics such as sunflower and sorghum-sudangrass are utilized for their ability to scavenge excess nutrients from deeper soil depths, thereby reducing soil nutrient leaching. Sorghum-sudangrass and other grasses are also examples of high-biomass cover crops that build soil organic matter and contribute to enhanced soil fertility over the long-term. There are many other examples and uses for cover crops, such as forage for livestock in integrated crop-livestock systems. Additionally, there may be trade-offs between the types of crops used and the types of and extent to which ecosystem services are provided (Schipanski et al., 2014). For instance, a cover crop mixture that is designed to maximize pollinator resources may provide poor quality forage for livestock in an integrated system.

Another example of an integrated approach unique to small-scale farms is the increasingly popular practice of aquaponics. Typically associated with greenhouse or other controlled environment production systems, aquaponics is the combination of fish culture (aquaculture) and soilless plant production (hydroponics). In this type of production system, nutrients derived from fish waste, with tilapia being the most common fish species used, are recirculated through the system and utilized by plants to meet their nutrient requirements. Typically, large quantities of fish are raised in small volumes of water to allow an accumulation of non-toxic nutrient concentrations (Rakocy et al., 2006). Solids from fish effluent are removed through filters and depending upon the type of aquaponics system, effluent may go through additional treatment processes to remove toxic waste products. Microbes break down remaining waste and convert nitrogen into a form that can then be taken up by plants. If optimal ratios are achieved, this approach creates a balanced system that intensifies production while minimizing adverse environmental impacts and reducing production costs.

While integration of crop-livestock is not unique to small-scale farms, small-scale systems typically allow for more diverse types of livestock to be utilized. For instance, chickens are more easily integrated into small-scale cropping systems with the use of mobile chicken coops that can be rotated across different areas on the farm. These so-called animal tractors, which can also include other types of livestock rotated in pens or paddocks, allow manure to be spread throughout the farm, which supplies fertilizer for crops. These types of systems also provide additional benefits to the system such as soil aeration through scratching and chicken pecking behavior, weed seed and insect pest consumption, and recycling of plant materials. Although less common in large-scale farms, additional livestock are sometimes included on a portion of the farm as available management and labor allow.

Regardless of scale, the most common form of crop-livestock integration occurs in forage systems whereby livestock graze on crop residues, cover crops following an annual crop, annual forages, improved pastures, and forages in alley-cropping systems. In under-developed countries, livestock commonly continue to provide energy with which to power farm equipment such as cultivators and plows. Livestock provide additional benefits by grazing on weeds, thereby reducing reliance on herbicides. As in animal tractor systems, livestock grazing provides direct manure application into the system, reducing the need for external fertilizer inputs. That is not to say that externally sourced animal manures and other soil amendments may not be transferred from off farm. For instance, many large- and very large-scale chicken, dairy, and mushroom production facilities sell composted organic waste from their operations to nearby farms at relatively low cost. This significantly reduces waste from large- and very large-scale farms while providing a locally-sourced, inexpensive and nutrient-dense fertilizer supply for farming operations.

In very large-scale farms, integration often tends to be less closely synchronized in time and space than in smaller-scale farms. Examples from the U.S. Corn Belt include farms where grain and forages are produced on the farm and fed to dairy or beef cattle in a feedlot on the farm. Often, some of the corn production is sold to a nearby plant for ethanol production, and resultant distillers' grains are fed to the livestock. Manure from the livestock is applied to the crop fields to recycle nutrients. Methane is captured from manure storage areas and is used to generate heat or electricity for use on the farm. This type of integration can occur on a single very large-scale farm, or regionally across multiple farms. Often, on a very large-scale farm, there may be multiple managers to divide management of separate enterprises. For example, the crop and livestock enterprises would often have separate managers. Integrated systems are well suited to farms where multiple managers (often family members) have different interests and abilities, so management of diverse enterprises can be subdivided. However, coordination among the multiple managers can represent an additional challenge.

Challenges and Opportunities to Integrated Farming

Despite the benefits of integrating farming, there has been a trend toward increased agricultural specialization in developed countries, whereby crop and livestock enterprises have become increasingly disconnected (Wilkins, 2008; Hilimire, 2011). Although mixed crop-livestock systems continue to dominate the landscape in Australia, there has been a shift toward crop-only systems over recent decades. However, some of this trend is attributed to relative crop and livestock prices and could be slowed or reversed if relative prices change (Bell and Moore, 2012). In places where agriculture has become more specialized, additional capital investments may be necessary if re-integration is to occur, and this may serve as a barrier to adoption of these systems. Integrated systems often require more labor, and may thus be challenged if there is a decreasing labor supply in agricultural sectors or increasing labor costs. While there has been renewed interest in integrated farming systems in the U.S., it remains to be seen whether this results in an increase in these systems. The current interest in cover crops, which serve a number of functions including forage in crop-livestock systems, has led to research and development of new technology such as specialized equipment for interseeding cover crops into existing cash crops. Such innovation is necessary utilize cover cropping in large scale farms, and will help to foster adoption of these systems by allowing integration to occur while retaining scale economies. However, the costs of these new technologies can serve as barriers to adoption.

Other technology trends in agriculture include continued advancement of precision agriculture, remote sensing, and information technologies. These technologies promote more efficient use of purchased inputs, and have helped producers to manage larger farms but may tend to reduce the relative benefits of integrated systems, and lead to further specialization. However, improving information technologies could help managers deal with the complexities of integrated systems and reduce an important barrier to their adoption. One of the many challenges for agricultural scientists will be to meld new and emerging technologies with integrated farming approaches in order to exploit the benefits of each approach and maximize efficiency.

An important driver for the adoption of integrated systems is the desire to restore the function of degraded soils. Biological soil amendments are an emerging technology purported to enhance soil biological function, and thereby improve nutrient cycling and pest suppression. These amendments would replicate some of the improvements in soil health attributed to integrated agriculture practices and might tend to reduce the incentives for integration. Other future trends that may influence adoption of integrated systems are increasing energy costs and the emergence of pesticide resistant pests. Both may favor the adoption of integrated systems which can reduce the use of energy intensive inputs, help reduce the development of pesticide resistance, and provide a suite of alternative methods for managing pesticide resistant pests.

Future market demands can also have a significant effect on integrated systems. The need to meet food demands of a growing population, but with limited land availability, will require increasing food production per unit land area in a sustainable manner. An important component of this is the variation in the suitability of land for grain and forage production and the need to match the mix of enterprises to land suitability. Farmers are more likely to adopt integrated crop-livestock practices in specialized cropping areas on marginal lands where productivity is low due to natural soil or environmental factors. Integrated farming systems are well suited to heterogeneous landscapes, where different portions of the landscape are better suited to different enterprises. While this can result in non-integrated enterprises within a farm, such as when crops are grown on the most productive land, and livestock are produced on less productive land, the proximity of these enterprises within a farm allow for greater opportunities to share resources among enterprises through integration. Integrated systems can often increase productivity per unit land area, and they can also be used to shift more livestock production toward forages, thereby freeing up grain production for human consumption (Bell and Moore, 2012).While meeting future food needs is important, this will need to be accomplished while maintaining or enhancing ecosystem services. The emerging market for sustainably produced foods may help provide economic incentives for integrated systems which enhance ecosystem services.

Several methods have been proposed for overcoming challenges and increasing the adoption of integrated systems. These include the use of environmental regulations and/or government payment to provide incentives for reducing environmental impacts, which may reward integrated farming producers. Since integrated farming systems are complex, farmers' ability to gain benefits through synergies is an important factor for enhancing the adoption of integrated systems. Farmers' management knowledge and skill can be improved through training and research at the local level. Combining increased knowledge and skills with technologies that help managers deal with complexity may facilitate greater adoption of these systems. Future developments in technology, regulations, labor availability, and demands for food and ecosystem services will influence the adoption of integrated farming systems, which may play a key role in meeting future food needs while maintaining or enhancing ecosystem services.

Island Biogeography

TW Schoener, University of California, Davis, CA, USA

As MacArthur and Wilson note in their revolutionary book *The Theory of Island Biography*, Charles Darwin was among the first to call attention to islands as a crucial subject for scientific study. As he was departing the Galapagos Islands in 1835, Darwin wrote

> when I see these Islands in sight of each other, & possessed of but a scanty stock of animals, tenanted by these birds, but slightly differing in structure & filling the same place in Nature, I must suspect they are only varieties … If there is the slightest foundation for these remarks the Zoology of Archipelagos will be well worth examination; for such facts would undermine the stability of species.

Of course Darwin's main interest was in evolution; we know now that islands can contribute enormously to our understanding of ecology as well. There are at least seven reasons why this should be so:

1. Islands are `simple', with relatively few species and habitats so that the often notoriously complex web of ecological relationships is manifested in a more easily understood state.
2. Islands are `discrete' and often small, providing a well-defined, manageable spatial unit for study.
3. Islands are `isolated', so that they are relatively immune from outside fluxes, much as a laboratory tank or greenhouse.
4. Islands are `natural', so unlike those human-constructed containers have biotas adjusted in at least the moderately long term to a confined state.
5. Islands are `combinatorial', so that species occur in various combinations, often with absences and presences of key species varying as if in experimental removals or introductions, allowing comparative inference of those species' effects.
6. Islands are `replicated' so that often a number are available with a given set of species or environmental conditions, allowing statistical analysis and experimentation.
7. Islands are `ubiquitous', not being limited to areas of land surrounded by bodies of water but generalizing to any patch of one type of habitat surrounded by another – mountaintops, river systems, hosts for parasites, etc. Indeed, as MacArthur and Wilson also pointed out, natural habitat is becoming increasingly fragmented, that is, insularized by human activities so that many areas of conservation interest are effectively archipelagal.

Finally, were such scientific rationale not enough, islands are esthetically pleasing, enamoring us all, scientists or not, with their charm and beauty (could this be the real reason many ecologists work on islands?).

The MacArthur–Wilson Equilibrium Theory

What was the revolution that MacArthur and Wilson effected in their 1967 book? The essence is that each island is in a state of species equilibrium, in which the number of new (not already on the island) species immigrating per unit time is balanced by the number of species becoming extinct per unit time. To see how this could be very different from previous theoretical constructs, we can examine the effect of an island's distance on its species count. Extensive collection of information on species distributions and compilation of faunal lists shows that number of species on far islands (those distant from a source of colonizing species) is less than the number on otherwise similar near islands. One possible explanation is that the far islands, so removed from the source, simply did not have time to acquire the number of species near islands possess but eventually would. An entirely different explanation was advanced by MacArthur and Wilson, who argued that far islands have fewer species because their low immigration rate is balanced at equilibrium by a low extinction rate; the fewer species on far islands means fewer to go extinct per time, thus achieving a balance at a smaller equilibrium number.

The model actualizing these ideas was first presented as a graph of gross extinction and immigration rates against the number of species present on the island. In its most general form it makes two assumptions (**Fig. 1a**):

A1. Rate of immigration of new species (those not yet on the island) decreases monotonically with increasing number of species already present. It reaches zero when all species in the source area (there are P of them) are on the island; and

A2. Rate of extinction of species increases monotonically as the number of species increases (the more species there are, the more to go extinct). These two assumptions imply

P1. An equilibrium between immigration and extinction will eventually occur, at which time the immigration and extinction rates will equal the same value, called the turnover rate at equilibrium.

Two additional assumptions allow some more predictions:

A3. Near islands have immigration rates higher than far, for the same number of species present (because near islands are closer to the source area); and

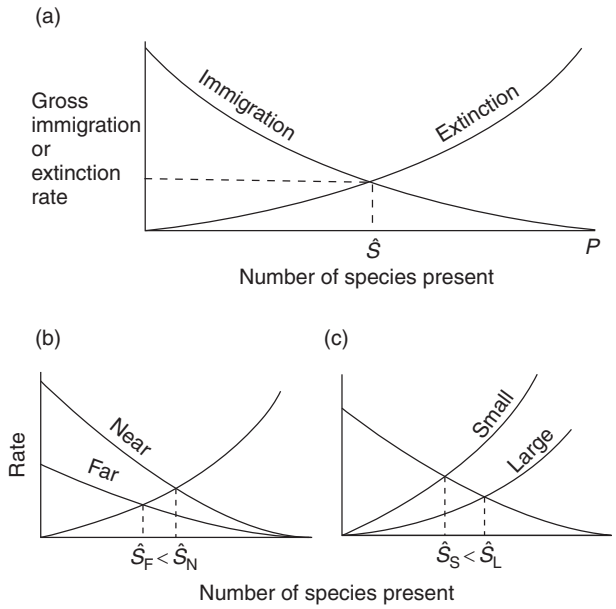

Fig. 1 (a) The graphical version of the MacArthur–Wilson equilibrium model. The model is for a particular island. $\hat{S}$ is the number of species at equilibrium (when gross immigration equals gross extinction), and P is the number of species in the source pool. Rate curves are monotonic but nonlinear. The intercept of the dashed line on the y-axis is the turnover rate at equilibrium. (b) The distance effect for the MacArthur–Wilson equilibrium model: far islands have lower immigration rates than near islands (for a given number of species present on the island), implying near islands at equilibrium have more species ($\hat{S}_N$) than do far islands at equilibrium ($\hat{S}_F$). (c) The area effect for the MacArthur–Wilson equilibrium model: small islands have higher extinction rates than large islands (for a given number of species present on the island), implying large islands at equilibrium have more species ($\hat{S}_L$) than do small islands at equilibrium ($\hat{S}_S$).

A4. Small islands have extinction rates higher than large, for the same number of species present (because average population size is smaller for the smaller islands, so the per-species extinction likelihood is greater). These imply the following predictions:
P2. Near islands of the same size as far have more species (**Fig. 1b**); and
P3. Large islands of the same distance as small have more species (**Fig. 1c**). This prediction is a version of the species–area relation, one for which there is much evidence, as discussed below.

Finally, certain assumptions lead to
P4. the colonization curve, or the curve relating number of species on the island to time since the colonization process begins, is convex.

Although the relation of extinction to area and the relation of immigration to distance are expected to be by far the dominant ones, the two other logically possible relations have also been proposed and documented. First, far islands may have extinction rates higher than near for the same number of species present (Brown and Kodric-Brown's `rescue effect'). The rationale is that near islands have populations supplemented by immigration more than do far islands; thus population sizes of the species present on near islands average larger so are less extinction-prone than populations on far islands (and/or near-island populations have more genetic variation, so again are less extinction-prone). Second, large islands may have greater immigration rates than small, for the same number of species present (the `target effect'). The rationale is that larger islands have a greater diameter or area to intercept laterally moving or vertically descending immigrants, respectively, so have a greater immigration rate. Evidence for both of these effects is widespread and will be discussed below, but we note here that all four postulates about rates, (A3) and (A4) and the two just mentioned, have been detected in the same system, spiders on subtropical islands of the Bahamas.

Tests of Species Equilibrium

A major claim of the MacArthur–Wilson theory was that a substantial portion of the world's islands are in fact at equilibrium, whereby the number of species colonizing balances the number becoming extinct. The evidence for a species equilibrium ranges from highly supportive to contradictory; we review the major cases in decreasing order of support.

1. *Birds of Krakatau*. In 1883 a tremendous volcanic eruption destroyed two-thirds of the Indonesian island of Krakatau and left its remnants and two neighboring islands under 30–60 m of ash, with no observable plants or animals surviving. As major confirmation of their theory, MacArthur and Wilson argued that equilibrium for land birds was re-attained only 25–36 years after the eruption. However, subsequent studies showed that the conclusion was premature: equilibrium has perhaps not yet

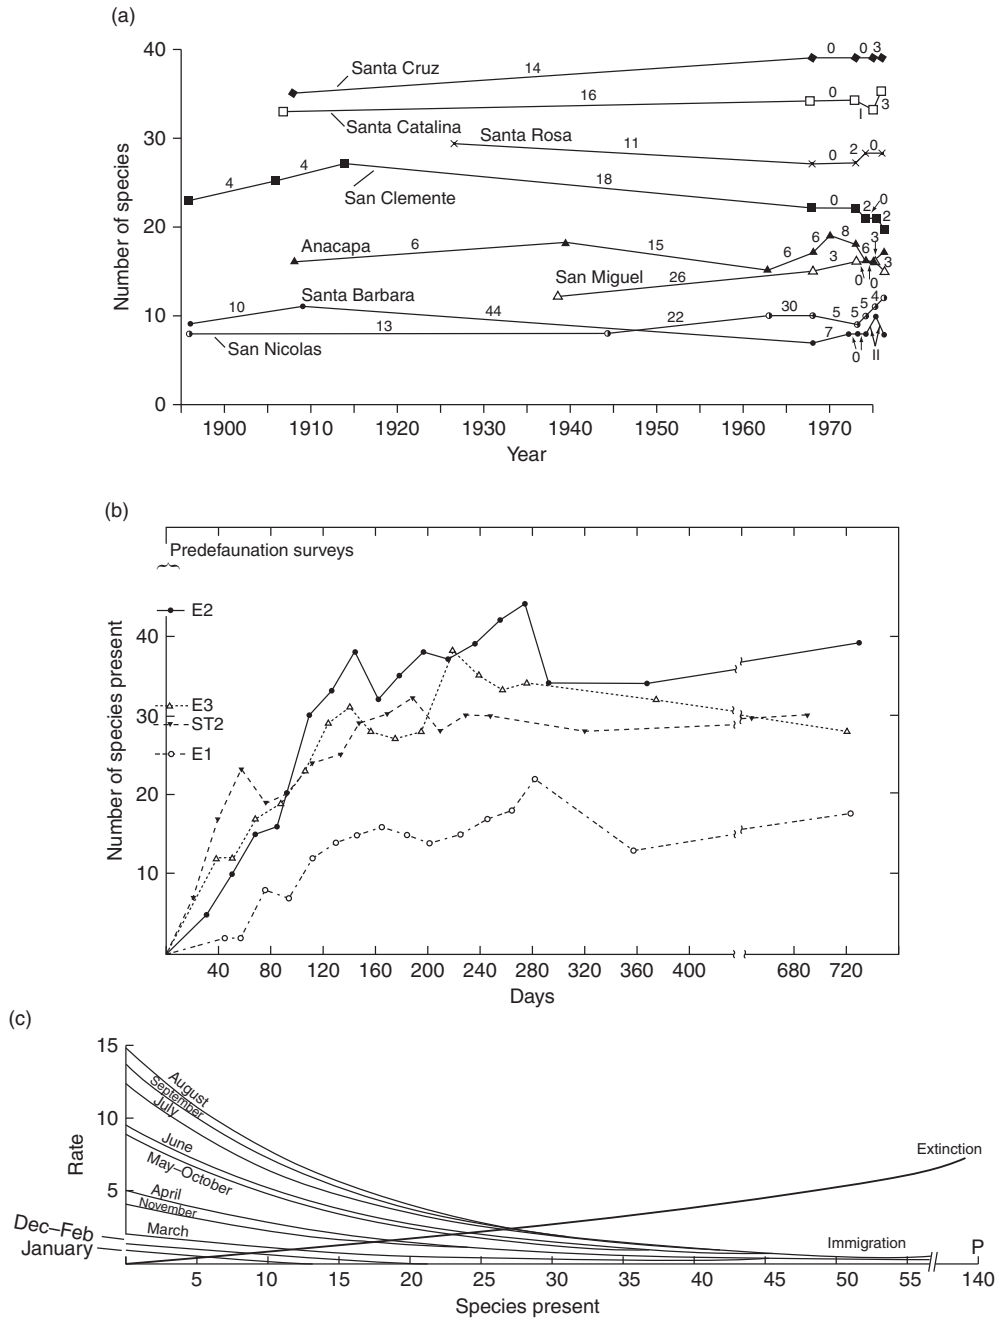

Fig. 2 (a) Birds on the Channel Islands, California (USA). Number of breeding species *S* for each island plotted against survey year. Fig. 2 (Continued)

been quite reached even after 100 years after the eruption. Much smaller gross extinction rates are now known to occur as compared to those predicted by MacArthur and Wilson (0.25–0.42% vs. 1–6% species per year).

2. *Birds of the Channel Islands*. The first systematic survey of birds on nine California Channel islands was accomplished in 1917. Since that time several surveys showed that the number of species over 50 + years has not changed much (**Fig. 2a**). The degree to which the islands showed turnover was controversial and will be discussed in the next section.
3. *Arthropods of Red Mangrove Islets*. The red mangrove *Rhizophora mangle* grows as an emergent shrub or tree from small floating dispersal structures that root on shallow marine banks; islands so created can range from moderately large down to extremely small. Investigators took advantage of the plethora of such islands to study experimentally the recolonization by arthropods that would occur after a devastating extinction event. A pest-extermination company was hired to cover each mangrove islet with plastic sheeting and spray insecticide within; this eliminated most of the arthropods, so that when the sheeting was removed, artificially `defaunated' islands resulted. Numbers of species rapidly increased, slightly overshooting the old equilibrium values before settling near it 1–2 years after inception of recolonization (**Fig. 2b**).
4. *Marine epifaunal invertebrates on rocks*. To simulate colonization of rocks in the intertidal, artificial panels were set out in the Massachusetts (USA) subtidal. This experiment produced an oscillating equilibrium (**Fig. 2c**), not unexpected in this highly seasonal environment. Thus the species equilibrium may manifest itself as a rather predictable oscillation, rather than necessarily having a constant value.
5. *Plants on Krakatau*. Plants showed a much slower rate of recovery after volcanic eruption than did birds (`1' above). In MacArthur and Wilson's original analysis, there was no real tendency for the colonization curve for plants even to begin leveling off. The most recent censuses (*c.* 100 years since the eruption) show that equilibrium has been nearly attained for seed plants (**Fig. 2d**) and ferns. However, like birds, the gross extinction and immigration curves are not monotonically related to number of species present as assumed by MacArthur and Wilson (**Fig. 1**); rather apparently ecological succession causes several changes in direction, especially for immigration. For example, water- and wind-dispersal plants were the first to colonize, whereas animal-dispersed species did not colonize until a certain amount of successional change had taken place.
6. *Birds on islands off Australia and New Zealand*. Records for 15 islands taken over periods ranging from 50 to 124 years showed that the number of passerine bird species increased on 14 islands, up to 900% of the original values. While humans have had effects on these islands, including habitat diversification in some cases (which would allow more species), those effects did not seem to be sufficient to account for such huge increases; perhaps climatic warming for these rather high-latitude islands was involved. The investigators characterized this variation as `nonequilibrial'; certainly it stands in contrast to Channel Island birds (`2' above), as change was quite unidirectional.

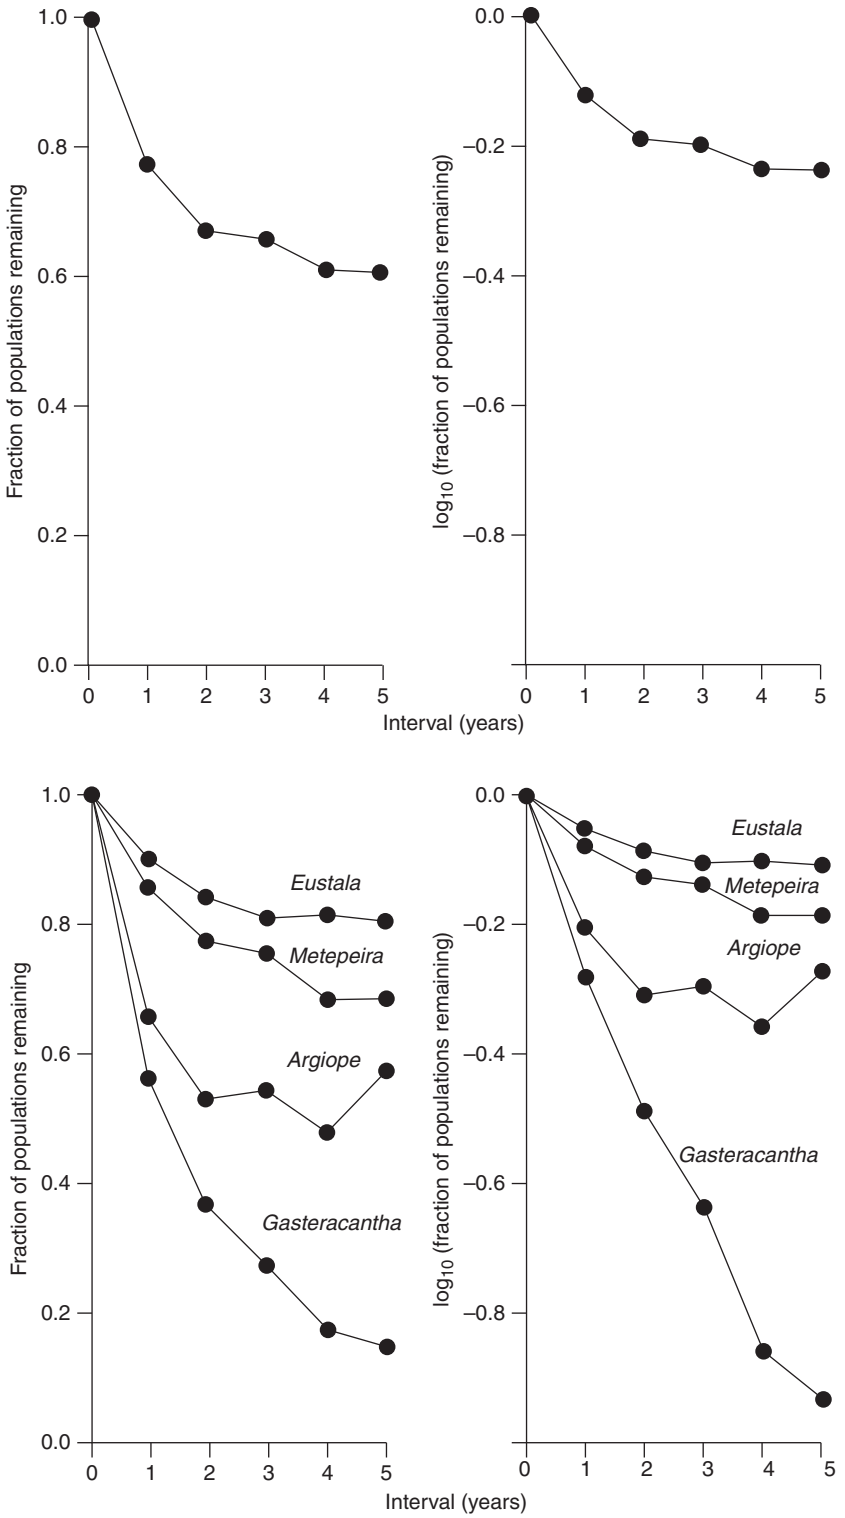

Fig. 3 Population persistence curves for orb spider on 108 islands of the Bahamas. Top: All species combined. Bottom: Individual species curves (see text for further explanation).

7. *Birds on Skokholm Island*. Data on numbers of bird species for this rather northerly island off the British mainland (taken 1928–39 and then 1946–67) showed that number of species fluctuated between 5 and 13, with substantial temporal autocorrelation. These are large percent changes (over 200% by one measure), so is this evidence against equilibrium? Certainly it is evidence against species constancy; however, MacArthur and Wilson's algebraic theory (as opposed to the graphical one

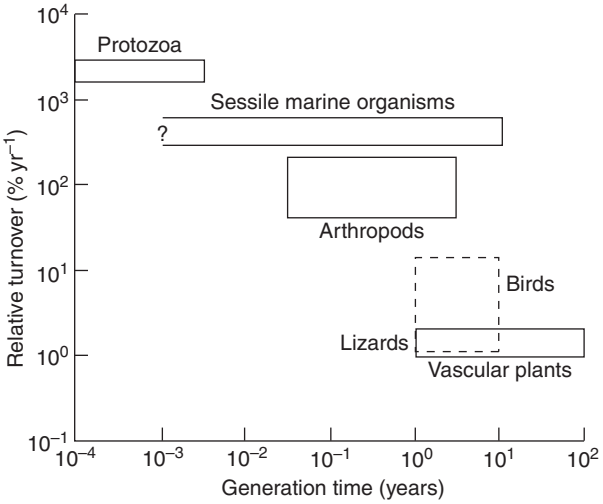

Fig. 4 Relative turnover (eqn [1]) as a function of generation time in six types of organisms. Reproduced from Schoener TW (1983) Rate of species turnover decreases from lower to higher organisms: A review of the data. *Oikos* 41: 372–377, with permission from Blackwell Publishing Ltd.

presented above) was a stochastic model with per-unit-time probabilities of immigration and extinction rather than fixed rates. Indeed, if we calculate for the Skokholm data the temporal variance and the mean number of species, the ratio is about 2/3, well within the possible range from the MacArthur–Wilson stochastic model, although higher than expected for equal (absolute) slopes of the gross extinction and immigration curves; an especially high extinction rate is consistent with the high ratio, unsurprising for such a small island.

8. *Spiders and lizards on islands decimated by hurricanes*. In 1997, certain Bahamas islands were completely inundated by the nearly 5 m storm surge of a major hurricane. As for Krakatau, no spider nor lizard individual survived; recolonization data a year later found spider species counts about where they were before the hurricane, whereas few islands to this day have been recolonized by lizards. In this case, the rapidly dispersing arthropods would be expected to reestablish equilibrium more quickly than large, terrestrial vertebrates such as lizards. Were hurricanes sufficiently frequent, certain taxa such as lizards might never reach a species equilibrium before the next disaster wiped them out again.
9. *Arthropods in soybean fields*. Soybean fields are an example of a highly temporary habitat that is frequently `defaunated', here by scheduled human activities combined with climatic seasonality. The arthropods inhabiting such communities do not have time to reach equilibrium before being `zeroed' again; hence they must constitute permanently nonequilibrium communities.

In summary, the value of the equilibrium concept varies from very useful for undisturbed islands to not so great for those that are frequently disturbed. The theory, however, does contain nonequilibrium dynamics, so that it is descriptively useful even for pre-equilibrium stages.

Tests of Turnover

Species turnover can be measured as

$$\text{Turnover (relative) over a unit item interval}(t_2 - t_1) = 100\frac{(\text{Extinctions of species already present} + \text{immigrations of new species})}{(\text{Number of species at}t_1 + \text{number of species at}t_2)} \quad [1]$$

Graphically, turnover at equilibrium is the height of the intersection of the gross rates (**Fig. 1**). That substantial turnover should exist is perhaps the most controversial part of the MacArthur–Wilson theory; museum people in particular found the concept of the species list for a given island changing much over time hard to stomach. What is the evidence for turnover?

1. *Arthropods of red mangrove islets*. Returning to the defaunation experiment (`3', last section), abundant turnover was demonstrated. Not only were there numerous extinctions and immigrations leading up to equilibrium, but once equilibrium had been achieved, species lists for particular islands were quite different from those before defaunation.
2. *Birds of the Channel Islands*. Returning to this example (`2', last section), Lynch and Johnson challenged the turnover data (first presented by Diamond) for two census times 51 years apart; among other problems they believed that species were missed in one or the other census, resulting in an inflated estimate of the degree of turnover. However, subsequent censuses by Jones and Diamond showed that turnover was in fact probably quite substantial over that period because of missed entire sequences of

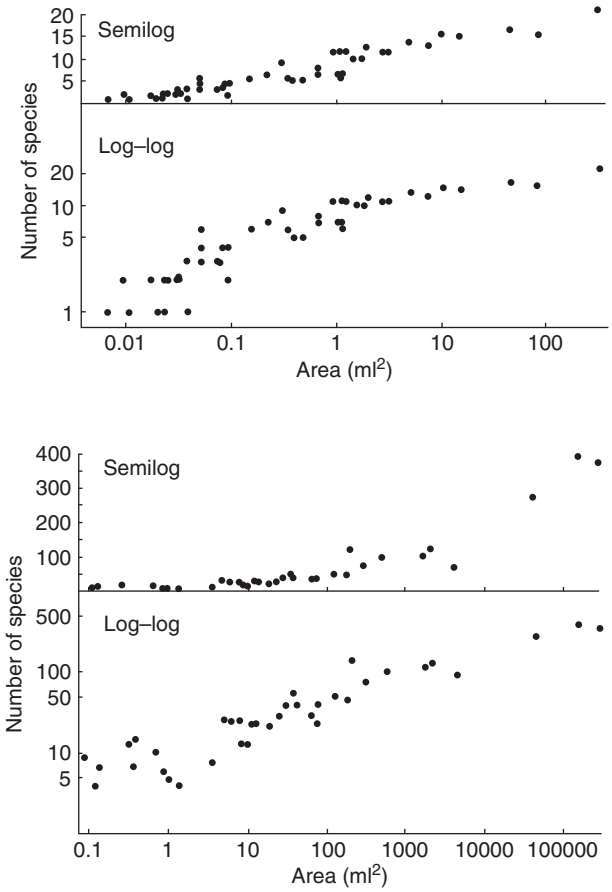

Fig. 5 Species–area plots showing the semilog (exponential) and log–log (power) relation, top and bottom, respectively. Top: Shetland land birds. Bottom: Malaysian faunal region land birds mi, miles. Reproduced from Schoener, T.W., 1976. The species–area relation within archipelagos: Models and evidence from island land birds. In: Proceedings of the XVI International OrnithologicalCongress., pp. 629–642.

immigration and extinction for particular species in the intervening half-century when surveys were not conducted. Their year-by-year data for a subsequent period in fact show turnover as 0.5–4.9% per year, whereas the two censuses in the original study gave 0.3–1.2%. Hence if the original two censuses missed species, this were more than compensated for by unobserved ins and outs during the long interval. Diamond and May presented an elegant stochastic theory predicting how `apparent' turnover (as measured eqn [1]) would decline with increasing time between censuses (between t_1 and t_2); the model successfully replicated annual breeding-bird data from the Farne Islands (another northerly group off the British mainland) and gave the result that for census intervals of decades, turnover is underestimated by about an order of magnitude.

Thus although Diamond's original conclusion for the Channel Islands was vindicated, apparently certain islands exist for which turnover is very slight. Two tropical representatives are at the extreme: Cocos Island had no turnover in 72 years, and the Tres Marias Islands had only two immigrations; perhaps tropical birds are more sedentary, thereby causing a regional difference between tropical islands and the temperate California or New Zealand islands (`6', last section).

3. *Birds on islands radically altered in area by human activity*. Various hydrological activities by humans created new islands while shrinking others in Lago Guri, Venezuela. Investigators found that a new equilibrium was achieved on the smaller remnants in just 7 years, while large islands are still declining. Similar phenomenology occurred in relation to the massive changes effected when the Panama Canal was constructed. Here as in Lago Guri, turnover was lower, the larger the island; it was also lower for far than near islands. Thus in these examples turnover is large even for tropical islands, albeit rather small, recently disturbed ones.
4. *Spiders on Bahamian Islands*. How important is turnover, in terms of the population sizes of species undergoing it? As assumed in the MacArthur–Wilson Model, there is a strong relation of population size to extinction rates in a variety of species (see final section below). Investigators calculated the percentage of individuals for all species and islands combined belonging to populations becoming extinct over particular intervals, ranging from 1 to 5 years. Using 1 year intervals, 2.8% belonged to populations becoming extinct. Using 5 year intervals, still only 4.8% did so. It seems that turnover, while quite large in terms of species number (about 35% per year), does not involve the most abundant species, those that should often be the major players and in any event are of most interest to ecosystem as opposed to biodiversity ecologists. In this system, mostly the same species go in and out, much as portrayed in Hanski's core-satellite concept. To illustrate, we can construct

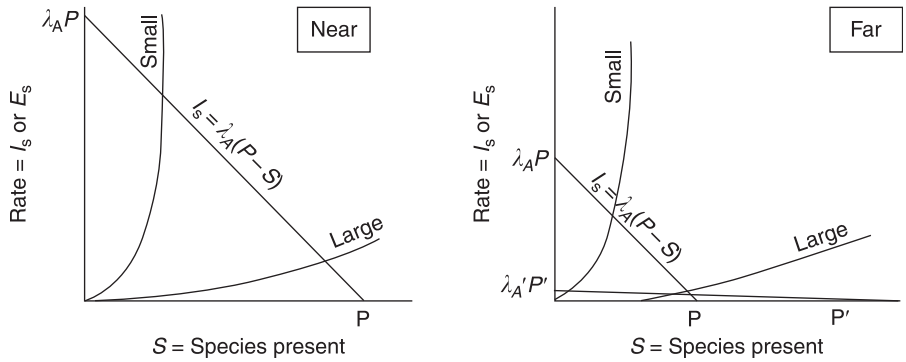

Fig. 6 Equilibrium for near and far archipelagos. Immigration for islands of a far archipelago is represented as two components: an intra-archipelagal component with low number of species in the source pool (P) and high λ_A (per-species immigration rate), and an extra-archipelagal component with high number of species in the source pool (P') but very low λ_A. Addition of this second component makes little difference except for the largest islands. Immigration for near islands has only a single component with large P and large λ_A. This single component represents the combined inter- and intra-archipelagal immigrations, here both assumed to have high (and identical) λ_A. Notice that small islands of the two archipelagos have about the same equilibrial species number, but large islands differ markedly. Reproduced from Schoener, T.W., 1976. The species–area relation within archipelagos: Models and evidence from island land birds. In: Proceedings of the XVI International OrnithologicalCongress., pp. 629–642.

population–persistence curves, which give the fraction of species populations remaining n years after a particular census (Fig. 3): note that the combined-species curve levels off quite sharply (even on a log-scale), but that particular component species vary in the degree to which this is true.

In conclusion, species turnover is a salient feature of islands. There is, however, substantial variation, not only with island size, distance and region of the world as reviewed above, but also with generation time (Fig. 4). Inasmuch as turnover involves rarer species it is of importance from a conservation view, yet perhaps equally unimportant from an ecosystem view.

Effect of Area

The species–area relation, whereby the number of species in a spatial unit increases with that unit's area, well predates the MacArthur and Wilson theory of island biogeography, having been documented for about 150 years. Two general kinds of models for this relation have been proposed. The first has number of species predicted from an assumed species–abundance distribution and the total number of individuals of all species combined (assumed proportional to area). The second develops species–area relations from MacArthur and Wilson's species-equilibrium approach.

May's paper coalesces the literature for the first sort of model. Two species–abundance distributions are of particular importance.

The first, a log-series distribution, has been used to describe light-trap data and other collections. It leads exactly to the following species–area relation:

$$S = \alpha \ln(1 + \rho A/\alpha) \quad [2]$$

where α is a parameter of the abundance distribution, and where ρ is the density of individuals. For A sufficiently large, this can be written

$$S \cong \alpha \ln(\rho/\alpha) + \alpha \ln A \quad [3]$$

Notice that this is an exponential or semilog–linear relation of species to area, that is,

$$S = c_1 + c_2 \log A \quad [4]$$

as opposed to the log–log–linear relation that the lognormal implies (below), that is,

$$\log S = \log c + z \log A \Rightarrow S = cA^z \quad [5]$$

Note also that eqn [3] is inexact for small A (or S) and that S flattens out as A approaches zero.

Various more or less plausible ways to arrive at a log-series distribution from hypothetical biological processes have been given, perhaps the most common of which is not a biological mechanism but rather a property of the sampling procedure: species–area data in which samples of different areas are taken randomly from some homogeneous large area should have a semilog–linear plot for sample areas sufficiently large.

The second species–abundances distribution, the lognormal, is expected when (1) per-individual population growth rates vary randomly over some substantial period of time or (2) the relative abundances of each species is governed by many factors acting on the per-individual growth rate (and therefore, on the logarithm of population size) independently of one another. Both follow from the Central Limit Theorem of statistics. For Preston's (the originator of this approach) one-parameter (`canonical')

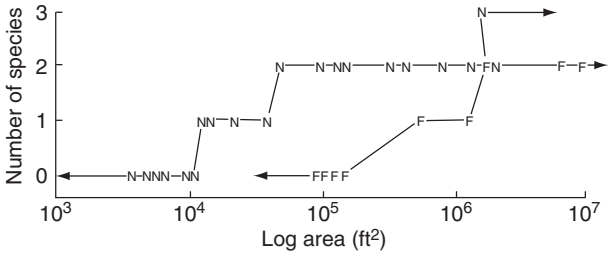

Fig. 7 Number of species of diurnal lizards on near (N) and far (F) islands in Lovely Bay, Bahamas, as a function of island area. Reproduced from Schoener, T.W., Schoener, A., 1983. Distribution of vertebrates on some very small islands. II: Patterns in species number. Journal of Animal Ecology 52, 237–262.

distribution, if we assume that J, the total number of individuals in all species combined divided by the number of individuals in the rarest species, is proportional to island area, then species number (S) increases as approximately the 0.26 power of area, that is, $S = cA^{0.26}$, a particular example of eqn [5]. However, the true relationship is not a power function but approaches one with power 0.25 as S gets large. For small S, the relation bends downward and approaches a linear relation of species to area (thus being quite different from the curves generated by the logseries distribution just discussed). Note this derivation assumes that something is constant about the shape of the distribution from small to large islands. Preston argues that what is constant is the number of individuals in the rarest species and the density of all individuals combined. It is fairly plausible that total number of individuals increases linearly with area for some well-defined taxon, although evidence bearing on this is not entirely supportive. While one study found that total density of birds increased with total species diversity, other results are more in accord with the assumption. On the other hand, while the assumption that number of individuals in the rarest species is constant is a natural one; given the mathematics of the distribution, it is perhaps less plausible biologically. For the two-parameter distribution, some other feature (e.g., standard deviation) also varies. However, the power of the species–area relation is fairly insensitive through the range of reasonable biological variation in the distribution (Engen has derived a species–area relation from yet a third species–abundance distribution, the broken stick; it is again a power function).

Which description is better, eqn [4] or [5]? Connor and McCoy interpret their review of 100 data sets to say that the two fit about equally. Clear examples of each of the two are given in **Fig. 5**.

The second type of species–area mathematical theory explicitly takes into account the ingredients of the MacArthur–Wilson equilibrium model. The model of Schoener that assumes abundances at equilibrium are complementary (summing over all species to ρA, where ρ is the density of all individuals combined and A is island area), has d log S/d log A (the slope on a log–log plot) not constant but ranging from 0.5 to 0; the midpoint of this range is very much like that given by the lognormal distribution ($z = 0.26$). The equilibrium and lognormal models differ, however, in the curvature of the species–area plot.

The equilibrium species–area model also predicts that the greater the per-species immigration rate λ_A, the smaller the d log S/d log A. Indeed z is smaller for less remote islands within an archipelago. But far archipelagoes have smaller z's than near archipelagos. This is probably because of a differentially high λ_A among birds that have been able to colonize such archipelagoes (**Fig. 6**). Various additional evidence suggests that this model is on the right track. For example, the species–area slope for birds on islands of Burtside Lake, Minnesota (USA) is unusually high, but P is very large and the islands are very small.

A final form for the species–area relation has been suggested by Lomolino and others, one having essentially an S-shape, that is., a greater rate of increase for intermediate-sized islands than either for small or large islands; note that the low slope for the smallest islands is the feature of this concept that makes it very different from any of the species–area curves proposed so far, descriptive or mechanistical. Although some evidence for such a slope was known for special cases (e.g., plants on a Micronesian atoll, in which freshwater lenses are absent on islets below a certain area), a recent survey found that the initial flat portion of the species–area curve typically included a substantial portion of an archipelago's islands. While the statistical significance of this result has yet to be evaluated, clearly its detection has proven more feasible than expected.

Although direct observation of species immigration is difficult, evidence for the target effect – larger islands intercept more immigrants – is also known from a variety of systems (e.g., Bahamian spiders, Australian sea-dispersed beach plants).

Effect of Distance

While the species–area effect is documented for nearly all quantitative studies of islands, a similar effect of distance is more rarely demonstrated. This is probably true for two reasons: first, the lack of variation in distance from an outside source for islands within single archipelagos, and second, even where a variety of distances are available, the necessity of taking into account the usually very strong effect of area before a distance effect can be detected. An example is given for lizards of the Lovely Bay archipelago in the Bahamas (**Fig. 7**): lizards are expected to be especially sensitive to variation in distance because they can only disperse by rafting (or swimming) over water, a rather tenuous process at best. Distance is not always a hindrance to species, however, and may even be an advantage. Thus migrating birds in the Bahamas tend to increase their species numbers with increasing island distance; this is

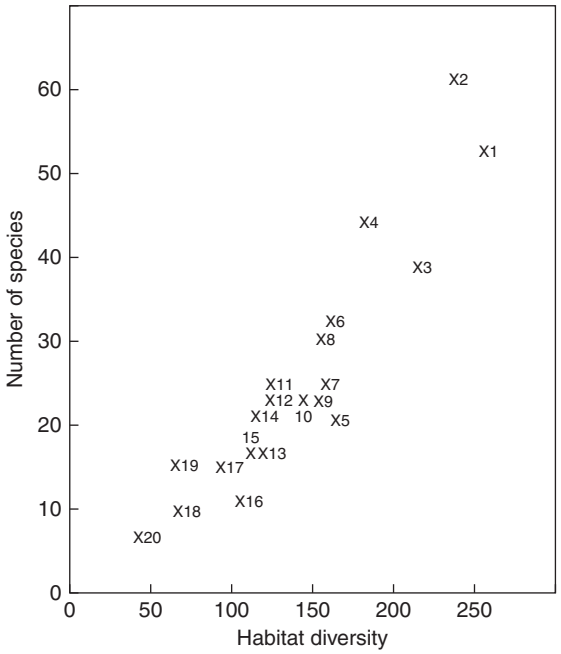

Fig. 8 Breeding passerine birds on Aegean islands: Number of species vs habitat diversity. Reproduced from Watson GE (1964) Ecology and evolution of passerine birds in the islands of the Aegean Sea. PhD Dissertation, Yale University, with permission.

the opposite of resident birds in the same region, perhaps because the latter's relative scarcity on distant islands results in more resources for migrants there.

The impact of distance is also involved in the rescue effect, whereby near islands have their populations boosted more frequently by immigration, conferring dual advantages – large population size and genetic variability – both would tend to forestall extinction. Somewhat surprisingly, few examples from water-surrounded islands are known, although more examples exist from islands *sensu latu*, so-called habitat islands (see above), including the founding study on arthropods inhabiting thistle heads.

Effect of Elevation

Perhaps the most obvious potential effect of island elevation (=altitude) on species occurrences is simple refuge from high water. Little documentation of such an effect has existed, but we now have a precise example. In 1999, a Category IV hurricane swept over small islands of the Great Abaco (Bahamas) region, completely inundating the lower ones with its storm surge. The islands were inhabited by a common lizard species, *Anolis sagrei*. Before the hurricane, island area was a better predictor (by logistic regression) of the occurrence of this species than was altitude. Immediately after, altitude was the better predictor. Apparently all lizards on islands lower than about 3 m maximum elevation had perished. After *c*. 1 year, area again became the better predictor: recovery occurred via overwater colonization (the islands were very close to the mainland) and propagation from eggs that survived inundation, mechanisms that were enhanced by a larger island area. While rapid recovery often follows catastrophic disturbance, as in this example and those given above, such is not always the case. Ricklefs and Bermingham postulated that a major change in the mean age of the Lesser Antilles avifauna occurred about 0.5 million years ago, perhaps caused by a catastrophic disturbance such as a tsunami; little postcatastrophic recovery was evident.

The most commonly discussed effect of altitude on species diversity is more indirect than simple protection from high water: the greater the altitude, the more kinds of habitats, and the greater the number of habitat kinds, the more species can occur. Examples exist for the plants of the Galapagos and, to a lesser extent, the birds of the East Indies. This argument is a special case of the argument for the importance of habitat, and we turn to that topic now.

Effect of Habitat

We have so far reviewed two kinds of explanations for the species–area effect: (1) relation to a species–abundance distribution (as in sampling) and (2) via the MacArthur–Wilson mechanism, extinction rate being assumed a function of population size. A third sort of explanation was advanced by Williams, who argued that area is just a proxy for habitat diversity, and it is the latter that directly drives the number of species on islands. By this interpretation, each species has its associated habitat type, and as area

increases, the amount of each habitat type also increases, exceeding the thresholds for each species' occurrence one-by-one. A classic example is the avifauna of the Aegean Islands. Number of species shows a very precise relation to habitat diversity (**Fig. 8**), equaling or surpassing many of the highly regular species–area relations exhibited by other groups. Multiple regression showed habitat diversity a more important prediction than area, just as was shown for elevation with respect to Galapagos plants (see above). Similar results have been obtained for species counts in pieces of larger, mainland areas, for example, forest birds of eastern North America.

In addition to the species–area effect, a correlation with habitat diversity has also been postulated as accounting for the distance effect: Lack argued that far islands had fewer species than near because their habitats were less varied. A definitive test of the Lack vs. MacArthur–Wilson explanation of the distance effect was performed for birds and lizards of the Bahamas. Measuring the occurrences of various habitat types directly, investigators found using partial correlation that both isolation and habitat poverty contributed to a tendency for fewer species to occur on more distant islands.

Although most research concerning the effect of area, habitat, etc. is directed toward understanding the number of species on islands, recent work is exploring effects of such biogeographic variables on population and life-history properties of island species. We measured survivorship of the lizard *Anolis sagrei* on Bahamian islands and found a very strong inverse relation to height of vegetation on the island. The result may perhaps be surprising in view of the tendency of these lizards to be arboreal and the apparent lack of resources on the scrubbiest islands (where annual survival was up to 80%!). The likely explanation is that itinerant bird predators prefer islands with higher vegetation, increasing the risk of predation on those islands. Studies involving life-history traits are becoming increasingly common, and we now turn to an area where this is of conservation importance, the understanding of extinction.

Extinction and Conservation

It is a universal property of the extinction process, including populations on islands, that the smaller the population, the more likely extinction is to happen, all other things being equal. This is a fundamental assumption underlying the area prediction of the MacArthur–Wilson equilibrium model, and it has been observed in some of the systems we have been discussing, including Channel Island birds and Bahamian spiders.

We can better understand the reasons for this relation if we examine the key processes responsible for extinction. First, demographic stochasticity, the chance occurrence of a series of deaths before any member of a population can give birth, acts at low population sizes and can cause the population randomly to go to zero. Second, environmental stochasticity, represented as variation in species traits generated by extrinsic environmental factors that themselves are varying, is important at moderate-to-large population sizes. The environmental variation can be chronic, occurring more-or-less continuously over time, or catastrophic, occurring very infrequently but being much more severe. Finally, population ceilings are important: no population has the capacity to increase indefinitely, but rather negative feedback (density-dependence) will set in as it expands, eventually forcing the population to hover at or near some ceiling in numbers. With lower and lower values of the ceiling, a population would be correspondingly more and more vulnerable to demographic–stochastic extinction.

Many models of population extinction exist that can be applied to islands, but rarely has a single model encompassed both kinds of stochasticity as well as population ceilings. An international collaboration recently attempted to apply such a model to data for spider populations on 77 islands, censused annually over a continuous 20 year period. Two species were contrasted, one with larger populations sometimes crashing quickly to extinction and having a much weaker relation of extinction likelihood to population size than the other species. A simple model ignoring life cycles and a more complex model with detailed life-cycle characteristics estimated from the field were constructed; both models did well for large population sizes, but the complex model was necessary to fit data from small population sizes, as the life cycles interact with the various forms of stochasticity. In particular, the prediction that extinction probabilities are very sensitive to juvenile survivorship emerged from the analysis. This is in contrast to a similar approach for a noninsular species, Bonelli's eagle (*Hieraatus fasciatus*), which predicted sensitivity to adult survivorship. Conclusions such as these are in fact detailed expectations about extinction likelihood, in turn guiding conservation efforts in preserving species.

Landscape Ecology☆

Jianguo (Jingle) Wu, Arizona State University, Tempe, AZ, United States; Beijing Normal University, Beijing, China

What Is Landscape Ecology?

Landscape ecology has been defined in various ways partly because the word, "landscape," means quite different things to people with different scientific and cultural backgrounds. Landscapes are spatial mosaics of interacting biophysical and socioeconomic components (Fig. 1). Just as in other ecological disciplines, a spectrum of views exists as to the relative salience or prominence of the two aspects of landscapes. The diversity of perspectives can often be related to the philosophical underpinnings of reductionism versus holism. Nevertheless, few would disagree that landscapes are compositionally diverse and spatially heterogeneous. A general definition of landscape ecology may be the science and art of studying and improving the relationship between spatial pattern and ecological processes on a multitude of scales and organizational levels. Landscape ecology is not only a field of study, but also represents a new scientific perspective or paradigm that is relevant to a range of ecological, geophysical, and social sciences.

Heterogeneity, scale, pattern–process relationships, hierarchy, disturbance, coupled ecological-social dynamics, and sustainability are among the key concepts in landscape ecology. Typical research questions include: How can spatial heterogeneity be quantified so that it can be related to relevant ecological processes? What are the processes and mechanisms responsible for existing landscape patterns? How does spatial heterogeneity influence the flows of organisms, material, and energy? How does landscape pattern affect the spread of disturbances such as pest outbreaks, diseases, fires, and invasive species? How do patterns and processes on different scales relate to each other? How can ecological information be translated from fine to broad scales and vice versa? How can the knowledge of spatial heterogeneity help improve biodiversity conservation, management and planning? How can sustainable landscapes be developed and maintained?

Studies in landscape ecology usually involve the extensive use of spatial information from field survey, aerial photography and satellite remote sensing, as well as pattern indices, spatial statistics and computer simulation modeling. The intellectual thrust of this highly interdisciplinary enterprise is to understand the causes, mechanisms, and consequences of spatial heterogeneity, while its ultimate goal is to provide a scientific basis and practical guidelines for developing and maintaining ecologically, economically, and socially sustainable landscapes (Fig. 2).

Evolving Perspectives in Landscape Ecology

Contemporary landscape ecology is characterized by a flux of concepts and perspectives that reflect the differences in the origins of ideas and the ways of thinking, both of which are shaped by physical and cultural landscapes. The term "landscape ecology" was coined in 1939 by the German geographer, Carl Troll, who was inspired by the spatial patterning of landscapes revealed in aerial photographs and the ecosystem concept developed in 1935 by the British ecologist, Arthur Tansley. Troll saw the need for combining the more structurally-oriented geographical approach with the more functionally-centered ecosystem approach, in order to allow for geography to acquire ecological knowledge of land units and for ecology to expand its analysis from local sites to larger regions. Thus, he defined landscape ecology as the study of the relationship between biological communities and their environment in a landscape mosaic on various spatial scales. In the same time, Troll also emphasized the holistic totality of the landscape which was perceived as something of a Gestalt (an integrated system organized in such a way that the whole cannot be described merely as the sum of its parts). This holistic and humanistic landscape perspective, focusing on landscape mapping, evaluation, conservation, planning, design, and management, has been often termed the European school of landscape ecology, but now widely embraced worldwide.

The concept of landscape ecology was introduced from Europe to North America in the early 1980s, and subsequently stimulated the rapid development of a stream of new ideas, theories, methods, and applications. As a result, the field of landscape ecology quickly flourished in North America, and became a widely-recognized scientific discipline by the mid-1990s around the world. While a landscape can be generally defined as a spatially heterogeneous area whose spatial extent varies according to research questions and processes of interest, most landscape ecological studies have focused on broad scales, ranging from tens to thousands of square kilometers. A multiple-scale concept of landscape is meaningful and necessary as it facilitates the theoretical and

☆*Change History:* October 2017. J Wu updated Fig. 1.

Fig. 1 Different kinds of landscapes as spatial mosaics of various patches on a range of scales. (A) An urbanizing forest landscape, (B) a wetland landscape, (C) a Sonoran desert landscape, and (D) a grassland landscape. All photos by Jianguo Wu.

methodological developments by promoting micro-, meso-, and macro-scale approaches. Despite their variations in details, the definitions of landscape ecology in North America all hinge on the idea of spatial heterogeneity or spatial pattern. In particular, the North American landscape ecology focuses more on the relationship between spatial pattern and ecological processes on multiple scales ranging from tens of square meters to thousands of square kilometers in space and from a particular point to a period of several decades in time. Its primary goal is to understand the causes, mechanisms, and ecological consequences of spatial heterogeneity.

More specifically, North American landscape ecology has had a distinct emphasis on the effects of spatial pattern on biodiversity, population dynamics and ecosystem processes in a heterogeneous area. This research emphasis is practically motivated by the fact that previously contiguous landscapes have rapidly been replaced by a patchwork of diverse land uses (landscape fragmentation), and conceptually linked to the theory of island biogeography developed in the 1960s and the perspective of patch dynamics that began to take shape in the 1970s. Island biogeographic theory relates the equilibrium-state species diversity of islands to their size (area effect on species extinction rate) and distance to the mainland (distance effect on species immigration rate). The heuristic value of the theory is apparent for understanding the ecology of habitat patches submerged in a sea of human land uses. The patch dynamics perspective, on the other hand, treats ecological systems as mosaics of interacting patches of different size, shape, kinds, and history, emphasizing the transient dynamics and cross-scale linkages of such patchy systems. In this view, a forest is no more than a dynamic mosaic of tree gaps of various age, species composition, and biophysical properties; thus the dynamics of the forest can be adequately predicted by aggregating the behavior of individual tree gaps. The perspective of patch dynamics has been evident in the conceptual development of landscape ecology in the recent decades.

In summary, the European approach is more humanistic and holistic in that it emphasizes a society-centered view that promotes place-based and solution-driven research. In contrast, the North American approach is more biophysical and analytical in that it has

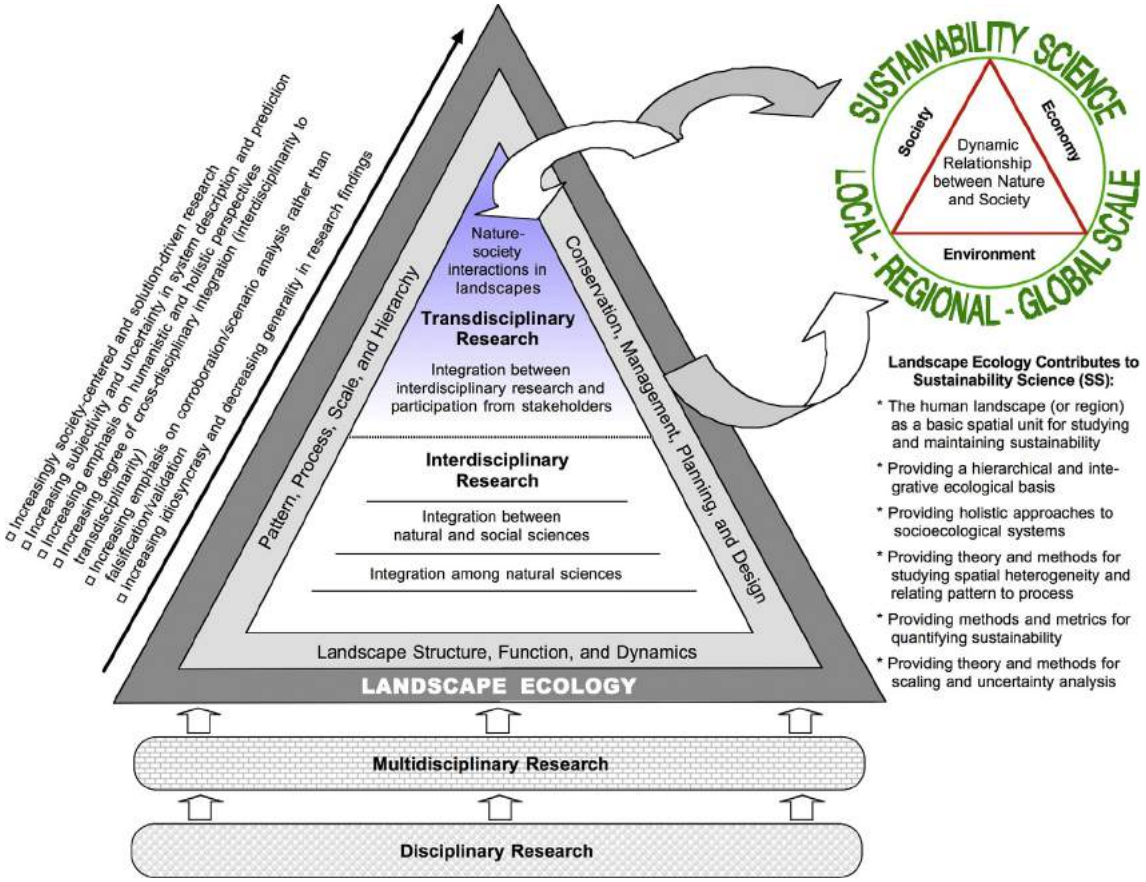

Fig. 2 A hierarchical and pluralistic view of landscape ecology. "Hierarchical" refers to the multiplicity of organizational levels, spatiotemporal scales, and degrees of cross-disciplinarity in landscape ecological research. "Pluralistic" indicates the necessity to recognize the values of different perspectives and methods in landscape ecology dictated by its diverse origins and goals. Reproduced from *Landscape Ecology*, 21, 2006, 1–6, Cross-disciplinarity, landscape ecology, and sustainability science, Wu J, with kind permission of Springer Science and Business Media.

been dominated by a biological ecology-centered view that is driven primarily by scientific questions. Here I hasten to point out that this dichotomy most definitely oversimplifies the reality because such geographic division conceals the diverse and continuously evolving perspectives within each region. In fact, many ecologists in North America have recognized the importance of humans in shaping landscapes for several decades (especially since the dust bowl in the 1930s). Although humans and their activities have been treated only as one of many factors interacting with spatial heterogeneity, more integrative studies have been emerging rapidly in the past few decades with the surging interest in urban ecology and sustainability science in North America. On the other hand, the perspective of spatial heterogeneity has increasingly been recognized by landscape ecologists in Europe and the rest of the world. Thus, the current development of landscape ecology around the world seems to suggest a transition from a stage of diversification to one of consolidation (if not unification) of key ideas and approaches.

In fact, both the European and North American approaches can be traced back to the original definition of landscape ecology. Carl Troll's proposal to integrate the geographical and structural approach with the ecological and functional approach is best reflected in the pattern–process–scale perspective, which enhances the scientific rigor of landscape ecology. The holistic and humanistic perspective, on the other hand, epitomizes the idea of landscape as a nature-society coupled system embraced by Troll and others. This perspective is entailed by any attempt to tackle practical problems in real landscapes on broad scales. Both the European and North American perspectives are essential to the development of landscape ecology as a truly interdisciplinary science.

Key Topics in Landscape Ecology

The scope of landscape ecology is quite comprehensive and dynamic. As with other interdisciplinary fields, it is impossible to define precisely the domain of landscape ecological studies. To get a sense of what the scientific core of landscape ecology is, here I discuss a series of key research topics based on the collective view of leading landscape ecologists and relevant publications, mainly in the flagship journal of the field, Landscape Ecology (http://www.springeronline.com/journal/10980/). These include: (1) pattern–process–scale relationships of landscapes; (2) landscape connectivity and fragmentation; (3) scale and scaling; (4) spatial analysis and

landscape modeling; (5) land use and land cover change; (6) landscape history and legacy effects; (7) landscape and climate change interactions; (8) ecosystem services in changing landscapes; (9) landscape sustainability; and (10) accuracy assessment and uncertainty analysis. Here I highlight six of these key topics, and more in-depth discussions of these key issues can be found in Further Reading at the end of this article.

1. Pattern–process–scale relationships and ecological flows in landscapes. Understanding how organisms, matter, and energy affect, and are affected by, the spatial pattern of landscape mosaics is a fundamental problem in landscape ecology. Much progress has been made in unraveling the effect of spatial heterogeneity on the spread of disturbances (e.g., fires and diseases) and the influence of landscape fragmentation on population dynamics, particularly, through studies of metapopulations (structurally discrete and functionally connected population ensembles). Research into the effects of landscape pattern on ecological processes across scales is still a rapidly developing area. Important areas for future research also include the spread of invasive species, the effects of landscape structure on population genetics (known as landscape genetics), and the effects of socioeconomic processes on ecological flows in landscape mosaics on multiple scales.
2. Mechanisms and consequences of land use and land cover change. Land use and land cover change, driven primarily by socioeconomic processes, exerts the most pervasive and profound influences on the structure and functioning of landscapes. Thus, quantifying the spatiotemporal pattern of landscape change and understanding its underlying driving forces are essential. More effort is needed to couple biophysical with socioeconomic approaches and to integrate ecological with historical methods in the study of land change.
3. Scale and scaling. Spatial pattern and ecological and socioeconomic processes in heterogeneous landscapes operate on multiple scales, and thus understanding the totality of landscapes requires relating different phenomena across domains in space and time. The process of translating information from one scale or organizational level to another is referred to as scaling. Landscape ecologists are leading the way in developing the theory and methods of scaling that is essential to all natural and social sciences. However, many challenges still remain, including establishing scaling relations for a variety of landscape patterns and processes as well as integrating ecological and socioeconomic dimensions in a coherent scaling framework.
4. Coupling landscape pattern analysis with ecological processes through spatial analysis and landscape modeling. Quantifying spatial heterogeneity is the necessary first step to understanding the effects of landscape pattern on ecological processes. Various effects of the compositional diversity and spatial configuration of landscape elements have been well documented, and a great number of landscape metrics (synoptic measures of landscape pattern) and spatial analysis methods have been developed in the past two decades. The greatest challenge, however, is to relate the measures of spatial pattern directly to the processes and properties of biodiversity and ecosystem functioning. To address these challenges, well-designed field-based observational and experimental studies are indispensable, and remote sensing techniques, geographic information systems (GIS), spatial statistics, and simulation modeling are also necessary.
5. Ecosystem services in changing landscapes. Ecosystem services are benefits that people derive from ecosystems. As a concept, ecosystem services bridges ecology and economy and has been increasingly used in the science and practice of conservation, resource management, and sustainable development. All ecosystem services are generated and used in landscapes that continue to change; the flows of ecosystem services are affected by landscape patterns; and certain spatial configurations of multiple ecosystems may synergistically render services (or disservices) that single ecosystems cannot produce. Thus, it is crucial to quantify spatiotemporal patterns, source-sink dynamics, trade-offs, and synergistic interactions of provisioning, regulating, and cultural ecosystem services at the landscape and regional scales. Place-based landscape theories of ecosystem services are needed.
6. Landscape sustainability. We may define landscape sustainability as the adaptive process of simultaneously maintaining and improving biodiversity, ecosystem services, and human well-being in a landscape. Because of the emphasis on broad- and multi-scale patterns and processes with interdisciplinary approaches, landscape ecology is uniquely positioned to provide a comprehensive theoretical basis and pragmatic guidelines for biodiversity conservation, ecosystem management, and sustainable development. These real-world problems cannot be adequately addressed by species-centered or individual ecosystem-based approaches. How do spatial processes occurring in landscapes (e.g., urbanization, agriculture, flooding, fires, biological invasion) affect the biodiversity, ecosystem functioning, ecosystem services, and human-wellbeing altogether? How do ecological, economic, and social processes interact to determine landscape resilience and sustainability? What are the design principles for sustainable landscapes? These are only a few of many challenging questions landscape ecology will continue to address in decades to come.

Concluding Remarks

Emphasis on heterogeneity begs questions of the relationship between pattern and process. Simply put, heterogeneity is about structural and functional patterns that deviate from uniform and random arrangements. It is this pervasively common non-homogeneous characteristic that makes spatial patterns ecologically important as it suggests nontrivial relationship to underlying processes. Thus, studying pattern without getting to process is superficial, and understanding process without reference to pattern is incomplete. Emphasis on heterogeneity also makes scale a critically important issue because heterogeneity, as well as the relationship between pattern and process, may vary as the scale of observation or analysis is changed. Thus, whenever heterogeneity is emphasized, spatial structures, underlying processes, and scale inevitably become essential objects of study. From this perspective,

landscape ecology is a science of heterogeneity and scale. On the other hand, with increasing human dominance in the biosphere, emphasis on broad spatial scales makes inevitable to deal with humans and their activities. As a consequence, humanistic and holistic perspectives have been and will continue to be central in landscape ecological research.

The above arguments also, in part, explain the two seemingly disparate views that have become known as the European and North American perspectives in landscape ecology. The world is already too fragmented ecologically, economically, and socially, and we certainly do not need a landscape ecology for each continent. As discussed earlier, the two perspectives should be viewed as being complementary rather than contradictory. To increase the synergies between the two approaches, not only do we need to appreciate the values of each, but also to develop an appropriate framework by which different perspectives and methods can be integrated. This requires a pluralistic and multi-scale perspective (Fig. 2). Landscapes out there are messy and are increasingly being messed up. Landscape ecology not only is expected to provide the scientific understanding of the structure and functioning of various landscapes, but also the pragmatic guidelines and tools with which order and sustainability can be created and maintained for the ever-changing landscapes. Landscape ecology is a science of spatial heterogeneity and scale, and its ultimate goal is to improve the sustainability of landscapes.

Landscape Planning☆

Ü. Mander and E Uuemaa, University of Tartu, Tartu, Estonia

Introduction

This article presents a scientific overview of the basic implementation of the principles of ecological engineering in landscape planning. The first two sections discuss the landscape definition, landscape functions, and multifunctionality. The subsequent sections give an overview of the landscape diversity and coherence, landscape fragmentation and its ecological consequences, landscape evaluation and landscape indicators, the levels and steps of landscape planning, ecologically compensating areas in the landscape, as well as of the leading principle in ecological landscape planning – the concept and implementation of territorial ecological networks (greenway networks) at the landscape level.

Landscape Definition

Landscapes as dynamic and characteristic expressions of the interaction between the natural environment and human societies can be considered in very different ways: from the scenery and 'total character of the Earth' (Alexander von Humboldt cit. Zonneveld, 1995) to the complexity of ecosystems. Depending on the degree of human interaction, landscape characteristics can be dominated by natural aspects on the one hand or human management on the other. In this article, we consider landscape as a geosystem or geocomplex, a comprehensive complex of natural (physical, chemical, biological) and anthropogenic factors distinguished at various hierarchical levels (i.e., micro-, meso-, and macrochores). The main natural factors in such a complex landscape system are water, topography, soil, geology, and climate conditions, as well as plants (vegetation cover) and animals (fauna). Likewise, the ecosystem approach deals with the same factors as ecosystem components, but in contrast to ecosystems, where all of the relations are considered via biota, the geosystem/landscape concept considers all of the relationships. However, different factors at different temporal and spatial scales play different roles in determining landscape character. Climatic and geological conditions cause the basic natural character of a landscape, whereas topography, soil, and vegetation cover are important in the formation of the detailed character of a landscape, and are influenced by human management.

Landscape Functions

Traditionally, the concept of landscape functions has been considered in the landscape planning system of Germany and German-speaking countries. According to that concept, landscape has the following functions: (1) production (economic) functions (biomass production, water supply, suitability of nonrenewable resources); (2) regulatory (ecological) functions (regulation of material and energy fluxes, hydrological and meteorological functions, regulation and regeneration of populations and bio(geo) coenoses, habitat (genetical) function); (3) social functions (psychological (esthetic and ethical) functions, information functions, human-ecological, and recreational functions).

This approach is very similar to the concept of ecosystem services and natural capital, which has recently gained extensive popularity. According to this concept, the typology of landscape functions includes four categories: (1) provisioning functions; (2) regulation functions; (3) habitat functions; and (4) cultural and amenity functions (see **Table 1**).

1. Provisioning functions comprise functions that supply 'physical services' in terms of resources or space. This category has been divided into two classes: production and carrier functions. Production functions reflect resources produced by natural ecosystems, for example, the harvesting of fish from the ocean, pharmaceutical products from wild plants and animals, or wood from natural forests. Carrier functions reflect the goods and services that are provided through human manipulation of natural productivity (e.g., fish from aquaculture or timber from plantations). In these cases, the function offered by nature is the provision of a suitable substrate or space for human activities, including agriculture, mining, transportation, etc.
2. Regulation functions result from the capacity of ecosystems and landscapes to influence ('regulate') climate, hydrological and biochemical cycles, Earth surface processes, and a variety of biological processes. These services often have an important spatial (connectivity) aspect; for example, the flood control function of an upper watershed forest is only relevant in the flood zone downstream of the forest.
3. Habitat functions comprise the importance of ecosystems and landscapes in maintaining natural processes and biodiversity, including the refugium and nursery functions. The refugium function reflects the value of landscape units in providing habitats

Table 1 Typology of ecosystem/landscape functions, goods, and services

Entry	*Ecosystem functions*	*Short description*	*Biophysical indicators (examples) (i.e., ecosystem properties providing the goods or service)*	*Goods and services (examples)*
1	Provisioning Production functions	Resources from unmanipulated ecosystems	Biomass (production and stock) Biochemical properties	Freshwater Food (e.g., fish, bush meat) Raw materials (wood, fodder)
	Carrier functions	Use of space to (enhance) supply resources or other goods and services	Depending on the specific land use type, different requirements are placed on environmental conditions (e.g., soil stability and fertility, air and water quality, hydrology, topography, climate, geology)	Cultivation (e.g., agriculture, plantations, aquaculture) Energy conversion (e.g., wind, solar) Mining (ore, fossil fuels) Transportation (esp. on waterways)
2	Regulation functions	Direct benefits from ecosystem processes	Role of ecosystems in biogeochemical cycles (e.g., CO_2/O_2 balance, hydrological cycle)	Climate regulation Maintenance of soil fertility
			Role of vegetation and biota in removal or breakdown of nutrients and toxic compounds	Waste treatment (e.g., water purification) Maintenance of air quality
			Physical properties of land cover	Water regulation (e.g., buffering runoff) Erosion prevention Storm protection and flood prevention
			Population control through tropic-dynamic relations	Biological control (of pests and diseases) Pollination
3	Habitat functions	Maintenance of biodiversity and evolutionary processes	Presence of rare/endemic species; species diversity Reproduction habitat for migratory species	Refugium for wildlife Nursery function (for commercial species)
4	Cultural and amenity functions	Nonmaterial benefits	Landscape (or ecosystem) properties with esthetic, recreational, historical, spiritual, inspirational, scientific, or educational value	Enjoyment of scenery (e.g., scenic roads) Ecotourism and recreation Heritage value/cultural landscapes Spiritual or religious sites Cultural expressions (use of landscapes as motif in books, film, painting, folklore, advertising) Research and education

Adapted from De Groot, R.S., Hein, L., 2007. Concept and valuation of landscape functions at different scales. In: Mander, Ü., Wiggering, H., Helming, K. (Eds.), Multifunctional land use: meeting future demands for landscape goods and services. Berlin: Springer, pp. 15 -36.

to (threatened) fauna and flora, and the nursery function indicates that some landscape units provide a particularly suitable location for reproduction and thereby have a regulating impact on the maintenance of populations elsewhere.

4. Cultural and amenity functions relate to the benefits people obtain from landscapes through recreation, cognitive development, relaxation, and spiritual reflection. This may involve actual visits to the area, indirectly enjoying the area (e.g., through nature movies), or gaining satisfaction from the knowledge that a landscape contains important biodiversity or cultural monuments. The latter may occur without having the intention of ever visiting the area. These services have also been referred to as 'information functions'.

The evaluation of landscapes for planning and management purposes, as well as landscape synthesis and decision making, is based on landscape functions.

Landscape Diversity and Coherence

One of the basic characteristics of landscapes is the diversity or heterogeneity of the landscape pattern (mosaic).

Hundreds of landscape metrics have been proposed by various researchers to analyze the landscape pattern. Most of these are covered by the computer program FRAGSTATS. The most typical use of the FRAGSTATS-based landscape metrics is for the prediction of species diversity. Also, several researchers have used FRAGSTATS-based landscape metrics as indicators of various landscape changes (management activities and natural disturbances) such as the change in the spatial structure of landscapes, forest planning and management, landscape destruction and rehabilitation, and landscape disturbances by fire and road construction. This demonstrates that temporal (time-series-based) indicators are inseparably related to spatial indicators. In order to control how landscape metrics respond to changing grain size, extent, the number of zones, the direction of analysis, etc.,

landscape simulators are applied. Gardner et al. introduced the concept of neutral models into landscape ecology. The aim of a neutral model is to have an expected pattern in the absence of specific landscape processes. In order to have a random pattern, the first application of this concept stemmed from the percolation theory, but different types of regular artificial landscapes are also used.

Landscape coherence has been considered one of the criteria for the development of sustainable rural landscapes. Proceeding from Bockemühl's concept of landscape identity and perception, which was developed in biodynamic farms, van Mansvelt classifies the ecological coherences of rural landscape in three groups: vertical (on site), horizontal (landscape-level), and cyclical (temporal) coherences. The first type can be referred to as coherence between biodiversity and the local abiotic environmental conditions. For instance, soil-bound agricultural production would be an example of vertically coherent biodiversity management. The horizontal type of ecocoherence is "that between coherence within a habitat (biotope or mini-ecosystem) and that of habitats in a landscape (macro-ecosystem)" (van Mansvelt, 1997). This coherence refers to the functional (ecophysiological) interdependency of species within the ecosystems, but also to the relationships of habitats within the larger system. According to Kuiper, horizontal coherence is characterized by the connectivity between similar ecosystems in a landscape. Cyclical (temporal) coherences are characterized not only by the full life cycles of species and systems, but also by the self-production of species and biotopes, and season-compliant management (e.g., sowing, mowing, coppicing, etc.).

From the methodological point of view, van Mansvelt's concept of landscape coherence is rather holistic and is used in the context of landscape perception and visual characteristics, with no studies that quantify this category in landscape validation. The most common estimates of different ecological coherences are their appearance or absence or relative scores. Another attempt to estimate coherence refers to the connectivity between landscape components. However, as in the case of various analogous indices that have been developed to describe landscape connectivity, this approach does not consider the quantification of coherence.

Wascher (2000) defines landscape coherence as the "adequacy of land use according to biophysical conditions." Mander and Murka developed a dynamic landscape coherent concept which links issues of landscape diversity and landscape change. This concept refers to the correspondence between changes in actual (cultural or man-made) landscape diversity caused by land amelioration or transformation of landscape pattern (e.g., due to changing socioeconomic conditions) and potential (biophysically determined) landscape diversity. According to this concept, the homogenization of landscape diversity caused by amelioration or other anthropogenic disturbances and determined on the basis of ecotone length per area unit can be lowest in the most sensitive (less resistant) landscapes. These are landscapes with both very simple and very complicated potential (biophysical) diversity, determined by heterogeneity of soil cover (**Fig. 1**). For measuring landscape coherence, Mander *et al.* (2010) proposed Moran's I correlograms and a simple characteristic of half-value distances: $h_{I=0.5}$ – the distance lag where Moran's I drops below 0.5 (**Fig. 2**). Half-value distance enables to compare patterns of different layers e.g. land use and soil. This concept of landscape coherence helps to find optimal rates for changing land use pattern via land reclamation or planning activities.

Landscape Fragmentation and Its Ecological Consequences

One of the main impacts of human activities on landscapes worldwide is the fragmentation of habitats and whole landscapes. Habitat fragmentation is the main reason for biodiversity decrease. It provides a familiar example of a critical threshold, that is, transition ranges across which small changes in spatial pattern produce abrupt shifts in ecological responses. As the landscape becomes dissected into smaller parcels of habitat, landscape connectivity – the functional linkage among habitat patches – may suddenly become disrupted, having important consequences for the distribution and persistence of populations. Landscape connectivity depends not only on the abundance and spatial patterning of habitat, but also on the habitat specificity and dispersal

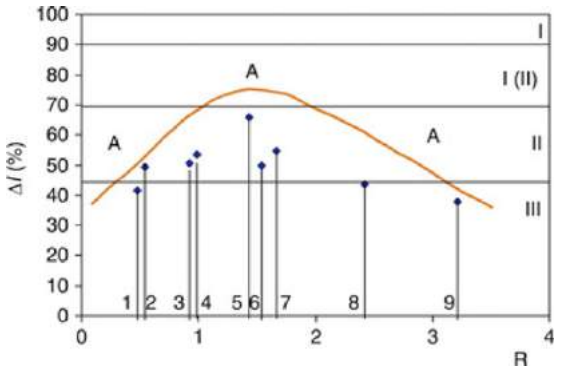

Fig. 1 Recommended change limits (ΔI) of actual landscape diversity (R) according to the dynamic coherence concept. *A* is area of diversity change at which undesirable anthropogenic processes (erosion, deflation, clogging of drainage, etc.) occur. The curve indicates the generalized coherence limit. II and III are the coherence levels for landscapes of resistance groups II and III, respectively. Adapted from Mander, Ü., Murka, M., 2003. Coherence of cultural landscapes: a new criterion for evaluating impacts of landscape changes. In: Mander, Ü., Antrop, M. (Eds.), Advances in ecological sciences 16: multifunctional landscapes, vol. III: continuity and change. Boston, MA: WIT Press, pp. 15–32.

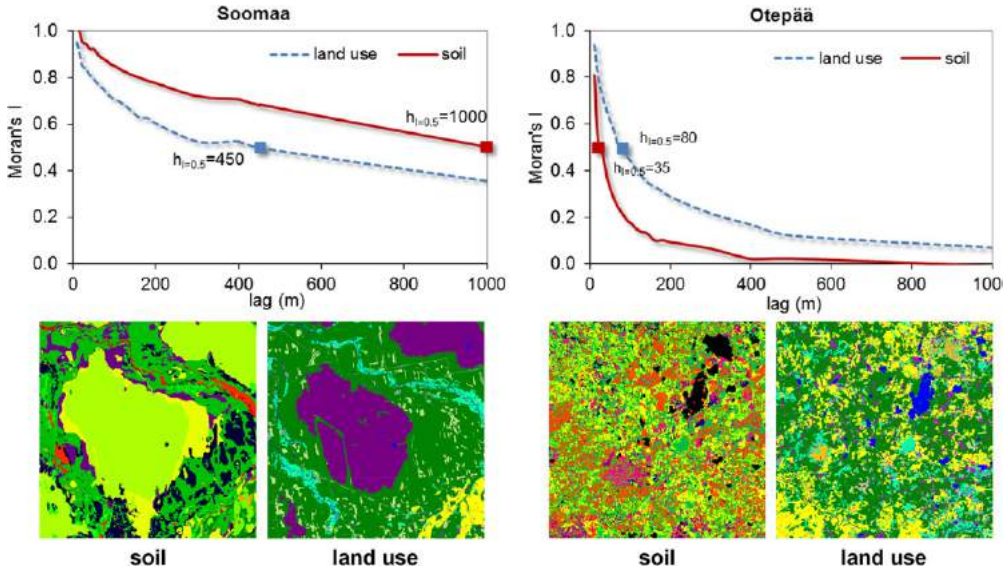

Fig. 2 Correlograms can be used to describe and compare the spatial structure of landscapes and also as an indicator fo coherence. Graphs show correlograms and $h_{I=0.5}$ values for land use and soil of two different landscapes – Otepää and Soomaa. Otepää is more heterogeneous than Soomaa and human influence has changed the landscape even more complex because landscape pattern is more fragmented than soil. Adapted from Mander, Ü., Uuemaa, E., Roosaare, J., Aunap, R., Antrop, M., 2010. Coherence and fragmentation of landscape patterns as characterized by correlograms: a case study of Estonia. Landscape and Urban Planning 94, 31–37.

abilities of species. Habitat specialists with limited dispersal capabilities presumably have a much lower threshold to habitat fragmentation than highly vagile species, which may perceive the landscape as functionally connected across a greater range of fragmentation severity.

The composition of habitat types in a landscape and the physiognomic or spatial arrangement of those habitats are the two essential features that are required to describe any landscape. As such, these two features affect four basic ecological processes that can influence population dynamics or community structure. The first two of these processes, landscape complementation and landscape supplementation, occur when individuals move between patches in the landscape to make use of nonsubstitutable and substitutable resources. The third process, source–sink dynamics, describes the consequences of having different individuals in the same population occupy habitat patches of different qualities, and is part of the metapopulation concept. The fourth process, the neighborhood effect, describes how landscape effects can be amplified when the critical resources are in the landscape immediately surrounding a given patch.

In generalizing from several studies, one can conclude that there is an optimum of landscape fragmentation at which biodiversity is the highest. For instance, in open patches, large natural (relatively) homogeneous forests caused by natural disturbances or human activities that can support various species with different ecological requirements can exist. On the other hand, excessively small patches in fragmented landscapes are unable to provide enough space and resources for various metapopulations.

Landscape planning measures, especially the implementation of territorial ecological networks, can provide greater connectivity and biodiversity in landscapes.

Landscape Evaluation and Landscape Indicators

The evaluation of nature is an inseparable part of the process of environmental/landscape planning, management, and decision making. In recent decades, its importance has reached the global level. At local and regional levels, landscape assessment for planning and decision-making processes is a key issue in sustainable landscape management.

One of the well-known conceptual frameworks for ecological/environmental indicators is the driving forces (drivers) → pressures → state → impact → responses (DPSIR) approach, which treats the environmental management process as a feedback loop controlling a cycle consisting of these five stages.

Regarding the EU policy in biological and landscape diversity management (e.g., PEBLDS, the Pan-European Biological and Landscape Diversity Strategy), it is useful to follow the DPSIR framework in reporting environmental issues. This approach treats the environmental management process as a feedback loop that controls a cycle consisting of these five stages. In addition, this introduces the term 'pressures' and adds 'impacts' – a concept that implies the cause–effect link.

The nitrogen cycle can be used as an example of the DPSIR approach in the intensification of agriculture:

- *Driving force*. Intensive agriculture;
- *Pressure*. Use of mineral fertilizers;

- *State*. Intensive loss of nitrogen from agricultural fields, high nitrogen concentration in rivers and groundwater, intensive gaseous N flux into the atmosphere, high excess nitrogen loading in ecosystems;
- *Impact*. Loss of biodiversity, eutrophication of water bodies, methemoglobinaemia, cancer risk, decreasing biodiversity, lower esthetical value of landscapes;
- *Response*. (1) Less mineral fertilizers and optimization of crop rotations with leguminous plants, especially in sensitive and potential core areas, (2) establishment of riparian buffer zones, (3) establishment of riverine and riparian wetlands.

On the other hand, the influence of marginalization (land abandonment) can also be characterized using the DPSIR approach (**Fig. 3**):

- *Driving force*. Marginalization (abandonment of agriculture);
- *Pressure*. Change of existing management scheme;
- *State*. Loss of open landscapes, loss of various (grassland) biotopes;
- *Impact*. Loss of biodiversity, loss of scenic values of landscape;
- *Response*. (1) Subsidies for farmers to support traditional low input or ecological agriculture, (2) restoration and rehabilitation of valuable biotopes (wooded meadows, alvars), (3) (re-)establishment of wetland biotopes in agricultural landscapes.

Using the DPSIR approach as a conceptual background, we consider landscape indicators as a system of structural and functional parameters that can be used to evaluate landscape pressure, state, and responses. The structural indicators are related to landscape structure (both temporal and spatial), whereas functional indicators can be divided according to landscape functions (**Table 2**).

Indicators are increasingly used to assess the effects of landscape change on the visual landscape. Visual scale is considered a key aspect of landscape perception. Visual scale is defined as the perceptual units that reflect the experience of landscape rooms, visibility and openness. The perceived visual scale is affected by both abandonment and spontaneous forest growth in previously open agricultural areas as well as of changes in agricultural and forestry strategies. Although visual landscape assessment using indicators simplifies the complexity of landscapes and landscape perception, the approach has gained ground for its repeatability, transparency and applicability in landscape planning and monitoring (**Table 3**) (Ode *et al.*, 2010a; Dramstad *et al.*, 2006).

Main Ecological Engineering Principles of Landscape Planning

Jørgensen presents 19 ecological engineering principles for application in landscape management:

- Ecosystem structure and functions are determined by the forcing functions of the system.
- Energy inputs to the ecosystems and available storage of matter are limited.
- Ecosystems are open and dissipative systems.
- Attention to limiting factors is strategic and useful in preventing pollution or restoring ecosystems.
- Ecosystems have a homeostatic capability that results in the smoothing out and depressing effects of strongly variable inputs.
- Match recycling pathways to the rates to ecosystems to reduce the effect of pollution.
- Design for pulsing systems wherever possible.

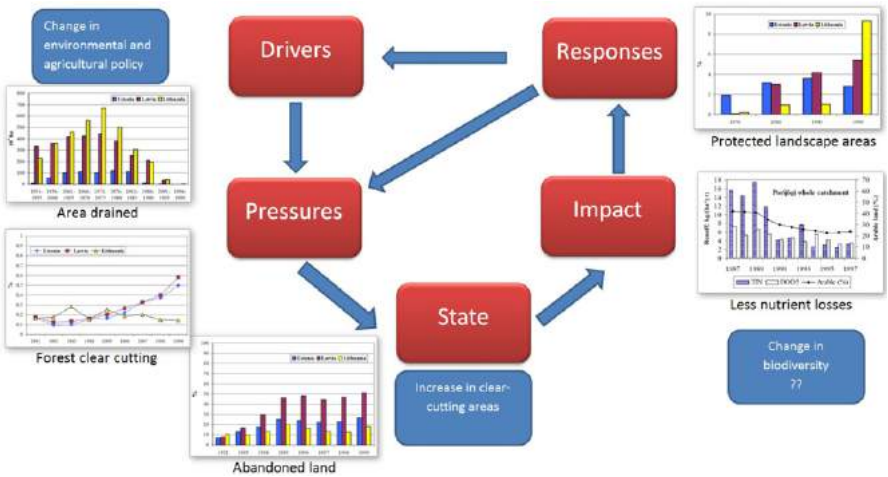

Fig. 3 The DPSIR framework for reporting on environmental issues: an example of the change in the political and socioeconomic system in Central and Eastern Europe at the end of the 1980s and the beginning of the 1990s followed by changes in environmental and agricultural policy, as a possible basis for indicator classification and landscape assessment. Adapted from Mander Ü and Kuuba R (2004) Changing landscapes in Mander, Ü., Kuuba, R., 2004. Changing landscapes in northeastern Europe based on examples from Baltic countries. In: Jongman, R.H.G (Ed.), The new dimensions of the European landscape. Dordrecht, the Netherlands: Springer, pp. 123-134.

Table 2 Potential indicators for determining (sustainable) use of ecosystem services.

Services comments and examples	*Ecological process and/or component providing the service (or influencing its availability) = functions*	*State indicator (how much of the service is present)*	*Performance indicator (how much can be used/provided in sustainable way)*
Provisioning			
1 Food	Presence of edible plants and animals	Total or average stock(in kg ha^{-1})	Net productivity (in kcal $ha^{-1}year^{-1}$ or other unit)
2 Water	Presence of water reservoirs	Total amount of water (m^3ha^{-1})	Max sust. water-extraction ($m^3ha^{-1}year^{-1}$)
3 Fiber & Fuel & other raw materials	Presence of species or abiotic components with potential use for timber, fuel or raw material	Total biomass (kg ha^{-1})	Net productivity (kg $ha^{-1}year^{-1}$)
4 Genetic materials: genes for resistance to plant pathogens	Presence of species with (potentially) useful genetic material	Total 'gene bank' value (e.g. number of species & sub-species)	Maximum sustainable harvest
5 Biochemical products and medicinal resources	Presence of species or abiotic components with potentially useful chemicals and/or medicinal use	Total amount of useful substances that can be extracted (kg ha^{-1})	Maximum sustainable harvest (in unit mass/area/time)
6 Ornamental species and/or resources	Presence of species or abiotic resources with ornamental use	Total biomass (kg ha^{-1})	Maximum sustainable harvest
Regulating			
7 Air quality regulation: (e.g. capturing dust particles)	Capacity of ecosystems to extract aerosols & chemicals from the atmosphere	Leaf area index NOx-fixation, etc.	Amount of aerosols or chemicals 'extracted' – effect on air quality
8 Climate regulation	Influence of ecosystems on local and global climate through land-cover and biologically-mediated processes	Greenhouse gas-balance (esp. C-sequestration); land cover characteristics, etc.	Quantity of greenhouse gases, etc. fixed and/or emitted → effect on climate parameters
9 Natural hazard mitigation	Role of forests in dampening extreme events (e.g. protection against flood damage)	Water-storage (buffer) capacity (in m^3)	Reduction of flood-danger and prevented damage to infrastructure
10 Water regulation	Role of forests in water infiltration and gradual release of water	Water retention capacity in soils, etc. or at the surface	Quantity of water retention and influence of hydro-logical regime (e.g. irrigation)
11 Waste treatment	Role of biota and abiotic processes in removal or breakdown of organic matter, xenic nutrients and compounds	Denitrification (kg N $ha^{-1}year^{-1}$); immobilization in plants and soil	Max amount of chemicals that can be recycled or immobilized on a sustainable basis
12 Erosion protection	Role of vegetation and biota in soil retention	Vegetation cover root-matrix	Amount of soil retained or sediment captured
13 Soil formation and regeneration	Role of natural processes in soil formation and regeneration	E.g. bio-turbation	Amount of topsoil (re)generated per ha/year
14 Pollination	Abundance and effectiveness of pollinators	Number & impact of pollinating species	Dependence of crops on natural pollination
15 Biological regulation	Control of pest populations through trophic relations	Number & impact of pest-control species	Reduction of human diseases, live-stock pests, etc.
Habitat or supporting			
16 Nursery habitat	Importance of ecosystems to provide breeding, feeding or resting habitat for transient species	Number of transient species & individuals (esp. with commercial value)	Dependence of other ecosystems (or 'economies') on nursery service
17 Genepool protection	Maintenance of a given ecological balance and evolutionary processes	Natural biodiversity (esp. endemic species); habitat integrity (irt min. critical size)	'Ecological value' (i.e. difference between actual and potential biodiversity value)
Cultural & amenity			
18 Aesthetic: appreciation of natural scenery (other than through deliberate recreational activities)	Aesthetic quality of the landscape, based on e.g. structural diversity, 'greenness,' tranquility	Number/area of landscape features with stated appreciation	Expressed aesthetic value, e.g., number of houses bordering natural areas # users of 'scenic routes'

Table 2 Continued

Services comments and examples	*Ecological process and/or component providing the service (or influencing its availability)=functions*	*State indicator (how much of the service is present)*	*Performance indicator (how much can be used/provided in sustainable way)*
19 Recreational: opportunities for tourism and recreational activities	Landscape-features attractive wildlife	Number/area of landscape & wildlife features with stated recreational value	Maximum sustainable number of people & facilities actual use
20 Inspiration for culture, art and design	Landscape features or species with inspirational value to human arts, etc.	Number/area of landscape features or species with inspirational value	#books, paintings, etc. using ecosystems as inspiration
21 Cultural heritage and identity: sense of place and belonging	Culturally important landscape features or species	Number/area of culturally important landscape features or species	Number of people 'using' forests for cultural heritage and identity
22 Spiritual & religious inspiration	Landscape features or species with spiritual & religious value	Presence of landscape features or species with spiritual value	Number of people who attach spiritual or religious significance to ecosystems
23 Education & science opportunities for formal and informal education & training	Features with special educational and scientific value/interest	Presence of features with special educational and scientific value/interest	Number of classes visiting, number of scientific studies, etc.

Adapted from De Groot, R.S., Alkemade, R., Braat, L., Hein, L., Willemen, L., 2010. Challenges in integrating the concept of ecosystem services and values in landscape planning, management and decision making. Ecological Complexity 7, 262 -270.

- Ecosystems are self-designing systems.
- Ecosystem processes have characteristic temporal and spatial scales that must be accounted for in environmental management.
- Biodiversity should be championed to maintain an ecosystem's self-design capacity.
- Ecotones and transition zones are as important to ecosystems as membranes are for cells.
- Coupling between ecosystems should be utilized wherever possible.
- The components of an ecosystem are interconnected and interrelated and form a network, implying that the direct as well as indirect effects of ecosystem development need to be considered.
- An ecosystem has a history of development.
- Ecosystems and species are most vulnerable at their geographical edges.
- Ecosystems are hierarchical systems and are parts of a larger landscape.
- Physical and biological processes are interactive. It is important to know both physical and biological interactions and to interpret them.
- Ecotechnology requires a holistic approach that integrates all interacting parts and processes as much as possible.
- Information in ecosystems is stored in structures.

The following five recommendations are implicitly embedded in the 19 principles: (1) know the natural and man-made ecosystems that make up a landscape and the corresponding ecological properties and processes; (2) use this ecological knowledge in landscape management; (3) develop models and use ecological indicators to enable a thorough overview of the many interacting components, the ecological networks, and the most crucial ecological processes; (4) maintain high biodiversity and a high-diversity pattern of ecosystems, zones, ecotones, corridors, ditches, ecological niches, etc.; the overloading from man-made ecosystems can be reduced and buffered considerably by planning a landscape with a mosaic of different man-made and natural ecosystems; (5) everything is linked to everything else in an ecosystem, and the entire system is more than the sum of its parts. These principles should underlie all ecological management decisions.

Levels and Steps in Landscape Planning

Typically, landscape planning provides information about the existing qualities of the landscape and nature, which are considered to be nature or landscape potentials, and their value as well as their sensitivity to impacts, the existing and potential impacts on these potentials, and the objectives and guidelines for the development of the landscape and nature, upon which proposed measures and development plans can be measured.

With this information, landscape planning provides evaluation guidelines for the impact regulations and for the part of the environmental impact assessment which is concerned with the landscape and nature. In the beginning phases of planning projects, landscape planning offers a background for the evaluation of alternatives, for example, in the placement of transportation corridors. Landscape planning provides a basis for preliminary opinions about proposed projects, even for projects which were proposed after the completion of the landscape plan.

Bastian and Schreiber describe four main steps in comprehensive landscape planning:

Table 3 Suggested indicators of visual scale for the different data sources landscape photos, aerial photographs, land cover data and field observation

	Landscape photos	*Orthophotos*	*Land cover*	*Field studies*
1. Open area indicators Example of basic data processing				
Proportion of open land	% of open land	% of open land	% of open land	% of open land
Viewshed size		Size of viewshed	Size of viewshed	
Viewshed shape	Classification of shape (one large open area/ split open area/patchy open area)	Shape index	Shape index	Classification of shape (one large open area/ split open area/patchy open area)
Depth/breadth of view	Estimation of depth of view (short/medium/long)	Length of radius of view	Length of radius of view	Estimation of depth of view (short/medium/ long)
2. Indicators for the view obstruction				
Density of obstructing objects	Density of obstructing objects	Density of obstructing objects		Density of obstructing objects
Degree of visual penetration	Proportion of vegetation with different levels of visual penetration (blocked/dense/semi-open/open)			Proportion of vegetation with different levels of visual penetration (blocked/dense/semi-open/open)

Adapted from Ode, Å., Tveit, M.S., Fry, G. ,2010. Advantages of using different data sources in assessment of landscape change and its effect on visual scale. *Ecological Indicators* 10: 24–31.

- Definition of problem (determination of: planning context, planning priorities, planning prerequisites);
- Inventory, analysis, and diagnosis (determination of the natural potentials: inventory, impact, protection; evaluation of the ecological and esthetic suitability of the existing and proposed lands);
- Planning concept (elaboration of: objectives for nature protection and landscape management, alternatives);
- Plan of action (definition of requirements and measures necessary to achieve the objectives);
- Product: landscape planning program, regional landscape plan, landscape plan;
- Implementation (the realization of planning measures through nature protection authorities, nature protection organizations, other planning agencies, local governments, public institutions, and individuals);
- Review (evaluation of: implementation, planning objectives, necessary alterations).

Landscape analysis involves the evaluation of elemental, spatial, and temporal pattern of landscape, as well as of dynamics of landscape and land-use pattern. The landscape diagnosis provides a comparison of landscape potential with social requirements (stability and load analyses).

As the products of this comprehensive multilevel hierarchical system, a landscape program, regional landscape plan, landscape plan, and open space master plan will be elaborated (**Table 4**).

Territorial Ecological Networks

The concept and implementation of territorial ecological networks (greenway networks) at the landscape level is considered to be the leading principle in ecological landscape planning. The widely used European-level approach defines territorial ecological networks as coherent assemblages of areas representing natural and seminatural landscape elements that need to be conserved, managed, or, where appropriate, enriched or restored in order to ensure the favorable conservation status of ecosystems, habitats, species, and landscapes of regional importance across their traditional range.

In addition to this approach, there are a wide range of names worldwide given to such 'patch and corridor' spatial concepts: greenways in the USA, Australia, and New Zealand, ecological infrastructure, ecological framework, extensive open space systems, multiple use nodules, wildlife corridors, landscape restoration network, habitat networks, territorial systems of ecological stability, framework of landscape stability. In Estonia, a concept of "the network of ecologically compensating areas" (Mander *et al.*, 1988) has been developed since the early 1980s. This network can be seen as a landscape's subsystem – an ecological infrastructure – that counterbalances the impact of the anthropogenic infrastructure in the landscape. In comparison with the traditional biodiversity-targeted approach, this concept also considers the material and energy cycling, socioeconomic and socio-cultural aspects.

According to the broader concept, ecological networks preserve the main ecological functions in landscapes, such as (1) accumulating material and dispersing human-induced energy, (2) receiving and rendering unsuitable wastes from populated areas, (3) recycling and regenerating resources, (4) providing wildlife refuges and conserving genetic resources, (5) serving as migration tracts for biota, (6) serving as barriers, filters, and/or buffers for fluxes of material, energy, and organisms in landscapes, (7) serving as support frameworks for regional settlements, (8) providing recreation areas for people, and, consequently, and (9) compensating and balancing all inevitable outputs of human society.

A network of ecologically compensating areas is a functionally hierarchical system with the following components: (A) core areas, (B) corridors; functional linkages between the ecosystems or resource habitat of a species, enabling the dispersal and migration of species and resulting in a favorable effect on genetic exchange (individuals, seeds, genes) as well as on other interactions between ecosystems; corridors may be continuous (linear), interrupted (stepping-stones), and/or landscape (scenic and valuable cultural landscapes between core areas), (C) buffer zones of core areas and corridors, which support and protect the network from adverse external influences, and (D) nature development and/or restoration areas that support resources, habitats, and species (**Fig. 4**).

The size of network components serve as another criterion of the network's hierarchy on three levels: (1) the macroscale: large natural core areas ($>1000\ km^2$) separated by buffer zones and wide corridors or stepping-stone elements (width >10 km); (2) mesoscale: small core areas ($10–1000\ km^2$) and connecting corridors between these areas (e.g., natural river valleys, seminatural recreation areas for local settlements; width 0.1–10 km); (3) microscale: small protected habitats, woodlots, wetlands, grassland patches, ponds ($<10\ km^2$) and connecting corridors (stream banks, road verges, hedgerows, field verges, ditches; width <0.1 km).

Megascale ecological networks can be considered at the global level. The human footprint map can serve as a basis for determining global ecological networks (**Fig. 5**). The macroscale of ecological networks is represented by regional-level activities such as the Pan-

Table 4 Scales of landscape planning in Germany.

Planning area	*Spatial comprehensive planning*	*Landscape planning*	*Scale*
State	State spatial plan	Landscape program	1:500000–1:200000
Region (regional district or county)	Regional plan	Regional landscape plan	1:50000–1:25000
Community	Land-use plan	Landscape plan	1:5000–1:2500
Part of the community	Master plan	Open space master plan	1:2500–1:1000

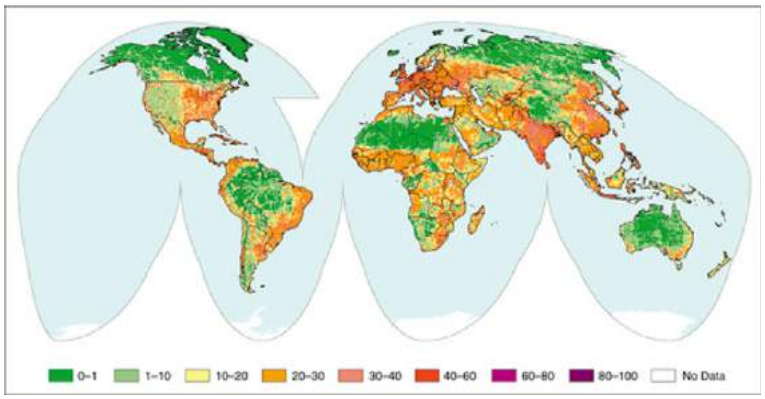

Fig. 5 A map of the human footprint as a basis for the ecological network system at the global scale. Summarized factors of anthropogenic pressure have been used, such as the Human Influence Index, which is the quantitative basis for the map. Adapted from Sanderson, E.W., Jaiteh, M., Levy, M.A., *et al.*, 2002. The human footprint and the last of the wild. BioScience 52 (10), 891–904. and Mander, Ü., Külvik, M., Jongman, R., 2003. Scaling in territorial ecological networks. Landschap 20 (2), 113–127.

European Ecological Network (PEEN) or national-level projects. In the Czech Republic, the Slovak Republic, and the Netherlands, territorial ecological networks are implemented and legislatively supported. In Estonia, Lithuania, and Poland, networks are designed and some aspects accepted by law. In Hungary, Latvia, Switzerland, and Ireland, network design is under development, and local or landscape-level ecological networks have been established in some parts of the territory of several European countries such as Germany, Belgium, the UK, Italy, Spain, Portugal, Russia, and Ukraine. Landscape-level ecological networks are designed or implemented on a wide range of spatial scales, from macro- and meso- to microscale projects. The most significant research on both species' migration and dispersal, as well as on energy and material fluxes, has been carried out at this level.

As an example of the designing of the national-level ecological network, we have presented a part of the PEEN that is based on Estonian data from a one square kilometer grid. The proposed ecological network design consists of three principal layers: (1) general topographical features like coastlines, the water network, major roads and place names for locating the depicted network; (2) a habitat-based field of suitability for the ecological network, calculated on the basis of network values of landscape features

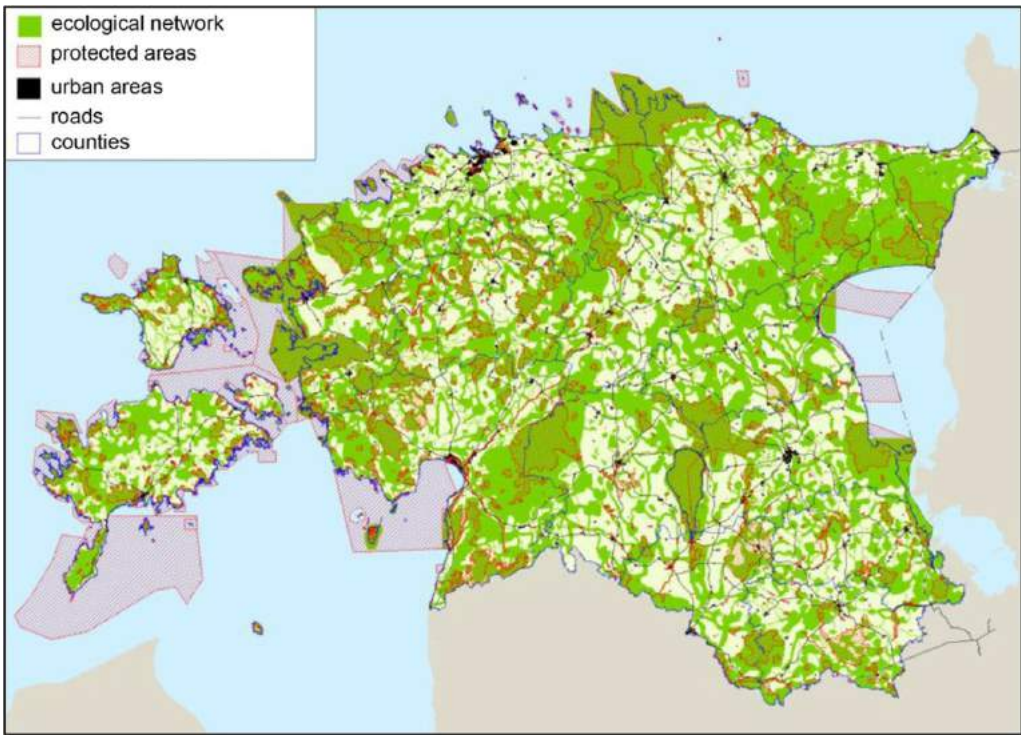

Fig. 6 Example of the ecological network of Estonia at the national level. Protected areas and areas not protected but suitable for an ecological network according to their present natural state. Adapted from Remm, K., Külvik, M., Mander, Ü., Sepp, K., 2004. Design of the Pan-European ecological network: a national level attempt. In: Jongman, R.H.G, Pungetti, G. (Eds.), New paradigms in landscape planning: ecological networks and greenways. Cambridge: Cambridge University Press, pp. 151–170.

using a predefined algorithm; and (3) the ecological network as an administrative decision. The second layer serves as a tool supporting decision making, while the third layer consists of the traditional components of an ecological network, such as core areas, corridors, buffer zones, and nature development/restoration areas. **Fig. 6** represents a combination of the last two layers as a map of protected areas (layer 3) and areas not protected but suitable for inclusion in ecological networks according to their present natural state (layer 2). Protected areas can be considered to be obligatory core areas of ecological networks, whereas areas suitable for ecological networks areas can be considered to be buffer zones and/or corridors.

Microcosms

FE Matheson, National Institute of Water & Atmospheric Research, Hamilton, New Zealand

Introduction

This article presents a scientific overview of the use of microcosms as a tool in the study of ecology. The article discusses what microcosms are, how and why microcosms have been, and continue to be, used for ecological research, and important factors to be considered in the design of ecological experiments using microcosms.

What Are Ecological Microcosms?

Microcosms are microecosystems. They are small, multispecies systems, consisting of a subset of the biotic community and abiotic properties of a larger ecosystem and have the common features of ecosystems such as food chains, production–consumption cycles, and hierarchies. A microcosm is a simplified, physical model of an ecosystem that enables controlled experiments to be conducted in the laboratory or *in situ*. They are often, and best, used in conjunction with theoretical mathematical models and field observational studies as part of a broader research strategy. Artificial microcosms are wholly or partially isolated from the external world in containers. Some natural microcosms also exist such as a phytotelmata (a contained aquatic habitat formed by a plant and populated by aquatic organisms, for example, bromeliads, tree holes) and communities confined to rock pools and moss patches.

Artificial microcosms may be derived directly from nature or gnotobiotic. Derived microcosms typically simulate a specific natural ecosystem, using species and components from it, and the exact species composition, particularly with respect to microorganisms, is unknown. In contrast, the exact species composition of gnotobiotic microcosms is known with these normally containing a set of physiologically well-studied species from pure (axenic) cultures that may or may not be normally found together.

Microcosms are similar to mesocosms but on a smaller scale. There are no strict definitions to delineate microcosms from mesocosms. However, microcosms are often considered to be structures of laboratory-bench scale while mesocosms are room size or larger. Due to their smaller size, microcosms are generally easier and less expensive to construct than mesocosms but as a result are often simpler systems that can only accommodate smaller ecological subjects, up to the size of small plants and animals (e.g., grasses, invertebrates). The term `macrocosm' is sometimes used to refer to the larger, natural ecosystems that the micro- or mesocosm system attempts to model.

Historical and Current Applications

Microcosms have been used in almost every area of terrestrial and aquatic ecology. They have long been used as a classroom teaching tool, bringing aspects of nature into the laboratory. The first ecological experiments using microcosms appear to be those of L. L. Woodruff in 1912 investigating protozoan succession in hay infusions. However, the majority of research with microcosms has been conducted since the 1960s. Early use of microcosms by prominent ecologists including G. F. Gause, H. T. Odum, R. Margalef, R. H. Whittaker, R. J. Beyers, G. D. Cooke, and E. P. Odum has contributed to the development of important concepts in ecology including the competitive exclusion principle, succession, self-organization, and the maximum power principle.

Microcosms continue to be widely used for general ecological studies. However, in recent times, they have also become popular tools to study the fate and effects of contaminants (e.g., heavy metals), pesticides and herbicides, stressors (e.g., high temperatures), novel compounds, and genetically engineered organisms (**Fig. 1**). They provide a comparatively safe means of assessing likely effects on ecosystems without direct exposure to the natural environment. Microcosms are not yet routinely used in ecotoxicological testing despite a strong argument from proponents that single-species tests are inadequate for full evaluation of ecosystem-level impacts. The problems with microcosm use relative to ecotoxicological single species tests include the higher costs, time involved, complexity, variability and difficulty in evaluating endpoints. Despite these issues, F. B. Taub and colleagues have worked to develop a standardized (nearly gnotobiotic) aquatic microcosm. This is now registered with the American Society for Testing and Materials as a standard method.

Design Factors

Sourcing, Seeding, and Energy Matching

Where a microcosm is designed to represent a model of a system that already exists, it should contain all of the characteristic features of the ecosystem that are necessary in the context of the problem to be described or solved. It is usually recommended that

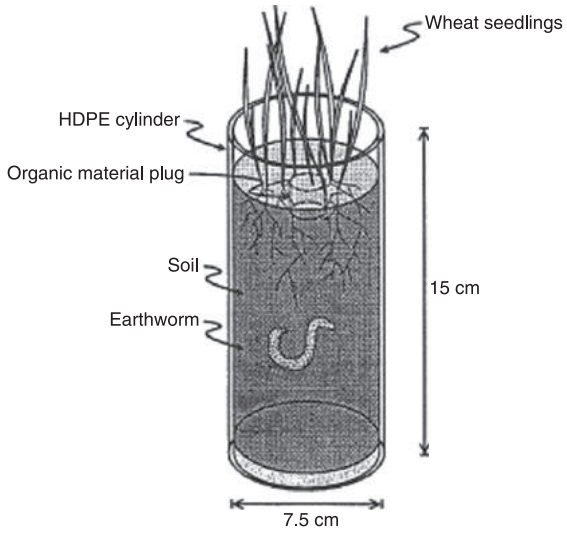

Fig. 1 A homogenous integrated soil microcosm, designed as a model terrestrial ecosystem to assess the effects of single pesticides on soil ecosystems. Reproduced from Burrows, L.A., Edwards, C.A., 2002. The use of integrated soil microcosms to predict effects of pesticides on soil ecosystems. European Journal of Soil Biology 38, 245–249.

Fig. 2 J. M. Quinn (National Institute of Water & Atmospheric Research) stands beside recirculating stream microcosms that have been used to investigate nutrient uptake and transfer in stream food webs and the effects of lighting and fine sediment deposition on stream biogeochemistry (Parkyn *et al.*).

components used in the microcosm (e.g., soil, water, plants, animals) are sourced from the natural ecosystem. It is also important to try and expose the microcosm to the same physical, chemical, and biological inputs or `energies' (e.g., light, temperature, nutrients, turbulence, species immigration) as the natural ecosystem. This is termed the energy signature approach to microcosm design. It can be more difficult to match some inputs for laboratory microcosms. For example, artificial light is a poor substitute for natural light. Constructing microcosms by isolating parts of the natural ecosystem *in situ* can minimize disturbance and enables matching of light and temperature inputs; however, other energies such as turbulence may not be equivalent (**Fig. 2**).

In synthesized, gnotobiotic microcosms, the researcher has the challenging role of system organiser while self-organization is prevalent in derived microcosms. A multiple seeding approach, where innocula from several natural assemblages are mixed together and left to self-organize, is a technique recommended by H. T. Odum to develop a more stable and sustainable microcosm system. Reinoculation can sometimes be necessary to maintain important species that do not develop sustainable populations.

Spatial Scaling, Wall, and Isolation Effects

Microcosm size affects the amount of diversity that the system can accommodate, with larger microcosms being able to support a greater diversity and more trophic levels, than smaller ones. Microcosm shape also has the potential to strongly impact on microcosm functioning and it can be useful to incorporate testing of microcosm size and/or shape into experimental design (**Fig. 3**). In particular, microcosm designs with a large wall surface area to volume ratio should be used with caution. The metabolic

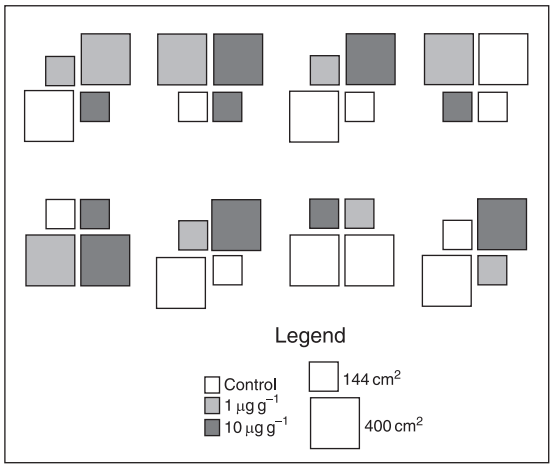

Fig. 3 Design of an experiment testing the effect of microcosm size and the pesticide chlorpyrifos on macroinvertebrate colonization of estuarine sediments. Average taxa richness was significantly higher in larger microcosms although average animal density was higher in smaller microcosms. In both large and small microcosms, animal density was significantly higher near the perimeter, indicating an `edge´ effect. Reproduced from Flemer, D.A., Ruth, B.F., Bundrick, C.M., Moore, J.C., 1997. Laboratory effects of microcosm size and the pesticide chlorpyrifos on benthic macroinvertebrate colonization of soft estuarine sediments. Marine Environmental Research 43, 243–263.

activity of microbial or periphyton biofilms (`edge communities') attached to these walls can be substantial and highly unrepresentative of natural conditions. To avoid these effects, larger microcosm volumes in relation to wall surface area are recommended. The composition of microcosm walls should also be considered. Wall materials should be inert and not leach or absorb substances that may affect the experiment. Gases such as oxygen can diffuse through more flexible plastics, which may or may not be desirable depending on the ecosystem being modeled. Consideration should also be given to the effects of artificial isolation, which restricts the movement of mobile organisms. The small size of microcosms also typically excludes higher trophic levels. However, the activities of some higher organisms or mobile species (e.g., grazing of vegetation, removal or replacement of individuals of a species by a predator or migration) may be simulated by human actions.

Temporal Scaling

A critical consideration for microcosm studies is the duration of experiments. Most microcosm experiments are generally conducted over a period of only weeks to months. However, the duration of microcosm experiments needs to be sufficient to assess effects on slow-responding organisms or processes.

As with natural ecosystems, conditions within microcosms can change over time and these changes should be evaluated during the course of a microcosm study. As the duration of a microcosm experiment increases, so does the likelihood of greater variability developing between replicates as a result of natural divergence. Time series sampling can be incorporated into experimental design to monitor changes. However, careful consideration of the impact of any repetitive sampling of components is required. A large number of microcosm replicates can be established at the outset of an experiment to enable complete (i.e., destructive) sampling of a subset of replicates at designated time intervals during the course of the study (**Fig. 4**).

Natural ecosystems are also subject to diurnal and seasonal variations as a result of light, temperature, and other climatic effects. In the laboratory, natural diurnal variations can be simulated to some extent by the use of controlled light–dark cycling of artificial lights (**Fig. 5**). For experiments of short duration, seasonal variability may be taken into account by repeating experiments on a seasonal basis.

Studies of longer-term ecological processes such as succession, predator–prey cycles, extinction, can be studied in microcosms with short real-time duration using organisms with very short generation times (e.g., microorganisms). This has been termed the biological accelerator approach.

Replication, Variability, and Divergence

Microcosm replication is an experimental design issue. The more complex the system to be studied, the more replicates are generally required to adequately describe and account for the associated variability in test results. Even when they are started similarly, microcosms often develop differently, particularly over longer periods of time. While this divergence can be problematic for microcosm replicability, this phenomenon does offer opportunities to test ecological theories and models about how different community structures can develop with, for example, different sequences of seeding (e.g., chaos and assembly theories, lottery and random models). The cross-seeding technique, where some of the contents of one replicate are regularly transferred to another, can

Fig. 4 Simple aquatic microcosms (4 l pails in a 1 m depth flow-through freshwater tank) used to investigate the effects of different sediment types on the growth responses of selected submersed macrophyte species (Matheson *et al.*).

Fig. 5 Riparian wetland soil microcosms set up in a climate-controlled laboratory and used to investigate the fate of nitrate and the effect of wetland plant growth on nitrogen transformation processes (Matheson *et al.*).

be a useful strategy to reduce variability and divergence among replicates. This is often done in the initial, setup stage but may also be incorporated into the experimentation period.

Sufficient replication in scientific experiments is critical to enable robust statistical evaluation of results. Analysis of variance (ANOVA) experimental designs are most commonly used in microcosm studies. Regression designs are sometimes employed which may enable testing of a broader range of treatments but results from these are more robust if some replication of treatments is also included. Replication enables a mean value for test results to be calculated along with the standard deviation and error of the mean. Three replicates is a recommended minimum for scientific investigations but higher numbers of replicates will provide more robust results. Power analysis and sample size estimation can be useful statistical techniques to employ to ensure that there is sufficient replication.

Similarity to Natural Ecosystem

Designing a microcosm or any model of a natural ecosystem (macrocosm) is a test in itself of how much is known about the ecosystem. A study using microcosms should include measurement of the characteristic biotic and abiotic features and functions of the natural ecosystem it is trying to model. Selection of features and functions to measure should be based on how critical they are to the natural ecosystem. These measurements enable an assessment to be made of how closely the microcosm represents the natural ecosystem. Any extrapolation of results from microcosm studies to natural ecosystems should be based on sound evidence of close matching of key features and functions between these systems (Fig. 6). However, ideally, results from microcosm studies should be confirmed with further field scale testing.

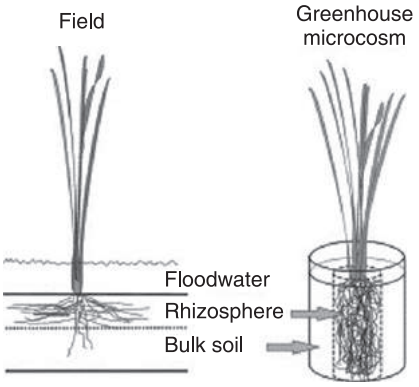

Fig. 6 Illustration of the different components examined in a study comparing the community structure of methane-oxidizing bacteria in microcosms to the natural ecosystem. In both systems, the main factors controlling the population size and activity of methane-oxidizing bacteria were plant growth and availability of nitrogen. Community diversity, activity patterns, and the population structure in both systems were comparable, although different quantities were detected. Reproduced from Eller, G., Kruger, M., Frenzel, P., 2005. Comparing field and microcosm experiments: A case study on methano- and methylo-trophic bacteria in paddy soil. FEMS Microbiology Ecology 51, 279–291.

Organic Farming

Karen M Nielsen, Organic Denmark, Aarhus, Denmark

Glossary

CMS Cytoplasmic male sterility

Roughage Fresh or processed grass, leaves, stems and similar coarse materials with relatively high amount of indigestible material. Roughage contributes to a healthy intestinal flora and gives a prolonged satiety as well as green materials adds to a healthier composition of fatty acids in dairy products, eggs and meat.

Introduction

Organic farming is an agricultural production form which has become increasingly important globally, due to a series of challenges and problems caused by traditional, industrialized agriculture. This concerns contamination of soils, drinking water and surface water; erosion and depletion of soils; an intensive industrialized animal production where animals have no access to outdoor areas, which puts pressure on animal welfare; degradation of nature and decreasing biodiversity; social poverty and cultural impoverishment.

The organic production and the organic commodities that the production supplies the consumer market with continuously develops, consistent with a continuous build up and exchange of knowledge in parallel to an increasing acknowledgement of this type of agriculture by authorities and decision makers as a multi-functional tool to achieve improvements of society. Organic production deviates from conventional farming by being based on local fertility of soils, recirculation of resources, high diversity in crops, consideration for the surrounding nature, more space and access to outdoor areas for animals as well as prevention rather than treatment.

Definitions

In 2005 the international organization of organic farmers, the International Federation of Organic Agriculture Movements (IFOAM) adopted the following definition of organic farming:

> Organic Agriculture is a production system that sustains the health of soils, ecosystems and people. It relies on ecological processes, biodiversity and cycles adapted to local conditions, rather than the use of inputs with adverse effects. Organic Agriculture combines tradition, innovation and science to benefit the shared environment and promote fair relationships and a good quality of life for all involved (ifoam.bio, n.d.-a).

Organic farming is a production form that aims at exploiting soils and keeping livestock in a more sustainable manner than intensive, conventional farming, which is characteristic for modern industrialized agricultural production. The notion of organic farming seriously spread through Europe and the USA in the 1970s and 1980s as a reaction to agricultural environmental problems—problems which became apparent during this period and which were often debated publicly. Meanwhile, the origin of the idea of organic farming is much older.

Depending on language and nation, various terms are used to describe organic products, for instance, organic, ecological and biological/biologique. At the same time, the terms do have ordinary, semantic connotations—organic refers to the living; ecology is the scientific wording for the studies dealing with the household of nature, that is, the description of interactions among living organisms and their ambient environment; and biology deals with the learning and teachings about the living.

This concurrent set of meanings may lead to unclear perceptions concerning aspects of production, the origin of food items and their quality.

The terms mentioned above are protected terms regarding food within the European Union (EU) and are reserved products that meet the standard of certified organic production (europa.eu, n.d.).

In addition to this, the term agro-ecology is used about environmentally friendly and sustainable production forms in developing countries where production is not necessarily certified, for instance, due to lack of infrastructure.

History

Today organic farming is connected to a set of production standards, certification, labelling and branding with relations to a market economy. Meanwhile, the off-set to the idea is different, as the pioneers at the beginning of the 20th century saw the establishing of a good and fertile soil as a proper response to poverty and low yields in agriculture. Other aspects were respects for traditions, life forms and social wellbeing, that some already considered to be threatened by the process of industrialization.

Experiments with new techniques capable of increasing soil fertility were initiated all over the world. Sir Albert Howard attracted some attention by introducing ways of composting, and in 1924 Rudolf Steiner gave his famous speeches on agriculture (Steiner, 1924) and founded the biodynamic movement and praxis, which developed throughout the 1930s and gained some popularity. At the same time agriculture in general took a different turn, due to the chemist Justus von Liebig's theories on specific minerals as nutrients of plants. With this knowledge and recognition followed the development and use of artificial fertilizers, that after the Second World War took over as a prevailing paradigm.

Biodynamic agriculture represented the holistic approach to farming, until the idea of organic farming gained support in the 1970s in line with an increasing environmental awareness in society among—among other things triggered by the consequences of environmental pollution due to agricultural activities.

As opposed to biodynamic farming, organic farming takes science as its starting point, and organic farmers and their organizations worldwide seek from the very beginning to establish a foundation of practice based on experiments, tests and exchange of knowledge. The first experimental evidence and comparisons between organic and conventional farming methods were described in "The Living Soil" authored by Lady Eve Balfours. It formed the basis of the Soil Association in the UK as early as in 1946. Soil Association served as inspiration to grassroots all over the world. The purpose of the organization was to work for soil fertility, animal welfare, nutritious food products and farming which does not have a negative influence on the surrounding environment (soilassociation, n.d.).

It is the Soil Association which in 1972 takes the initiative to form the International Federation of Organic Agricultural Movements, IFOAM. Thereby, a formal cooperation among organic grassroot movements and NGOs all over the world is established. Today, IFOAM facilitates knowledge exchange, is responsible for international conferences and formulates the basic principles of organic farming.

Standards and regulations are based on these principles and have developed along with the development and establishing of real market for organic food products.

Four Governing Principles

Organic farming is based on four governing principles described and adopted by IFOAM, the international umbrella organization that organic movements worldwide are members of (ifoam.bio, n.d.-b). The principles deal with a set of overall ethical principles which are meant to serve as inspiration to implementation of concrete action locally and regionally. The four principles are:

Health

Organic agriculture should sustain and enhance the health of soil, plant, animal, human and planet as one and indivisible.

This principle points out that the health of individuals and communities cannot be separated from the health of ecosystems—healthy soils produce healthy crops that foster the health of animals and people.

Health is the wholeness and integrity of living systems. It is not simply the absence of illness, but the maintenance of physical, mental, social and ecological well-being. Immunity, resilience and regeneration are key characteristics of health.

The role of organic agriculture, whether in farming, processing, distribution, or consumption, is to sustain and enhance the health of ecosystems and organisms from the smallest in the soil to human beings. In particular, organic agriculture is intended to produce high quality, nutritious food that contributes to preventive health care and well-being. In view of this it should avoid the use of fertilizers, pesticides, animal drugs and food additives that may have adverse health effects.

Ecology

Organic agriculture should be based on living ecological systems and cycles, work with them, emulate them and help sustain them.

This principle roots organic agriculture within living ecological systems. It states that production is to be based on ecological processes, and recycling. Nourishment and well-being are achieved through the ecology of the specific production environment. For example, in the case of crops this is the living soil; for animals, it is the farm ecosystem; for fish and marine organisms, the aquatic environment.

Organic farming, pastoral and wild harvest systems should fit the cycles and ecological balances in nature. These cycles are universal but their operation is site-specific. Organic management must be adapted to local conditions, ecology, culture, and scale. Inputs should be reduced by reuse, recycling and efficient management of materials and energy in order to maintain and improve environmental quality and conserve resources.

Organic agriculture should attain ecological balance through the design of farming systems, establishment of habitats and maintenance of genetic and agricultural diversity. Those who produce, process, trade, or consume organic products should protect and benefit the common environment including landscapes, climate, habitats, biodiversity, air, and water.

Fairness

Organic agriculture should build on relationships that ensure fairness with regards to the common environment and life opportunities.

Fairness is characterized by equity, respect, justice and stewardship of the shared world, both among people and in their relations to other living beings.

This principle emphasizes that those involved in organic agriculture should conduct human relationships in a manner that ensures fairness at all levels and to all parties—farmers, workers, processors, distributors, traders, and consumers. Organic agriculture should provide everyone involved with a good quality of life, and contribute to food sovereignty and reduction of poverty. It aims to produce a sufficient supply of good quality food and other products.

This principle insists that animals should be provided with the conditions and opportunities of life that accord with their physiology, natural behavior and well-being.

Natural and environmental resources that are used for production and consumption should be managed in a way that is socially and ecologically just and should be held in trust for future generations. Fairness requires systems of production, distribution and trade that are open and equitable and account for real environmental and social costs.

Care

Organic agriculture should be managed in a precautionary and responsible manner to protect the health and well-being of current and future generations and the environment.

Organic agriculture is a living and dynamic system that responds to internal and external demands and conditions.

Practitioners of organic agriculture can enhance efficiency and increase productivity, but this should not be at the risk of jeopardizing health and well-being. Consequently, new technologies need to be assessed and existing methods reviewed. Given the incomplete understanding of ecosystems and agriculture, care must be taken.

This principle states that precaution and responsibility are the key concerns in management, development and technology choices in organic agriculture.

Science is necessary to ensure that organic agriculture is healthy, safe and ecologically sound. However, scientific knowledge alone is not sufficient. Practical experience, accumulated wisdom and traditional and indigenous knowledge offer valid solutions, tested by time.

Organic agriculture should prevent significant risks by adopting appropriate technologies and rejecting unpredictable ones, such as genetic engineering. Decisions should reflect the values and needs of all who might be affected, through transparent and participatory processes.

Organic Farming Management

When it comes to practical implementation of the principles of organic farming one will notice differences between countries and regions as well as among farmers. Often a common set of standards has been adopted which sets the standard for the practice of producers and production methods.

Guide to Best Practise

IFOAM has developed a guide "Best Practise Guideline for Agriculture and Value Chains," which sets the direction for formulation of specific standards for organic farming management. The guide contains examples of organic farming management of soil and water resources, husbandry, nature values and genetic diversity (ifoam.bio, n.d.-c) (Table 1).

Plant Production

In brief, plant production in an organic farming system deviates from that of conventional farming by the absence of mineral fertilizer, pesticides and genetically modified crops. As an alternative, organic farmers use organic fertilizers and leftovers from livestock and plants. Weeds, pests, and diseases are reduced by crop rotation, mechanical weeding and the establishing of biotopes with higher species diversity and adequate living space for beneficials.

Table 1 Best practise guideline for agriculture and value chains, selected examples

Soil and fertility
- Soil is protected from loss due to erosion and exposure to the elements. Soil is kept covered by living plants and mulch
- Organic matter content is increased. Farmers enhance biological activity of the soil and are careful with heavy equipment
- Perennials and agroforestry are promoted
- Farms obtain their soil fertility primarily from the farm itself due to crop rotation, recycling of plant residues, nitrogen-fixing species, cover crops and manure
- Manure from intensive conventional animal production is not used
- Farmers rely on crop rotation, natural enemies and biodiversity management to control pests, diseases and weeds
- Synthetic and toxic pesticides are avoided

Biodiversity
- Not all land on any given holding is used for production. At least some is set aside for biodiversity habitat
- Farmers maintain or re-establish natural vegetation areas around springs, along natural watercourses, on steep slopes and other sensitive parts of the ecosystem. Natural wetlands should not be drained
- Avoidance of mono-cropped areas
- Farmers choose varieties that can be multiplied on the farm and avoid varieties and breeds, that rely on a continued use of high levels of off-farm inputs
- Organic farmers choose organically grown seeds when possible. GMO breeds are not used
- Farmers raise animal breeds, that reproduce naturally and give birth without routine human intervention

Animal husbandry
- Farmers raise no more animals than can be carried by the land itself and takes into consideration the potential impact on pollution, non-renewably energy use, greenhouse gas emissions and nutritional profile of the animal products
- Feed is all organic
- Farmers provide animals with their most natural diet. A diversity of feeds and forage types is desirable
- Farmers create an environment where animals can access their food as much as possible in the field, e.g., through grazing or foraging for insects and worms
- Ideally, feed is grown on the farm itself or on closest possible farms and grasslands
- Animals are allowed to express their natural behaviors, they have access to outdoors, pasture and shelters if needed
- Animals are protected against stress. They are grouped and managed in a way, that keep them from harming each other
- Avoidance of mutilation
- Livestock health are maintained through proper diets and living conditions. Natural remedies are used before synthetic materials, if treatment is necessary

Atmosphere and energy
- Farmers optimize use of trees, permanent pastures and perennials to sequester carbon and reduce greenhouse gas emissions
- Farmers optimize manure use and slurry storage, application method and timing to prevent losses of methane and nitrous oxide
- All operations work to minimize carbon emissions from internal combustion engines and strive to increase energy efficiency and reduce dependence on non-renewable sources of energy

Meanwhile, we are not dealing with absolutes. Certain mineral fertilizers are still allowed in case of risk of severe crop damage. The same applies to pesticides based on naturally occurring compounds such as plant extracts. In some regions compounds that are known to have damaging effects on environment are still in use as an exception, for instance, copper against fungal diseases in fruits and wine. There is, however, a mutual understanding that such substances should be phased out. In addition, the ban against the use of genetically modified crops is continuously challenged by technological achievements in plant breeding. In practice, it has been shown that it is difficult to define whether modern technology can be identified as genetical modification or not. CMS hybrid seed production is an example of such technologies.

A relevant and ongoing discussion is for how many generations organic farming must be practised for the crops produced to be organic and certified as such. Would it be sufficient that the seeds used for sowing are derived from organically produced plants or should the parental generations to these plants also be produced according to organic standards? Today organic farmers do only to a certain extent have access to organic seeds in the market. Due to increased research efforts, knowledge distribution and growth in organic area and number of producers a gradual development towards increasing integrity in organic farming is generally observed. This will eventually apply to plant breeding and propagation too. Meanwhile, it has been shown to be difficult to keep plant material healthy and disease free when producing organically over generations.

Actual breed of varieties adapted to organic farming exists but is still not wide spread, primarily because the market for organically grown seeds is economically uninteresting to multinational companies working on plant breeding. Some organic farmers and organizations do work on locally adapted varieties and farm based breeding.

Nature and biodiversity

Organic farming affects soil, water, flora and fauna on and in soil surface in the cultivated areas as well as surrounding non-cultivated areas. Organic farmers are committed to consider their agricultural system as part of a larger ecosystem, and they must protect, restore or remediate natural elements on the farm. Organic farming has positive effects on nature and uncultivated areas close to the farms. It has been observed that organically grown fields and nearby biotopes contain 30% more plant and animal species than conventionally managed fields and their surroundings. This also applies to soil living organisms such as earthworms. The reason for difference is first and foremost the absence of chemical pesticides, but the use of organic manure and compost as well as a more diverse composition of crops—including perennial species—also play a significant role (Bengtsson et al., 2005; Hole et al., 2005).

Livestock Production

Organic livestock production is characterized by an ambition to offer production animals living conditions that meet their specific requirements and need to express normal behaviour in a system that supports health and a minimum need of medical interference.

Animal welfare

Animal welfare is central to the practice of organic livestock production. Animal welfare can be described as particular considerations to animals for their own sake. Animal welfare is difficult to measure. A common approach used is to define welfare in accordance with what the animals are free to do, and what they are free from. A definition based on such a view may be found in "the five freedoms" presented by the Farm Animal Welfare Committee, UK (gov.uk, n.d.) (Table 2).

Regarding animal welfare, free access to outdoor facilities for all animal groups for their entire life or at least part of it is central to organic livestock production. For cattle, an example might be access to pasture. For pigs and poultry, it might be access to express natural foraging activities such as digging and scraping in soils. The standard that animals must have access to outdoor areas is a simple standard, which contributes to ensure several of the freedoms mentioned above to individuals as well as to groups. Plenty of space and freedom to move around also allow the animals to express social behavior, forage and take care of their plumage and brood. Meanwhile, outdoor access does not solve all welfare related problems. It can be dangerous to be a chicken or a new born piglet in outdoor managed systems where they are exposed to attacks by predators. Access to a natural life does not necessarily correspond to good animal welfare. Nature is not considerate and just. Consideration of the natural behaviour of animals must therefore be matched against the protection that any animal keeper is obliged to exhibit. In free production systems surveillance and intervention is more difficult, and may consequently lead to increased mortality of piglets, calves and laying hens.

In an organic farming perspective animal welfare includes a divers and most natural diet. Therefore, it is mandatory that all animals—not only ruminants—are given roughage like clover grass and other green feeds. The diet for organic cattle is typically based on grass, whereas conventional diets are based on maize, corn, and waste products.

Table 2 Five freedoms

- Freedom from hunger and thirst; by ready access to water and a diet to maintain health and vigor
- Freedom from discomfort; by providing an appropriate environment
- Freedom from pain, injury and disease; by prevention or rapid diagnosis and treatment
- Freedom to express normal behavior; by providing sufficient space, proper facilities and appropriate company of the animal's own kind
- Freedom from fear and distress; by ensuring conditions and treatment, which avoid mental suffering

Clover grass and similar fodder are natural food sources of cattle, but also pigs and poultry may benefit from roughage. Roughage promotes a healthy intestinal flora and makes the animals feel full longer than corn and concentrates rich in energy would. In addition, it provides activity and can prevents stress and fights in a herd.

Animal health—prevention and treatment of diseases

The health of organic livestock is attempted to be maintained through fodder, access to the outdoor and the connected possibility to move, as well as attention to the overall surroundings in general. At the same time, organic livestock may be less productive, grow slower, give less milk etc. Hence illness is in general less abundant as in intensive, indoor, stable-based production systems.

Resistance and risks of infection

A significant societal impact of the organic production system is a noteworthy lower use of antibiotics in organic livestock. The use of antibiotics in the industrialized livestock production—curative as well as preventive/growth enhancing—leads to development of bacteria resistant to antibiotics, which poses a threat to public health. FAO/UN has adopted an action plan seeking to avoid antimicrobial resistance (FAO, n.d.).

Methicillin-resistant *Staphylococcus aureus* (MRSA) and Salmonella sp. infections are present in organic livestock production systems, but to a much lower extent than in conventional systems. A Danish investigation carried out in 2016 demonstrated MRSA to be present in 6% of organic pig herds as compared to 70%–80% of conventional pig herds. This despite the fact, that organic livestock brings in conventional animals for breeding purposes. A European research project on antibiotic resistance concludes that resistance is common among organic slaughter pigs, but occurs on significantly lower levels than is the case with conventional slaughter pigs (Aabo, 2014).

It may be difficult to point out causal relations, but an explanation might be that access to fresh air, space and roughage prevent the resistant bacteria from surviving and multiplying.

Global Organic Farming

Organic Farming in the Industrialized Part of the World

The market for organically grown products is particularly well developed in industrialized countries such as the United States and Europe, where purchasing power and willingness to pay for food free from pesticides and with high standard of animal welfare exists and is relatively high. Here one may find a wide spread environmental consciousness as well as a production and processing apparatus that is heavily regulated and authorized through legislation or standards and certification set by private organizations.

Organic farms in this part of the world are characterized by yields which are 20%–30% lower than yields obtained by normal conventional agriculture (de Ponti et al., 2012). The reason for this is primarily the absence of artificial fertilizers and pesticides.

The explanation for the lower yield is the fact that the soil potentials for production are almost fully exploited. When the use of artificial fertilizers, pesticides, GMO etc. are left out, the result will be a decrease in yields as crop rotation and natural enemies are not efficient to compensate. However, organic farming could on a longer time scale contribute to a significant carbon sequestration in soils, increased species diversity, more pollinators and similar effects which gives benefit to society. Such effects are not measurable on a short time scale.

Organic Farming in Developing Countries

While organic farming in western intensive agricultural system are characterized by a production yield being approx. 20% lower, organic farming at small farm scale in developing countries hold the potential to increase yields and stabilize economy. A UN-report from 2008 based on the examination of 114 African studies concludes that organic farming gives double the yield as conventional farming (UNEP-UNCTAD, n.d.). Other studies showed more diverse results, but all in all there seems to be a potential for yield growth by implementing organic farming methods.

The explanation of the difference is that the yield potential in intensive agricultural systems at present seems to have been exploited to a maximum level. This is far from being the case in extensive farming systems. The use of rotation crops, agroforestry and soil amendment using organic compost as fertilizer etc. contribute to an increased production per area unit.

Likewise, the use of artificial fertilizers and pesticides would possibly contribute to an increasing yield, but to many small-scale farmers such aids are out of reach as they require capital and thereby poses an increased risk in an environment that is already threatened by climate changes, draught, flooding, erosion, etc. Agricultural methods based on organic farming principles on the other hand makes the soil and crops more resilient with regards to such threats. At the same time, organic farming serves to stabilize yields, which is often more important to the family farmers than a potential but risky increase.

Organic or agro-ecological methods

Organic farming in developing countries is not necessarily certified. Certification connects to a market and trade with goods. For most small-scale farmers certification is not a crucial issue. Meanwhile, the implementation of organic farming principles can bring small scale farmers in a situation where they produce a surplus of food which makes access to a market a relevant issue.

An increasing middle class in the larger cities of developing countries demonstrates an increasing concern about food safety which leads to an increasing demand of organically grown food products without pesticides. Meanwhile, this market is still inaccessible to many small-scale farmers and excess production is sold at the local markets without certification. When a farmer uses techniques of cultivation based on organic farming principles but does not meet the demands of certified production one may say the food item is produced by agro-ecological methods.

Organic Farming and the SDG's of United Nations

In 2015 The United Nation (UN) adopted 17 Sustainable Development Goals for achieving a sustainable world (SDG's). The SDG's outlines the direction for national and international strategies of development and points out targets to achieve the goals towards 2030 (un.org, n.d.).

The principles of organic farming in many ways comply with the SDG's and offers solutions that can be achieved within several goals. This is particularly valid to the sustainable use of resources, improvements of health and the fight against pollution. According to Food and Agricultural Organization (FAO) of the United Nations, it is possible to improve food safety, local rural development, and sustainable living and environmental protection by implementing agricultural farming and through capacity building (fao.org, n.d.) (Figs. 1–5).

Growth and Extension of Organic Farming

Organic farming is growing on a global level. This applies to cultivated areas, the number of organic farmers and turnover expressed in market share as well as actual value (Willer & Lernoud, 2017) (Table 3).

Area and Area Use

50.9 millions hectares are managed organically, which corresponds to 1.1% of the globally cultivated areas. In addition, 39.7 millions hectares are non-cultivated organic areas for production of honey, collection of raw materials, forests, etc. The area used for organic farming has grown to a level which is fivefold that of 1999. Two thirds of the organic farming area are permanent grasslands. This crop type has increased dramatically and reflects among others the restructuring of vast areas in Australia to organic farming. Other perennial crops, like coffee and fruits, make up 8.0% of the area—the largest crop being coffee followed by olives and nuts. Only 20% of the area used for organic culture is in rotation—with corn being the dominating crop.

Organic Producers

The number of organic farmers on a world level is uncertain due to lack of data on the topic. The latest accounting estimates 2.4 millions of organic farmers. Approximately one third of these live in Asia—India being the country with the highest number of organic farmers. In the period from 2014 to 2015 the number of organic farmers has increased by 21%.

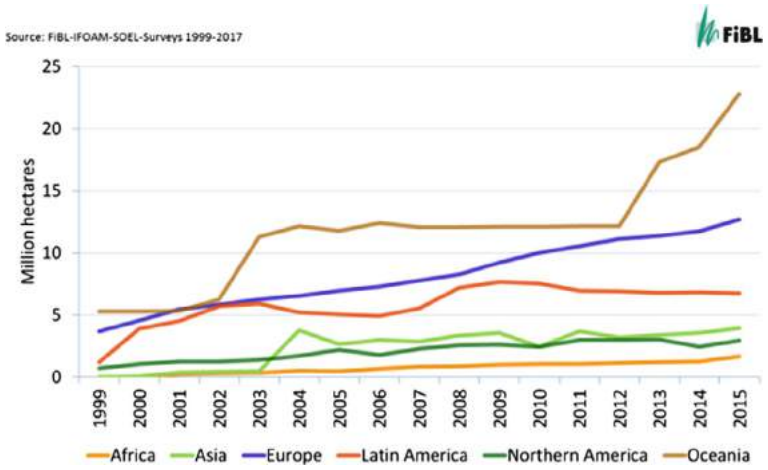

Fig. 2 Growth of the organic agricultural land by continent 1999–2015.

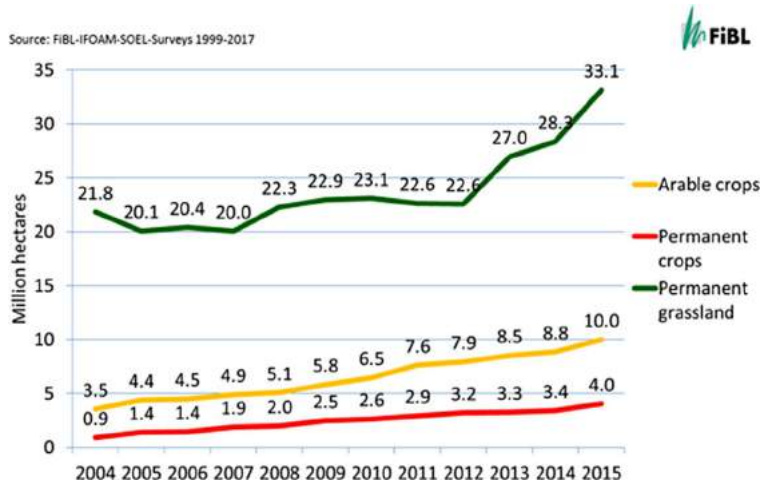

Fig. 3 Development of the organic land by land use type 2004–2015.

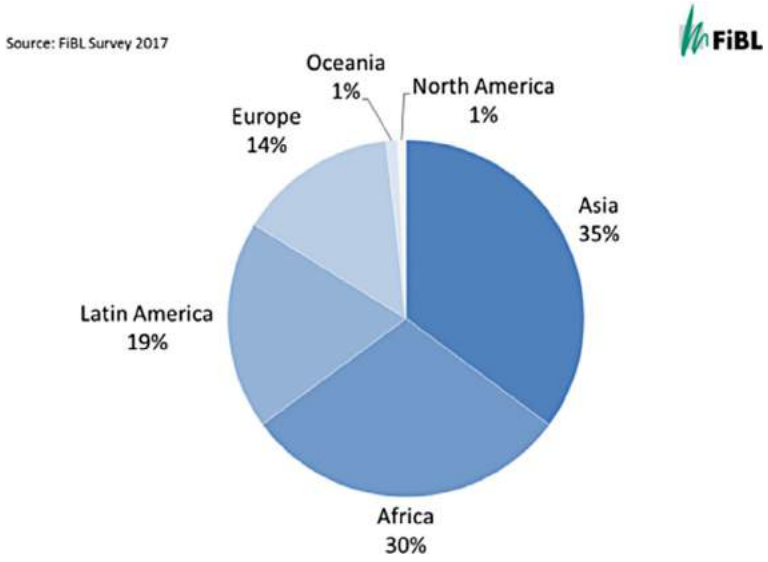

Fig. 4 Distribution of organic producers by region 2015.

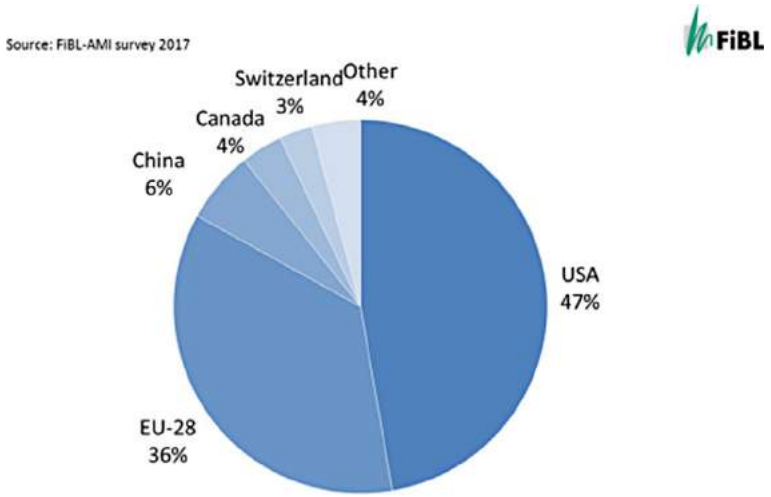

Fig. 5 Distribution of retail sales by single market 2015.

Table 3 17 sustainable development goals—goals where organic farming may play a particularly important role and offer relevant solutions are in bold (by author)

End poverty
End hunger
Improved health and wellbeing
Ensuring quality and access to education
Gender equality
Ensuring clean water and sanitation
Ensuring access to energy
Decent jobs and economic growth
Industrial innovation and infrastructure
Reduce inequality
Sustainable cities and communities
Responsible consumption and production
Climate action
Sustainable use of the oceans and marine resources
Sustainable use of terrestrial ecosystems
Peace, justice and strong institutions
Partnerships for the goals

The Organic Market

The turnover of organic food at world level is estimated to 75.7 billion €, half of this in the United States alone. The turnover corresponds to a per capita average of 10.3 €. The numbers are uncertain due to lack of reports.

Glossary

Agroecosystem The basic unit of study in agroecology that is defined as a spatially and functionally coherent unit of agricultural activity, which includes biophysical (soil, climate, plants, animals) and social components (human practices, values, objectives, organizations) and their interaction.
Agroforestry Land use management system in which trees or shrubs are grown around or among crops or pastureland.
Emergy Is a methodology which aggregates all different forms of energy and resources (e.g., sunlight, water, fossil fuels, minerals) used in the work processes that generate a product or service.
Food forest Polyculture mimicking forest ecology with multiple plant layers (annual plants, shrubs, trees, and liana) which produce a diversity of edible produce.
Holistic Refers to a global thinking or design approach which aims to integrate all dimensions of a situation (which can involve subjective and objective aspects) rather than analyzing only one aspect.
Intercropping Growing different plant species together on the same plot at the same time.
Modern/premodern/postmodern "Modern" refers to a philosophical movement developed in Europe since the 17th century relying on the idea that mastering the material world through rational knowledge will guarantee human progress and emancipation from nature, which is perceived as distinct from humans. "Premodern" refers to traditional worldviews which were born before modernism and where human beings are often seen as part of the natural world. "Postmodern" refers to a thinking tendency which criticizes the modern beliefs around progress and in which all assumptions are open to question. According to postmodern thinkers, elements from different systems and traditions can be combined without regard for any fixed aesthetic or tradition.
Silvopastoralism Land use management system in which animals graze in habitats where trees are present. Animals can feed partially on these trees (fruit fallen on the ground) and benefit from the microclimate they create (shadow, temperature, protection against wind).

Brief Overview of Permaculture

Permaculture is an international grassroots network focused on the sustainable design of human settlement, both in rural and urban areas although it was initially developed in a rural setting. Permaculture's central concept is that humanity can reduce or replace energy and pollution-intensive industrial technologies, especially in agriculture, through intensive use of biological resources and

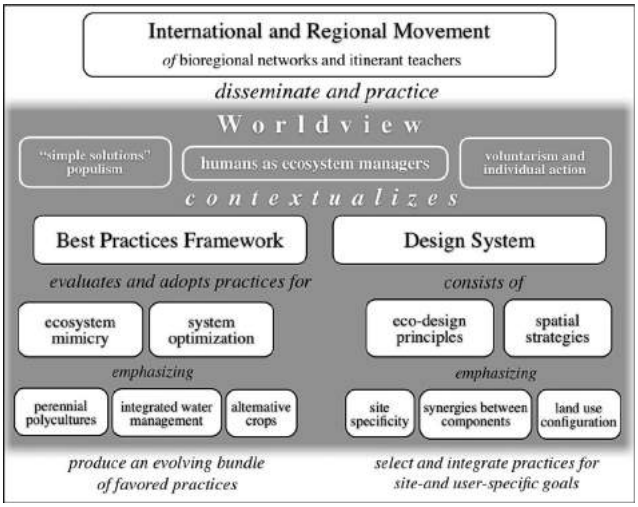

Fig. 1 Stratified definition of permaculture (Ferguson and Lovell, 2014).

thoughtful, holistic, design, patterned after natural ecosystems (eco-mimicry). Despite a relatively high public profile and broad international distribution, until recently permaculture has received little scholarly attention.

The definition of permaculture varies among sources and expands over time. In the founding text, permaculture's originators define it as "an integrated, evolving system of perennial or self-perpetuating plant and animal species useful to man" (Mollison and Holmgren, 1978). By 2002 Holmgren defined permaculture more broadly, encompassing broader issues of human settlement while maintaining an agricultural focus: "Consciously designed landscapes which mimic the patterns and relationships found in nature, while yielding an abundance of food, fiber and energy for provision of local needs" (Holmgren, 2002). Recent scholarship has identified four levels or components within permaculture presented in Fig. 1 (each of which may be referred to by the term): the international movement, the worldview carried by and disseminated by the movement, the design system, and the set of associated practices (Ferguson and Lovell, 2014). We will introduce each in turn.

Worldview

Key elements of the permaculture worldview include a theory about human–environment relations, a populist orientation to practice, and a model of social change. The permaculture literature highlights the positive role of humans in the landscape, as ecosystem managers. This perspective is expressed through a literature-wide insistence on the need for holistic planning and design and an optimistic assessment of what these styles of management can achieve. This perspective on human–environment relations cuts against the grain of the dualistic worldviews of both growth-oriented development and preservation-oriented conservation, each of which describe a fundamental conflict between the needs of society and those of nature. At the core of the permaculture worldview is the idea that—with the application of ecologically informed holistic planning and design—humans can meet their needs while increasing ecosystem health.

Design

The permaculture design system utilizes ecological and systems-thinking principles, and spatial reasoning strategies, which are used to analyze site conditions, select practices, and integrate them with site conditions and land use goals. The most distinctive aspects of the permaculture orientation toward agroecosystem design are its emphases on (1) site specificity, including attention to microclimate; (2) interaction between components at multiple scales, from field-scale polycultures to agroecosystem-scale land use diversity; and (3) spatial configuration as a key driver of multiple functions.

Practice

Land use in permaculture shares much with agroecology, agroforestry, and traditional and indigenous land use. Since the techniques associated with permaculture rarely originate from within the movement itself, the practical stratum is better regarded as a best practices framework than a bundle of techniques. Best practices in permaculture are evaluated by two broad criteria of ecosystem mimicry and system optimization. Ecosystem mimicry regards the structure and function of unmanaged ecosystems as models and attempts to create highly productive systems with analogous structure and function using species that produce yields for human use. System optimization does not refer to a model ecosystem, but seeks to identify strategic points of leverage where minimal intervention may enhance performance of desired functions beyond that of naturally occurring systems. Together, these criteria outline an implicit conceptual framework for the evaluation of practices in the permaculture movement.

Movement

The permaculture movement communicates the worldview and disseminates elements of practice and design through networks of practitioners and small institutes. The growth and dissemination of permaculture is built on two basic patterns: a widely dispersed network of "itinerant teachers" and local/regional organizing based around "bioregional" cultures and the development of alternative economic and social institutions. The permaculture movement today consists of a loosely affiliated network of individuals and projects, connected through permaculture courses and workshops, online forums, and local projects, as well as through and regional, national, and international convergences. Groups generally display a low level of institutionalization, and projects encompass a wide variety of functions, commonly including community gardens, campus greening initiatives, educational efforts, and less commonly, demonstration and/or research sites, periodicals, and farming-focused education and support efforts.

Conceptual Foundation and Dissemination

The Genesis of Permaculture

"To many of us who experienced the ferment of the late 1960s, there seemed to be no positive direction forward, although almost everybody could define those aspects of the global society that they rejected. These included military adventurism, the bomb, ruthless land exploitation, the arrogance of polluters and a general insensitivity to human needs. An unethical world could waste more on killing people than on earthcare or on helping people."

This quotation is from Bill Mollison, creator of permaculture and coauthor with David Holmgren of the founding book "*Permaculture one*" published in 1978. Permaculture is anchored in the multifaceted critical movements that emerged in the late 1960s with the North American counterculture and the birth of human ecology. These movements relied on emerging critiques of the resource-intensive materialism of consumer society, of sexism and racism at home, and militarism, imperialism, and unequal development leaving third world countries behind. In this context, social movements emerged with radical propositions for new ways of organizing society that could act as an alternative to a socio-economic system rooted in overexploitation of natural resources and the exponential growth of energy consumption, consumerist individualism, and the political and moral norms that of the economic elites. While some of these movements engaged in fairly "classical" political struggle, permaculture was among those that spurned conventional movement politics to work directly on concrete interventions, practical solutions for building an "other world," one whose key-word would be self-sufficiency.

The "back to the land" projects that multiplied in the 1970s, and spread from Australia to Europe via California, are part of this latter logic and set the stage for the emergence of permaculture. Faced with the hegemony of the dominant socio-economic model, their bearers sought to "withdraw from the world" by settling in isolated and/or abandoned by industrial development areas, in hopes of using the practice of traditional agriculture to rebuild a premodern link with nature. They acknowledged that nature could not entirely be grasped by rationality and that a (re)-developing a subjective and respectful relationship to nature was critical. The romantic or naturalist inspiration (e.g., Thoreau's Walden) of this movement was obvious, as was its apocalyptic dimension: this world, which in its irrepressible greed seemed to want to destroy its natural environment irremediably, would end before long. Those who have built and preserved havens based on the renunciation of a utilitarian and dominating vision of nature, would be the guarantors of the salvation of humanity.

Permaculture's founders and early adopters articulated a set values and principles in parallel with identifiable currents of ecological thought, based on the belief that industrial societies based on fossil fuel threaten the survival of human beings, on the rejection of anthropocentrism, and on a holistic worldview that opposes utilitarian reductionism. These positions were close to James Lovelock's Gaia Hypothesis or Deep Ecology (Naes, 1973). The relationship with deep ecology is particularly evident in Bill Mollison's later remarks (AtKisson, 1991): "Permaculture exhorts a total cooperation with every other and every other thing, animate and inanimate". For the founders of permaculture, this cooperation between humans and nonhumans is the basis of a global transformation of societies respecting three fundamental ethical principles: caring for the Earth; caring for people; and establishing limits on consumption and redistributing surplus (Mollison and Holmgren, 1978). They believe that this transformation must start from the initiatives of individuals anxious to act by and for themselves, re-building communities as they reconstruct human-environment relationships—gradually and from the bottom up. This logic of horizontal and bottom-up construction of a new society suggests affinities between permaculture and the nonviolent and ecological component of the anarchist movement of the end of the 19th century, of which Elisée Reclus, Geographer and French anarchist activist, is one of the most prominent figures, and which would be renewed in the United States in the latter decades of the 20th century with activist thinkers like as Murray Bookchin.

In the same interview cited above, Bill Mollison, however, refutes this connection. He rejects any form of power relationship or coercion as inseparable, from his point of view, from political action, even anarchist, and considers that the multiplication of individual initiatives cooperating with each other is enough to change the world. If permaculture is claimed to be subversive, this subversion does not involve political struggle, but rather a gradual dissemination of a belief translated into located concrete experiences: the construction of a sustainable world requires the reincorporation of humans into ecosystems natural. Permaculture proposes principles, conceptual tools that can guide the action of each one in this direction. It is thus defined as an "aid to the decision-making ethic" (Holmgren, 2002). In this perspective, the expansion of the permaculture network may require training in

principles and tools, but this training is more about awakening to another way of being in the world than the acquisition of established technical knowledge.

Permaculture, a Pragmatic Ecology for Self-Sufficiency

Permaculture proposes pragmatic methodological principles to create autonomous, resilient, and equitable living spaces. For Bill Mollison and David Holmgren, the fundamental flaw of industrial societies lies in the inextinguishable thirst for energy that structures their development and precludes any long term sustainability. To escape from this addiction, they postulate that permaculture design must be inspired by the structure and function of natural ecosystems. This perspective is directly inspired by the works of scientific ecology, particularly those of Eugene Odum, and even more by the approach of ecological thermodynamics and environmental accounting proposed by Odum (1971, 1995). These works are one of the main references cited by Holmgren (2002) in "Permaculture: Principles and Pathways beyond Sustainability," a book in which he resumes and deepens the principles of design defined in "Permaculture One" (Mollison and Holmgren, 1978).

In this line, permaculture interprets the dynamics of natural ecosystems as an accumulation of energy that drives ecosystems toward "closed loop" cycles of matter, in which less and less materials are lost from the ecosystem over time. Inspired by these natural processes, the design of self-sufficient human settlements must emulate ecosystems by maximizing the interrelations and synergies between the various human and non-human components and trigger a dynamic of aggradation. Perennial elements, especially trees and soils, play an essential role in this process by storing energy and carbon. For permaculturists, biodiversity and agrobiodiversity are valued for the functional redundancies they create and their beneficial effect on resilience, e.g. the provision of high-energy foods should be provided by cereal crops as well as root vegetables or trees producing fruits rich in starch. The same element must also fulfill several functions, for example, a legume supplies of protein and improves the soil fertility; a pond stores water and helps regulate the microclimate. Design must project itself into the future, the landscape it draws is an evolutionary structure and this evolution must be considered as much as possible at the outset. Thus, by planting trees, one must imagine how they will grow and what will be the consequences for herbaceous plants at their feet. The elements to cover human needs should be as much as possible found or produced within the system, and efforts should be made to minimize these needs. Self-sufficiency is thus an objective as much as a means of the project. Under these conditions, human settlements can be part of a process of global ecological and human improvement, in which the needs for inputs of energy and materials as well as human labor diminish gradually.

Holmgren (2002) has defined 12 principles of permaculture design. These principles form the basis of a reflective design process geared toward outcomes that align with the principles described above and the underlying ethical principles. These principles are: (1) observe and interact, (2) catch and store energy, (3) obtain a yield, (4) apply self-regulation and accept feedback, (5) use and value renewable resources and services, (6) produce no waste, (7) design from patterns to details, (8) integrate rather than segregate, (9) use small and slow solutions, (10) use and value diversity, (11) use edges and value the marginal, (12) creatively use and respond to change. Each principle is individually described and discussed in the permaculture literature with concrete design illustrations. For example, principle (6) highlights that waste production should be as low as possible and that their recycling must be systematized, as in nature where the concept of waste does not exist since elements are used and recirculated locally. Permaculture books presents simple solutions to apply this principle, such as breeding poultry to transform kitchen waste into eggs, meat and manure. The implementation and combination of all principles implies and demands a systemic vision. For Mollison and Holmgren this vision cannot be achieved through exhaustive analytical knowledge of the ecosystem, its components, and its mechanisms—which is in any case unattainable. Rather, it must be the result of a holistic, sensitive, and critical understanding of the place, for which scientific knowledge is merely one form of support among other aesthetic, spiritual, or moral considerations.

This holistic reading of space implies that permacultural design combines an objective perspective, based on empirical and/or scientific knowledge, and a subjective perspective, reflecting personal sensitivity. To achieve this difficult synthesis, Bill Mollison was inspired by the Australian aborigines, with whom he had worked for many years during his academic career in Tasmania (Mollison, 1988). Aboriginal thought is organized around the central concept of Dreamtime, the original cosmological dimension in which the different spirits and ancestors physically shaped the world, physically impregnating it with the organizing patterns that underlie the "just order" of things. In order to understand these patterns and the relationships between them, the observation of nature is central. It not only involves the intellect but also the intuition and the humble and silent perception of the world called dadirri by the aborigines. As in aboriginal thought, permaculture invites both objective and sensitive observation of landscapes, enabling us to identify the patterns and interfaces that structure it and on which design will have to rely. The purpose of this design process is not only utilitarian. It is the conjunction of utilitarian, spiritual, ethical, and moral dimensions that makes this space a "place for life," inhabited more than occupied, shared with other living species.

Presence of Permaculture in the World

From the foundational work articulated by Mollison and Holmgren in the late 1970s, permaculture concepts, worldview and practices have been spread through a quickly growing and largely decentralized, informal movement (Ferguson and Lovell, 2015). Given its Australian origin, permaculture first was disseminated in the 1980s in industrialized English speaking countries (mainly Australia, United States and Britain) through the development of generally small-scale projects designed to increase individual,

family or community self-sufficiency as a response to the growing environmentalist concerns, especially about peak oil. Most of these initiatives aimed to make people "responsible and productive citizens" instead of being consumers dependent on fossil fuel driven economy and production. Since the 1990s, permaculture was brought to southern countries mainly by northern NGOs and activists as a framework for enhancing the sustainable development and resilience of marginalized communities facing the issues of limited resources, climatic uncertainty, and social inequality.

Permaculture projects are now present in more than 120 countries on all continents around 2500 permaculture projects were referenced in 2017 (international permaculture website permaculturegloba l.org). The number of permaculture projects led by NGOs or civil associations is estimated around 4000 including 140 humanitarian projects. The Permaculture Design Certificate (PDC) is considered by many permaculturists as a mandatory "entrance point" to permaculture. The PDC can be obtained after a collective and participatory training session intended to provide participants with a global view of the permaculture framework and the design tools which would help them to further carry out their own experimentations. The collective dimension of PDC training aims to create strong links between students which can lead to future collaborations, exchanges of know-how, feedbacks on putting permaculture into practice and contributes to the vitality of interactions between practitioners. The number of people with PDC is estimated from 100,000 to 500,000. Given the informal nature of the global permaculture movement, it is impossible to estimate the number of practitioners implementing permaculture approaches or inspired by permaculture with no certification. This number is likely to be high especially in southern countries where development and humanitarian oriented permaculture training and workshops are organized in rural communities outside the framework of the PDC.

Regionally, permaculture initiatives and projects are sometimes promoted and connected through structured networks and local organizations. In line with its worldview favoring grassroots and small scale initiatives, permaculture is globally far less institutionalized and organized than other social and environmental movements. Regional and international gatherings, like the International Permaculture Convergence happening every second year in a different country, help creating links between practitioners and maintaining the feeling of collective belonging to the permaculture community.

Itinerant teachers, including Mollison and Holmgren, have played a major role in the rapid dissemination of permaculture, providing PDCs and other training all around the world and writing books. Based on their notable differences in personality and approach (they stopped working together shortly after the publication of *Permaculture One*), they have promulgated their visions of permaculture with different emphases and in different directions, in turn encouraging subsequent generations of permaculturists to develop new and distinct areas of focus. For example, Geoff Lawton (http://www.geofflawtononline.com/) is well known for having developed design practices related to water conservation and farming in hyper-arid areas, based on his experience of "Greening the desert" in Jordan. Morrow (2010) has achieved international recognition for developing and teaching permaculture approaches adapted to poor and postwar countries in Asia, Africa and Eastern Europe. She strongly focuses on nonviolence methods and the design of highly nutritional gardens easy to maintain with local resources while providing a high diversity of nutrients and vitamins to prevent diseases linked to extreme poverty conditions. Building on the successful dynamic first developed in the British town Totnes, Hopkins (2008) has promoted collective approaches to design and manage solidary human settlements adapted to a post-petrol society. Such processes are supported by a set of facilitating tools and principles to release the "genius of the community" and find creative alternatives to petrol which often result in rethinking globally various dimensions of human communities such as education, health, food, habitat, transportation, economic exchanges (local money) etc. (Aiken, 2017). Hopkins' approach inspired from permaculture has given birth in 2006 to the rapidly growing Transition Network (https://transitionnetwork.org). In 2017, this network regrouped more than 500 initiatives committed to the postpetrol transition and willing to exchange on their experiences at different scales: neighborhoods, villages, towns, cities and even regions, in more than 50 countries (mainly industrialized countries).

Specificity and Originality of Permaculture

Agricultural Implementation of Permaculture

In the field of agricultural production, the practical implementation of permaculture shares many similarities with other alternative farming approaches such as organic farming, biodynamic farming, agroforestry or agroecology. All these movements have historically promoted the development of resource-efficient and pesticide-free agroecosystems favoring local nutrient cycling (e.g., using compost, green or animal manure) and favoring biological regulation by maintaining a high level of biodiversity to keep plants and animals healthy. Permaculture echoes agroecology and agroforestry for the central place given to spatial association of species (combination of trees, animals, crops; intercropping; diversified landscapes). As organic and biodynamic farming, permaculture attaches a great attention to soil fertility. Permaculture has much in common with traditional organic farming, agroecology, and biodynamic farming, in the sense that all these approaches promote a harmonious and respectful integration of human beings in nature. However, historically biodynamic farming stems from spiritual preoccupations (theosophy), organic farming and agroecology are more connected to peasant's movements collectively and politically fighting for their sovereignty, whereas permaculture was born to support individual and community-scale self-sufficiency initiatives in preparation for a postpetrol world.

Compared to other alternative farming approaches, one major specificity of permaculture is the central emphasis on the conscious global design of agroecosystems rather than focusing on specific techniques. In the design process, the different functions expected from the agroecosystem (e.g., "providing food for chickens," "keeping water available in summer," "mitigating the

dominant winds," "fertilizing the garden") are listed. Different elements are integrated in the design (e.g., "a vegetables garden," "a pond," "a hedge," "poultry") ensuring that every function is fulfilled by various elements and every element fulfills various functions, thereby mimicking the functional redundancy of natural ecosystems and fostering system resilience. The different elements are combined and spatially organized using a set of design tools (e.g., checklist of principles, mapping of site specificities, chart of interactions) in order to maximize the positive interactions between elements, benefit from the specific opportunities, and to mitigate the constraints of the site Influenced by the work of H.T Odum, plant and animal species are regarded as distinctive but interchangeable system components which should be selected from a global pool based on functional criteria without regard to their place of origin. The conscious design of permaculture landscapes aims to mimic natural ecosystems and maximize positive interactions within the agroecosystem (e.g., biological regulations, creation of favorable microclimates). This global approach echoes "ecological engineering" by its systemic dimension and the importance given to design to create sustainable ecosystems (Mitsch and Jørgensen, 2003). However, ecological engineering, mainly implemented for the restoration of natural areas, is based on "self-design" (or self-organization) which tends to let ecosystems organize themselves as naturally as possible. Although permaculture design is flexible and values creative response to change during the management phase, the evolution of the system should be planned as much as is to maximize the chances that that human goals for the productive ecosystem (food, fiber) will be met.

Permaculturists tend to implement complex multistrata polycultures, intercropping, agroforestry (e.g., food forests), crop-animal integration (e.g., silvopastoralism), and to promote a high diversity of habitats, integrating landscape features such as ponds and hedges. Soil tillage is often limited and soil is constantly covered by plants or organic mulch to favor the development of soil organisms that will work for humans and structure the soil (e.g., earthworms), store carbon and limit erosion. Trees and perennial plants often play a key role as they are considered energy accumulators (storing carbon and making nutrients available for other species).

Perennial plants and trees are prioritized with the aim of reducing human labor (i.e., annual planting), together with an ergonomic zoning of the site where production areas are spatially organized according to the degree of human intervention they require. Permaculture landscape planning organizes space and elemetns into five areas with different levels of intensification: from "zone 1" where human intervention is the highest and most frequent (e.g., vegetable garden) to "zone 5" which is a natural area left deliberately unmanaged (Mollison, 1988). Zone 5 is seen both as a reservoir of biodiversity and a place where practitioners can observe "how local nature works," which can provide inspiration and design ideas for the rest of the site. In this way permaculture design integrates the spatial logics of "land sparing" (separating intensive production zones and natural areas) and "land sharing" (managing areas with reduced intensification to preserve biodiversity in productive areas) (Fischer et al., 2014). However, permaculture goes beyond this distinction as even the most productive areas are designed to maximize biodiversity as a way to maintain resilient and productive ecosystems, echoing the logic of "ecological intensification" (Bommarco et al., 2013).

As the edges between zones are regarded as being spaces of maximal diversity and interaction between species, permaculturists often maximize edge by designing cultivated areas with curved and undulated shapes rather than straight lines. The use of earthworks, dams and swales for water harvesting and control is central, as is the development of renewable sources of energy on the production site (e.g., solar panels, passive solar buildings, wind turbines, biomass and hydroelectric devices).

Rethinking Modernity and Empowering People Beyond Optimizing Ecosystems

In providing conceptual tools and design methods to observe and mimic patterns from complex natural ecosystems with the goal of designing resource efficient human settlement, permaculture could be seen as a modern, biologically-inspired approach to system optimization. In this way permaculture could be read as replicating the rationalist, instrumental relationship with nature that characterizes modernity and the industrialized world. In industrialized countries, modernity has become politically dominant in the 19th century and has spread all over the world with western culture and globalization. A growing number of philosophers and scientists argue that modern thinking, which consider nature just as an objective pool of resources which have to be rationally exploited, may be one of the major causes of the environmental issues that humanity is facing now. Permaculture departs from this tradition in several ways. Inspired by what Holmgren calls "traditional cultures of place"—premodern cultures where human beings have developed through time ecological knowledge and sensibility adapted to their specific environment—permaculture encourages practitioners to develop emotional and subjective links with the earth that will foster a feeling of responsibility toward the places where they live (2002).

Permaculturists also acknowledge that diversified ecosystems are complex, will unlikely ever be fully understood rationally, and that global environmental crises call for rapid human action despite limited ecological knowledge available. This is why permaculture encourages practitioners to develop skills and senses such as imagination and creativity in addition to rational, instrumental skills of observation, analysis, and system optimization. In this sense, permaculture has sometimes been described as a postmodern approach where elements from different systems and traditions are hybridized without regard for any fixed aesthetic or tradition, and where the importance of rational knowledge is consciously balanced and integrated with more subjective and relational human capacities.

Postmodern or not, it is clear that permaculture questions the modern and industrial world as we know it. It invites practitioners to become creative "new indigenes" while developing knowledge, interaction capacity with their local environment and community, and useful skills to become more self-sufficient in order to move from their status of dependent and demanding consumers to interdependent and responsible producers (Holmgren, 2002). This empowerment of individuals and communities is aimed both as

a way to decrease the dominance of industrial systems today, and to prepare and for survival in a future postindustrial era with no access to fossil resources.

Criticism, Controversies and Research Perspectives

A Tendency Toward Oversimplification and Overreaching

Permaculture has a troubled relationship with ecological science. Permaculture has received criticism for overreaching and oversimplifying claims. This tendency is encapsulated in the notion that humanity already possesses all the knowledge necessary to replace current land use with permaculture systems, across all social and ecological contexts, and that the process of redesigning is itself straightforward. In the absence of reliable data to support these proposals, permaculturists often rely on limited case studies and sweeping extrapolation from ecological principles. Most permaculture texts do not refer to contemporary scientific research. Much documentation available is found in gray literature which is difficult to access or verify. The effects of this isolation include the lack of reference to contemporary developments in relevant science, the accompanying persistence of idiosyncratic or misleading terminology, and the potential for influence of pseudo-scientific theories. The permaculture literature assigns the blame for this isolation on the inability of scientists and institutions to comprehend or appreciate the radical proposals put forth by permaculture. Permaculture opponents argue that permaculture practitioners may be reluctant to get involved in systematic scientific research whose results could challenge or temper their idealistic claims.

One common example of oversimplification is the conflation of net primary production with agricultural productivity. One point where this becomes apparent is in permaculture's advocacy for perennial production systems—justifying this proposal, in part, based on the high photosynthetic surface area and correspondingly high primary productivity of these systems. While forest ecosystems are among the highest in NPP, perennial plants allocate a higher percentage of photosynthetic activity to structure than annuals and therefore have a slimmer margin for export as edible tissue, rendering the comparison of potential yields a complex empirical question rather than a simple maxim. Another example is the claim that complex shapes in fields, garden beds, and ponds will increase productivity—what is called the "edge effect." This claim was originally based on the permaculture principle of edge effects that was itself extrapolated from the ecological characteristics of ecotones and anecdotal reports of edge effects in grain cropping systems. While edge effects are real, their strength, reliability, and practical applicability across widely varying contexts (i.e., from cereal fields to intensive garden beds to pond edges) is not supported by scientific evidence and is likely exaggerated. Increased biological productivity may not translate to increased harvestable yields, and the benefits of an increase in harvestable yields may be swamped by the increased labor required by complex edges.

Limited Political Impact and Scaling-up

The simple solutions populism of permaculture suggests that the best responses to global crises can be implemented immediately with readily accessible materials and skills. This worldview is reflected in a model of change that mostly spurns systematic engagement with existing institutions in favor of direct intervention into the means of subsistence, reintegrating production and resource management under the stewardship of local individuals and communities. The flat network structure that accompanies this mode of action appears to be a conscious strategy to avoid the twin dangers of cooptation and outright suppression to which grassroots efforts are vulnerable. This model has met with some success, as evidenced by its international distribution and positive influence on urban land use, horticultural and agricultural practices, and other sustainability-relevant behaviors across contexts.

The evident successes of the permaculture network are balanced by problematic assumptions and implications that evoke the hazards of insularity, exclusivity, particularity, and scale mismatch to which grassroots networks are prone. The permaculture movement displays significantly less organization and institutionalization than other international agroecological movements, e.g., La Via Campesina, Campesino à Campesino, or International Federation of Agricultural Producers. This lack makes the coordination of action beyond the immediate community scale difficult or impossible and thus limits the potential for mobilization of political support for diversified farmers. Low levels of institutionalization may also constrain capacity for program development, systematic tracking of outcomes, and engagement with potential allies. Recent research suggests that the permaculture network in the United Kingdom is vulnerable to insularity, and thereby leads to a lack of capacity to influence relevant institutions and communities.

Permaculture's optimistic focus on holistic and positive action, on personal responsibility, and on the simplicity of needed solutions, is empowering for participants and is likely a significant driver of the spread of the movement. However, the portrayal of agroecological transition as something that individuals can contribute to, using simple techniques at home, is a double-edged sword. While prioritizing the perspectives and capacities of land users is important, it may also run the risk of depoliticizing aspects of agroecological transition that are fundamentally political, and trivializing the complexity of socio-ecological processes and struggles.

Permaculture, Traditions and Neocolonialism

Permaculture has also received criticism on socio-political grounds. Critics have observed that permaculture was brought to developing countries from "knowing westerners" visiting poor communities in a similar way to humanitarian action and green

revolution packages which may be seen as a form of neocolonialism. However, scientific literature has highlighted that the principles of permaculture teaching based on individual observations and collective learning favored the empowerment of poor communities while not providing ready to use solutions designed by westerners but providing people conceptual and organizational tools to design creatively themselves their own solutions (Conrad, 2014). The little data available on permaculture in international development suggests a mixed record: sometimes implemented in a responsive and accountable fashion, and sometimes with a neocolonial savior mentality.

The movement has received criticism for a failure to acknowledge the similarity of permaculture's proposals to indigenous cultures of land use and for re-packaging indigenous land management practices as an innovation originating within permaculture. The extensive permaculture literature on small scale multistrata agroforestry uses the terms "food forest" and "edible forest garden" but rarely makes reference to the pan-tropical homegarden traditions that forms the conceptual basis for these practices and provide the vast majority of their existing land user base. Indeed, home gardens in tropical areas—from Javanese homegardens to the Creole gardens in the West Indies—traditionally involve multipurpose trees and shrubs in intimate association with annual, perennial agricultural crops and livestock, (Fernandes and Nair, 1986). Similarly, the integration of aquaculture in ponds, crops and livestock often practiced by permaculturists is drawn from traditional production systems in Asia (Prein, 2002). The founders of permaculture, Mollison and Holmgren, consider that if these sources are clearly acknowledged and respected, their use in permaculture contributes to the preservation of this rich heritage and to the recognition that westerners seeking to create sustainable human settlements have much to learn from indigenous (Mollison, 1988; Holmgren, 2002). In the same way many permaculturists seek to incorporate plant and animal species according to their functions and not to their origin, Mollison and Holmgren consider that elements of traditional knowledge from the global "indigenous pool" can be detached from their original paradigm and combined to other elements and sources of information such as scientific knowledge "to create new local cultures with hybrid vigor" (Holmgren, 2002). Critical social studies have argued that this process could be considered cultural appropriation of traditional knowledge by "university-educated white males from a wealthy country" (Conrad, 2014). Nevertheless, in many developing countries, poor rural communities have adopted permaculture as a way to reassert the value and authority of indigenous knowledge and reclaim the rights to farm "as their ancestors did" (Conrad; Millner). Some "local traditions" have been reimagined and hybridized with useful practices, principles, and scientific concepts coming from other parts of the world. In this regard, some studies have considered that permaculture has been appropriated by poor communities to create new cultural identities adapted to the modern world based on traditional ecological knowledge (Millner, 2016). Conflict on the topic of the use of indigenous knowledge in permaculture, and more generally in ecological engineering, continue and can be a fascinating research field for anthropological and sustainability studies (Veteto and Lockyer, 2008).

A Need for Research About the Agricultural Efficiency of Permaculture

Despite permaculture's origins within academia, Mollison's and Holmgren's work received very little academic attention when published in the late 1970s and 1980s. Academic reactions were mainly negative because the disciplinary specialization at that time left academics ill-prepared for the holistic approach that permaculture offered (Veteto and Lockyer, 2008). Permaculture embraces many themes and has been given many often very vague definitions, which may have caused confusion and limited systematic discussion. Its idealistic aspects have been perceived as impractical by many scholars (Ferguson and Lovell, 2014). Most private companies do not have financial interest to research and disseminate it. Since the 1980s, permaculture books and articles have mainly been written by practitioners outside academia benefiting from the high interest and enthusiasm that permaculture received from civil society. Over the decades following permaculture's emergence, sporadic academic papers have dealt with permaculture in different fields such social and behavioral sciences, architecture, education. These papers were mainly descriptive of permaculture principles and applications, with little critical analysis—though this has changed in recent years.

Very little scholarly work was carried out on permaculture from an ecological or a life science perspective based on quantitative data, especially in the agricultural field which was permaculture first priority and historic starting point. Permaculture claims to provide tools and methods to design resilient, productive resource and labor efficient farming systems based on a high level of biodiversity and beneficial ecological interactions. These assumptions remain little documented and controversial. In this regard, the most significant studies have been led for doctoral dissertations. In industrialized countries (the United States and France), they have shown that the productivity and economic returns to labor of commercial permaculture farms could benefit from high level of cultivated diversity, crop/animal integration and be economically successful even with low levels of fuel consuming motorization (Morel et al., 2016; Ferguson and Lovell, 2017). Building on the strong public interest for permaculture, some permaculture farms develop cultural or training activities to diversify their incomes in a logic of pluriactivity. This strategy raises strong criticism from permaculture opponents who argue that permaculture profitability only comes from teaching permaculture and not from applying concretely permaculture to build productive systems. The cost of permaculture training or cultural activities (workshops, demonstration site visits) is another topic of controversy. Critics from within and without the permaculture movement argue that the ways in which these costs limit access to programming contradicts permaculture's principles of equity and sharing. In response, others claim that a fair cost of training has to pay teachers for their time, labor, the depth of their experience, and the value of what they offer. Some permaculture teachers do offer free or limited-cost courses for people who cannot otherwise afford training.

Nevertheless, many permaculture farms only focus on production and are not involved in teaching. The levels of production, inputs, labor, and incomes of farms inspired by permaculture are highly variable and similar in their range to other diversified, organic, low-input., and agroecological farms (Ferguson and Lovell, 2017; Morel, 2016). In developing countries, farmers using

permaculture can experience agricultural, environmental, economic, and nutritional benefits in comparison to farmers solely using conventional agriculture, as demonstrated in Malawi by Conrad (2014). However, benefits of permaculture at the farm level are limited by the broader dominant agro-food system, constraints on access to resources and markets, and wider structural, political, and technical context. Such exploratory works mitigate both idealistic views of permaculture activists presenting permaculture as a way to solve all problems and strong critics presenting permaculture as an unrealizable utopia.

For permaculturists, a high level of biodiversity and functional redundancy are supposed to guarantee that agricultural systems will be resilient. The idea that "diversity begets stability" is deeply anchored in the ecological literature since the 1950s, especially in H.T Odum's work which has inspired permaculture. The "stability-diversity controversy" running in the ecological academic field since the 1970s has however underlined that the link between diversity of species/functions and stability of ecosystems is complex, and that other factors and properties of ecosystems have to be considered. As many gaps in academic literature remain, further studies are required to examine the efficiency, resilience, ecological dynamics, and impacts of permaculture farms in different contexts, and in the light of contemporary ecological concepts and methods, and to assess the extent to which permaculture could contribute to a large-scale transformation of food systems. Accompanying the growing public awareness of permaculture, recent years have seen a shift in the isolation of the permaculture movement from the scientific community. This bridge is being built from both sides. There is an emerging push for community-based research and partnership with institutionally-based researchers coming from the permaculture movement. For example, the Permaculture International Research Network (PIRN) was formed in 2015, sponsored by the UK Permaculture Association, and reports having over 400 members in over 40 countries. The appearance of permaculture in publications in peer-reviewed journals has increased sharply in recent year. More and more universities are developing research projects about permaculture which may announce promising perspectives for the future.

Phytoremediation

SC McCutcheon, US Environmental Protection Agency, Athens, GA, USA
SE Jørgensen, Copenhagen University, Copenhagen, Denmark

Phytoremediation and Other Biotechnologies

`Phytoremediation' is the cleanup or control of wastes, especially hazardous wastes, using green plants. There are many types of phytoremediation, as shown in Table 1, including the use of phreatophytes to control plumes of groundwater contaminants and contaminated vadose zones. Photoautotrophs, including vascular plants, green algae, cyanobacteria, and fungi, must be involved in the synthesis or maintenance of biomass, or in the direct metabolism, storage, detoxification, or control of contaminants. Glycosylation, occurring in plants and saprophytic fungi but not bacteria, is usually important in direct metabolism, detoxification, and accumulation or storage of pollutants by plants. Glycosylation is a sequestration of contaminant molecules by the addition of a glycosyl group to form a glycoprotein that plant cells can easily transport and store or transform. Not all applications of phytoremediation involve glycoproteins but the occurrence of glycosylation in pollutant transformations does distinguish whether the metabolism of organic contaminants or transformation of other contaminants is bioremediation or phytoremediation.

If heterotrophs are solely responsible for the metabolism or mineralization of organic contaminants and the accumulation of metals and other elements using local accumulations of nonliving organic matter and oxidized inorganic compounds, these processes are part of the allied field of `bioremediation'. However, when photoautotrophs are involved in treating contaminants by

- actively releasing organic matter during growth, maintenance, and senescence that increase the number and biomass of heterotrophs;
- selectively favoring specialized microorganisms that degrade or accumulate contaminants by pumping oxygen into the root zone, releasing exudates, or depositing secondary metabolites during root die-back in the rhizosphere to favor aerobic, facultative, or anaerobic organisms with enzymatic activity for the secondary products released or deposited; and
- transporting pollutants into active microbial zones by evapotranspiration, blockage of flows, or other means.

These processes are a vital part of phytoremediation. Depending on the various interactions of photoautrophs and heterotrophic microbial communities and the contaminant transformations involved, these processes are known as `phytostimulation', `rhizo (sphere) degradation', `rhizosphere bioremediation', or `plant-assisted bioremediation' (see Table 1).

Distinction of bioremediation from phytostimulation is important in at least three cases. First, some heterotrophs sustainably derive carbon and energy from the degradation of organic contaminants. Second, anthropogenically synthesized organic or oxidized inorganic chemicals added to a contaminated site could temporarily free bioremediation from natural photo- or chemoautotrophic synthesis long enough by cometabolism to achieve some cleanup. Third, chemoautrophs synthesizing biomass from inorganic compounds to provide organic carbon and energy for heterotrophs conceivably could be used in sustainable bioremediation. If any amendments and cofactors are obtained and added sustainably, then these bioremediation processes are sustainable. The most common amendment is fertilizer, used primarily to bulk up plant biomass and thus increase microbial biomass and activity in the rhizosphere.

Redundant ecological engineering of both plant and microbial processes in remediation is usually the sustainable and successful approach. In practice, distinctions between phyto- and bioremediation are only important for some specific contaminants at different sites. Different management approaches and techniques are required when microbial heterotrophy versus photoautotrophy dominates. Critical rates of pollutant control, uptake, storage, and metabolism, whether microbial or botanical, define whether plant or microorganism management techniques must be applied. When critical rates for microbial and botanical uptake and transformation are comparable, both techniques should be applied simultaneously for engineering redundancy and ecological resilience.

One of the most significant advances in phytoremediation is that green liver metabolism is much more important in waste management than early biotechnology research revealed. Sandermann first coined the term `green liver' to convey the great similarity between plant and mammalian sequestration and metabolism. So great is the similarity that many view plant metabolism more akin to mammalian metabolism than to bacterial metabolism. In fact, many fundamental metabolic processes first evolved in early cyanobacteria and bacteria and were carried forward, sometimes without evident purpose, into higher forms of life present today, including vascular plants and mammals. But for future xenobiotic and highly complex hazardous wastes, the most sustainable applications may need to concentrate on use of the most highly evolved enzymatic systems available only in plants and animals. In part, bacteria versus higher forms of life have evolved different survival strategies. Microbes are present in great numbers, almost ubiquitous on this planet, usually passively mobile, more adaptable, and capable of evolving rapidly. Thus, a toxic insult will kill many microorganisms but the species will usually survive, maybe even the rigors of outer space. If the die-off is extensive or long term, new protections may evolve by selection of the fittest.

 doi:10.1016/B978-0-444-63768-0.00069-X

Table 1 Types of phytoremediation ranked in terms of sustainability and applicability

Type	*Definition*	*Applications*
Phytodegradation: phytoassimilation, phytotransformation, phytoreduction, phytooxidation, and phytolignification	Aquatic and terrestrial plants take up, store, and biochemically degrade or transform organic compounds to harmless by-products, products used to create new plant biomass, or by-products that are further broken down by microbes and other processes to less harmful compounds. Growth and senescence enzymes, sometimes in series, are involved in plant metabolism or detoxification. Reductive and oxidative enzymes may be serially involved in different parts of the plant	Soils, sediments, wetlands, wastewaters, surface waters, groundwater, and air contaminated with chlorinated solvents (CCl_4, trichloromethane, tetrachloromethane, HCA, PCE, TCE, DCE, and VC), methyl bromide, tetrabromoethene, tetrachloroethane, dichloroethene, atrazine, DDT, other Cl- and P-based pesticides, PCBs, phenols, anilines, nitriles, TNT, DNT, RDX, HMX, NB, picric acid, NT, nitromethane, nitroethane, and nutrients. *Field demonstration*: Iowa Army Ammunition Plant successfully restored using wetland plants (TNT and RDX). *Proof of principle*: (a) field – *Populus* spp. Carswell Air Force Base, Texas; Aberdeen Proving Grounds, Maryland; and using lysimeters at Tacoma, Washington (TCE); and (b) horseradish peroxidase pilot-tested in unit process to degrade phenols, aniline, and other aromatic contaminants in wastewater. *Proof of concept*: *Rosa* spp. cv. Paul's Scarlet (PCBs).
Phytostimulation: rhizodegradation, rhizosphere bioremediation, and plant-assisted bioremediation	Plant exudation, root necrosis, and other processes provide organic carbon and nutrients to spur soil bacteria growth by 2 or more orders of magnitude in number; stimulate enzyme induction and cometabolic degradation by mycorrhizal fungi and the rhizomicrobial consortium; provide diverse root zone habitat; and attenuate chemical movements and concentrations. Live roots transfer oxygen to aerobes, and dead roots may support anaerobes or leave aeration channels	Soils and wetlands contaminated with crude oil, BTEX, other petroleum hydrocarbons, PAHs, PCP, perchlorate, pesticides, PCBs, and other organic compounds. *Field proof of concept*: BTEX, other hydrocarbons, PAHs, PCP, and TCE. *Field tests*: crude oil in wetlands of *Spartina alterniflora* and *S. patens*. *Fungi*: (1) field-scale tests: of white rot fungus degradation of BTEX and (2) proof of concept: for DDT, dieldrin, endosulfan, pentachloronitrobenzene, and PCP.
Phytocontainment:	Trees and other phreatophytes transpire large quantities to contain shallow groundwater plumes or contaminated soil leaching by reversing horizontal aquifer hydraulic gradients, or vertical soil moisture pressure gradients	Groundwater, vadose zone, wetlands, wastewater, and leachate contaminated with water-soluble contaminants (e.g., chlorinated solvents, MTBE, explosives, other organic contaminants, salts, and some elements).
(1) Phyto- or solar pumping, phytohydraulic control, and phytohydraulic barriers (also biobarriers)	(infiltration and leaching minimized) both year-round or seasonally to fully or partially capture contaminants. Applications normally coupled with rhizo- and phytodegradation	(1) Field proof of principle: *Populus* spp. (TCE, PCE, MTBE, and CCl_4)
(2) Control of soil and landfill leaching		(2) Concept not proven
(3) `Pump and tree', phytoirrigation, or other plant treatment *ex situ*		(3) Proposed and undergoing testing: (a) pine (*Pinus* spp.) (TCE and by-products) and (b) *Salix* spp. (organic solvents, MTBE, petroleum hydrocarbons, and nutrients) (Numbers correspond to those in column 1)
Brine volume reduction	Brines pumped onto halophytes planted in wetlands that accumulate or excrete salt and the smaller volume residual brine transported and disposed of more economically	Deep groundwater or oilfield brines. Wetland halophytes pilot tested in Oklahoma oilfield. No plant residuals: halophytes fed to cattle as a source of salt after toxicity testing of plants
Rhizofiltration: phytofiltration, blastofiltration, phyto- or biosorption, biocurtain, biofilter, contaminant uptake, and epuvalization	Compounds taken up, rapidly sorbed, or precipitated by roots (rhizofiltration) and young shoots (blastofiltration) or sorbed to fungi, algae, and bacteria (biosorption mainly to cell walls involving electrostatic attraction and formation of complexes). Marine algae possess large quantities of biopolymers (polysaccharides, uronic acids, and especially sulfated polysaccharides) that bind heavy metals. 10–60% dry weight of plant may be accumulated metals	Wetlands, wastewater, landfill leachates, surface water, and pumped groundwater contaminated with metals, radionuclides, organic chemicals, nitrate, ammonium, phosphate, and pathogens. Plant roots or shoots, aquatic plants, or algae, all live or dead, are added to or contained in wetlands, tanks, flowing water channels, or columns. Disposal of residuals unresolved. US practice is to dispose of residuals in hazardous waste landfills. Conceptually, metals sorbed to cell walls may be acid-extracted. Economic recovery of metals needs to be explored. *Field*

Table 1 Continued

Type	*Definition*	*Applications*
		proof of concept: sunflower (*Helianthus annuus*) at Chernobyl, Ukraine (Cs and Sr), and field pilot, Ashtabula, Ohio, for U. *Proof of concept for phytosorption*: aquatic plants (*Salvinia* spp. and *Spriodela* spp.) (Cr and Ni from wastewater and Pb, Cu, Fe, Cd, and Hg), algae (several metals), and marine algae (*Sargassum* Au: 40% of the algal dry weight). *Proof of concept for rhizofiltration*: sunflower (*Helianthus annuus*) and Indian mustard (*Brassica juncea*) (Pb, Cr, Mn, Cd, Ni, Cu, U(VI), Zn, and Sr)
Phytovolatilization: biovolatilization andphytoevaporation	Volatile metals and organic compounds are taken up, sometimes re-speciated (metals), and transpired. Some recalcitrant organic compounds are more easily degraded in the atmosphere but most multimedia transfers require a risk assessment before testing	Soils, sludges, wetlands, and groundwater contaminated with Se, tritium, As, Hg, *m*-xylene, chlorobenzene, tetrachloromethane, trichloromethane, trichloroethane, and other chlorinated solvents. *Field proof of principle*: Se from wastewaters and soil. *Field proof of concept*: tritium from groundwater. *Current technical consensuses*: (1) TCE volatilization has not proven significant to date but site risk assessments are required to be certain. The risk of volatilization of other organic pollutants has not been explored. (2) Transgenic plants volatize Hg in the lab but redeposition from the atmosphere makes field applications less feasible.
Phytoextraction (including chelator induced): phytoaccumulation, phytoconcentration, phytotransfer, hyperaccumulation, and phytomining	Contaminants taken up with water by cation pumps, absorption, and other mechanisms and usually translocated above ground. Harvested shoots or roots put in hazardous waste landfills or could be smelted after volume reduction by incineration or composting. Hyperaccumulation is approximately 100 times normal plant accumulation of elements and is 0.01% by dry weight for Cd and other rare elements, 0.1% for most heavy metals, and 1% for Fe, Mn, and other common elements	Extraction from soil of metals, metalloids, radionuclides, perchlorate, BTEX, PCP, short-chained aliphatic and other organic compounds not tightly bound to soils (although phytodegradation of inorganic and organic molecules is more sustainable). US practice is disposal of residuals in hazardous waste landfills but Ni smelting is feasible. Composting to reduce disposal volume conceptualized. *Pilot field-testing eastern US*: unproven at six sites with Pb using *B. juncea* but proven at two sites with Zn and Cd using *Thlaspi caerulescens*. *Phytomining Ni*: two US locations and testing in Albania and South Africa. *Field proof of concept*: Ni, Zn, Sr, Cs (see following warning), and Cd from long-term application of sludges using *Brassicaceae* hyperaccumulators in UK; Mariupol and Chernobyl regions, Ukraine; and Pennine Mountains, UK (plus Ag, Al, Co, Fe, Mo, and Mn). Failed two evaluations using chelators for Pb; thus questionable for Cr, Cs, and other tightly bound elements. New lab proof of concept now required for Pb and other tightly bound elements. *Proof of concept*: 1993–95 for Cd, Ni, Zn, Cu, Se, B, and other elements. *Bench testing*: at arid western US site for Cr, Zn, Hg, Ag, and Se using *Salix* x, *Kochia scoparia*, and *Brassica napus* and perchlorate using wetland halophytes.
Phytoslurry	Enzymatically active plant material ground and slurried with wastewater, contaminated soil, or sediment	*Lab proof of concept*: wastewater, soil, or sediment contaminated with DNT and TNT
Phytophotolysis	Contaminant translocated from soil or water into leaves and broken down by photolysis	Proposed concept for soil, wastewater, wetlands, and groundwater contaminated with RDX

(*Continued*)

Table 1 Continued

Type	*Definition*	*Applications*
Phytostabilization: biogeochemical stabilization, biomineralization, phytosequestration, and lignification	(1) Revegetation to prevent erosion and sorbed pollutant transport	Soil, mine tailings, wetlands, and leachate pond sediments contaminated with metals, phenols, anilines, some pesticides, tetrachloromethane, trichloromethane, and other chlorinated solvents
	(2) Plants control pH, soil gases, and redox that cause speciation, precipitation, and sorption to form stable mineral deposits (effects of ecosystem succession unknown on long-term stability and thus sustainability)	(1) *Extensive applications*: revegetation grasses established for different metals dominated wastes in UK and US erosion prevention handbooks available for many countries
	(3) Humification, lignification, and covalent or irreversible binding of some organic compounds are expected	(2) *Bench proof of concept*: for stabilization of some pesticides, phenols, and anilines (3) *Lab proof of concept*: for Pb and Cr^{6+} (VI)[a] (the numbers correspond to those in column 2)

BTEX, benzene, toluene, ethyl benzene, and xylene; DCE, dichloroethane; DDT, dichloro-diphenyl-trichloroethane; DNT, dinitrotoluene; HCA, hexachloroethane; HMX, octahydro-1,3,5,7-tetranitro-1,3,5,7-tetraazocine; MTBE, methyl *tert*-butyl ether; NB, nitrobenzene; NT, nitrotoluene; PAHs, polycyclic aromatic hydrocarbons; PCBs, polychlorinated biphenyls; PCE, tetrachloroethene; PCP, pentachlorophenol; RDX, hexahydro-1,3,5-trinitro-1,3,5-triazine; TCE, trichloroethene; TNT, 2,4,6-trinitrotoluene; VC, vinyl chloride.

Plants are normally rooted in place and are much fewer in number. Thus, plants may have evolved greater numbers of metabolic proteins used to detoxify insults in place, than microorganisms evidently require for survival. Plants are different from animals in the lack of (1) an immediate flight response and (2) excretion of transformation products. Animals tend to excrete transformation products, whereas plants tend to accumulate some transformation products in vacuoles or between layers of molecules in cell walls. Plant transformation products are accumulated and could be released into the environment upon death and lysis of plant cells.

Ecological Engineering

Sustainable phytoremediation is a vital element of the new applied science field of ecological engineering; so are bioremediation and other biotechnologies used in sustainable waste management. For the first time in the long history of engineering, this new field will strive to develop a new discipline of engineering that values equally ecosystem and human needs. All existing engineering disciplines, including environmental engineering, have completely or partially overweighted human infrastructure in a manner that may not completely sustain life on this planet.

`Ecological engineering', first conceptualized by H. T. Odum in 1957, is environmental manipulation by humankind using small amounts of supplementary energy to control systems in which the main energy derives from natural sources or ``the design of human society with its natural environment for the benefit of both.'' This definition clarifies why photoautrophic, and, to a degree, heterotrophic processes like sustainable phytoremediation and bioremediation are important components of this new field. Thus, ecological engineering is an appropriately holistic concept to organize and understand how different biotechnologies can be best used to sustainably manage wastes. The degree of self-organization by different species, populations, and communities of organisms is the key to understanding how phytoremediation fits into the sustainable ecological engineering of waste management.

`Self-engineering' is the reorganization, substitution, and shifting of ecosystem dynamics and functions to adapt to super-imposed environmental stresses and limitations. Adapting to ambient conditions, species, populations, and communities of plants, animals, and microorganisms `self-design' or control the local environment. Examples include the development of microclimates under plant canopies, control of soil geochemistry by roots and microbial communities, control of water levels in soil by evapotranspiration, and control of metals speciation in soil to prevent enzyme poisoning.

Other important ecological principles that define why ecological engineering and phytoremediation are sustainable waste management concepts include

- Ecosystem structure and function are governed by and can be quantitatively related for design and analysis to dynamic forcing functions like availability of sunlight, water, organic matter, nutrients and other building blocks of life, and toxins and many other stresses.
- Materials, especially carbon and nutrients, are recycled in ecosystems, making these most self-sustaining.
- Sunlight and the stored heat of the planet are sustainable sources of energy used to organize cells, organisms, populations, communities, ecosystems, and the Gaia (the planetwide ecosystem) that results in the degradation in quality of some energy to unusable states, thus increasing the system entropy, and requiring a constant and consistent source of energy for sustainability.

- Ecosystem processes have characteristic temporal and spatial scales that are usually fundamentally different from the normally static, stable, steady-state designs of human infrastructure over limited geographic areas.
- Ecosystems are dominated by momentary, diurnal, seasonal, annual, decadal, geologic, and other timescales and these pulses are often highly productive in combined energy and matter, and all types of diversity.
- Ecosystems are extensively linked and coupled spatially and dynamically with extensive feedback to form an Earth-dominating web of life known as Gaia (the preeminent example of ecosystem self-engineering and self-design), whereas human infrastructure (exclusive of the environment) is not yet as extensively linked worldwide except by the Gaia.
- By definition, an `ecosystem' is an arbitrarily defined web of life with every organism linked and coupled to everything else (including the ambient environment or habitats, overlapping ecosystems, and forcing conditions or adjacent ecosystems at all boundaries) with extensive and dynamic feedback and resilience, conservation of materials, and flow and degradation of energy quality from one trophic level to the next in all food chains systemwide.
- Organisms and cells maintain internal `homeostasis' (equilibrium achieved by adjustment of physiologic, enzymatic, and synthetic processes) of biological and physiological functions by biochemical conversion and control of sunlight energy, organic matter, other sources of energy, and nutrients, which in turn are based on ambient conditions.
- Ecosystem feedback, resilience, a buffering or waste assimilative capacities are defined by the evolutionary and life histories of the cells and organisms involved.
- Enzymatic, proteomic, and other biochemical diversity enrich feedback, resilience, a buffering or waste assimilative capacities of an ecosystem.
- Ecosystems are typically defined by geographic edges (shorelines, ridgelines, and similar geographic features) which are normally `ecotones' (transition zones between communities dominated by greater diversity and numbers or mass of organisms), so that forcing conditions from adjacent ecosystems and the surrounding environment are most evident and quantifiable and thus ecosystems are usually most vulnerable at these boundaries.

A good example of natural self-design was observed at the Alabama Army Ammunition Plant near Talladega. Built in 1942 and operated during the Korean conflict, widespread trinitrotoluene (TNT) contamination of soil and water was observed from the 1960s to the 1990s cleanup. The extensive contamination caused large bald spots of soil that were effectively sterile, the drainage from which turned local streams pink with the photodegradation products of TNT. Beavers dammed at least one on the pink-tinged streams allowing parrot feather (*Myriophyllum aquaticum*; see **Fig. 1**) and other wetland plants to grow, spread, and break down the TNT and by-products. By the early 1990s, these waters and sediments in the ponds and streams were free of detectable TNT.

The sterile bald spots, reported to be up to 60 m (200 feet) in diameter in the 1960s, were reduced to about half of this diameter by the early 1990s by encroaching forests. Concentrations were of the order of 10 000 mg of TNT per kg of dry sterile soil. As of 1991, hardy grasses grew at the margins, followed by small pine (*Pinus* spp.) trees. Some of the grasses and small trees succumbed to the highly toxic soils, probably during periods of higher environmental stresses (drought, frost, rainfall saturation of soil and mobilization of highly toxic TNT, and other stressful events). These plants usually fell into the sterile areas to increase soil organic carbon at the ecotone, allowing other plants to grow further inward year after year. Concentrations were on the order of 1000 mg kg^{-1} of soil in the ecotone. Adjacent to the ecotone were more mature pines that transitioned to hardwoods in a short

Fig. 1 Parrot feather (*Myriophyllum aquaticum*) growing in a natural wetland.

distance as part of the normal succession in southern forests. In the reforested fringe of full size trees and underbrush, TNT concentrations were on the order of 10–100 mg kg^{-1}. To ecologically engineer the cleanup of this site, the natural process of breaking down TNT in the sterile soil could have been accelerated using limited energy in collecting and transporting local forest accumulations of detritus to the sterile bald spots to get indigenous plants growing. The beaver ponds downgradient could have been kept in place to continue to capture and break down the residuals draining from the bald spots until all contaminants were removed from the soil and wetlands.

At the Carswell Air Force Base in Texas, an ecological engineering design is being used to inexpensively avoid energy-intense mechanical pumping and treating a shallow, surficial groundwater plume of trichloroethylene (TCE), a chlorinated solvent used in cleaning metal parts. Two small plantations of cottonwood (*Populus deltoides*) whips and 1-year-old trees were planted 1 m (3 feet) deep across the plume, the depth of which was approximately 3–3.5 m (10–11 feet) below the ground surface. Within months the transpiration of the fast-growing cottonwoods seasonally halted the contaminant plume as evidenced by recurring depressions in the water table. At the end of 5 years, about 30% of the plume was removed by the trees and microorganisms. Scaleup of this pilot plantation of approximately 900 trees by a factor of 4 or more is likely to completely halt this small plume. But the complete dewatering of the aquifer by transpiration is neither necessary nor desirable. Some of the TCE residual can be dehalogenated by enhanced vadose zone reduction and spurring of microbial growth from the added trees. Complete aquifer dewatering will dry up an adjacent stream and cause the death of some of the trees due to lack of water.

Remarkably, the cottonwoods self-engineered the vadose zone redox conditions to at least 3 m (10 feet) deep by the release of sugars and other simple exudates. The switch to reducing conditions favored the microbial dehalogenation documented at the site. Seasonal pulses of percolated, oxygenated rainfall prevented any buildup of carcinogenic vinyl chloride and other intermediates. Contaminants taken into the trees with the transpiration stream were mineralized by dehalogenation and oxidation pathways. Elevated chloroacetic acids in tree leaves were temporary accumulations not expected to persist or cause toxicity.

Genetics and Biochemistry of Phytoremediation and Ecological Engineering

Plant genomes typically have approximately 25 000–110 000 genes. By comparison, the human genome has a little over 32 000 and typical species of bacteria have about 2500 genes. These order of magnitude differences do not necessarily translate into orders of magnitude differences in protein and enzyme synthesis because (1) some genes seem to lack a specific function, (2) several genes are necessary to express or synthesize some proteins, and (3) some genes generate or contribute to several different proteins. Thus, while anchored in place, fewer in number than microorganisms, lacking an immediate flight response to toxins and environmental insults, and while not being able to excrete as many transformation products as do mammals, plants may not be more highly evolved than humans and other mammals.

The overall number of unique genes for all organisms is difficult to estimate, but the effects of genetic diversity are well known in general and need to be applied more in place of predominant monocultures typically used in early phytoremediation applications. Nevertheless, approximately 10 000 plant proteins and 200 000 plant secondary metabolites are known to exist, which must include the full suite of biomolecules necessary to govern, control, and otherwise contribute to growth, maintenance, and senescence. Some of the growth, maintenance, and senescence enzymes serve dual functions in plant metabolism and in detoxification and defense from insults. Less than a hundred enzymes have been identified as useful or potentially applicable in phytoremediation. Thus thousands of other proteins could be important but have not yet been fully characterized as to activity and function.

Because of shorter life spans, microorganisms are expected to evolve responses to xenobiotic and anthropogenic stresses faster than plants and animals. Thus the future tracking of microbial enzymatic activity may be more complicated. But with a typical genome of 2500, many fewer proteins seem to be uncharacterized for bioremediation or plant-assisted bioremediation applications.

Some simple enzymatic activities such as nitroreductases (EC 1.6.6.-; see **Fig. 2**) may be common to all forms of life due to evolution in the earliest forms of bacteria or cyanobacteria. But animals and plants, which seem to have similar genetic diversity from overlapping ranges of genome sizes, seem to have at least an order of magnitude more proteomic diversity than bacteria. This order of magnitude greater plant enzymatic diversity should be investigated not only for waste management applications but also for the development of new fibers, pharmaceuticals, nutraceuticals, and other products.

The fact that some plant genomes exceed the size of human and some other mammal genomes does not necessarily indicate that plant enzymes and proteins are more evolved. Some plant genomes may have greater genetic redundancy and greater numbers of `introns' (polynucleotide sequence in a nucleic acid or gene sequence that does not code information for protein synthesis). But some plant enzymatic activities seem more evolved as evident from what seem to be the great number of medicines derived from plants. By contrast, some mammalian genes seem more evolved than plant genes. At least one human gene 2E1 expresses a more active cytochrome P450 (EC 1.6.4.2) for transformation of chlorinated solvents than that expressed by plant genes. The number of plant metabolites used in pharmaceuticals cannot be compared to the one investigation of the human gene activity in transgenic plants, because the engineering of transgenic plants with human genes is presently quite rare.

As a result, plants seem to have an order of magnitude more enzymes than bacteria. Plants have more elaborate metabolic synthesis and photosynthesis, whereas bacteria are normally simple heterotrophs that specialize in metabolism of organic

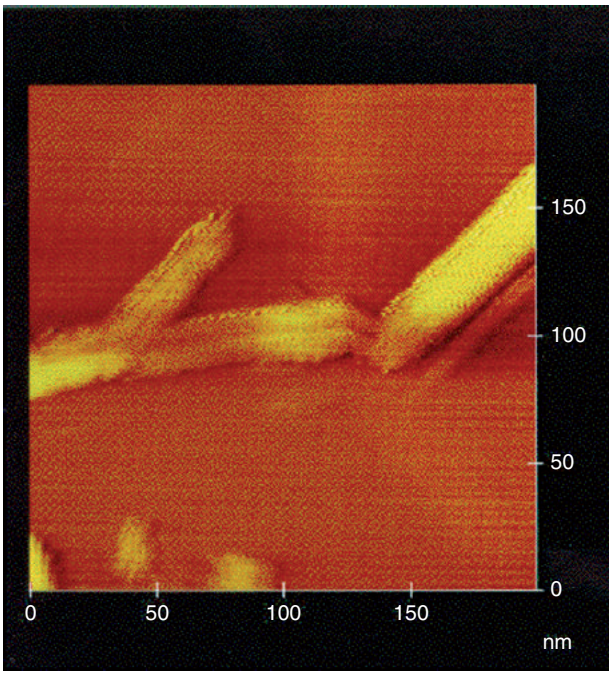

Fig. 2 Tunneling electron miscopy of a monoclonal antibody attached to a putative nitroreductase-humic acid complex shown at 200 nm by 200 nm. Courtesy of George Bailey, US EPA (deceased).

compounds for energy to grow and reproduce. Some animal enzymatic activity seems more evolved than plant metabolism and vice versa. Evolutionary history, practical control of organisms to minimize spread of genetically engineered organisms, and genetic and proteomic diversity must be used to determine if plants or animals are better suited for the genetic engineering that may be necessary to sustainably manage some hazardous wastes in the long term.

From a more holistic and appropriate perspective, microbes, plants, and animals symbiotically cycle nutrients and organic material and manage available energy in ecosystems planetwide. Thus contrasts of genome sizes, genetic diversity, and enzymatic activities are not as important as understanding when unique processes can be lightly managed in the ecological engineering of ecosystems to cleanup and manage wastes. Thus the activities of proteins common to microbes, plants, and animals need to be explored to determine which enzymes are more evolved to use in management of hazardous wastes and for other purposes. The predominant uncharacterized enzymatic activities of plants and animals should be investigated in a systematic manner for waste management and other societal purposes. To understand how contaminants can be sustainably managed, the seminal differences in metabolism must be known to select and lightly manage appropriate ecosystems.

Recently, community effects of plants and insects have been shown to further the transformation of some compounds. (The effects of nutrient cycling by microbes in these simple plant–insect ecosystems have not been fully explored.) This is another indication that plant metabolism seems to be more similar to animal metabolism. This genetic similarity of enzymatic activity also bodes well for addressing general concerns about food chain accumulation of organic contaminants and by-products in animals during phytoremediation applications.

Proteomics in Phytoremediation Research

At least two approaches have been used to characterize and apply knowledge of plant enzymes in the sustainable phytodegradation of organic pollutants. These include the following types of investigations.

1. Natural reactions, usually very fast, dominate transformations, are traced to plant and microbial enzymes.
2. Roles for well-characterized enzymes are developed.

Microarrays of common contaminants, secondary metabolites, or typical enzymatic activities (which could be used simultaneously to develop pharmaceuticals and nutraceuticals) do not seem to have been applied to explore untapped plant enzymatic activities.

All approaches to applying enzymatic activity to phytoremediation involve some element of trial and error, and are thus similar to the development of new medicines. The trial- and-error testing of plant and insect samples from diverse but unusual settings like jungles, deserts, or evolutionarily isolated environments to discover high metabolic and other activities is the same as reacting

representative compounds with environmental samples to discover natural transformations of contaminants in different media. In most cases, classical techniques in biochemistry are used or have been used to identify and purify the enzymes and other proteins responsible for the activity. A pathway analysis and characterization of the contaminant fate is equally important to efficiently guide the characterization of the enzymes reacting with and controlling pollutant fate and transport. Early insight into potentially more toxic metabolites must be followed with interim toxicity tests, including phytotoxicity tests to select the best plants to apply.

Natural reactions have been explored in two complementary ways. One focused initially on enzyme isolation and characterization, the other on inferring enzymatic activity from contaminant transformation pathway analysis. Both were necessary to comprehensively define and apply the reactions involved.

The most useful approach to developing new phytodegradation applications to date is to start with observations of a fast natural reaction of a compound of interest and isolate and characterize the active components. In three of three isolations from reducing sediments, stable plant enzymes in reducing sediments have proven to be responsible for the fast reactions discovered, not microbial enzymes as expected. Starting with fast natural reactions or unusual accumulations of metals and inorganic compounds usually ensures that an inexpensive *in situ* process is possible, and some suboptimal, black box applications are always possible before full characterization of the natural processes has occurred.

Starting with a known enzyme like peroxidases (EC 1.11.17) or phosphatases (EC 3.1.3) and finding roles in phytoremediation is much less successful so far. Potential applications are generally highly controlled *ex situ* unit processes that provide vital cofactors and control of toxic intermediates, if applications can be developed at all. High degrees of control are usually unsustainably expensive and energy intensive, but normally more reliable in meeting cleanup standards.

The proteomics of phytodegradation seems to be more broadly understood than that for metals accumulation by plants. There are at least three bodies of knowledge that contribute to the breadth of information on plant proteomics used in phytodegradation practice today. First, the extensive investigation of plant proteomics for the development of pesticides and herbicides used in agriculture provides invaluable insights into not only plant tolerance, but more importantly metabolism, detoxification, and transformation of different classes of organic compounds. Much of this experience is readily extrapolated to waste management using plants because pesticides and herbicides are important contaminants at some sites, especially worldwide. More importantly, pesticide development has been carefully organized in terms of plant effects and the structure and activity of the synthesized pesticides, which is easily extrapolated to similar contaminants. The most significant drawback is that much of the research is proprietary and has never been published, especially for candidate compounds not developed into pesticides.

Second, quite a few enzymes are common to microbes and plants and the field of bioremediation has pioneered exploration of the proteomics and more recently the genetics of some important enzymatic processes. The pioneering pathway analyses for bioremediation are a vital tool used to accelerate the acceptance and use of phytoremediation.

Third, the vital insight that plants are green livers means that the more extensive medical and veterinary research on the proteomics, genetics, and genomics of cell biology could be translated in the development of phytoremediation using the seminal differences between plant and animal cells as a basis for extrapolation. Unfortunately, medical research seems to have less strict process endpoint requirements in some cases and the rates of transformations are not always defined well enough for immediate extrapolations to phytoremediation applications.

The impact of other research on plant biochemistry does not seem to have been as important, but seminal research on allelochemicals and natural pesticides and synthesis and transformation of plant metabolites should prove vital in the future. Knowledge of the approximate 200 000 plant metabolites should be vital in developing new applications and defining the limits of phytoremediation. When a plant or any organism produces an allelopathic, poisonous, or other toxic secondary metabolite, there must be a transformation process that prevents these toxic compounds from eventually building up and swamping the planet. An example is plant lignification and delignification that uses peroxidases (EC 1.11.17) both to synthesize and degrade woody tissue. The seminal conclusion is that the existence of a primary or secondary metabolite similar to a contaminant molecule provides a good chance that phytotransformation or ecological processes can be used to degrade and control the waste sustainably, given enough time and land area. The approximate 200 000 plant secondary metabolites alone provide up to 200 000 potential metabolic pathways for degradation. However, a number of these pathways will share common transformations, the number of which may not have been estimated yet.

The enzymatic processes involved in metals accumulation by plants may not be as broadly explored as for organic metabolism and detoxification, but those investigations that have been undertaken for cadmium, lead, mercury, nickel, zinc, and a few other elements do delve deeply into the genetics and proteomics of these processes. The investigations of the proteomics of metal accumulation are similar to those used to define the role of enzymes in organic transformations and mineralization. Hyperaccumulating plants are the basis of proteomic and genetic characterizations supporting some applications, while specific genes and enzymes have been investigated for other applications of metals `phytoaccumulation'. For `phytosorption', much less is known about plant and algae cell wall characteristics and the effects on electrostatic attraction and formation of complexes or the role of polysaccharides, uronic acids, and sulfated polysaccharides that can bind heavy metals. Thus the selection of plants and algae species and other design decisions are made by trial-and-error testing at the moment.

`Hyperaccumulation' is arbitrarily defined as occurring when a plant contains more of a metal than 0.01%, 0.1%, or 1% by weight, depending on how frequently the metal occurs in the environment (**Table 1**). These hyperaccumulating plants are relatively rare and usually consist of slow-growing herbs. Some of these hyperaccumulators seemed to have evolved on metal outcroppings that normally poison plants; some may have evolved to accumulate metals as a natural insecticide or perhaps as an elemental

allelopathic defense. Some hyperaccumulators may benefit from `mutualism'. Mutualism may include (1) mycorrhizal or plant ecosystems that make metals in soils more available and less toxic with chelating ligands or enzymes and (2) accumulation of metals in seed and pollen to select only certain-metal-tolerant animals for the transport of this important genetic material. Commensalism in the form of epiphytism could explain some hyperaccumulation, but some hyperaccumulators cannot be explained functionally or evolutionarily.

Genetic Engineering

Because humankind has been highly inventive of xenobiotic molecules (e.g. DuPont's ``better living through chemistry'') and has unsustainably used concentrated energy to smelt metals and create other toxins, some genetic engineering of plants and microbes will be necessary to achieve more sustainable waste management. Some xenobiotic substances such as polychlorinated biphenyls (PCBs), dichloro-diphenyl-trichloroethane (DDT), and several others have been partially or completely banned because of increasing accumulations in the environment. The lack of sufficient analogs among the 200 000 primary and secondary plant metabolites are the reason for these accumulations, but some microbiological and botanical transformations of these persistent pollutants do occur. Unfortunately, unmanaged ecosystems may not have all the transformation processes available in the same locations at the right times to achieve sustainable and safe degradation of persistent pollutants over the times scales consistent with most human endeavors. In addition to the need to develop better-managed ecosystems in order to treat and control wastes, some metabolic and genetic engineering of organisms will be necessary to clean up persistent organic pollutants and to properly manage xenobiotic compounds invented in the future.

Plants are the most likely candidates for most genetic engineering to support sustainable waste management. While microbial enzymatic activity is better adapted to mineralization of organic pollutants, microorganisms lack the degree of self-engineering that plants exhibit. Most animals, especially mammals, may be too mobile and too charismatic to genetically engineer for waste management based on the ethical values of most contemporary societies. In contrast, plants are easier to control and manage because the most likely candidates are rooted in place and propagation can be controlled with single-sex clones and harvesting before reproduction occurs. Fencing, netting, and other techniques control plant exposure to other organisms. Compared to animal husbandry, humankind has more experience in agricultural control and production of plants for food and fiber. Because of the role of sunlight as the primary energy source for synthesis, plant management is generally less intensive and less expensive than animal husbandry and unit process production of microbial enzymes.

In general, the control of genetically modified organisms seems to favor large plants, rooted in place and capable of controlling groundwater, soil redox, and many natural insults. Microorganisms are not easily detected in real time, are difficult to control in the environment, and lack the genetic diversity of plants and animals. Animals are much more mobile and these ranges of movement are not always known, especially in response to environmental insults. As precedents for genetically engineering plants for waste management, the use of genetically modified soybeans to tolerate glyphosate-type herbicides, genetically modified corn for animal feed, and modified tomatoes are standard practices in the US and some countries, but not in Europe and elsewhere.

Already important research on the development of transgenic plants (genetically engineered deoxyribonucleic acid (DNA) with genes from microorganisms or animals) provides insight into what is possible and what other research is needed. The initial work includes testing and developing

- transgenic *Arabidopsis thaliana*, yellow poplar (*Liriodendron tulipifera*), tobacco (*Nicotiana* spp.), Indian mustard (*Brassica juncea*), and eastern cottonwood (*P. deltoides*) to tolerate and `phytovolatilize' (see **Table 1**) mercury and selenium (but any application to mercury contamination can only be done with a site-specific assessment to establish that the atmospheric release of mercury does not present an increased risk; **Table 1**);
- transgenic plants to tolerate, accumulate, or speciate arsenic, cadmium, cooper, zinc, nickel, lead, and iron;
- transgenic tobacco (*Nicotiana* spp.) expressing cytochrome P450 from the human gene 2E1 that breaks down TCE 640 times faster than control plants;
- transgenic tobacco (*Nicotiana* spp.) expressing the *Enterobacter cloacae* nitroreductase *nsfI* to tolerate and more rapidly transform explosives like TNT;
- transgenic poplar (*Populus* spp.), Indian mustard (*B. juncea*), tobacco (*Nicotiana* spp.), rice (*Oryza sativa*), and potato (*Solanum tuberosum*) enhanced tolerance and metabolism of herbicides;
- transgenic flowering plants to remove atmospheric nitrous oxides in major cities around the world;

These case studies establish what is possible. But so far these pioneering studies do not establish that genetic engineering is useful and applicable in waste management. Merely speeding up the degradation of explosives or TCE is not useful until proof is available that genetic engineering is less expensive and more sustainable that planting up to 640 more wild-type plants or taking 640 times longer to remove TCE from a site. By contrast, the lack of natural plants that tolerate and phytovolatilize mercury and arsenic are justification for genetic research on mercury and arsenic management. Because only microorganisms transform nitrous oxides, there is also a high likelihood of applicability of transgenic plants for atmospheric cleanup in large cities.

The studies so far do not establish that transgenic plants efficiently maintain transgenes from one generation to another. This further reduces the risks of transgenes being dispersed in the environment and favors longer-living trees as the best organism to

engineer. Applications are much more expensive, and perhaps unsustainable if each generation of plants must be re-engineered genetically.

Genetic engineering is not only necessary to sustainably manage persistent organic pollutants and some new xenobiotic chemicals, but perhaps for sustainable phytoaccumulation of heavy metals, metalloids, and other elements as well. In addition, transgenic plants can be engineered to take advantage of a wider range of specialized genes in bacteria to mineralize versus transforming contaminants to more or less toxic by-products. Transgenic plants might also express more active enzymes from mammals. These transgenic enhancements can be put into phreatophytes, fast-growing crops, long-living trees, or other specialized plants to achieve much wider control of wastes in the environment. However, a super-transgenic plant to control and manage every witches' brew of hazardous chemicals at all contaminated sites is highly unlikely.

Future Directions and Needs

Estimates of cleanup costs for hazardous waste sites planetwide are of the order of US$ 1×10^{12}. These massive costs to clean up national defense and industrial facilities are effectively unsustainable and largely being deferred to later generations, especially at sites such as Chernobyl in the Ukraine. Waste disposal requirements of the twentieth century were usually followed, but these practices were rarely based on environmental and other resource sustainability. In the future, any development and further use of xenobiotic compounds for better living must be accompanied by the development of sustainable biotechnologies or other approaches to sustainably manage any wastes. Classical plant breeding and agroeconomic practices may be used to develop some sustainable waste management practices. But more likely the inventiveness of humankind in chemistry for better living will not be limited to xenobiotic compounds analogous to primary and secondary metabolites.

This concern is especially acute for the nascent development of nanotechnologies. These micron-scale particles are conceived to have almost unlimited applications based on the development of macromolecules that have intense concentrations of activities or energy that secondary metabolites, natural macromolecules, and microorganisms do not currently possess. Thus any development of applications of nanosize particles should be preceded by environmental fate and transport investigations and the ecological engineering of sustainable biotechnologies to manage any risks of uncontrolled environmental releases.

The ecological engineering of the cleanup of existing unsustainable releases of hazardous wastes is also very much needed to reduce the impact of the original manufacturing and disposal decisions. For example, the cleanup costs in the US may be reduced on the order of US$ 1×10^9 using phytoremediation, but additional optimization of applications is necessary and fundamental research is necessary to provide additional methods of cleanup. To achieve these and even greater cost savings, research investments on the order of 10% of the savings (US$ 1×10^8) are normally justified. Current research investments for phytoremediation in the US seem to be on the order of US$ $1 \times 10^6\ \mathrm{yr}^{-1}$, a difference that may explain why some twentieth-century waste management costs are being deferred to future generations.

The development of phytoremediation applications is particularly vulnerable to shortfalls in fundamental research. For the field of phytoremediation to continue to grow at a very rapid pace compared to bioremediation and other innovative cleanup technologies, significant investments are required in fundamental investigations of plant enzymatic activities, genetics, proteomics, and primary and secondary metabolites. The US EPA Contaminated Sites Program and the US Strategic Research and Development Program were vital in initiating the field in the early 1990s. If not for the European Cooperation in the Field of Scientific and Technical Research (COST, http://lbewww.epfl.ch/COST837/) to guide research, applications of phytoremediation may have already stalled despite recent limited programs to support applications research from the US National Science Foundation, EPA, Strategic Research and Development Program, and Office of Naval Research.

Compared to microbes and mammals, much less of plant proteomes seem to have been explored for enzymatic activities useful in waste management, pharmaceutical and nutraceuticals development, and other societal needs. Yet over the history of modern scientifically based medicine and the much longer application of traditional medicine, many plant activities have been found to be useful. For the approximately 10 000 plant proteins known, less than 1% have been investigated for waste treatment applications. In addition, only a few classes of compounds have been tested for transformation by plant and microbial enzymes.

Investigation of these enzymes for various applications is of the highest priority. Development of microarrays of enzyme activities, DNA, and chemical compounds can significantly decrease screening time. When screening for phytoremediation plants, other arrays could be useful to simultaneously screen for new pharmaceuticals, nutraceuticals, and other products.

Future applied research should continue to investigate plants and microorganisms that are associated with unique and unusual poisons and other natural toxins. Uniquely evolved plants and microorganisms near metal outcroppings, in deserts, in cold regions, and in other rigorous environments, or evolved in secluded regions like Australia, should continue to be investigated. However, better comprehensive plant proteomes cross-referenced to pollutants must be developed to guide this important research, as was done in the development of pesticides and herbicides during the green revolution.

Understanding genetic and proteomic diversity is vital to better engineer ecosystems rationally in place of plant monocultures and simple ecosystems of highly controlled plants and microorganisms. Furthermore, current simplified design procedures for wetlands, grasslands, crops, and plantations are rarely if ever based on optimized engineering protocols and infrequently make use of sustainable ecological engineering design. Thus many phytoremediation applications, while more cost effective than most other

alternatives, still may not be sustainable if excess fertilization, irrigation, and soil augmentation are used to apply monocultures and imported plant species. Ecological engineering needs to be introduced to phytoremediation, starting with a comprehensive reorganization of applications and research to date in terms of basic ecological engineering concepts. Without ecological engineering optimization, the costs of increased eutrophication and decreased water quality, water shortages, and poor soil may be unsustainable in the face of growing populations of humans planetwide.

Next in priority is that classical breeding techniques need to be explored to select optimal plants to use in phytoremediation. So far the little experience in plant breeding seems to have come from characterizing metals accumulating plants.

Finally, metabolic and genetic engineering research must be pursued further to sustainably manage xenobiotic and heavy metal pollutants. Highly evolved, large, immobile plants that dynamically self-engineer provide the best opportunity to control and apply microbial, animal, and plant genes in complex cleanups using transgenic organisms.

So far, transgenic plants are feasible for some phytoremediation applications but have not been shown to be fully necessary and useful.

So much more is necessary to define potential roles of thousands of plant enzymes, define how all of the approximately 200 000 secondary metabolites are metabolized, and optimize and engineer the necessary transgenic plants. Thus *de novo* development of new genes does not seem to need to be a current waste management priority. First, the reliability of libraries of pathogenic gene sequences is not known well enough so to be sure that the genetically engineered organism can be used in the environment. Second, the release in the environment of a *de novo* gene may not have been adequately assessed in terms of risk.

State of the Practice

Despite the paucity of ecological engineering optimization of phytoremediation applications to minimize costs and to achieve full sustainability, a number of *ad hoc* applications have been successful. These are summarized in **Table 1**. Wetlands prevent all discharge of explosives-contaminated groundwater at the Iowa Army Ammunition Plant (**Fig. 3**). Fertilized grass plantings and marshes of *Spartina alterniflora* and *S. patens* have cleaned up petroleum spills at a number of sites and are overdue for optimization

Fig. 3 One of two constructed wetlands at the Iowa Army Ammunition Plant that has zero discharge of TNT and other explosives seeping out of the contaminated groundwater below the explosives manufacturing line shown in the upper right-hand corner. Explosives-contaminated soil was dug up along a stream channel leaving a pit that was then shaped to capture all contaminated groundwater and favor indigenous aquatic plants known to transform explosives. By not having to refill the pit with clean soil, approximately US$ 700 000 was saved. Sediment from local wetlands was used to seed the constructed wetland and provide nutrients. The stream channel was moved to the left as shown to convey less-contaminated stream flow around the wetland. The initial 28 months of monitoring showed elevated explosives concentrations entering the wetland each spring, decreasing in peak concentration the second spring, and dropping to undetectable levels by fall due to plant and algae uptake and transformation. Thorough sampling and analysis established that explosives and the associated transformation products were undetectable and thus did not accumulate in the indigenous wetland plants and algae. The wetland control structure at the lower right of the photograph has never been opened, thus achieving a zero discharge. Evaporation prevents flow out of the wetlands. Slightly more was spent than the US$ 700 000 cost savings and this small difference was due to added monitoring costs of these pilot applications. Thus phytoremediation is not only less expensive, but reduced site restoration costs can also fully offset construction and monitoring costs. and development of design guidance. Tree plantations have successfully stopped and mineralized groundwater plumes of chlorinated solvents and methyl *tert*-butyl ether (MTBE). A number of treatability investigations using standard groundwater and vadose zone models establish that transpiration can be adequately forecast and can control plumes in difficult settings. Three-year-old trees have been planted in casings up to 15 m (50 feet) deep to reach contaminated aquifers underlying clean aquifers and soil. Highly toxic cyanide-contaminated soils shown in **Fig. 4** are being cleaned up using a tree plantation in Holte, Denmark; this is so effective that the site is being used as a park during the process. Vegetation capping and control of landfill leachate has been successful at a number of sites across the US (see **Fig. 5**) and is being applied in Australia and a number of other countries.

The feasibility of metals' phytoaccumulation, the process first called phytoremediation, has been investigated, but very few field-scale tests have been attempted. Unfortunately, a few critical field tests have been unsuccessful. **Fig. 6** describes some of the

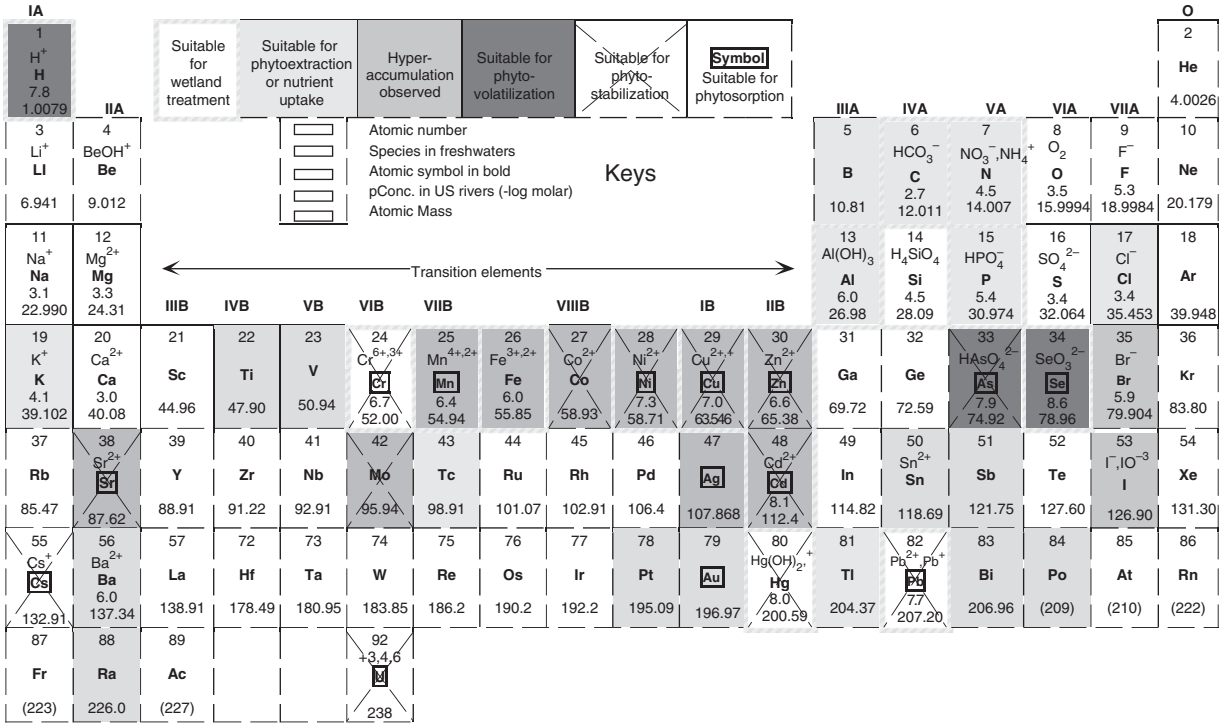

Fig. 6 Periodic table of elements for which phytoextraction, rhizofiltration, phytosorption, phytostabilization, and phytovolatilization are feasible. For many elements, cleanup has not been proven in concept or principle in laboratory, pilot, or field tests. Some elements have not been tested to determine if phytoremediation is a feasible management option. Selenium and arsenic are also subject to phytoextraction and hyperaccumulation by some plants. Tritium is phytovolatilized and hydrogen ions, of which pH is a measure, can be controlled with wetlands specifically designed to treat acid mine drainage. Some wetlands do not remove and accumulate all the metals listed under all conditions (e.g., lead and nickel).

elements for which plant uptake or control is feasible. Pilot investigations by the US Bureau of Mines establish that some plants accumulate enough nickel to be cost-effectively smelted or refined. Pilot field testing of cadmium and zinc hyperaccumulation has been successful at two sites. Unfortunately, six field-scale pilots and rigorous demonstrations for lead accumulation have failed. The failure to optimize chelator applications to release lead and other tightly bound metals like chromium have resulted in only approximately 25% of the lead released from the soil being accumulated by plants. The remainder leaches into the groundwater or deep soils.

In addition, residual management of plants with accumulated metals has not been sustainably optimized. Unless the multimedia transfer to one generation of plants is sufficient to reduce soil or water concentrations to acceptable levels of risk, phytoextraction requires the harvest and disposal of plant materials. The rate of metal uptake per unit area, the target residual accumulation at harvest, the time available for cleanup on different parts of a contaminated site, and monitoring requirements are design variables selected to achieve economically and sustainably optimized solutions. The US state of the practice at this early stage requires metal-laden plants be disposed in expensive hazardous waste landfills. Metal recycling to smelters, established as feasible for nickel, and composing or incineration to reduce the volume disposed in landfills do not seem to have been rigorously explored.

For phytodegradation and accumulation of organic compounds, food chain accumulation and exposure off site is the primary concern. Extensive pathway analysis based on advanced chemical analysis and mass balances of radiolabeled compounds; monitoring of accumulations in roots, stems, leaves, insects, and animals; and toxicity testing of plant residues establish that most phytoremediation applications do not cause exposures off site or during treatment. For polyaromatic hydrocarbons (PAHs), insects take up the contaminant and by-products during phytoremediation but have some of the same enzymatic activity that completes transformation without further food chain exposure. Insects that take up explosives and by-products depurate within hours of ending the exposure. However, not all potential exposures have been explored and thus each application requires monitoring of accumulations for 3–5 years depending on the contaminant and the setting involved.

Because phytoremediation approaches have not been optimized and design guidance written, all almost all applications require pilot or treatability studies before full scale-up is undertaken. In a number of cases, phytoremediation is inexpensive enough that pilot studies may be undertaken at full scale if adequate backup options of cleanup are provided.

Many successful phytoremediation applications are actually restorations that save money after contaminated soil removal (e.g., wetland construction to offset hauling clean soil to fill excavations) and after other cleanup methods are applied. Some applications are temporary plantings of grass and trees to hold soil and contaminants in place during assessment of risks and cleanup

alternatives. Selection of the right plants and monitoring have led to temporary vegetation becoming a final remedy for cleanup and control of a site until complete removal occurs.

In general, phytoremediation is a niche waste management technique, normally applied to manage or clean up low levels of contaminants over large areas. Some cleanups may occur within months to a year or two, but typically 3–5 years are required and some difficult-to-manage sites may require decades to clean up. `Phytostabilization', which does not seem to be sustainable, may be the only technically feasible option for large sites on which animal and human exposure can be controlled while innovative options are explored and developed.

While most phytoremediation applications are limited to sites with chronic toxicity or conventional waste disposal of municipal sewage or sludge because of phytotoxicity, some innovations allow cleanup of acutely toxic wastes. For example, sterile, contaminated soils can be flooded and nonrooting wetland plants used to rapidly transform leaching TNT. Wetland cells can be designed with hardy pioneers, dead plant materials, and highly active sediments to buffer the highest incoming explosives concentrations. Because cyanide is a secondary metabolite, some trees grow into soils that are acutely toxic to mammals and break the waste down completely enough that tree plantations with appropriate ground cover can be converted early to parks and other less restrictive land uses (**Fig. 4**). Burrowing animals must be excluded until the tree roots have sufficient time to explore all parts of the soil and break down the cyanide complexes.

Some acutely toxic wastes can be treated in more expensive and energy-intensive unit processes. Cofactors, amendments, and hazardous by-products can be highly and reliably controlled. *Ex situ* treatments tradeoff cost savings achieved with *in situ* treatments for control of pH, temperature, and other factors. For example, a feasible unit process to remove phenols from liquid wastes uses horseradish peroxidases, but to date, this process does not seem to have been scaled up and applied to an actual waste stream. Treatment of liquid wastes contaminated with explosives have been proposed using slurries of plants high in nitroreductase activity and excavated soils contaminated with explosives could be buried with plant material high in nitroreductase activity.

Most phytoremediation applications are limited to root zones and shallow waters, but occasionally exudates leach below root zones to generate reducing conditions and spur microbial dehalogenation 3–5 m (10–15 feet) deep. Transpiration can pull slow-moving groundwater plumes into the root zone, into wetland soils, and into plants to completely clean up some sites. Feasibility studies indicate plumes may be controlled to depths up to 15 m (50 feet) by very large plantations depending on the hydraulic conductivity of the aquifer, the control of surface runoff, and the rooting depth of the trees or grasses employed. Some solar pump-and-treat applications apply root training and management to optimize root contact with contaminated soil and water.

Even though very few phytoremediation applications have been optimized for sustainability, most applications are inexpensive and have many secondary benefits. Sunlight is the chief energy source in most applications. Ecological restoration begins during treatment, rather than after, compared with many cleanups that rely on heavy equipment, incineration, and other intense treatments, harsh chemicals, and traffic of heavy vehicles into and out of the site. These intense cleanups may be necessary when longer periods of time and sufficient land areas are not available, or acute phyto- and human toxicity cannot be managed *in situ*.

Plant Demography

Christian Damgaard, Aarhus University, Aarhus, Denmark

The ecological success of a plant species within its realized niche is typically described by the observed change in plant abundance. In order to more fully understand changes in plant abundance and make ecological predictions of the effects of environmental changes and gradients, it is necessary to investigate and quantify the underlying ecological processes. In principle, this means that all the different interactions between the species in the plant community need to be investigated (Damgaard, 2003). However, this is typically an exceedingly demanding task in multi-species plant communities and, instead, we investigate how the vital rates of the most common species, when competing with other species, are affected by the environment (Harper, 1977).

Furthermore, demographic processes, such as colonization and mortality, have been increasingly used in spatiotemporal modeling of plant populations (Normand *et al.*, 2014). This is motivated by the notion that changes in the probabilities of colonization and mortality may be the driving changes in species ranges. Furthermore, a demographic approach to understanding and predicting species' range dynamics has the advantage of being rooted in ecological theory (reviewed in Normand *et al.*, 2014), and has been shown to improve predictive ability of niche dynamics as it includes plasticity and local adaptation (Morin and Thuiller, 2009). This connection between the Hutchinson realized niche and demography was first pointed out by Maguire (1973), who modeled niche space as functions of demographic parameters.

The Consequences of Being Sedentary

Most plants are firmly rooted into the ground and this sedentary life form has a profound impact on the life history and ecology of plants (Harper, 1977). Germinated seedlings cannot move away from larger neighboring plants, and the competitive effect of neighboring plants are the universally most important biotic limiting factors of plant establishment and growth, although, positive plant-plant interactions have been reported in extreme environments (Callaway, 1995; Stoll and Weiner, 2000). Other biotic factors that control plant establishment and growth are herbivores and pathogens, but their role is more variable and less important than the negative competitive effect from neighboring plants as conveyed by the "green earth hypothesis" by Hairston *et al.* (1960).

As an adaptation to the sedentary life form and competition for limiting resources (light, water or nutrients) from neighboring plants, the same plant genotype may display a large variation in phenotypic characters. Especially the number of different plant parts, i.e. branches, leaves, flowers, fruits etc., may vary considerably (Harper, 1977), and in plant populations at medium or high densities where will often be a large size variation among conspecific individuals of approximately the same age (Weiner, 1990).

Self-fertilization is also an adaptation to a sedentary life form; after a colonization event, isolated sexual plants may have difficulties to receive compatible pollen if they are self-incompatible. With self-compatible individuals a single propagule is sufficient to start a sexually reproducing population, making its establishment much more likely than if the chance growth of two self-incompatible individuals sufficiently close together spatially and temporally is required (Baker, 1955).

A necessary adaptation to the sedentary adult life form is seed and/or vegetative dispersal. After a local extinction event, plant species have to be able to re-colonize the area, and on a larger time scale, plant species have to colonize new areas due to the recurring environmental changes, e.g., climate change. This dispersal is uneven and the number of dispersal units will typically decrease with the distance from the parent plant. Consequently, plant populations have an aggregated spatial distribution within a plant community, where the local abundance is determined by demographic processes.

In order to measure the effect of demographic processes on plant community dynamics it is an essential prerequisite that plant abundance may be measured in an unbiased and meaningful way. However, for many plant species, and ultimately a further consequence of their sedentary life form, it is not possible to distinguish individual plants from each other, and while the number of individuals or density is the theoretically most natural measure of plant abundance, this measure is not a relevant measure in many habitat types, e.g. grasslands.

Measuring Plant Abundance

The ultimate way of measuring plant abundance is by assigning the local species abundance or biomass as an attribute to a geographic position. While such geographical abundance data most certainly will be more and more common due to new sampling techniques from drones and satellites; most existing and currently sampled plant abundance data use a plot design, where several relatively small plots are sampled within a larger area.

This is an update of F.X. Picó, A. Rodrigo and J. Retana, Plant Demography, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 2811–2817.

The classic measure of plant abundance is the probability of occurrence in small plots (Raunkiær, 1910). In order to collect presence - absence data, it is necessary to record all the plants in the plot, so that the absence of a species can be deduced from not being a member of the list of recorded plant species. If a plant species is inconspicuous or difficult to recognize the recorded number of presences may be down-biased relative to the true number of presences. However, it is possible to correct for such a bias if there is independent information on the detection probability of the species. Most of the plant species data in museums collection, atlas data, and the plant data collected by citizens are occurrence data or "presence-only data", where only the spatial location of an observed species is recorded without systematically recording all the plants in the same plot. Such occurrence data may be used to make maps of the species distribution or they may be regressed to maps of background data in order to investigate the effect of other factors on species occurrence. However, we cannot estimate the probability of occurrence without making simplifying assumptions.

If the size of the sample area for recording presence - absence data is reduced to a point then the recorded presence-absence data only depends on plant abundance, or more precisely, the frequency of presence-absence data collected at a point is an unbiased estimate of the surface-projected relative area of the plant species, which is called plant cover. Plant cover may also be assessed by a visual estimation of the surface-projected relative area of the plant species.

The measure of plant cover may be integrated with probability of occurrence by measuring the shortest distances from a sample of sampling points to the nearest aboveground part of plant species (up to a maximum search distance). Such measurements allow the calculation of an Integral occurrence probability (van Calster and Damgaard, 2017).

Furthermore, an important aspect to consider when measuring plant abundance in natural communities is that many plant species have an aggregated spatial pattern at the local scale due to e.g. the size of the plant, clonal growth, or limited seed dispersal. This local spatial aggregation lead to inflated spatial variance compared to a spatial randomness and, if not considered in the statistical modeling process, a pseudo-replication effect with biased estimates of *P*-values (Damgaard, 2013). If plant abundance data are sampled using a hierarchical sampling procedure where plots are sampled from a number of different sites, then the possible among-site variation in plant cover must be taken into account as well.

Plant Demographic Processes

Many plant species has a modular structure with a large size variation among individuals, and since plant demographic processes to a large extent depend on plant size it is not sufficient to simply count the number of individuals in an investigation of plant demographic processes (Harper, 1977). Consequently, plant size and the competitive growth of plants is an essential feature of plant demographic processes.

Competitive Growth

The energy requirement for plant maintenance and growth depends on the amount of photosynthesis that again depends on available water, carbon dioxide, and sunlight of a sufficient quality, i.e. short-wave solar radiation. Simply put, factors such as temperature, water and nutrient availability determine the potential for growth, but growth is only realized if plants receives sufficient good-quality light.

Neighboring plants limit the growth of each other because they compete for resources needed for plant growth. The mode of competition depends on the resource and the size of the competing plants. Some resources like short wavelength light, which is depleted approximately exponentially by successive leaf layers, may be monopolized by tall plants. Other resources, like phosphorus, are more or less evenly distributed in the soil, so that a large root system cannot prevent a small root system of phosphorus uptake. For resources that may be monopolized larger plants may be able to obtain proportionally more of the resource than their relative size advantage, and suppress growth of smaller individuals (Begon, 1984; Weiner, 1990). This positive effect of size on the competitive ability of a plant is known as size-asymmetric competition, although often-used synonyms in the ecological literature include, "one-sided competition", "contest competition", or "dominance-suppression competition".

Mortality

Plant mortality may be caused by either density-independent or density-dependent factors, although, in practice it is difficult to separate the two types of mortality. Harper (1977) gives the following example: "The mortality risk to a seedling from being hit by a raindrop or hailstone might be thought to be density-independent. Presumably the risk of being hit is independent of density but whether a seedling dies after being hit is a function of its size and vigor, both of which are strongly effected by density." Generally, the relative importance of density-dependent factors is expected to increase with density and plant size, and density-independent mortality may primarily occur at the seed and seedling stages by death during seed dormancy, some forms of seed predation, unfavorable soil conditions, local water availability etc.

Density-dependent mortality or self-thinning in synchronous monocultures show a surprisingly regular pattern: there seems to be a maximum density of surviving plants primarily controlled by the biomass of the plants. In an experiment with buckwheat (*Fagopyrum esculentum*) sown at different densities, Yoda *et al.* (1963) found that the three populations with the highest densities had reached similar densities 63 days after sowing. When plants in a synchronous monoculture grow, self-thinning will reduce the number of surviving plants to a maximum density and since the individual growing plants need more space and resources, the

maximum density decreases with time. For many species it has been found that if the average biomass is plotted against the maximum density in a log-log plot, then the relationship is approximately linear (e.g. Yoda *et al.*, 1963).

Reproduction

Fecundity, i.e. the number of seeds produced by a plant, is highly species-specific and mainly determined by the life history and adaptive strategy of the species. Generally, there is a trade-off between fecundity and seed size, where large seeds has a higher probability of establishment (Harper, 1977; Rees *et al.*, 2001).

Monocarpic plant species, e.g. annual plant species, convert all available resources at the time of reproduction into seeds and only reproduce once before they die. On the other hand, polycarpic perennial plants reproduce usually every year after a juvenile period. The perennial plants allocate resources between seed production and investment in structures that increase the survival probability and facilitate growth the following year. There is a weak tendency that the juvenile period is positively correlated with the expected life span of the species (Harper, 1977), and in general, the fecundity of polycarpic perennial plants is a function of plant size, which again is a function of age and environment.

In a pioneering study by Cole (1954), that was later slightly generalized and explained by Bryant (1971), it was demonstrated that a monocarpic annual plant only had to produce one extra effective seed compared to a polycarpic perennial plant in order for an annual life strategy to be an evolutionary adaptive strategy.

Dispersal and Colonization

Seed or vegetative dispersal is a necessary adaptation to a sedentary adult life form. Most plant communities are dynamic with continuous local disturbances followed by a relatively long succession process or may go locally extinct due to demographic or environmental stochasticity. After such local extinction events, it is important for the long time ecological success of the plant species that it will be able to re-colonize the area by immigration of seeds or vegetative propagules. In many habitats, seeds buried in the soil (the seed bank) plays an important role in preventing local extinction.

Seeds are dispersed by different dispersal vectors; some species rely primarily on wind dispersal, whereas other species invest in fruits for attracting animals that disperse the seeds after eating the fruits.

Seed dispersal is a highly stochastic and species-specific process, but generally, most seeds disperse only short distances and most likely will germinate in an environment that resemble the environment of parent plant. However, the invasion potential of the species after large catastrophic events such as ice ages, depend on rare long-distance events, where the establishment of secondary foci of spread will determine the overall speed of invasion (Shigesada and Kawasaki, 1997).

In a theoretical spatial community model with either local or global dispersal, Bolker and Pacala (1999) demonstrated that the only possible adaptive strategies are colonization, exploitation, or tolerance, which correspond to the three life history strategies, i.e. ruderal, competitive, and stress tolerant, suggested by Grime (1979). Furthermore, they observed two different short-dispersal adaptive strategies that both were weakly excluded in the non-spatial case; either a rapid exploitation strategy, or a phalanx strategy, where the plants form dense stands that exclude the establishment of other species (Bolker and Pacala, 1999).

It has been suggested that the range of realized niches primarily is determined by the ability of a species to colonize new resource space in competition with other species rather than securing survival at an already colonized resource space (Damgaard *et al.*, 2017). This hypothesis is related to the seed limitation hypothesis, i.e., that many plant species are limited by colonization (Turnbull *et al.*, 2000; Rees *et al.*, 2001). Likewise, Adler *et al.* (2010) has demonstrated that the recruitment process is more important than both survival and growth processes in determining niche differences. They hypothesized that pathogens and natural enemies have relatively strong effects during recruitment and mediate coexistence mainly at this stage of recruitment. The importance of dispersal traits for the ecological success of plant species has previously been demonstrated by (e.g. de la Riva *et al.*, 2011), and Schulze *et al.* (2012) showed that clonal growth is more important than sexual reproduction for determining population growth.

Population Growth

The demographic processes of competitive growth, mortality, reproduction and dispersal determine the local plant abundance and knowledge on the demographic processes may be used to predict population growth. However, the probability of germination, establishment, and reaching reproductive age in a natural habitat are highly stochastic processes and population growth can only be predicted with large uncertainty. Crawley *et al.* (1993) compared estimates of population growth of transgenic rapeseed (*Brassica napus*) in a natural habitat obtained by either using independent information on seed germination, mortality, and fecundity, or by measuring population growth directly by the difference in the number of seedlings from year to year. When population growth was modeled using the independently obtained information on mortality and fecundity the rapeseed population was predicted to increase in density, whereas the directly obtained estimate of population growth showed that the rapeseed population decreased in density. Later it was observed that the population actually was decreasing until it went extinct (Crawley

et al., 2001). Likewise, Stokes *et al.* (2004) found that variation in the probability of germination and establishment led to a high variation in the predicted population growth rates of *Ulex gallii* and *Ulex minor*.

In a pioneering study, Rees *et al.* (1996) measured population growth rates of four annual species in a natural habitat, and modeled their growth rates as a function of density. Using this density-dependent population model, the authors concluded that the population growth of the four annual species mainly was regulated by intraspecific competition (Rees *et al.*, 1996). The fitting of such density-dependent population models to time series data of plant abundance in natural habitats will surely be increasingly important in the investigation of the underlying ecological factors that regulate plant population growth.

Age-Structured Populations

The population growth of age-structured populations may be modeled by Leslie matrices, which are transition matrices of age-specific survival probabilities and fecundities (Caswell, 2001), or by using the renewal equation in continuous time (Gurtin and MacCamy, 1979).

A matrix population model is a convenient tool in the description of the demographic processes at the existing density and may provide predictions on the immediate future of the plant population. If the transition matrix consists of constant density-independent probabilities and fecundities, the mathematical property of the model is sufficiently simple so that the dominant eigenvalue, which corresponds to the growth rate of the population, may be determined (Caswell, 2001). However, if the transition probabilities and fecundities are functions of plant density, the mathematical properties of matrix models become more complicated and has to be calculated using numerical methods (e.g. Stokes *et al.*, 2004).

The complexities of stage-structured population growth with density-dependence are considerably reduced in the important case of an annual plant with a seed bank. The life cycle may be reduced to two stages and four recursive equations of the densities of seeds in the seed bank and plants at the reproductive age, respectively (Jarry *et al.*, 1995; Damgaard, 2005b).

Matrix population models for several hundred plant species has been collected within the COMPADRE network (Salguero-Gómez *et al.*, 2015). This database may be used to make comparative analyses of different life histories.

The spatial effects of disturbance and local recruitment in structured plant populations may be modeled in lattice models, which may be approximated with comparatively simple recursive equations. For example, the spatial demography of the perennial bushes *Cytisus scoparius* and *Ulex europaeus* has been described by recursive equations of the frequencies of each spatial site, which is respectively unsuitable for recruitment, open for recruitment, or already occupied by the plant (Rees and Paynter, 1997; Rees and Hill, 2001).

Size-Structured Populations

Since plants are plastic and have variable growth rates, two plants of the same age will not necessarily have equal survival probability or fecundity. Consequently, the demography of plant populations may be described by a stage-structured matrix model with transition matrices of stage-specific probabilities of moving to another stage and fecundities, or alternatively, using continuous life history characters by an integral projection model (Easterling *et al.*, 2000).

In an integral projection model, the state of the population is described by the size distribution $n(y,t)$, which is the number of individuals of size y at time t. A time step later, the population will have changed into,

$$n(y, t+1) = \int (p(x, y) + f(x, y))\, n(y, t)\, dx$$

where $p(x,y)$ is the probability that an individual size x at time t is alive and one time step later has size y, and $f(x,y)$ is the number of off springs of size y produced by individuals of size x. The model is parameterized using regression models of observed survival, growth and fecundity (Easterling *et al.*, 2000).

For many plant species the available life history data are naturally measured as continuous functions of size, and integral projection model is often a better choice when modeling plant population dynamics than traditional population matrix models (e.g. Rose *et al.*, 2005).

Occurrence at a Point

When fitting the above-mentioned population models to empirical data it is a requirement that the individual plants may be distinguished. However and as mentioned above, many plant species, and especially many of the grass species, forms carpet like multi-species plant communities, where it is impossible to distinguish individual plant from its neighbors. In such a plant community, it is not possible to measure e.g. size dependent fecundities, and instead population growth may be determined by the change in the occupancy of space.

If a species was present at time t at a specific spatial point, but absent at time $t + 1$, we may loosely speak of a mortality event. Additionally, if a species is absent from a specific pin-position at time t and present at time $t + 1$, we may loosely speak of a colonization event. Using such time series data at a point (pin-point or point intercept data) it is possible to estimate the probability of survival and colonization, and investigating the importance of either mortality or colonization as the cause for observed plant cover changes (Damgaard *et al.*, 2011; Damgaard *et al.*, 2017).

At Equilibrium

The demographic processes are highly stochastic and most plant communities will probably never reach an ecological steady state or an ecological equilibrium. Nevertheless, knowledge on the equilibrium states under certain rather strict assumptions may provide valuable information in predicting the future states of the plant community (e.g. Damgaard, 2005a). Consequently, it is of ecological interest to analyze the relevant population model with respect to possible equilibria and stability properties.

>Generally, density-dependency act as a stabilizing factor in most population models. For example, Verhulst (1838) proposed the continuous logistic equation as an adequate model for the negative effect of density on population growth, where population growth approached zero when the population size approach a carrying capacity of the population. Only if reproduction is high and regulated with a time lag the population size trajectory will become chaotic (May and Oster, 1976; Hoppensteadt, 1982).

Long-Term Ecological Data

In order to test various ecological hypotheses, e.g. the effect of density on plant population growth, it is valuable to have plant ecological data where plant abundance has been recorded repeatedly in a time series (Damgaard and Weiner, 2017), and long-term ecological data series are important for detecting causal relationships or predictability (Granger causality) in complex ecosystems (Sugihara *et al.*, 2012).

There are a few classic examples of long-term data sets of plant abundance, which have had a large impact of our knowledge on plant demography and ecology. Notable examples are the Park Grass Experiment, which was initiated in 1856 (Silvertown *et al.*, 2006), and the Cedar Creek Ecosystem Science Reserve, which investigates the effect of a nitrogen gradient (e.g. Tilman *et al.*, 2001). Fortunately, there is an increasing interest in the collection of long-term plant abundance data in order to answer important ecological questions, such as effects of climate change, and today new long-term ecological research sites are initiated and several networks are coordinating the research.

Several countries have set-up ambitious monitoring programs of terrestrial habitat types. For EU countries, these initiatives has partly been motivated by the EU habitat directive from 1992 (EU, 1992). Generally, monitoring programs are less focused and measure fewer variables than long-term ecological research (LTER) sites, but instead the monitoring programs has a better coverage of the geographical variation of different habitat types.

An interesting possibility of obtaining long-term demographic data is to use fossil pollen to estimate population sizes in the past at different spatial scales. Pollen grains are very robust and are present in high numbers in lake sediments and as the lake sediment gradually builds up during time, it is possible to determine when the pollen grain settled in the lake. From such pollen profile data and using species characteristics of pollen production and pollen dispersal, the number of plants within a certain area may be estimated. Alternatively, a demographic history of a species may be determined using a constructed phylogenetic tree based on a sample of DNA sequences. It has been shown that the distribution of coalescence times is a function of whether the population size is constant, decreasing or increasing and this effect may be explored in a statistical framework to test different demographic models (Emerson *et al.*, 2001).

Conclusion

The terminology and methodology of demography has historically been developed in the study of human and animal populations. However, plants are qualitative different from animals in several important aspects and these differences have important implications for the study of plant demographic processes.

Plant demographic processes are controlled by competitive interactions with neighboring plants in most terrestrial habitats (e.g. Hairston *et al.*, 1960). This fact together with the sedentary lifeform of plant species has important consequences for the investigation of plant demographic processes, which often only make sense in the light of local plant density and competitive growth. Furthermore, limited dispersal distances, which often leads to spatially aggregated plant populations and may affect the possible life history strategies (Bolker and Pacala, 1999), needs to be included in the population ecological modeling to a larger extent than presently is the current practice in most empirical plant demographic studies.

For many plant species, it is not possible to distinguish individual plants from each other, and while the number of individuals or density is the theoretically most natural measure of plant abundance, this measure is not a relevant measure in many habitat types, e.g. grasslands. Consequently, it is important to develop new methods for measuring demographic process for such plant species. This simple but crucial point has perhaps received too little attention in the plant ecological literature, and plant demographic studies are generally biased towards plant species that are readily counted and with conspicuous flowers and seeds. For example, in the COMPADRE database of matrix population models there were 316 records of *Poaceae* out of 6242 total plant records, which probably is an underrepresentation of the family compared to its important ecological role.

In summary, plant demography is a relatively mature scientific discipline, but it is important to critical assess the currently used terminology and methodology in order to align the empirical studies of plant populations with the typical features of plant life history.

Spatial Distribution

MK Borregaard, DK Hendrichsen, and G Nachman, University of Copenhagen, Copenhagen, Denmark

Organisms do not occur randomly in space. Any species of plant or animal may be found in some areas, while they are completely absent from others. Likewise, the individuals of any one species are distributed in relation to each other in distinct patterns. The reasons for the readily apparent nonrandomness of the spatial distribution patterns of organisms are numerous, and the patterns result from processes acting throughout the whole life cycle of the organism, and on various spatial scales. Although this spatial structuring of populations is often ignored in ecological theory, it has profound implications for the mediation of biological processes: interactions between individuals and across species all take place in space as well as in time, and an understanding of spatial patterns is basic to understanding real-life ecological processes. Indeed, patterns of spatial distribution play an important role in shaping a wide range of ecological dynamics, such as intra- and interspecific competition, mating systems, predation, population genetics, and the spread of contagious diseases.

This article presents an overview of how spatial patterns in the distribution of organisms are created, and how they influence the way ecological processes run their course in ecological communities, exemplified by predator–prey dynamics. These patterns are scale dependent: organisms which are distributed in one way when observed at a large spatial scale may be distributed very differently at closer scales. To accommodate this, the presentation is structured according to the main spatial scale of the patterns under discussion. The initial focus lies on the way organisms are distributed at a landscape level, at which spatial distribution is mainly influenced by topographical features and variation in habitat availability. The subsequent discussion moves the scale to patterns in the dispersion of individuals, which can be seen primarily as an effect of behavioral interactions with conspecifics and with those of predator and prey species. To conclude, large-scale regional distribution patterns are briefly discussed, in relation to how they may contribute to the observed spatial distribution patterns at smaller scales.

The Distribution of Organisms Over Landscapes

An organism may only persist where the physical conditions (temperature, humidity, etc.) are tolerable and the food resources are adequate. In other words, the environment should match the niche space of the species. Consequently, all organisms are associated with a specific type of habitat, and hence view the area around them in widely different manners. In this context, it is useful to think of the landscape as a mosaic, consisting of patches of favorable habitat surrounded by uninhabitable areas. Within such patches the species may form more or less permanent local populations (also called subpopulations), while the species is only rarely found in the intervening areas.

The dynamics of a subpopulation are driven by several processes, as shown in **Fig. 1**. Individuals enter the population through birth and immigration, and leave it as a result of death and emigration. Of these processes, birth and death rates may be controlled by the number of individuals already present, their density, and the resource availability. Immigration and emigration may also be affected by these factors, as well as by the favorability of the surrounding landscape and the size of the adjacent subpopulations.

If we increase our vantage point to include several such subpopulations located over the landscape, which are separated by uninhabitable areas but with migration occurring between them, then a very complex picture appears (**Fig. 2**). All these interacting subpopulations can be viewed as one large spatially structured population, known as a metapopulation. The complex spatial dynamics of the metapopulation result from the patterns of between-patch movement and local birth and death rates, as well as local extinction and colonization of subpopulations which occur over larger timescales. These processes can be modeled by a set of connected differential equations, which allows quantitative predictions to be made about the dynamics of the metapopulation.

Other factors, which are not accounted for by the basic model described above, may be included in more sophisticated representations. These factors include the size and favorability of patches, their relative isolation, and the nature of the intervening habitat relative to the dispersal ability of the organism. There are also dynamic processes affecting the occupancy of each patch over time. These processes rely on the observation that over time, the subpopulation in many cases causes a reduction in the quality of the patch which it inhabits (e.g., reduces the amount of resources and/or attracts predators, parasites, and pathogens). As the environment deteriorates, mortality and emigration is likely to increase while the rate of reproduction correspondingly decreases. In addition, Allee effects (see later) can hasten the demise of the subpopulation. A further complication to this pattern is that these effects are not restricted to the species in question, but are equally likely to affect its predators and the vital bioresources, such as food resources on which it depends.

An interesting consequence of the spatial movement of individuals between subpopulations is that some patches may be occupied, even though they cannot in themselves sustain viable populations of the species. The subpopulation of such a patch is actually kept alive by the immigration of individuals from more productive patches in the vicinity. The movement of individuals resembles water flowing from its source to a sink, and correspondingly this type of system is usually termed source–sink dynamics. In some areas, especially in transition zones between habitats or biomes and in areas severely affected by human disturbance, such source–sink dynamics may play a key role in structuring the occurrence and distribution of individuals.

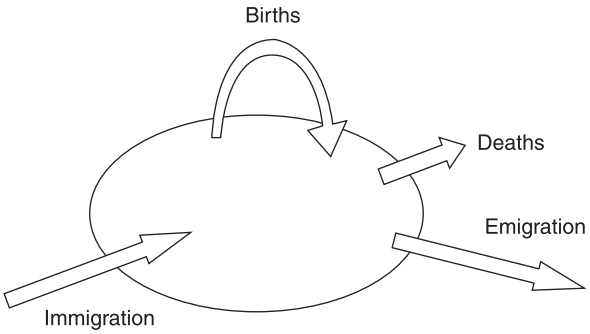

Fig. 1 The abundance of a subpopulation within a patch of suitable habitat is affected by the processes of birth, death, immigration, and emigration.

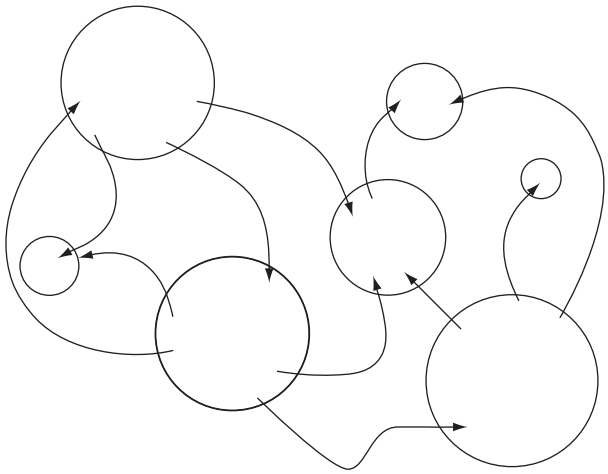

Fig. 2 In a landscape consisting of several suitable habitat patches, the population dynamics become dependent on dispersal and colonization between interconnected subpopulations. Such a system is described by metapopulation dynamics.

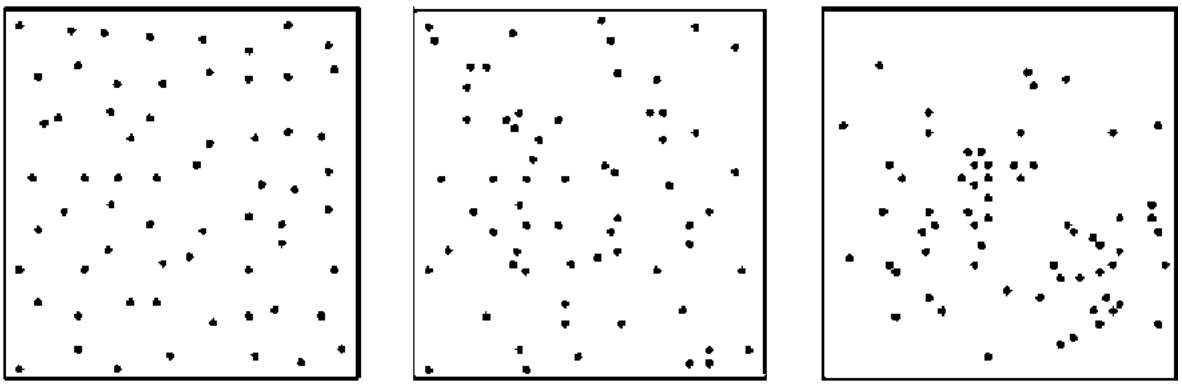

Fig. 3 A schematic representation of the dispersion of individuals in a subpopulation with (from left to right) either a regular $(s^2 < \bar{x})$, a random $(s^2 \approx \bar{x})$, or a clumped $(s^2 > \bar{x})$ distribution.

Dispersion of Individuals

An alternative way of describing spatial distributions is to move the focus to the position of separate individuals in space. When viewed from above, the distribution of individuals over the landscape can be visualized as a pattern of tiny dots dispersed over a blank area. This pattern may in theory be completely random, but usually individuals are either clumped together, or at the opposite, spread out in a regular fashion (see Fig. 3).

Empirically, dispersion patterns can be characterized by the average number of individuals in randomly sampled units of area within the landscape ($\bar{x}$) and the variance between number of individuals occurring per sampling unit (s^2). The ratio $s^2/\bar{x}$ is commonly known as the index of dispersion. In randomly distributed populations, the index of dispersion is approximately equal to 1 (see **Box 1**).

Clearly, dispersion patterns are strongly dependent upon the scale at which they are perceived – for instance, the distribution of an insect species living on leaves of trees can be studied on many different spatial scales, such as the distribution on each leaf, among leaves within a branch, among branches within a tree, and between trees within a forest.

From the beginning, it seems obvious that there should be some clumping of individuals – organisms do not appear out of the thin air. Each individual originates from a parent, and as such appears in close vicinity to other individuals, which in most cases are relatives. After birth, or at a later stage in the life cycle, they undergo some juvenile dispersal before settling down in a favorable location, but some degree of aggregation is still retained. Another factor which predisposes for aggregation is that individuals of the same species are attracted to a set of conditions and resources, which are themselves patchily distributed.

Aggregated dispersion patterns are very common in nature. An example of an extremely aggregated species is the Kashmir cave bat (*Myotis longipes*), which is only known from nine localities in the Himalaya region, each home to populations of a thousand individuals or more.

A regular or even distribution, on the other hand, is the result when individuals compete for limited resources. This type of pattern is commonly exhibited by many sessile organisms such as trees, which space themselves evenly as a result of competition

Box 1 Analysis of spatial data

As the null hypothesis, it is assumed that individuals in a population are randomly distributed among the n sampling units of a sample. If this is the case, it is expected that the variance should equal the average so that the `index of dispersion', $s^2/\bar{x}$, is approximately equal to 1. If the ratio exceeds 1, it indicates that the population has a patchy (or clumped) distribution whereas a value less than unity indicates an even (or regular) distribution. However, since data originate from sampling, they will always be associated with some variation, so it is likely that some deviation in $s^2/\bar{x}$ from unity will occur even if the underlying distribution is random. Especially if the sample size n is small, $s^2/\bar{x}$ will exhibit large variation due to sampling noise. A χ^2-test can be used for testing whether $s^2/\bar{x}$ deviates significantly from 1 since $\chi^2 = (n-1)s^2/\bar{x}$ with $n-1$ degrees of freedom. It should be noted that the test is two-tailed (in contrast to the majority of cases where χ^2-tests are used) since values significantly smaller or larger than $n-1$ can lead to rejection of the null hypothesis.

Though the index of dispersion indicates whether a population is evenly, randomly, or patchily distributed in space, it does not explicitly reveal information about the underlying spatial distribution. This requires that the empirical distribution of sampling units with x individuals can be fitted by a theoretical `probability function' called $P(x)$, which denotes the probability that a randomly selected spatial unit contains exactly individuals. As all probability functions, $P(x)$ for all possible integer values of x equal to or larger than 0 should sum to unity.

The Poisson distribution is used to describe the underlying distribution when it is random, the positive binomial distribution when it is even and the negative binomial distribution when it is clumped. However, other less frequently used distributions are also available to model clumped populations, for example, the Thomas distribution, the logarithmic series distribution, the Pólya–Aeppli distribution, and Neyman's type A, B, and C distributions. Once an adequate probability function has been identified and fitted to data, the quality of the fit can be assessed by means of a goodness-of-fit test, usually a χ^2 one-sample test or a Kolmogorov–Smirnov one-sample test.

A problem often encountered in analyzing spatial data statistically is the fact that they do not represent independent observations. Thus, if sampling unit i is separated from sampling unit j by a distance d_{ij}, it seems likely that x_i will be more similar to x_j, the smaller the d_{ij} is. This phenomenon is known as `spatial autocovariation'. Spatial autocovariance is often depicted as a so-called `semivariogram' where the `semivariance' (γ_d) is plotted against d. The semivariance at distance d is calculated as $\gamma_d = \sum_{i=1}^{n_d} (X_{i+d} - x_i)^2 / 2n_d$, where x_{i+d} is the value of x measured at distance d from another measurement x_i and n_d is the number of measurements separated by distance d.

Spatial patterns can be depicted graphically by means of a technique known as `kriging'. The principle is to place a large number of points spaced out over the entire area under study. Each point is characterized by its coordinates in the two-dimensional x–y space, and by the value of a given attribute (for instance the population density in the area around the point). The value of the attribute is denoted the z coordinate, which represents a height above the x–y plane. Hence, small and large values of z will appear as troughs and peaks in a three-dimensional (3-D) landscape. 3-D landscapes can be projected into two-dimensional (2-D) landscapes by means of contour plots where points with identical z-values are connected with lines (isoclines), similar to how temperature and atmospheric pressure are depicted in meteorological maps. The more fine-grained the information is, the more precise the map will be. Various algorithms have been developed to interpolate values between neighboring points so as to estimate z in points that have not been sampled, and to smooth out the landscape by removing local peaks and troughs caused by sampling noise.

Since kriging is computationally demanding, various specialized software products exist to perform it, for example, easy_krig, DACE, GS$^+$. In addition, kriging can be handled by some statistical packages, such as R.

for water or sunlight. Also many animals have approximately regular distributions – a familiar example is the territories of songbirds.

Biological Impacts on Spatial Patterns

As mentioned above, the dispersion pattern of individuals is affected by the structure of the landscape and the resource demands of the organism. Theoretically, if individuals were similar and completely free to move, they would be dispersed over the landscape so that each individual had the same access to the resource. This pattern is known as the ideal free distribution, and will simply reflect the instantaneous distribution of resources. However, differences between the competitive abilities of individuals, habitat barriers hindering free movement, and the individuals' lack of perfect knowledge about the distribution of resources all contribute to making examples of populations following the ideal free distribution rare in nature.

The behavior and life styles of organisms are extremely varied, and patterns of spatial distribution exhibit a great deal of variation. Mobile organisms move around in order to acquire resources and may also engage in social interactions with conspecifics. This means that behavioral choices play a profound role in shaping occurrence patterns. One of the most obvious cases of this effect is the congregation into cooperative flocks seen in many animal species. The exact nature of these flocks differs widely among organisms – from the loose aggregations of resting brent geese (*Branta bernicla*), via the socially complex cooperative units of wolf (*Canis lupus*) packs to the super-individual hive structure of eusocial insects.

Optimal Group Size

Despite the great variation in types of animal groups, the biology of flock behavior has important commonalities across all species. An example is the determinants of group size, which can be seen as a function of the costs and benefits of being part of a group.

A group consisting of N individuals can increase its size without recruitment of individuals from outside as long as the group's per capita growth rate r in eqn [1] is positive:

$$\frac{dN}{dt} = rN \quad [1]$$

r is likely to be a function of group size, reflecting the difference between benefits and costs of adding further individuals to the group. Hence, r may be modeled as a difference between two functions:

$$r(N) = \text{benefits} - \text{costs} = f(N) - g(N)(N \geq 1) \quad [2]$$

where $f(N)$ denotes the benefit function and $g(N)$ the cost function. Both functions can either be independent of N or increase with N. Since groups cannot be infinitely large, there will exist a value for N satisfying the condition that $r(N) = 0$ for $N = N_{max}$ and $r(N) < 0$ for $N > N_{max}$. Benefits of increasing group size are likely to level off with N, while costs are likely to accelerate as N becomes large as indicated in **Fig. 4a**. N_{max} corresponds to the value of N when costs and benefits balance.

When group size reaches its maximum size, r will be 0, indicating that the fitness of group members is low. By reducing group size from this point, the fitness of each individual will increase. The optimal group size (denoted N_{opt}) is reached when r is at maximum (**Fig. 4b**). If N_{opt} is close to 1, individuals will gain by living alone, for instance, in territories, and their spatial distribution will tend to be regular or random. In contrast, species with high values of N_{opt} will be patchily distributed. This will apply to species that can adjust their group size in accordance to net benefits, for instance, in animals where individuals can join (if $N < N_{opt}$) or leave groups (if $N > N_{opt}$). If groups are not formed by such behavioral mechanisms, as with plants, group size will continue to grow until $N = N_{max}$. A special case of eqn [2] is when benefits and costs balance at two different group sizes, as shown in **Fig. 4c**. When N is below N_{min}, the group will go extinct because the smaller the group the more negative r becomes (the so-called Allee effect). The only way the extinction of such a group can be avoided is by recruiting individuals from outside.

Population-Level Variation in Dispersion Patterns

As noted above, the behavioral life styles of animals determine their distribution. While some animals, such as the wildebeest (*Connochaetes taurinus*), live in groups that migrate over large areas or restrict their dispersal to extended home ranges, many others are territorial, dividing the available habitat into separate areas which are defended against the intrusion of conspecifics.

In addition, different members of a population may exhibit widely different patterns of dispersion, resulting in highly complex overall spatial patterns. Territoriality, for instance, causes all reproducing individuals to adhere to a regular dispersion pattern – but for nonreproducing individuals the situation may be very different.

An example is provided by the tawny owl (*Strix aluco*) which is a long-lived, monogamous, territorial bird (**Fig. 5**). Juveniles only get access to optimal resources when adults die and thereby leave vacant territories. Adults defend their territories fiercely against intruders, though they are more willing to accept juveniles within the territory boundaries during July and August, when the juveniles disperse from their natal territories.

This difference between the lifestyles of adults and juveniles means that only few individuals survive to reach adulthood. Adult birds within their territories have a relatively high survival; telemetry studies show that a main cause of death within the

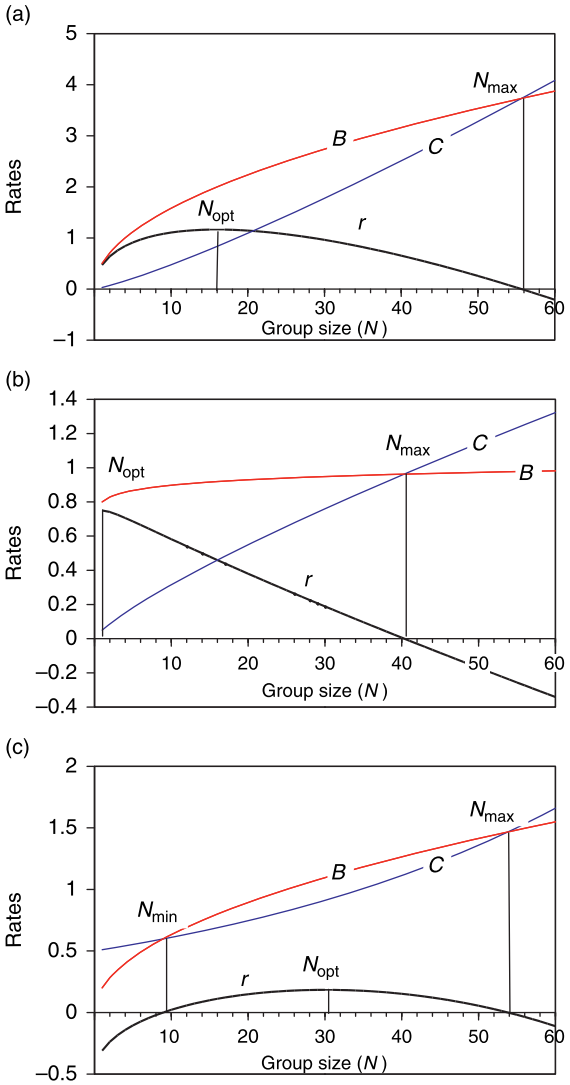

Fig. 4 Group formation is predicted to occur when the relative growth rate (r) increases with group size. Depending on how the benefits (B) and costs (C) of group behavior change with group size (N), three different cases can be identified: (a) Benefits increase more steeply than costs when group size is small, and vice versa when group size is large, leading to an optimal group size (N_{opt}) toward which the group is predicted to converge. If a group does not split up when $N > N_{opt}$, it will continue to grow until $N = N_{max}$. (b) Solitary behavior (i.e., $N = 1$) is predicted if costs increase more than benefits as group size increases. (c) A group must be larger than N_{min} in order to persist and grow, whereas it is goes toward to extinction if N falls below N_{min} because the relative growth rate is negative (the so-called Allee effect).

fragmented landscapes of Western Europe is traffic. The juveniles, on the other hand, are vulnerable to a range of factors. Since they have no territory, they are forced to move around and hunt in unknown areas and marginal habitats where survival chances are poorer (**Fig. 6**). They are also more vulnerable to predators. Because only individuals possessing a territory can breed, the density of breeding animals is relatively constant, even though the production of young varies significantly between years.

Heterogeneity in the spatial distribution of individuals is not limited to territorial species. Cods (*Gadus morhua*) have size-specific habitat selection – the smallest individuals stay in areas with dense vegetation. Here they are protected against predators, while the plants and their associated fauna provide an ample supply of food. When the cods grow larger, they move out into deeper waters to hunt.

Another example of variation in spatial distribution patterns is differences between the two sexes of the same species. The interests and the behavior of males and females can be widely different, and this is reflected in the distribution of individuals over space. In the African bush elephant (*Loxodonta africana*), for instance, the females are highly aggregated into small family groups spaced over the landscape, while the males wander alone over large areas, yielding a dispersion pattern which is probably best described by a random dispersion.

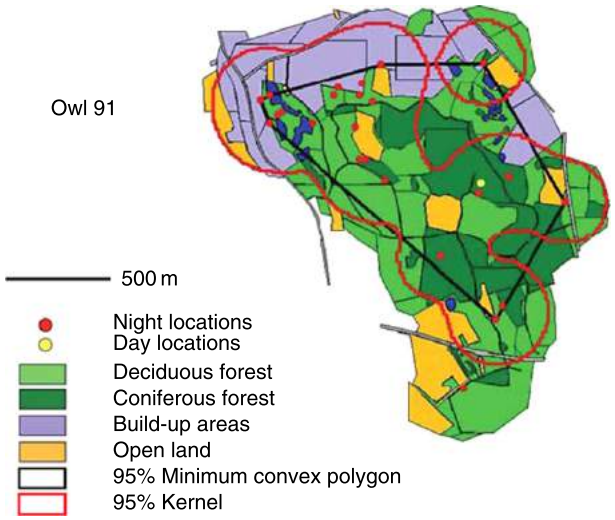

Fig. 5 Habitat map showing observations of juvenile individuals of tawny owl (*Strix aluco*) in a mosiac landscape of agricultural land, forest, and urban areas. The minimum convex polygon and the Kernel denote different methods of establishing the core area used by an individual or a group of individuals, and provide information on the habitat preferences, home range, and territory boundaries. Processes Mediated by Spatial Structuring of Populations

Spatial patterns may have profound implications for the outcome of ecological processes, since the frequency of meetings between individuals and the intensity of interactions all depend on their relative positions in space.

Predator–Prey Interactions

An example of the ways spatial patterns influence ecological processes is provided by the dynamics between predators and their prey. Spatial structuring of populations may rescue prey from extinction, in many cases where conventional models may provide little hope for their survival. An example is given by the two-spotted spider mite (*Tetranychus urticae*), which is an important pest in commercial greenhouses. Many growers control this pest species by introducing predatory mites, such as *Phytoseilus persimilis*, which maintain spider mites at low densities without eradicating them completely. Though the introduced mites are voracious predators, spatial structuring on the leaves and plants of the greenhouse maintains the coexistence and persistent survival of both the spider mites and their predators. Small populations of the spider mites survive in temporary 'refugia' on the leaves of plants, even in greenhouses where the overall density of predatory mites is otherwise large enough to drive the spider mites to extinction.

A large-scale example of the influence of spatial patterns on the outcome of predator–prey dynamics is given by the population dynamics of microtine voles. Vole populations (mainly species of *Microtus* and *Clethrionomys*) in Fennoscandia exhibit a wide range of population dynamics patterns, from regular multiannual cycles in the north gradually shifting to stable or biennially fluctuating populations toward the south. Several explanations have been proposed to explain these dynamics, those attracting most attention in Fennoscandia being interactions with predators.

These hypotheses seek to explain spatial differences in dynamics between northern and southern populations by variations in predator composition and density, together with changes in landscape structure. The basic idea is that the specialist predators which are common in northern regions, such as mustelids (*Mustela* sp.), can generate population fluctuations since their numbers are strongly coupled to those of their prey. This means that when there are few voles, there will be few predators. This allows vole populations to grow rapidly, followed by an increase in the number of predators, and so on.

Generalist predators, on the other hand, may switch to other prey types when vole densities are low, and hence their population numbers are much less strongly coupled to the density of voles. These predators are thus thought to stabilize the density fluctuations of the microtines.

Habitat structure in Fennoscandia may also influence the population dynamics of voles. Whereas the landscape in northern Scandinavia is characterized by large tracts of homogenous habitat, southern regions are dominated by agricultural land with multiple patches of different habitat types. The variation in habitats in the south allows a greater number of prey and predator species to exist, and favors generalist predators which stabilize the population fluctuations of the prey.

An added effect of habitat fragmentation is that the isolated habitat patches occurring in fragmented landscapes each supports separate subpopulations of voles, with relatively independent population dynamics. This independence prevents the abundances of predator species from tracking those of their prey too closely, and also facilitates local outbreaks in prey abundance in those

Fig. 6 Juvenile tawny owls (*Strix aluco*) live a precarious life as vagrants while they are waiting to take over a vacant territory when an adult individual dies. Copyright: Peter Christiansen.

patches where the subpopulations have gone undiscovered by predators. However, even though the prey density of local patches shows high temporal variability, the asynchrony between such localized outbreaks ensures that average density, when viewed at a large spatial scale, remains relatively constant over time.

Large-Scale Distribution Patterns

An aspect of spatial patterns which should not be overlooked is the distribution of species at very large, global scales. At such scales, the creation and extinction of species interact with long-range dispersal and large-scale differences in climate to generate patterns of species richness and control the composition of regional species pools. Over time, new patterns are created as species expand into new areas while going extinct in others, and as isolated subpopulations give rise to new species due to evolution.

The basic unit of large-scale ecology is the geographic distribution range. Ranges can be represented in many ways, from the colored blotches known from popular field guides to exact mapping of territories and point counts of individual locations, and the definition of ranges is, like most spatial patterns, strongly scale dependent.

The concept of ranges and their distribution has attracted considerable attention in recent years, because of their profound importance for biodiversity. Identifying and describing patterns of overall species richness and the location of areas with large numbers of endemics (i.e., species with small range sizes) play a key role in the conservation and management of nature, since they are instrumental in directing conservation efforts to the most optimal areas. In addition, an understanding of these patterns is at the center of attempts to predict the result of the recent changes in diversity following human habitat destruction and global warming. These patterns all result from the location of species ranges and the manner in which they overlap.

What determines large-scale distribution patterns remains the subject of debate: a long-standing controversy in ecology regards whether the size and location of species' ranges are primarily decided by contemporary ecological (mainly climatic) factors, or by the interaction of dispersal and competition with other species present in the area.

The shape and location of the range at large scales are also mirrored by the distribution of individuals at smaller scales. Toward the edges of a range, populations of the species tend to become more patchily distributed, with more widely separated individual subpopulations. Additionally, peripheral populations are smaller and support fewer individuals, so that the abundance and

occupancy of the species co-vary across the range. What creates this pattern is not completely known, but it seems likely that it reflects that the density of habitats with optimal conditions for the organism is higher in the core area than in the periphery.

In this way, large-scale patterns interact with local processes, behavior, and biotic interactions to produce the distributions of plants and animals in nature. The complexity of these distributions underline the increasing realization that a consideration of spatial patterns is a vital part of any comprehensive framework for biology.

Summary

Patterns in the spatial distribution of organisms are extremely varied, and are affected by numerous factors in the ecology and behavior of species. Distribution patterns not only differ between species as a result of differences in trophic level and relative commonness, but may also vary with the age, sex, and social status of individual organisms. Nonetheless, the overall patterns can be described using relatively simple models, providing a key factor for the understanding of ecological processes such as the relationships between predator and prey populations.

Glossary

Bound energy The energy dissipation with heat flux and entropy of outcoming solar radiation.

Exergy The maximum useful work that can be obtained by contacting of the working medium or the energy source with the natural environment when achieving equilibrium with it. Under the useful work of ecosystem most researchers understand the maintenance of the moisture cycle.

Internal energy increment Which is the transition of the absorbed solar energy into the internal energy of the system.

Internal energy increment Internal energy increment of the system (DU), which is the transition of the absorbed solar energy into the internal energy of the system—accumulation organic matter.

Kullback's information increment Measuring the distance between the distribution of energy in the spectrum of the incoming and outcoming solar radiation.

Theoretical Background

On the early stages of thermodynamics development it became apparent that the living systems cannot be described based on the laws of thermodynamics, for the closed systems. Nevertheless, Ludwig Boltzmann, whose input into the thermodynamics can hardly be overestimated, was sure that his laws for equilibrium processes once will be applied to the open systems, including those with living matter presence (Klimontovich, 2002). The fundamental works published by L. Boltzmann and J. Gibbs allowed to regard the living matter as a macro system, which condition can be defined as "entropy" (Schrödinger, 1947). In fact, E. Schrödinger was one of the pioneers to form the generally accepted concept, that the living matter maintains its own order (structure) by extracting the orderliness or "negative entropy" from the environment: "It feeds upon negative entropy, attracting, as it were, a stream of negative entropy upon Itself, to compensate the entropy increase it produces by living and thus to maintain itself on a stationary and fairly low entropy level" (Schrödinger, 1947). The primary source of the "negative entropy" for the living matter is the sunlight (energy), which is consumed by plants and then conveyed to animals in the form of more or less complex organic compounds. While analyzing and generalizing different concepts of living matter, Schrödinger has noticed that on this stage of the physics development the living matter cannot be described by the existing physical laws and thus he has foreseen new discoveries. In the quoted work "What Is Life?…" Erwin Schrödinger (1947) recognizes the necessity to describe the system with living matter by thermostatic and thermodynamic models in order to understand how the orderliness forms from chaos. Thus the main objective of the synergetics was formed.

The applicability of the thermodynamic laws to the living systems was widely discussed in the scientific community at the end of the first half of the XX century. The main stumbling bloke for the researches was the second law of thermodynamics, which states that the growing entropy in a closed system should have made the existence and emergence of the living matter impossible according to the physical laws. Max Planck, who was researching entropy increase, stated that from the biological standpoint the process should be regarded rather as degeneration than improvement (Zeyde, 1968). Karl Heisenberg, one of the founding fathers of the quantum theory, claimed that apart from the physical and chemical laws there should be present an additional component, essential for the biological processes comprehension (Zeyde, 1968).

The inapplicability of the entropy increase law for the biological processes suggested that the evolution modeling based on physical systems is impossible. Discussions formed the major concepts of the living system functioning from the physical point of view—it was agreed that the key features of the living systems were openness and nonequilibrium.

The concept of the living matter's free energy is the basics of the biosphere concept developed by Vernadsky (1945, 1978). According to Vernadsky, the role of the living matter in the biosphere is to transform the cosmic (mostly solar) energy into the "effective terrestrial energy"—electrical, chemical, mechanical, thermal, etc. (Vernadsky, 1945). The solar radiation activates and transforms the living matter into a completely different condition in relation to nonliving substance. In this condition the living matter can concentrate and distribute the energy in the biosphere, converting it into the energy, which is "free in the Earth's environment, capable of producing work". The solar energy transformation occurs in the primary thermodynamic field of the biosphere. The living matter creates its own autonomous thermodynamic field, characterized by different variables than ones of the biosphere field. "The ability to introduce the solar energy into physical and chemical processes of the Earth's crust makes the organisms fundamentally different from other independent variables of the biosphere. Though, the organisms change the equilibrium course of the crust in the same way as other variables, they are autonomous and represent the secondary systems of the dynamic equilibrium in the primary thermodynamic field of the biosphere" (Vernadsky, 1945). The transformation of the solar energy in the living matter field forms the specific chemical

compounds. In the thermodynamic field of the biosphere these compounds are unstable, and with their decomposition the energy releases into the biosphere. Therefore, in the course of the transition from the thermodynamic field to the nonliving environment field the matter becomes the free energy source, hence the equilibrium of the system is disturbed. Almost at the same time as Vernadsky, Bauer (1935) invented the principle of the stable nonequilibrium of the living systems: "The living and only the living systems are never in equilibrium, and, on the debit of their free energy, they continuously onvest work against the realization of the equilibrium within the given outer conditions on the basis of physical and chemical laws (Bauer, 1935, p. 19). Similar to Vernadsky, Bauer (1935) saw the work source of the living matter in the gradient between the living matter itself and the lifeless equilibrium around. According to Bauer, the nonequilibrium state of the molecular order is maintained exclusively at the expense of external energy. Bauer claimed the stable nonequilibrium state is realized in a special configuration of the protein molecules: "A source of the work done by living systems is at the final account free energy specific for this molecular structure, for this state of molecules" (Bauer, 1935, p. 56). The thermodynamic free energy is the amount of work that the system can perform after it reaches the equilibrium with the environment (thermodynamic potential).

The Vernadsky's claimed the living matter should be treated as a thermodynamic system, and the idea was developed by Khilmy (1966, 1972). Vernadsky and Bauer believed the living system's work on the solar energy transformation contradicts the second law of thermodynamics (every spontaneous process is followed by the entropy increase in an isolated system, bringing it closer to the equilibrium), yet Khilmy proved the applicability of the second law to the biosphere, regarding it as an open system. "Energy resource of the biosphere is a result of the cosmic external free energy transformation into the biosphere energy – especially into the energy of its living matter. The fact that during this transformation the biosphere energy does not decrease and may even increase, does not contradict the second law of the thermodynamics. The point is that the second law effects realize not in the biosphere, but outside it. As a result, the entropy increases outside the biosphere, where the transformed energy decreases in the quantities, that exceed the role of the free energy in the biosphere" (Khilmy, 1972). Thus Khilmy has nearly classified the biosphere as a dissipative system (structure), and the same idea was developing at that time in some Brussel's school works (Prigogine *et al.*, 1972). The concept of regarding dissipative systems as an open systems, which use the outer energy to maintain its structure and emit the produced entropy in return, made it possible to form the relevant thermodynamic laws for open systems. Three laws of the thermodynamics were formed so far. One of the last editions of the thermodynamic laws is outlined in a monograph "Towards a Thermodynamic Theory for Ecological Systems" (Jorgensen and Svirezhev, 2004):

1. The amount of energy is constant, though its ability to produce work, that is, the quality of energy, varies. Solar energy is transformed by anabolic processes, particularly by photosynthesis, as soon as it inters an ecosystem and also when it exits, during metabolic processes, though its quantity remains the same.
2. The dominance of the outward energy flux over the inward flux plays an important role for the system's order. The structural organization maintenance is due to the exchange of energy and entropy with an environment—it reaches a stable state, which is far from the thermodynamic equilibrium (maximum entropy).
3. The living systems' functioning is possible solely at temperatures above the absolute zero.

Ecosystem Evolution From Thermodynamic Standpoint

Since Lotka (1922, 1925), who was one of the first to define the living matter evolution course from the thermodynamic standpoint, the tendency of the consumed energy to increase was regarded as an aim of the evolution. According to the law stated by Lotka, "the evolution course assumes that the overall energy flux, which passes through the system, reaches the maximum possible value" (quoted from Buenstorf, 2000). The principle, suggested by Bauer (1935), "principle of the maximum external work effect" is that the biological systems development and the result of their work increase are expressed by the impact of those systems on the environment. Based on this principle and other biogeochemical principles V. Vernadsky and V. Kaznacheev formulated two laws (the law of Bauer-Vernadsky): (1) geochemical biogenic energy of the biosphere tends to maximum; (2) during the evolution of species, only the organisms that increase this biogenic chemical energy in a process of their life will survive (Kaznacheev, 1989, p. 31). In the classic ecology papers the law of Eugene and Howard Odum (the law of energy maximum) is more popular: "Systems that survive are those which get the most energy and use energy most effectively in completion with other systems." (Odum, 1977). The same law was formulated by Pechurkin (1982) as an "energetic principle of extensive development," which implies that "in a process of super organisms' biological development (evolution, ecological succession and transformation) the quantity of the biological energy flux increases and reaches the maximum values in a steady-state" (Fursova *et al.*, 2003).

If the issue of energy maximum in a process of evolution does not appear to be controversial, the definition of evolution from the entropy standpoint remains a subject of discussions. On the one hand, the principle of maximum entropy (the second law of thermodynamics for nonequilibrium systems) states that the processes, that are far from thermodynamic equilibrium, conform to the stable state, disperse the energy and produce the maximum possible entropy level (Martushev, 2006). On the other hand, I. Prigozhin (Kondepudi and Prigogine, 1998, Prigogine and Stengers, 1984) formed and proved the theory of minimum entropy production, in which in a nonequilibrium system under stationary conditions the entropy production stays at a minimum level). The seemingly controversial principles of maximum and minimum production were solved by Khazen (2000). He proved that they work at different stages of the process and united the minimum entropy production in stationary state principle and maximum entropy production principle as the basics of the choice on the evolutionary scale (Puzachenko *et al.*, 2011). Khazen

claimed that due to maximum entropy production principle in the nonequilibrium systems the entropy production works as a steady flux, according to Lyapunov criteria. The stability of the flux means that it can be described as a consequence of stationary states with a locally functioning minimum entropy principle. In a one function plane works the Lyapunov criteria for the dynamic equilibrium, so it is supplied by the minimum of entropy with the maximum capacity, and in the perpendicular plain works the Prigozhin's criteria for the static equilibrium with the maximum entropy and minimum capacity (Khazen, 2000). The structure, order and information maintain the system in a stationary nonequilibrium state with a local minimum of entropy production and its ability to carry out the useful work nonequilibrium maintenance. During the evolution the system tends to deviate from the stationary state, towards the nonequilibrium with less entropy, and it uses different ways to reach this state (Klimontovich, 2007). The degree of the deviation is characterized by the Lyapunov criteria, the Kullback's information increment or the Kolmogorov-Sinay's entropy increment. If the system receives the sufficient amount of the information, that defines its structure and allows it to reach the new local stationary state, it can remain on the new level of useful work production. Kay and Fraser (2001) formulated the modern thermodynamic standpoint: the functioning of a living matter system is equal to exergy transformation and assumed that the system development aims at the efficiency increase, thus the evolution can be regarded as the movement of the living matter towards the complexity for the more effective use of exergy (destabilizing thermodynamic equilibrium). According to Kay and Fraser (2001), the evolution criteria is the decrease of the heat flux from the active surface of the ecosystem, that transforms the solar energy. The ecosystems that cool their active surface more effectively receive competitive benefits due to evanotranspiration (Lina *et al.*, 2009). As a result, the less is the heat flow from the active surface and the more of consumed energy is spent on evaporation, the higher position occupies the system on the evolutionary scale.

Jorgensen and Svirezhev (2004) have conducted a deep analyzes of thermodynamic ideas applied to ecology, using a wide range of empiric data. At the moment they are developing the forthcoming forth law of thermodynamics: the maintenance of living matter and the systems connected with it in a nonequilibrium stationary state depend on the exergy flux. The forth law of thermodynamics is proposed to explain the growth and development in ecosystems. The growth is regarded as the tendency of a system to expand, and the development as an orderliness increase, disregarding the system's size. In the end, the living matter objective is regarded as exergy increase, that is, the ability to do useful work. To check this hypothesis (Sandlerskiy and Puzachenko, 2009) different thermodynamic characteristics of the ecosystems were compared and the hypothesis of the exergy increase in the evolution order was not proved: exergy decreases from coniferous forests to grasslands, but the exergy increase was detected in a succession sequence, during the short ecological period.

Thermodynamic Variables of Landscape Cover

The adaptation of the thermodynamic basics to ecological field continued by introducing physical concepts, which describe the energy quality (i.e., its ability to perform work maintaining the system's organization) into ecology. One of the first to introduce the idea of energy quality to ecology was H. Odum (1977). He stated that the flux assessment and energy accumulation require the idea of emergy. Solar emergy is a useful energy, which can be used directly or indirectly for goods and services production (Odum, 1977). Emergy is measured in solar emjoules. Despite the idea of emergy, Odum introduced several terms: potential energy, capable of doing work and changing in the process of production and transformation—emergy contained in one emergy unit. The transformation into emergy preserves both the qualitative and quantitative features of energy, because the more significant the transformation is for the type of energy, the higher position in the energy hierarchy it takes (Odum, 1996). With the emergetic approach the emergy calculation is based on standard formulas of physics, chemistry, economics, geology, etc., herewith the data might be measured in joules, grams, currency unions, time spent, etc. However, emergy, as a controversial concept, is not used in ecosystem studies and remains more ecological or even ecological and social term with no equivalent in physics. The disadvantage of the approach is its economic focus, that is, its assessment is mainly conducted from the goods and services production standpoint.

From the middle of 20th century the parameter used in thermodynamics to describe the quality of energy is exergy (in Greek the prefix "*ex*" means the superlative form and "*ergon*" means work)—the term was coined by the Ugoslavian physicist Rant (1956)." Exergy is a maximum useful work possible to be produced by the contact of the working body or the energy source with the natural environment, at the moment of the equilibrium" (Petela, 1964), thus exergy is often referred to as to "the energy of transition". Exergy is measured in joules, it is often expressed in capacity (the amount of work performed per one time unit—watt). Exergy is an analogue to the Gibbs free energy of nonequilibrium. The degree of the system's nonequilibrium, which transforms energy depending on the structure, defines exergy — this feature makes the exergy constructive enough for the thermodynamics of living matter. In the end of 20th century the term "exergy" came to ecology (Jorgensen and Mejer, 1982; Kay and Schneider, 1992; Jorgensen *et al.*, 2000; Kay and Fraser, 2001; Jorgensen and Svirezhev, 2004) and formed a new research course, "exergy system analysis." Nowadays the term is used for the description of the wide range of systems, for example, social and economic (Brodyansky and Bandura, 1996; Wall and Gong, 2001; Wall, 2002). The ecological branch of the economics focuses on the natural resources efficiency use during its consumption decrease—the natural resources cost, the cost of labor and exergy potential of various energy sources are calculated by exergy analysis (Brodyansky and Bandura, 1996; Patterson, 2002). In some papers the term "exergy" is applied as an indicator of the environment condition, especially under anthropogenic influence (Chamchine *et al.*, 2006; Ho and Ulanowicz, 2005; Wagendorp *et al.*, 2006; Silow and Mokry, 2010; Gornyy *et al.*, 2011). This approach began to evolve recently, but has received more recognition then the emergetic one, since it is based on a purely physical parameter with

thermodynamics origin in contrast with seemingly fetched "emergy" term (Hau and Bakshi, 2003, 2004). Finally, under specific circumstances, the two approaches may be combined (Hau and Bakshi, 2003).

The supporters of the exergy approach claim that exergy is an entropy analogue, which can hardly be measured for the living systems and systems which condition is far from thermodynamic equilibrium (Kay and Schneider, 1992; Etkin, 2003). Unlike exergy, the entropy transition between systems is not persistent,for example, heat exchange between two differently heated systems: the entropy lost by one of the systems is not equal to the entropy received by another one, while the exergy lost by one system is equal to the transferred exergy and to the exergy, received by another system, provided that the energy loss does not accompany the transformation. Exergy is equal to zero only if the system is in the equilibrium state with the environment. Therefore, the systems always have a potential to do the work and the quality of exergy defines how far is the system from a thermodynamic equilibrium. The isolated system tends to reach a limiting state, that is, thermodynamic equilibrium, so that the thermal, mechanical and chemical equilibrium is achieved in every point of the system. Therefore, the thermodynamic equilibrium for the living systems can never be reached, since these systems are open. One of the major principles of the exergy approach, the so-called theorem of Gouy-Stodola, states that exergy may only be consumed, not generated (Wall and Gong, 2001).

The simplest balance equation of the open nonequilibrium system in thermodynamics is:

$$R = \mathrm{Ex} + \mathrm{STW} + U$$

where R is the energy balance, Ex is exergy, the energy capable of performing the useful work; STW is the bound energy, unviable to do useful work, emitting the energy dissipation into the environment with the outward thermal energy flux (TW) and entropy (S), U is the internal energy of the system (the energy of chemical and nuclear particle bonds).

With regard to the living systems, exergy is a part of the incoming energy which can do the useful work to maintain the system in the nonequilibrium state with low entropy (Jorgensen and Svirezhev, 2004). The "useful" work of such system lies in the hydrological exchange between the soil and the atmosphere (evanotranspiration) and the biological production process maintenance. The internal energy of the ecosystem associates with different species and system's parts interactions and the energy accumulation within the system in the partially closed exchange circles. Apparently, the ecosystem's internal energy may be associated with the soil formation processes as well, particularly with the carbon accumulation and the stabilization of carbon content. Bound energy is an irreversible energy dissipation. Estimation of the ecosystem's overall energy balance appears to be a hardly feasible task, as soon as it requires the measurement of multiple fluxes, the calculation of the chemical bonds energy, etc. Thus, for the detailed modeling of the flux and energy transformation in the ecosystem the theoretical and practical researches are necessary. The overall exergy of the water exosystem (Ex) can be described as (Jorgensen, 2008):

$$\mathrm{Ex} = RT \sum_{i=0}^{n} C_i \ln\left(\frac{C_i}{C_{i,0}}\right)$$

where R is a universal gas constant, 8.317 J/mole k = 0.08207 atm/mole k, T is the temperature of the environment, C_i is the concentration of the thermodynamic equilibrium state.

For the integral assessment of the ecosystem energy balance is sufficient to assess the balance components of the consumed solar energy as the main energy source for the living matter: the solar energy exergy, the bound energy and the inner energy increment. The solar energy in the ecosystem can be calculated based on the temperature assessment method, developed by James Kay with coauthors (Kay and Schneider, 1992; Kay and Fraser, 2001), and on the nonequilibrium state assessment (i.e., the ratio of the incoming and emitted energy method) developed by Jorgensen and Svirezhev (2004).

According to Kay and Fraser (2001) the exergy of the solar energy is

$$\mathrm{Ex} = \Phi T_{\mathrm{solar}}\left(1 - \frac{4}{3}\frac{T_0}{T_{\mathrm{solar}}} + \frac{1}{3}\frac{T_0^4}{T_{\mathrm{solar}}^4}\right)$$

where ϕT_{solar} is blackbody radiation, $\Phi T_{\mathrm{solar}} = \sigma A T_{\mathrm{solar}}^4$, T_{solar} is the solar surface temperature (5762 k), σ is a Stefan-Boltzmann consonant ($5.67 \times 10{-}8\ \mathrm{W/m^2\ k^4}$), T_0 is the surface temperature, A is the square of the surface.

The temperature, being the main thermodynamic parameter of the ecosystem, directly connected with exergy. Though despite the temperature itself, the energy is transferred by the nonthermal radiation, the radiant energy. These two types of fluxes obey different physical laws: the thermal type of flux is controlled by the temperature gradient, that is. the Newton's law of cooling (the cooling rate is proportional to the temperature difference between the object and the environment), the radiant type of flux obeys the Stefan-Boltzmann law. Therefore, the suggested exergy assessment method does not describe the actual process of solar energy transformation in the ecosystem: the transformation of the shortwave solar radiation (the long wave solar energy is negligible) into the long wave thermal radiation, which the ecosystem emits to the atmosphere.

The solar radiation exergy calculation, proposed by Jorgensen and Svirezhev (2004) is based on the assessment of the nonequilibrium active surface, which transforms the solar energy. In order to implement this method is enough to have at least the shortwave and longwave data for the incoming solar energy flux and the ecosystem's emitted flux. The nonequilibrium degree can be estimated by the Kullback's information (Kullback, 1959) as a non-stationary system parameter, characterized be the emitted energy spectral deviation from the equilibrium spectral, which is proportional to the solar constant. In fact, the spectral deviation from the equilibrium (the state in which the incoming energy of a specific diapason is equal to the emitted energy) is the information increment in an ecosystem during the solar energy consumption. The Kullback's information increment is calculated by the equation:

$$K = \sum_{v=1}^{n} p_v^{out} \ln \frac{p_v^{out}}{p_v^{in}}$$

where $p_v^{in} = e_v^{in}/E^{in}$ is the share of the incoming energy in the spectral diapason from the overall incoming energy (E^{in}), $p_v^{out} = e_v^{out}/E^{out}$ is the share of the emitted energy in the spectral diapason from the overall emitted energy (E^{out}).

If the emitted radiation spectral is similar to the incoming radiation spectral, the Kullback's information equals zero and the information receiver (an ecosystem) remains equal to the transmitter. If the Kullback's information is more than zero, then it is possible to suggest the presence of the information increment in a receiver and the misbalance between the emitting surface and the solar radiation spectral.

Exergy (Ex), which can be assessed by the information increment, can be calculated as

$$\mathrm{Ex} = E^{out}(K + \ln A) + R$$

where $A = E^{in}/E^{out}$ is an albedo, $R = E^{in} - E^{out}$ is the energy consumed by the ecosystem (balance).

The above method of solar radiation exergy estimation was implemented by its authors for the average annual energy balance calculation (exergy and internal energy increment, excluding bound energy) for the biosphere as a whole based on shortwave (200–5000 μm) and long wave (5000–50,000 μm) energy balance data for 1992 with a resolution 2×2^{o} on the terrain (Jorgensen and Svirezhev, 2004).

According to the obtained estimates, the oceans at equatorial and tropical latitudes have maximum exergy, while maximum increment of internal energy is typical for the continents at the same latitude, for the rainforest area. In general, the distribution of the energy balance components is directly proportional to the balance itself and to the vegetation density. In the oceans exergy reaches its maximum in the areas with intensive circulation and upwelling zones. The authors of the calculations believe that internal energy increment distribution is connected with zones of intensive carbon circulation.

The most compete outline of the the energy balance calculations was implemented by Yuriy Puzachenko with coauthors (Sandlerskiy and Puzachenko, 2009; Puzachenko *et al.*, 2011). In the paper Puzachenko *et al.*, (2011) he considers the assessment of the energy balance components—the thermodynamic variables, calculated by the stated method with the satellite data of Terra MODIS for 2002 collected every 16 days for 2002 with a resolution of 0.5×0.5^{o}. The calculations were carried out by the shortwave radiation measurements in seven spectral channels and in long wave (thermal) channel. In spite of the Kullback's information increment, in the paper the energy of emitted solar radiation (S_{out}) was assessed:

$$S_{out} = -\sum_{v=1}^{7} p_v^{out} \ln p_v^{out}$$

To sum up, this work investigates the space and time variations of the thermodynamic parameters: the consumed solar energy (W/m^2), the information increment (nat), emitted solar radiation entropy (nat), the thermal flux of the active surface (W/m^2), solar radiation exergy (W/m^2), bound energy (W/m^2), internal energy increment (W/m^2)

$$\mathrm{STW} = \mathrm{TW}^{*}\mathrm{Sout},$$

where TW is heat flux of active surface, recorded by the thermal channel.

The internal energy increment of the system (DU), which is the transition of the absorbed solar energy into the internal energy of the system, is estimated as the residual of the absorbed energy balance equation (R):

$$\mathrm{DU} = R - \mathrm{Ex} - \mathrm{STW}.$$

Thus, the following thermodynamic characteristics were calculated: those forming the balance of the absorbed solar energy (W/m^2), which are exergy (W/m^2), bound energy (W/m^2nit) and internal energy increment (W/m^2); structural system characteristics, describing its nonequilibrium, which are information increment (nit) and entropy of outcoming radiation (nit); system heat flux (temperature).

The analysis of the components ratio shows that the biosphere is an open, nonlinear, dissipative physical and chemical system, which works in two phase forms: the first is defined by a small information increment and a high emission; the second by the high information and exergy increment and a low bound energy and internal energy increment (Puzachenko *et al.*, 2011).

Thus, the thermodynamic variables in the southern and northern hemispheres are fundamentally different. In the northern hemisphere with the snow cover the system stabilizes and entropy of the emitted solar radiation reaches maximum, while the information increment, solar radiation exergy and heat flux are minimal. During the vegetation period in summer, exergy and heat flux are little different from the rainforest's values. In the southern hemisphere the biomes are nonequilibrium during the whole year. The assessments presented in this paper and the assessments of the relationships between thermodynamic variables and vegetation index revealed in "Thermodynamics of biogeocoenosis based on remote sensing data" (Sandlerskiy and Puzachenko, 2009) have shown that the solar radiation input to exergy is insignificant and exergy has almost no connection with the biological productivity and therefore represents exclusively the energy spent on evapotranspiration and that contradicts the exergy interpretation made by S. Jorgensen and Y. Svirizhev. At the same time, the information increment closely relates to the vegetation index, thus the biological productivity is determined by the nonequilibrium degree of the system, which transforms the solar energy. "The evaporation work is primitive, does not require a high degree of nonequilibrium and therefore does not have an origin in exergy. Exergy has sense only in relation to the part of energy, which is spent on the bioproduction. Nonequilibrium and high unsteadiness are absolutely crucial for the bioproduction process (Sandlerskiy and Puzachenko, 2009).

On the basis of multispectral measurements from Terra MODIS (Puzachenko *et al.*, 2016), and Landsat (Puzachenko *et al.*, 2013) satellites in the framework of an additive Gibbs-Shannon thermodynamic it was shown that the seasonal dynamics of the thermodynamic variables is consistent with the theory of nonequilibrium thermodynamics. The transition from winter to summer nonequilibrium state corresponds to the Kantorovich S-theorem and Haken information theorem. At the global level in the northern hemisphere, the system comes out of winter quasi-equilibrium state in March, reaching a maximum disequilibrium (minimum entropy-maximum Kullback's information in mid-July), and the information values are maximal during periods of transition. The system in March shows a maximum accumulation of internal energy, which is spent on the maintenance of its useful work and relatively slow reduction of its useful work (exergy) in the fall. An analysis of seasonal dynamics of multi-dimensional entropy calculated for combinations of values of albedo and spatial thermodynamic parameters was conducted for the first time. It is shown that the seasonal variation of these parameters demonstrate a sharp decline in the spatial entropy during the transition from winter to summer. In all parts of the planet the system tends to the most optimal ratio of the albedo in different spectral bands and keeps this ratio during the entire growing season. It has been shown that the target function of the system is to maintain a constant albedo in the PAR throughout the growing season (May–August). Heat flow is linearly related to the influx of solar radiation, and effectively controlled by evaporation heat costs. On the basis of ground multispectral measurements and measurements of entropy production on bioclimatic sites it is shown that the function of maintaining albedo constancy effectively implemented by forest communities. To a lesser extent it is implemented by meadow vegetation and for bogs a PAR self-regulation effect is nonexistent. Thus it can be assumed that the main weight in maintaining the constancy of the albedo and the biosphere as a whole lies on forest vegetation. Analysis of the dynamics of the thermodynamic variables at the regional level for North-west part of the Russian Plain showed high contribution to the regulation of the heat flow (temperature) and precipitation of the forest vegetation. Positive feedback loop between the forest and precipitation creates a trigger effect and a sharp boundary in the transition from forest to steppe. These results suggest that the forest is a key factor in the self-regulation system "biosphere and climate." By itself, the conclusion is not new, but it demonstrated the leading role of forest vegetation in the regulation of climate. However, the subject cannot be considered concluded. The analysis of seasonal dynamics of thermodynamic variables in the northern Baikal showed weak regulatory capabilities pine and larch forests greatly inferior to the capabilities of Eastern Europe forests.

Conclusion

The considered methods for thermodynamic properties of landscape cover assessment of thermodynamic variables on the basis of multispectral remote information are absolutely new and aren't yet approved by scientific community. Therefore at the present stage it is prematurely to consider the various technical details which would allow to bring together as much as possible the estimates with values of thermodynamic variables in the nature. It is very important to show that such estimates have physical sense and don't contradict with fundamental ideas of thermodynamics of open systems and comparison of the thermodynamic variables calculated on a basis of different measurement systems for different scales shows reproducible the results.
