At the same time, nature, by developing a food chain into a complex food net, allows for greater food availability and diversity for the individuals on the top of the food web or food pyramid, such as the human species, and also ensures their sustainability. However, when biodiversity of the food web is disrupted by the establishment of a monoculture (industrial cropping system) and/or when the environment is under subjection of a degradation process, a population outbreak of the more resistant or adapted members of the food web may occur such as the so-called parasites and pathogens.[12]

The soil is one of the most diverse habitats on Earth and contains one of the most diverse assemblages of living organisms, mainly in the humid tropics,[13] due to its plant diversity. In a broader view, it is advisable to consider soil as the undisassociable soil–plant interaction, mainly in the tropics and subtropics. Soil without a permanent living plant cover will lose its main function of harvesting rain and storing resident available freshwater, essential for life and biological production (food, fiber, wood, biofuel, etc.). This interaction will improve the degree of soil biodiversity, including also the rooting system architecture of the so-called weeds. Their rooting structure, as well as that of crops, may be used as a visible indicator of the degree of soil health.[14,15]

In both natural and agricultural ecosystems, the different groups of soil biota interacting with plants and their debris are responsible for, or strongly influence, the soil properties and optimize processes or ecosystem services such as soil genesis, soil structure, carbon, nutrient and water cycles, agrochemical movement or breakdown, plant protection, growth, and production.[5,16]

Soil organisms act in processes of synthesis or production, transformation and decomposition, or consumption of organic material, affecting abiotic and biotic components, transportation, and soil engineering. Therefore, soil biodiversity is a keystone for sustainable agriculture and it could be used as a good indicator of agro-ecosystem or soil health. Soil biodiversity does not necessarily refer to the number of individuals or species, but to the ratio of functional groups,[17,18] and the result or the tool of their activities, such as the presence and intensity of enzymatic activity.[12] It is necessary to remember the importance of soils.

The settlement of terrestrial environments by life was only possible by storing rainwater in rocks that nature developed to permeable soils, and these soils were maintained permeable by a triple-protection layer: plant canopy, litter, and surface rooting system. To succeed in our activities and also to meet our quality of life, it is necessary to maintain, restore, or mimic this structure and the processes involved using artificial technology.

It can be said that the disappearance of several ancient human civilizations with populations concentrated in cities was partially caused by food insecurity due to soil degradation, combined with freshwater shortage due to destruction of forests and soil permeability, therefore reducing the long water cycle, and by lack of sanitation and waste disposal affecting public health.[19] These problems of slowing down or disrupting ecosystem services are at present global in scale, with the emergence of a new problem—global warming and climate change. Besides, there occurs programmed or accidental inclusion of poisons, toxic substances, heavy metals, nitrates, phosphates, hormones, etc.

To have an idea of the current importance of the whole biodiversity, the monetary value of 17 ecosystem services required to sustain life and the biological production capacity of landscapes was estimated to be about $33 trillion/yr, against the $18 trillion of the global gross domestic product (GDP).[9]

What Destroys Biodiversity and Ecosystem Services?

This can be answered by the simple elimination of plants covering the soil and the prevention of their complete regrowth and occupation of soil surface, as well as by turning the soil impervious, by crusting, compaction, pavement, etc.

How Do We Take Care of Biodiversity and Essential Ecosystem Services?

An interesting point is that, instead of considering the natural climax ecosystem as reference for good environmental practices, we use the primary natural ecosystem (rocky landscape) as reference for characteristics we do not want in our agricultural or urban ecosystems. The following are environmental characteristics we have to avoid in our management program: the primary environment has no capacity to store water; it has no biological carrying capacity for higher species; it sustains no food chain nor web; it presents a very short water cycle (rain, evaporation and runoff); and it shows high temperature and air humidity amplitude during the day.

Hence, primary environments are unsuitable for life and production. For example, land and soil degradation will turn life- and production-friendly environmental characteristics into life- and production-unsuitable conditions (with impervious, compacted, dry, hard soil, like a rock), similar to that occurring in primary natural ecosystems.

Considering the growing soil and landscape degradation, for example, due to further erosion and salinity, we need to be aware that the process of desertification[23–25] is a great challenge in dry lands. These dry lands support 44% of all cultivated systems and are the origin of 30% of world's cultivated plants.[26,27]

Thus, first of all, we need to stop the landscape and ecosystem services degradation, by conservation practices. The second step is to recover soils and landscapes by simple harvesting and storing rainwater, and reducing water losses, e.g., by runoff or evaporation in excess, by protecting the soil surface against erosion, and by allowing the growth of a diverse plant cover, to turn the soil permeable and to stabilize air temperature and humidity.

It is necessary to prevent the destruction of the whole plant cover and their debris. The biologically diverse green areas in rural and urban environments are mandatory. Under tropical and subtropical conditions, this means that we have to avoid large-scale areas of pasture or cropland or buildings (cities) without trees. A permanent tree cover is important to maintain the evapotranspiration and windbreak service and to stabilize air temperature and humidity.[8]

Considering that the greatest land-use change, with massive deforestation, is mainly for agricultural purposes (as well as for wood harvest, coal production, and mining activity), it will significantly alter the micro- and mesoclimate in a region, increasing infrared radiation and heating up of lower atmosphere, and because it will promote the significant degradation of other essential ecosystem services due to its scale, agricultural practices based on ecological principles are advisable.

For large areas, the first step should be the practice of conservation agriculture[20] complemented by windbreaks and vaporizing tree cluster. For small areas, agroforestry[21,22] production systems are useful, mainly under tropical and subtropical conditions, considering that the tropics are the engine of global climate dynamics. Without trees, the heat production over terrestrial areas will be greater, the cloud production will be smaller, and the climate dynamics will be faster or stronger, more dangerous.

Examples of successful ecosystem services restoration are those in conservation agriculture[20,28–30] agro-ecological production systems,[31–33] and agroforestry,[34–39] aside from forest management[40] and those biodiversity conservation practices[41,42] that substitute paid environmental services for free ecosystem functions or services, by using ecological principles.

Also, the need to reduce the use of toxic substances, as well as the production of wastes and their random release to the environment, is urgent. Gaseous wastes affect human and biodiversity health, especially when considering the troposphere ozone and acid rain production, the increasing carbon footprint, and the large amount of smog production, brought about by landscape fire, fire from furnaces (used for coal production), or fire from household wood-burning stoves. Liquid waste degrades freshwater, turns it dangerous for human health, and increases freshwater shortages. Solid waste released in large amounts on the landscape will reduce land and water quality and will increase the ecological footprint.

The best indicator of biodiversity that provides adequate ecosystem services is when we have a greater number of plants per unit of area. Plants are associated with fauna and microorganism.[6]

Which Tools Should Be Used to Improve Biodiversity?

Considering the process nature uses to develop a certain site, or to recover a degraded soil or land under fallow, it could be seen that plant diversity is the key tool used. This is because it allows the complementary activity of individuals with different structures, functions, wastes (debris, root exudations, and others), and needs to flourish in one of the different habitats created by the diverse interaction of the abiotic and emergent biotic factors occurring.

Therefore, vegetative techniques to recover the permanent diverse plant cover together with the improvement of environmental legislation and education are in place.

Environmental Health

What Is Environmental Health?

According to the World Health Organization,[43,44] environmental health addresses all the physical, chemical, and biological factors external to a person, and all the related factors impacting behavior. It encompasses the assessment and control of those environmental factors that can potentially affect health. It is targeted towards preventing disease and creating health-supportive environments.

Which Environmental Conditions Will Affect Health?

Ecosystem degradation or disruption can impact on health in a great variety of ways.[43–46] The most important ones are freshwater pollution (lack of sanitation), contamination (heavy metals, hormones, poisons, and excess of medicines), and degradation (siltation and increase of nitrates and phosphates).

Perhaps we need to have a broader view of what is environmental health, considering that persons are also participants of our environment. In a health environment, for example, aside from waterborne diseases due to pollution and acute and chronic respiratory diseases due to air pollution, we need to also consider malnutrition due to food lacking micronutrients, extreme heat and very low air humidity, lack of education and training, low (or no) income, and so forth.

What Is the Importance of Environmental Health?

A healthy environment, with its natural resources and main structures conserved or improved, will allow the ecosystem services to run in order to benefit our well-being. A healthy environment will provide enough clean, fresh water (150 to 200 L/person/day); it will secure food (1500 to 2000 kcal/person/day, without toxic or dangerous substances and contaminants); it will provide clean air with enough humidity (around 10 g water as vapor/m^3 air, or 40%–60% relative humidity in a range of 20–24°C, the comfort range, without solid microparticles, smog, dangerous gases and substances, and inconvenient odor); and it will lead to stabilized temperature.

An excess or low level of air humidity will bring about and increase the occurrence of several diseases.[47] Unprotected surface/soil will produce higher temperature (Figure 1) and therefore greater amount of long-wave infrared radiation, heating up the lower atmosphere. In addition, increasing air temperature will mainly result in decreasing air humidity, because of the increase of atmospheric demand for water, when no water is available to be evaporated or transpired by plants (Figure 2).

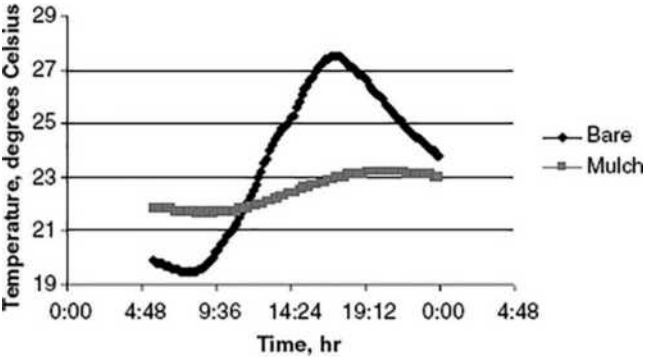

FIGURE 1 Temperature variation (amplitude), at 15 cm depth, in a bare and mulch-covered soil, under tropical conditions (November). The graph shows that it is possible to manage temperature extremes using mulching technique.
Source: Adapted from Torres (1997) in Primavesi.[8]

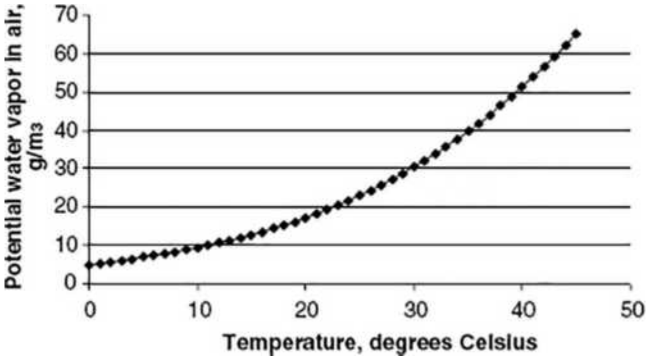

FIGURE 2 Relation between air temperature and potential water demand for air saturation.
Source: Adapted from Addams et al.[52]

Heat in excess, above 30°C, will sharply increase the productivity loss of labor and increase the mistakes or errors in the production line,[48] while polluted and dry air will increase respiratory diseases.[47] Polluted water will cause several gastroenteritis processes.[49–51] Human health degradation will cause problems for the production system, the health care service, and to our well being, with expectation of an earlier death.

What to Do?

The reactivation of the ecosystem services is needed, with the restoration of biodiversity, on a permeable soil, increasing rainwater yield and storage. It is also necessary to reduce waste production, by reduction, reuse, and recycling, as well as by neutralizing and adequate disposal of all harmful materials. We need to use water more efficiently.[52]

Another very important point is to stabilize air temperature (avoiding extremes) and air humidity amplitude, by restoring green evapotranspiring areas, by establishing shade (Table 1) or soil cover (Figure 1), or by managing the surface albedo.[54–62] Nature manages albedo or sunshine reflectivity in function of available liquid water. Water bodies, humid soils, or live plants are darker (with lower albedo) and may absorb more sun energy than dry surfaces, dry leaves (straw), or solid water (snow and ice) fields (with greater albedo).

A notable complementary problem is when fire use is routine in landscape management,[63] especially in dry periods, turning the albedo very low (black surfaces), increasing the heat, and therefore knocking down air humidity and quality, affecting health. Since we have global areas experiencing water shortage[64] [being dry for moderate (3 to 5 months) to long (>6 months) periods], this may result in

TABLE 1 Temperature of Shaded and Unshaded Surfaces in the Tropics

	Temperature		
	Shaded	Unshaded	Increase
Surface	°C		%
Green lawn	32	35	9
Dry lawn	35	52	48
Concrete	37	52	40
Asphalt	37	57	54

Source: Addams et al.[5]

heating up of soils and surfaces, with temperatures above 52°C,[65] and this will produce atmospheric heat in excess (>300 W/ m^2),[66] surprisingly where there were no forests.[67]

Trees, due to their darker color, will absorb more sun energy and produce more heat, warming up a cold environment, but when air temperature rises above a certain level, it starts the evapotranspiration process, keeping away the heat in excess. Trees may warm up and cool down an environment, depending on the need. Therefore, it is advisable to make a global effort to plant trees (forests) and manage agroforestry systems to restore ecosystem services such as temperature and air humidity stabilization, as well as to maintain a longer water cycle with more and better- distributed rain.[68–76]

It is necessary to take into account that there are biophysical limits for economic growth (adjusted to nature's biological carrying capacity), which are mainly responsible for pollution as well as for biodiversity and land degradation. From the nine main limitations (biodiversity loss, nitrogen and phosphorus cycle, climate change, acidification of seawater, ozone reduction in stratosphere, freshwater availability, change of soil use, chemical pollution, and aerosol pollution in atmosphere), we did trespass the first three, endangering our health and livelihood.[77]

Indicators of Improvement

The presence of biodiversity developing on permeable soils and the absence of pollution, waste disposal in landscapes, and contaminants result in clean freshwater, soil, air, and food.

Tools to Be Used

Processes and tools based on ecological principles and processes to recover soil permeability (Figures 3 and 4), biodiversity, and ecosystem services need to be used. The keystone of the food web we depend on is plants, especially those with healthy roots. Roots need to be in aerated and humid soil, protected (against temperatures above 33°C, which harms root health), and rich in organic material.

The concept of integrated natural resource management considering the watershed scale, aside from integrated and efficient water, fertilizer, and pest management, is advisable. In relation to waste disposal, pollution, and contamination, environmental technology, eco-technology, and cleaner technology are all in place. In the case of fossil fuel use, the reduction of wasteful use and the substitution by alternative renewable energy sources are advisable. In all cases, improvement in environmental legislation and education is necessary.

Sustainability

What Is Sustainability?

In biology, sustainability means the processes running to maintain biological systems diverse and productive over time.[5] In 1987, the World Commission on Environment and Development established a definition of sustainability, known as the Brundtland Report. It stated that sustainable development should reach the needs of the present without compromising the ability of future generations to meet their own needs. Although this definition has become widely publicized, the term *sustainability* is not limited to one precise definition.[78]

Several authors have discussed the real meaning of sustainability and sustainable development.[16,28,79] Munoz[80] has presented a theoretical model of true sustainability or sustainable development ideas with global to local implications based on the need to balance social, economic, and environmental goals; stakeholders' interests; and issues to induce or determine fairer or more appropriate development solutions, options, and actions.

However, the social component can be seen as part of the environmental component, and the interaction of a health and developed environment (essential ecosystem services running) with educated, trained, organized, and health persons will generate a long-lasting economic component. Hence, the environmental component is the keystone, to sustain the virtual world as well, and only its improvement and quality will allow us to reach a stable social welfare and a sustainable economic profit.

What Is the Importance of Sustainability?

Historically, the first known examples of worry on sustainability, and the establishment of a definition, were from those growing up in the forestry sector, and this is because of wood shortage for a salt mining activity in Germany or for house building and coal production in Japan. Both cases resulted from poor forest management and overexploitation. The question was, "What should we do to maintain a constant wood yield and cash flow for current and future forest owners', managers', and local workers' livelihood?" This question was discussed since 1442 in various regions of Germany, where wood consuming salt-mining activities did occur, and the concept was formulated firstly in 1650 in Saxonia (Germany) and later, independently, in 1666 in some deforested regions of Japan.[81]

The idea was that regenerative living resources, like wood/trees, could only be used/harvested in the same amount of the natural regrowth/recover/refill (with no use of external inputs, like water, energy, or fertilizer), and this by maintaining productivity, vitality, rejuvenation capacity, and biological diversity, in a time span of around 120 years (the time needed by trees to grow for cutting), to avoid natural resource shortage, labor and cash shortage, and livelihood and health problems (mainly related to erosion and flooding).[81]

In 1732, the idea on sustainable use of forest was published for the first time by von Carlowitz, and in 1795, Georg Ludwig Hartig described how to manage a sustainable forest.[81] History shows us also that a sustainable activity may last for 5000 years and more.[82]

Related to sustainable forest management, the current definition is as follows: "The stewardship and use of forests and forest lands in a way, and at a rate, that maintains their biodiversity, productivity, regeneration capacity, vitality and their potential to fulfill, now and in the future, relevant ecological, economic and social functions, at local, national, and global levels, and that does not cause damage to other ecosystems."[40]

Nature teaches us that the real development process of a natural primary environment occurs with the development or restoration of a permeable soil, protected by a diversified vegetation cover with an active rooting system, and the return to soil of diversified organic material, the energy source for the diversified and active soil life.

The soil–vegetation and associated biodiversity interaction could improve the available resident water of a site and also a longer water cycle. The more resident water, the more vegetation and the more permeable the soil, in a growing feedback loop. With greater amounts of available resident water-permeable soil-diversified vegetation and soil life, there is also an improvement in micro- and mesoclimate, with an increase in relative air humidity and a decrease in the maximum temperature and thermal amplitude, characteristic for desert environments.

This friendlier mesoclimate helps more sensible plant and animal species to establish and improves biodiversity, with their additive and emergent characteristics, mainly observed in the humid tropics. Ecology considers desert ecosystems sometimes as sustainable as drier tropical forest ecosystems, due to their richness in biodiversity. Thus, what level of environmental sustainability is desirable? It depends on the biological carrying capacity we want.

The biological carrying capacity represents the concept of primary productivity of an ecosystem, or the rate and amount in which energy is stored by photosynthetic or chemosynthetic activity of the producer organisms as organic substances, food for the food web.[5] The biological carrying capacity also considers the feeding capacity of grazing cattle, or grain equivalent available for humans (4 or 16 persons/ha/yr, with a minimum need of 1000 kcal/day), calculated as available digestive energy or calories per surface unit and year. The biological carrying capacity depends on the recovering capacity of a site (resilience) to produce biomass, after yield, extraction, degradation, or pollution activities.

Hence, considering the exuberant flora and biomass production by the Amazonian forest, the question arises: What is the biological carrying capacity of the around 40% sandy soils (<15% clay content) in the Amazonian basin without that great vegetation and the aggregated or dependent mesoclimate? Something similar to the Sahara? This example shows that the biological carrying capacity may be managed in a certain range by improving the natural resource structural tripod of resident water (harvested and stored rainwater) in permeable soil (organic matter rich) under biodiverse, permanent, alive plant cover and the ecosystem services.

Some agricultural production systems—although their processes result in improvement in environmental characteristics, income, and social inclusion—are not sustainable, because of their great dependence on external inputs [fertilizer, energy, water (including fossil underground water), and technical support]. We could observe, however, that, with time, it is possible to reduce part of this dependence, by switching to more organic and biological processes, after building up a minimum of fertility and organic matter level in soil, and introducing nitrogen-fixing leguminous trees. The goal of such process is to be more efficient and productive while maintaining or improving environment (natural resources) quality.[29]

What Needs to Be Focused on Sustainability?

Considering that the main objective of all human activity, from a global to a local scale, is to promote life and its quality, environmental sustainability will be reached when the biological carrying capacity is adequate to supply the minimal health life requirements of a given human population.

An increase in the biological carrying capacity level will allow a rise in human population density. Instead of this, what occurs now is the destruction of the main natural resource structures and functions (or ecosystem services), a decrease in the biological carrying capacity with an increase in human population density, and an increase in the production of solid, liquid, gaseous, and radiative wastes, thrown randomly in landscapes and marine ecosystems. We are currently watching a global ecological regression process of terrestrial and marine ecosystems, back to conditions unsuitable for human health, livelihood, and life.[8]

We need to reduce losses and wasting of materials, as well as to avoid pollution and contamination of natural resources and products.

Which Indicators Are Usable?

First, we need to reduce our ecological footprint (optimal land use),[83–88] our water footprint (optimal and efficient water use),[89–93] and our carbon footprint (carbon equivalent production in processes and carbon cycle)[94–96] by turning our production systems or life system more efficient and adequate to the global ecosystem carrying capacity. The measure of total sun energy use[97–100] is perhaps the best way to measure and turn the processes more sustainable.

Which Tools Should Be Used?

The following are the main tools we need to use: primarily, knowledge on ecological principles and processes;[5,97] a better understanding of the processes using energy, land, water, and primary products; a retooling of the processes to turn them more efficient, using materials more harmless to the environment and health; and a reduction of waste disposal in ecosystems. All of these are geared towards improving environmental legislation and education.

Conclusion

It is necessary to stop the degradation or regression and pollution processes of terrestrial and marine ecosystems and restore their health. The processes nature uses to develop complex resilient ecosystems with great biological (including human) carrying capacity are known. To conserve, restore, or improve a sustainable and healthy planet with the immense carrying capacity of the human species, biodiversity and ecosystem services should be considered, based on the ecological knowledge of essential natural structures and processes.

Moreover, as in nature, all kinds of wastes need to be reduced and recycled. Our technologies and processes need to maintain, restore, or mimic natural structures and processes to succeed and improve sustainability. A global awareness on the ecological principles and processes for a regional planning of the integrated local participatory activities to restore, maintain, or even improve the environmental health for sustainability of human societies is necessary.

Biofertilizers

J. R. de Freitas

Introduction

Biofertilizers include microorganisms and their metabolites that are capable of enhancing soil fertility, crop growth, and/or yield. These include both indigenous microbes and microbial inoculants, that is, microorganisms that replace fertilizers or increase a crop's fertilizer use efficiency. Soil microorganisms such as bacteria, ectomycorrhiza, arbuscular mycorrhizal fungi, and soil algae, especially the N_2-fixing cyanobacteria have potential as biofertilizers. Nitrogen-fixing inoculants based on *Rhizobium* species were among the first biofertilizers introduced into agroecosystems back in the 19th century. In the 21th century, biofertilizers will become an increasingly important area of research and development.[1] The use of fertilizers and pesticides has increased steadily since the 1970s; consequently, concerns about the impacts of these chemicals on land, air, and water have become significant environmental issues. Biofertilizers provide an alternative to agricultural chemicals as more sustainable and ecologically sound practices to increase crop productivity. Biofertilizer sales forecasts in the United States for the years 2001 and 2006 represent $690 million and $1.6 billion, respectively. Examples of some biofertilizers currently in use worldwide are shown in Table 1.[2]

TABLE 1 Organisms, Mode of Action, Crops, and Producers of Biofertilizers Currently in Use for Agriculture

Type	Mode of Action	Crop	Used in
Rhizobium spp.	N_2 fixation	Legumes	Russia; several countries
Cyanobacteria	N_2 fixation	Rice	Japan; several countries
Azospirillum spp.	N_2 fixation	Cereals	Several countries
Mycorrhizae	Nutrient acquisition	Conifers	Several countries
Penicillium bilaii	P solubilization	Cereals, legumes	Western Canada
Directed compost	Soil fertility	All plants	Several countries
Earthworm	Humus formation	Vegetables, flowers	Cottage industry

TABLE 2 Market Price and Potential Price Increments with Yield Increases of 5% and 25% in Selected Vegetable Crops

		Price Increments ($ per acre)	
Vegetable Crop	Market Price ($ per acre)	5% Yield Increase	25% Yield Increase
Carrot	4,520	226	1130
Cauliflower	4,179	209	1045
Celery	10,132	507	2533
Cucumber	3,296	165	824
Lettuce	5,882	294	1471
Tomato	9,966	498	2492

Market for Biofertilizers

The market potential for biofertilizers includes the high value vegetable industry. A comparison of the base value of various crops and the increased value that can be obtained as the crop yield rises is illustrated in Table 2. Due to high nutrient requirements and high susceptibility to diseases, vegetable growers spend substantial amounts to protect this valuable produce. For example, average broccoli and tomato crops grown in California require ca. $62 and $170 worth of fertilizer and/or fungicide per acre, respectively. When the U.S. government prohibits the use of methyl bromide as a soil fumigant, as anticipated in 2005, development of biological products will be stimulated as an alternative to the use of chemicals.[3]

Mechanisms of Growth Promotion

The mechanisms covered in this entry are those that show commercial market potential; thus, it does not include all modes of action by which biofertilizers promote crop growth. Biofertilizers promote crop growth using several mechanisms with the primary one varying as a function of environmental conditions. Although the mechanisms of commercially available biofertilizers are not always entirely understood, growth promotion has been classified as the result of indirect or direct mechanisms. Indirect plant growth promotion may be associated with the repression of negative effects caused by phytopathogenic organisms, that is, biological control. Conversely, direct growth promotion mechanism may either provide some compound essential to crop development and/or stimulate nutrient uptake. Biofertilizers based on biological control agents *Mycorrhizae* and *Rhizobium* will be discussed in more detail elsewhere in this encyclopedia (e.g., Biological Pest Controls; Mycorrhiza; Rhizobia).

Phytohormones

Production of phytohormones is a commonly noted direct mechanism of plant growth promotion.[4] The nature of growth response may be the result of phytohormone production in the rhizosphere. Phytohormones are produced by many biofertilizers and include a list of plant growth regulators that are important in the plant's metabolism. For example, auxins such as indole-3-acetic acid are known for their ability to stimulate root cell division, differentiation, and promote cell elongation. Other phytohormones such as cytokinin, gibberellin, and ethylene also play key roles in plant development and have been reported to increase the growth of various commercial crops. The horticulture market for biofertilizer products based on gibberellin and other auxins is currently estimated at $600 million per year.

Plant Nutrient Acquisition

Several direct mechanisms are responsible for increased nutrient acquisition.

Biological Nitrogen Fixation (BNF)

Nitrogen (N) is an essential macronutrient, that is, it is the key building block of proteins, thus an indispensable component of the protoplasm of microorganisms, animals, and plants. The supply of biologically available N to agriculture through BNF represents ca. 140×10^6 ton/year, globally.[1] Therefore, BNF represents an economy of millions of dollars. N_2-fixation by free-livingbacteria such as *Azospirillum, Azotobacter, Bacillus,* and *Derxia* species have beenexploited in agricultural systems for many decades and constitute an important source of Ninput into agro-ecosystems.[5] Other BNF associations include the water fern *Azolla* that forms asymbiosis with the heterocystous cyanobacterium *Anabaena azollae.* The *Azolla–Anabaena* system has been used as a biofertilizer in Vietnam and China for rice production and has the potential to supply the entire N requirement (30–50 kg N/ha) for a rice crop during the growing season.[6] Another diazotroph, the N2-fixing actinomycete *Frankia,* forms nodules (actinor- rhizae) in ca. 17 genera of nonlegume wood species with *Alnus* (alder) and the genus *Casuarina* being the most important for forestry and agriculture. Estimates of total N2 fixed range between 50–250 kg/ha/year, depending on the plant species and region. However, in some cases, inoculation with *Frankia* is necessary for nodulation to occur. Ac- tinorrhizal plant species have been successfully inoculated with *Frankia* on a large scale. For example, millions of actinorrhizal trees, especially *Alnus* spp., inoculated with *Frankia* were used in land reclamation programs established in Canada.[7]

Phosphorus Solubilization

Certain microorganisms are very effective in solubilizing phosphorus (P) from insoluble phosphate compounds such as hydroxyapatite through the action of organic acids. Numerous claims have been made about biofertilizers that can enhance plant growth by solubilizing P. A classical example is the bacterium *Bacillus megaterium,* which was formulated into an inoculant under the name of Phosphobacterin in the former Soviet Union. A similar biofertilizer based on P-solubilizing fungi is currently marketed in Canada as JumpStart™ for use on wheat, canola, mustard, and N2-fixing legumes.

Microbial Siderophore Uptake

Iron (Fe) is an important plant micronutrient. Plants assimilate iron by acidifying the rhizosphere and/or secreting phyto-siderophores with subsequent reassimilation of the iron–siderophore complex. However, plants also may benefit from the direct uptake of microbial siderophor–iron complexes. For example, some biofertilizers synthesize siderophores that can solubilize and sequester Fe from soil and provide it to plant cells, thus contributing to the nutrition and development of crops. In fact, studies demonstrate that ferric pseudobactin 358 may stimulate chlorophyll synthesis in carnation and barley.[8]

Other Nutrients

Studies with *Azospirillum* spp. and plant growth-promoting rhizobacteria (PGPR) have demonstrated the ability of these biofertilizers to promote enhancement of nutrient and water uptake into the plant. For example, inoculation of winter wheat seeds with pseudomonad PGPR stimulated the uptake of soil-Fe and fertilizer-^{15}N by winter wheat cultivated in two Canadian soils.[9] Similarly, inoculation of canola seeds with a *Pseudomonas putida* increased phosphate uptake from nutrient solution.[10] In these cases, the authors speculated that plant growth regulators produced by the biofertilizers in the plant's rhizosphere stimulated root development which, in turn, enhanced nutrient acquisition.

Future Research Directions

It is clear that commercial crops can benefit directly from biofertilizers. Certainly, with the development of molecular biology and genetic manipulation of biofertilizers to improve N_2-fixation, rhizosphere competence and ability to be used together with specific chemicals, will contribute to an integrated strategy to reduce the total amount of chemicals used in agriculture. Although biofertilizer products are currently available on the market, consistency is still the major factor that limits their use. Elucidation of mechanisms, development of stable formulations, effective delivery systems, and field demonstration of effective biofertilizers will definitely improve reliability and enhance their use as commercial biofertilizers.

Ecosystems: Large-Scale Restoration Governance

Shannon Estenoz,
Denise Vienne,
and Alka Sapat

Introduction

Large-scale ecosystem restoration involves layers of complexity including, at the most fundamental level, ecological cause/effect relationships that may not be well understood, immediately observable, or measurable. Ecological complexity alone ensures that ecosystem restoration will be characterized by difficulty and uncertainty. However, in the context of large-scale ecosystem restoration, ecological complexity is compounded by other complexities including, for example, governance systems and regulatory frameworks not designed to approach restoration at the ecosystem scale and complex political interactions associated with resource consumption, private property rights, and economic development. Restoration leaders have created new governance structures, alternatively termed "collaborative resource governance" (CRG) or "collaborative environmental management," designed to work through and around such layered complexity.[1] While these structures vary in form and scope across restoration programs, there are common threads among them that include the scale and complexity of problems they are designed to address, emphasis on locally tailored solutions, the allowance for experimentation and dynamic adaption, and the importance of information sharing and collaborative problem solving at multiple overlapping levels.[2] The main focus of this entry is on the nature of CRG as a means of managing complexity and cross-jurisdictional issues in large-scale ecosystem restoration. In doing so, we review the evolution of these approaches in environmental and ecosystem management and the characteristics, challenges, and opportunities that such approaches present for governance and ecosystem restoration. More specifically, we discuss collaborative governance structures that have been adopted to manage two of the largest ecosystem restoration programs in the country, Gulf Coast ecosystem restoration and Everglades restoration.[3,4] Similar institutional mechanisms, i.e., ecosystem restoration taskforces, were put in place for both these ecosystems. These two programs present an opportunity for ascertaining whether synergies can be created in an ecosystem restoration program by cross-pollinating engagement at many levels with another restoration program.

We begin our discussion of this topic by examining how collaborative governance has emerged as one of the predominant mechanisms for addressing complex policy problems. Next, we note the evolution of environmental management in the United States toward large-scale ecosystem management through employment of collaborative governance. Although ecosystem restoration projects increasingly rely on this approach for governance and implementation, they are extremely diverse as a reflection of their political, administrative, and environmental contexts. Thus, the following section attempts to derive important lessons gleaned from these specific projects. Then, CRG will be defined as a distinct type of governance model that exhibits several general characteristics. A specific example of CRG, the ecosystem restoration task force model is the focus of the final sections. The Florida Everglades and the Gulf of Mexico, two of the world's largest ecosystem restoration projects that employ the task force model, will be discussed and compared. The conclusion elaborates how experience with these models can serve as the basis for future comparative research and as a guide for governance structures and environmental management.

Governance Models: Collaborative Environmental Management

Since the 1980s, collaborative governance has emerged as a predominant paradigm to resolve various policy issues, and this shift has been part of a gradual and broader movement in both the theory and praxis of public administration. Public managers have increasingly been addressing complex problems through networks, strategic partnerships, alliances, coalitions, contractual relationships, committees, consortia, and councils; these mechanisms have been used to develop collaborative mechanisms across jurisdictions, governments, and sectors. Collaborative governance approaches are thus increasingly being used in response to public demands and to deal with boundary-spanning policy problems that cannot be addressed by traditional regulatory approaches relying on single agencies and jurisdictions.[5,6]

Governance models for natural resource management have mirrored and, in some instances, even led to the gradual shift in collaborative governance, due to the emergence of various forms of partnerships and civic environmentalism that emerged to deal with environmental problems.[7,8] Reasons for the emergence of collaborative environmental management are many, overlapping, and varied. Some types of collaborative environmental governance emerged as a result of federal cutbacks, leading to civic environmentalism and citizens pushing for environmental changes.[8] For the most part, though, forms of collaborative environmental management came about as a result of the problems stemming from command-and-control measures, which often resulted in protracted conflict or failure to achieve key objectives. This led to calls for change from bureaucratic, adversarial, technology-based regulatory approaches, which were the basis for many environmental policies in the 1970s and early 1980s, to "results-based" and voluntary approaches to regulation.[9] Similar to other policy problems, calls for more collaborative measures also stemmed from the complexity of environmental problems that were not effectively addressed by conventional rule-based, top-down, and hierarchical approaches. The latter were seen as problematic in that they did not allow for more democratic forms of participation, stymied potential innovation, were ineffective in addressing multimedia environmental hazards and those stemming from nonpoint sources of pollution, and relied on unrealistic models of administrative and individual rationality.[7,9–11] To deal with these cross-jurisdictional problems, there were calls for more holistic and integrated approaches to deal with ecosystems such as large watersheds and forests. The adoption of more holistic approaches through collaborative environmental management grew during the 1990s particularly the Clinton administration; during this period, the ecosystem approach was greatly expanded both to better administer large restoration projects (such as the Everglades and the Northwest Forest plans) and to address smaller ecosystem and habitat conservation planning.[12]

Collaborative environmental management takes many forms: some entail collaboration between multiple agencies only, while others are characterized by the presence of multiple stakeholders such as actors in the private and nonprofit sectors. In some cases of collaborative environmental management, government has led the efforts; in others, government has encouraged it through grants and other incentives; and, at times, the efforts at collaborative management have been pioneered by other stakeholders such as citizens or nonprofit groups.[13] What distinguishes these collaborative approaches from earlier forms of environmental management is the movement away from command-and-control policies toward those that are both more inclusive of and seek to incentivize public participation. The search for mutually beneficial policy solutions by encouraging broad participation from local stakeholders, underscoring the importance of consensus and voluntary approaches, and building trust-based policy networks are defining characteristics of collaborative environmental approaches. In addition, collaborative environmental governance also involves improvements in scientific understanding of how ecological processes affect resource outcomes across artificial jurisdictional and political boundaries[14] and careful scientific monitoring to allow for managerial adaptation as necessary.[12]

Since collaborative environmental governance is an institutional mechanism for natural resource management, its development and success may depend on the set of institutional rules applied in ecosystem management. As noted by Elinor Ostrom, successful institutions tend to have certain design principles, such as rules adapted to local circumstances, clearly defined resource boundaries, information about resource variability, monitoring and sanction mechanisms, and local conflict resolutions forums.[15] While these principles may not ensure success, they could be contributory factors, as noted in our discussion about CRG structures adopted for large-scale ecosystem restoration.

In the next section, we discuss how collaborative governance approaches have been used in ecosystem management, which has seen a shift from place-based to species-based conservation.

Collaborative Governance Approaches and Ecosystem Management

Over the past 30 years, place-based and species-based approaches to environmental conservation have been giving way to more holistic and collaborative approaches to ecosystem management.[16] The earlier strategies involved prescriptive, or command-and-control, regulatory approaches that targeted discrete, identifiable sources of environmental damage.[17] Traditional regulatory approaches target the "low-hanging fruit" with respect to environmental problems, but they are insufficient for resource management and the restoration of ecosystems that are subject to multiple interdependent and interacting conditions, lacking clear or easily discernable sources of damage.[17] Collaborative ecosystem governance is a response to seemingly intractable environmental problems that do not fall neatly within the domain of any one governmental jurisdiction or agency.[1] Comparatively speaking, there is a great deal of variation in how such collaborative governing bodies are convened, their constellation of participants, the type and pattern of interactions, and the ecosystem problems they manage.

On the surface, these diverse institutional arrangements appear to be distinct problem-specific environmental responses because they conform to the particular resource systems they are designed to manage. However, collaborative ecosystem governance models share common characteristics that set them apart as a distinctive alternative to the traditional legal and institutional approaches relied upon for environmental management.[2] Furthermore, since they are characteristically more flexible, participatory, deliberative, and heterarchical forms of organization, they are considered to be more responsive, legitimate, and effective. Yet, little is known about the preconditions for their effectiveness or the ultimate consequences for democratic processes.[16]

The concern for democratic process is not inconsequential, and it is twofold. In the most general sense, the nature of these new governance structures precludes direct lines of political accountability. The decision-making process encompasses a diverse range of public and private actors along with nonelected administrators, and it supersedes jurisdictional authority. This not only threatens political accountability but also can be an impediment to collaboration to the extent that it undermines the political autonomy of participants. For example, governors are likely to be faced with choosing which to subordinate—the political will of their state or the will of the collaborative governance structure. In the case of interstate water compacts, this dilemma lies at the heart of legal conflicts. Despite commitment to interstate water agreements, legal recourse is often the only viable mechanism for conflict resolution when public officials are trapped between the terms of their compact agreements and evolving demands of their constituencies.[18] Given the long-term nature of these governance models, the challenge is to address both the issue of democratic process and strategies for maintaining broad-based public support and the political will necessary to sustain and inform them.

Opportunities and Challenges of Large-Scale Ecosystem Restoration

There are numerous challenges presented by collaborative ecosystem governance that stem from the complexity inherent both in the nature of large-scale ecosystem restoration and in the governance models themselves. Conceptualizing resource management as ecosystem management expands the range of considerations to include multiple competing uses and users, nonpoint sources of damage, nonlinear environmental reactions, and uncertain interactive effects and threshold points. The corresponding governance models are no less complex because they involve designing governing arrangements to accommodate specific environmental issues that are often framed by competing economic, political, and social contexts. As such, they necessarily overlap political jurisdictions and the functional boundaries of agencies, and they encompass multiple levels of governmental decisionmakers, regulatory bodies, and nongovernmental participants. Sustaining active cooperation, maintaining public and political support, and securing sufficient commitment resources necessary for uncertain and changing environmental problems over an indeterminate time frame are just some of the practical challenges. At the same time, embracing postsovereign governing arrangements, "rolling-rule" regulatory models, and adaptive management techniques represent paradigmatic shifts that entail philosophical challenges, which depend on more fundamental changes.[16,17,19,20] Reliance on intersovereign agreements and sovereign-dominated approaches has not been an adequate match for the scale of ecosystem problems particularly when they merely result in lowest-common-denominator agreements on uses and measures.[19] Nevertheless, expanding the range of issues addressed and the number of parties involved in governance raises questions about the role of government in facilitating effective decisions operating outside direct political control and in the "shadow of hierarchy."[16] In addition to overcoming philosophical and practical challenges, there is the additional challenge of designing the appropriate governance structure given the context and the particular ecosystem problem to be addressed.[20]

The propensity to focus on the challenges overlooks important opportunities presented by large-scale ecosystem governance. Collaborative environmental management offers a highly dynamic and participative approach to policy implementation that integrates localized knowledge and scientific learning into future decisionmaking.[2] Adaptive management approaches are more conducive to experimentation required in conditions of uncertainty, allowing for creativity, flexibility, and learning.[17] Broad-based participation improves the public and political buy-in necessary for credibility and legitimacy, the commitment and pooling of resources, and long-term collaboration.[20] Moreover, collaborative governance models offer an opportunity to address long-recognized challenges presented by the decentralization and devolution of government and related concerns about democratic control associated with the increasing discretion afforded networks of administrators and nongovernmental actors in performing functions of the state. The state has an important role to play in preventing dysfunction and facilitating these governance models by ensuring democratic processes and integrating technical and normative considerations toward effective implementation.[16] Distinct from networks of policy actors, public–private partnerships, or devolved federal responsibilities, CRG is a much narrower, issue-specific, model of democratic governance.

Collaborative Resource Governance

Collaborative resource governance can be defined as a diverse group of public and private stakeholders working together to address shared problems that extend beyond their individual capacities.[1,16] Unlike other policy configurations common in the literature, such as public–private partnerships, policy networks that seek to influence government, or networks of government actors that informally coalesce around "wicked problems," they are distinctive problem-solving, polyarchic governance models focused on complex ecological problems that overwhelm the capacity of the sovereign state.[17] Although examples of CRG vary in scale, focus, and structure, they are an increasingly important focus of research for the purpose of ascertaining factors that determine their effectiveness, the specific role of the state, and their level of success in managing large-scale ecological problems.[20,1]

The form a collaborative governance model assumes depends on environmental, political, and economic contexts. Comparative research is beginning to identify specific factors that contribute to how they function, as well as emergent concerns. For the most part, the diversity of these initiatives belies similarities among them. Some defining characteristics of CRG are its hybrid public-private structure, the scale and complexity problems they are designed to address, emphasis on locally tailored solutions, the allowance for experimentation and dynamic adaption, and the importance of information sharing and collaborative problem solving at multiple overlapping levels.[2] Success, on the other hand, is highly dependent on how they are organized, funded, and governed.[21] Integrating science into the decision-making process has also been seen as critically important, necessitating broad-based participatory processes that preclude science from being manipulated, or trumped, by the political process.[20] Process is just as important as structure for ensuring flexibility and adaptability in order to incorporate new scientific information and to make necessary course corrections. Despite the dependence on nongovernmental actors and decentralized and fragmented approaches, there is a critical role for government in providing definitional guidance, participatory incentives, and enforcement capabilities.[16] One common problem is that most initiatives severely underestimate the expense (financial, time, and personnel investment) of collaborative approaches to ecosystem management relative to traditional regulatory approaches.[20] Examples of CRG programs are indicative of specific lessons learned.

The Chesapeake Bay Program is generally acknowledged as one of the oldest and most organizationally successful of these programs despite questionable improvements in water quality.[17] It exemplifies the importance of having reliable mechanisms in place in order to facilitate participation, public outreach, and the integration of scientific information into decisionmaking.[20] Diffuse governance that is not contained by traditional political authority requires special effort not only to capitalize on the respective strengths of participants but also to cultivate legitimate and credible processes.

The California Bay-Delta Program (CALFED) has demonstrated the importance of generating broad-based scientific input, instituting internal and external peer review of scientific proposals, and devising conceptual models for communicating scientific information to decision makers and stakeholders. The CALFED has also shown the benefit of dedicating facilitators and planners to ensure vertical integration and secure long-term funding. However, problems did emerge with CALFED; for instance, several independent reports criticized its governance structure, stakeholders moved water management decisions outside the CALFED process using environmental litigation, the executive director and lead scientist resigned in 2004, and faced with mounting criticism, the CALFED Bay-Delta Authority voted to disband itself in 2005.[14]

The Comprehensive Everglades Restoration Plan (CERP) is an example of how clearly defined problems and agreement over the urgency of an environmental issue can coalesce political and financial support. However, CERP is also an example of how political tensions between state and federal levels can impede cooperation. These tensions stem in part from prematurely determining CERP's organizational structure and possible alternative solutions for Everglades restoration prior to scientific involvement, which constrained options by favoring methods preferred by the United States Army Corps of Engineers (USACE).[20] The CERP has demonstrated the benefit of adaptive monitoring in the early stages of new strategies and also, for the sake of long-term goals, the need for clarifying performance measures and indicators.

Since the 2010 oil spill, the Louisiana Coastal Area Ecosystem Restoration Program (LCA) has transitioned to the task-force model followed by CERP. However, problems with its previous model are instructive. The LCA, like CERP, experienced state-federal tensions for differing reasons but which were also exacerbated by restrictive control under the USACE. Options available to the LCA were severely constrained by political pressures by powerful stakeholders. Still, the LCA's structure and processes were not adequately designed to facilitate broad-based participation, generate public buy-in, or integrate science in ongoing decision-making.[20] The result was an excessive focus on local symptoms to the exclusion of root causes tied to resource practices in the Mississippi Ohio–Missouri river basin.

Lastly, the Glen Canyon Adaptive Management Program exemplifies the potential for adaptive management in these new governance models.[20] Adaptive management emphasizes learning, adjustment, and the acceptance of rolling rules rather than grounding in static regulatory or managerial approaches. However, there is still much misunderstanding about these approaches that requires education in order to facilitate a transition from traditional, static approaches to adaptive methods of regulation and localized policy implementation.[17] The experiences of these CRG programs are indicative of jurisdictional issues relating to ecosystem management that do not easily correspond with traditional forms governance or regulatory approaches.

Cross-Jurisdictional Issues

Jurisdictional issues are of particular importance to CRG because the geographic dimensions of ecosystem restoration defy traditional political and functional boundaries, presenting new challenges for environmental regulation and management. The geographic scale of an ecosystem means that it often will encompass some combination of municipalities, counties, states, regions, and nations.[17] Similarly, resource users and sources of environmental degradation are not contained by any particular jurisdiction or subsumed under any one political authority. Thus, problems neither fall neatly within the control of any particular authority nor the functional realm of any particular agency. Nevertheless, the magnitude of environmental problems exceeds the capacity, resources, and expertise of any one governmental entity.

Traditional regulatory methods are not equipped to deal with uncertainty, complexity, and continuous change. They are appropriate for targeting point-source problems but cannot account for the diversity presented by numerous local circumstances.[16] Legal scholars are examining the implications of CRG for the future of environmental regulation and the use of adaptive rolling rules more suitable to uncertainty and change.[16,17,19] Similarly, the decentralized and fragmented governance structure necessitated by the nature and magnitude of resource problems presents an enormous challenge for management. There are numerous public and private parties involved, and addressing problems of this scope depends on long-term commitment and public support. This requires managing collaborative activities of numerous parties from multiple jurisdictions and diverse functional backgrounds that often have competing interests. The challenge is not only to coordinate participants but also to sustain cooperation. Although CALFED demonstrated the importance of broad participation and "bottom-up" policy approaches, the problems that emerged highlighted the importance of having a clear direction and identifiable goals. Authority may be diffuse, but leadership is imperative in order to maintain momentum, negotiate compromises among competing interests, and translate and communicate across functions (e.g., political decisionmakers and scientists, scientists and the public, and across agency missions and cultures). Adaptive management is appropriate for CRG because it allows for experimentation, learning, adaptation, and course corrections.[17,20] Adaptive management represents a paradigm shift, and possibly a hurdle, for politicians, administrators, and regulators used to operating within defined jurisdictions. As researchers consider the list of factors that determine the success or failure of CRG as a general approach to large-scale ecosystem restoration, it is helpful to highlight one specific CRG structure that has been both in place for a considerable period of time and recently replicated. As such, may provide important and unique opportunities to increase understanding of CRG.

Focus: Ecosystem Restoration Task Force Model

The restoration of the Gulf of Mexico and the restoration of the Florida Everglades are two of the largest and most complex ecosystem restoration programs in the world.[22–24] The highest level of intergovernmental coordination for both programs occurs under the auspices of intergovernmental task forces created by the federal government. This model warrants closer consideration because although the two task forces differ somewhat in constitution and scope, there are enough similarities between them to make the case that they are two examples of a single intergovernmental coordination and governance structure. This "duplication" of a specific CRG structure in two large-scale ecosystem restoration programs provides an opportunity to observe the successes and challenges for this institutional design and structure over time in a way that cannot occur when focused solely on a structure that is unique to a specific ecosystem. In addition, the model warrants closer consideration because of its longevity in the case of the Everglades and, in the case of the Gulf Coast, its relevance to the most current and high profile issues in large-scale ecosystem restoration.

South Florida Ecosystem Restoration Task Force

The origins of the South Florida Ecosystem Restoration Task Force (SFERTF) can be traced to the fractured state of intergovernmental relationships that existed in the late 1980s due to contentious litigation between the federal government and the state of Florida over degraded water quality in the Everglades.[23] The litigation, which began in 1988 and continues today, produced a settlement agreement in 1992 that, for the time being, opened a window of opportunity to improve intergovernmental relations in order to begin addressing a broader range of Everglades restoration issues.[23,25] At the beginning of the Clinton administration, then secretary of the U.S. Department of the Interior, Bruce Babbitt, exploited the litigation lull and ushered in a new era of collaboration on Everglades restoration issues, which included the first incarnation of the SFERTF, created by Bruce Babbitt.[23,25]

Membership of this original SFERTF was limited to six federal agencies, but 3 years later, Congress created a new task force (also called the SFERTF) and expanded its membership to include nonfederal representatives.[23] The new Task Force was to be chaired by the Secretary of the Department of the Interior and was to include the secretaries of the Commerce, Army, Agriculture, and Transportation departments, the Administrator of the Environmental Protection Agency (EPA), and the attorney general. Congress allowed these Presidential Cabinet members to designate appointees to represent them; however, the statute requires that designees be at the assistant secretary or equivalent level of authority.[4] The SFERTF also includes representation for the state of Florida, the Miccosukee Tribe of Florida, the Seminole Tribe of Florida, the South Florida Water Management District, and local governments. In the same legislation, Congress directed the Secretary of the Army to develop a "... proposed comprehensive plan for the purpose of restoring, preserving and protecting the South Florida ecosystem" [(4) §§ 528(b)(1)(A)(i)-528(f)(3)].

Initially, the SFERTF was charged with a number of coordination and oversight responsibilities during the restoration plan development phase; however the statute did not include a sunset provision to dissolve or transform the SFERTF at the completion of that phase. On the contrary, over the decade that followed, the Congress wove SFERTF oversight into the implementation phase of restoration, as did federal regulations governing the restoration program that were developed in 2002.[26,27] The responsibilities of the SFERTF include consultation with the Secretary of the Army; coordination of restoration policy, strategy, priorities, and programs; the exchange of information among task force members; facilitation of intergovernmental dispute resolution; coordination of restoration science;

the support of implementing agencies; the coordination of financial reporting and budget requests; and reporting biennially to Congress on its own activities and on the progress of restoration efforts and results.[4]

Gulf Coast Ecosystem Restoration Task Force

In the spring of 2010, the Deepwater Horizon oil spill became one of the worst man-made environmental disasters in American history.[22] In total, an estimated 4.9 million gallons of oil was released into the Gulf of Mexico, resulting in short- and long-term environmental and economic impacts that may not be fully quantified or understood for years to come.[22] The emergency response to the Deep-water Horizon crisis required significant intergovernmental coordination to address rescue and recovery, well closure, and cleanup.[3,22] During the response period, U.S. President Barack Obama ordered the Secretary of the Navy, Ray Mabus, to develop a vision for moving from response to recovery and restoration in the Gulf of Mexico.

The so-called "Mabus Report" was released in September 2010 and took an expansive view of Gulf restoration that went beyond ecological damage caused by the oil spill and included consideration of the broad range of ecosystem challenges in the Gulf and Gulf Coast that preceded the Deepwater Horizon crisis.[22] Secretary Mabus issued a set of recommendations, which in part focused on short- and long-term intergovernmental coordination in the recovery and restoration effort. The secretary recommended that Congress establish the Gulf Coast Recovery Council to coordinate federal, state, and tribal restoration and recovery actions and to coordinate with and support activities conducted under the Natural Resources Damage Assessment (NRDA) process.[22] However, the Secretary also recommended the immediate designation of a lead federal restoration agency and the immediate creation of the Gulf Coast Restoration Task Force. The executive branch of government could carry out these recommendations without Congressional action. Mabus suggested that the task force initiate the development of a restoration and recovery strategy for the Gulf and pointed out that if Congress acted to establish the recommended council, it could subsume the task force.[22]

A month after the release of the Mabus Report, President Barack Obama created the Gulf Coast Ecosystem Restoration Task Force (GCERTF) by Executive Order.[3] The President's order states that "[t]o effectively address the damage caused by the BP Deepwater Horizon Oil Spill, address the [sic] long-standing ecological decline, and begin moving toward a more resilient Gulf Coast ecosystem, ecosystem restoration is needed" (Section 1). The Executive Order specifies federal membership of the GCERTF as including "senior officials" [Section 2 (a)(1)] of the Departments of Defense (Army Civil Works), Justice, Interior, Agriculture, Commerce, and Transportation; the EPA; the White House Offices of Management and Budget and Science and Technology Policy; and the White House Councils on Environmental Quality and Domestic Policy. The task force includes representatives of the five Gulf coast states and has the authority to add representatives of affected tribal governments.[3] The GCERTF was created as an advisory body to coordinate intergovernmental restoration efforts, support the NRDA process, present to the President a strategy for Gulf restoration, coordinate scientific research, engage stakeholders and the public, and report to the President biennially on the progress of the restoration strategy.[3]

Common Threads between the SFERTF and GCERTF

The similarities of structure and scope are evident between these two governance bodies. Every federal agency represented on the SFERTF is also represented on the GCERTF, a reflection of the significant jurisdictional and geographic overlap between the Everglades and the Gulf Coast; both include state representation, and both are responsible for strategic planning, the coordination of intergovernmental activities and science, stakeholder engagement, and biennial reporting on restoration progress.[3,4] Both task forces are administered by senior executives of the federal government who supervise full-time staff dedicated exclusively to task force administration.

More than 700 miles of Gulf coastline and 100% of the Everglades ecosystem are located in the state of Florida, and in fact, the Greater Everglades Ecosystem includes significant Gulf Coast resources such as the Caloosa-hatchee Estuary.[24,28] This shared geography not only ensures a great deal of intergovernmental cross-pollination at both the political and staff levels, but it also ensures high levels of cross-pollination among stakeholders, nongovernmental organizations, scientists, journalists, and elected officials involved in both programs. Operational or "day-to-day" collaboration, above and beyond the collaboration that flows from formal governance structures like the GCERTF and SFERTF, is an important factor in many large-scale ecosystem restoration programs.[1] Over time, the cross-pollination occurring between the Gulf Coast and Everglades restoration programs may have synergistic effects on operational collaboration for both. These two programs may help operationalize the premise that collaboration among ecosystem restoration efforts creates synergies, efficiencies, and benefits across programs, a premise central to the mission of efforts such as America's Great Waters Coalition.[29]

Conclusion

As discussed in this entry, large-scale ecosystem restoration, as an approach to solving complex, multidimensional environmental problems, presents challenges of scale, causality, and jurisdiction that can overwhelm the capacity of a single state, jurisdiction, or authority. Configurations of governmental, private sector, and nongovernmental actors have produced a variety of collaborative arrangements in response to addressing high levels of complexity. While models vary across restoration programs and tend to pursue strategies tailored to specific environmental problems, there are identifiable common features among models, such as the integration of adaptive management principles, stakeholder engagement processes, and the incorporation of science in decisionmaking. The government's comprehensive approach to ecosystem restoration in the aftermath of the Deepwater Horizon oil spill may be an indication that CRG is an approach to environmental management that is in its ascendancy. The Gulf ecosystem restoration program borrows its model of collaborative governance from a model that has been in place in the Everglades restoration program for 16 years. This is an opportunity for comparative research on collaborative resource management that can inform future applications of CRG about specific challenges and opportunities relating to large-scale ecosystem restoration. Importantly, future research must also account for several issues that are beyond the scope of this entry. For example, a nuanced understanding of the political, administrative, and logistical challenges requires an in-depth understanding of the histories and the legal challenges confronted in each of these cases, as well as assessments of the level of success in meeting respective environmental goals.

Ecosystems: Planning and Trade-offs

Ioan M. Ciumasu,
Keith Culver,
Mihai Costica,
and Jean-Paul
Vanderlinden

Introduction

This chapter presents an updated and extended version of prior work, while retaining an earlier definition and overview of the notion of ecosystem planning—and the related prospect of reconciliation of disciplinary tensions and realities slowing progress in understanding of the merits of ecosystem planning.[1] This chapter extends the original discussion of natural landscapes and urban systems to the potentially positive roles of ecosystem planning in communities of actors and stakeholders dealing with the concurrent effects of urbanization and climate changes.

Humans have a long history of modifying their environment to suit their own perceived needs. Science and technology provide a certain, limited capacity to anticipate the behavior of ecosystems and plan a chosen set of desired ecosystem responses. However, because ecosystems are complex systems, i.e., governed by nonlinear behavior via self-organization and thresholds, true planning activities are bound to have a very limited relevance and effect. In various ecosystem contexts, some planning may or may not be possible—depending on the type and scale of the intended ecosystem responses. Therefore, it is important to define the scope of ecosystem planning. The term ecosystem planning is very rarely used in the literature, and this formulation might well be regarded as arriving with negative connotations likely to hamper the future use of the concept in disciplinary contexts. However, its simplicity and straightforwardness have a certain appeal for environmental managers in their search for a synthetic vocabulary to help them in the necessary integration of knowledge from many fields and disciplines. The term "ecosystem planning" may, for this reason, be usefully adopted in practice, albeit in epistemologically controversial ways. An eventual adoption of the term by the growing community of problem-solving-oriented environmental managers will require some substantial definition clarification efforts and responses to epistemological difficulties.

Context

Any observer of the use of the expression "ecosystem planning" in the extant literature will see it frequently used as shorthand for "ecosystem management planning," most notably in situations of management of environmental resources. For example, silvicultural practices often employ the term "planning" in the context of forest management, sometimes referring to "forest planning" or even "ecological forest planning."[2] Such contexts are typically described in terms of managerial objectives such as "multi-objective managerial planning," to which descriptors such as "ecological" or "ecosystem" are often applied to account for the natural processes involved.[3] In this context, planning seems to refer to procedures applied to attain some desired, pre-established objectives in terms of exploitation of resources. One can observe that, despite occasional claims of the contrary, the literature tends to recognize that planning refers to some empirical knowledge-related procedure to obtain a benefit *from* ecosystems, not a procedure to *make* ecosystems. Yet, this distinction is not always sufficiently clear, with certain confusions persisting in the authors' understanding of the fundamental differences between the aspiration to plan and the nature of ecosystems. Ecosystem planning is often mentioned in contexts that imply manipulating ecosystems to the purpose of obtaining desired outcomes. This fact, together with the lack of agreement on what ecosystem planning is supposed to designate, is a warning that more work is needed to clarify the concept and the practice. This entry takes on this objective and retains the original definition as baseline for further developments and reviews.

To various extents, properties of ecosystems may be changed. At one end of the spectrum (gradient) of human intervention in ecosystems is the domain of conservation biology, which mainly aims at protecting–preserving a given ecosystem (or components of it) as is.[4,5] At the other end of the gradient is "ecological engineering," which essentially pursues objectives related to "ecological reconstruction" or "ecosystem restoration" of heavily degraded areas or even aims at developing new ecosystems.[6] The term ecosystem planning incorporates an inbuilt contradiction between the self-organizing, nonlinear character of ecosystems[7,8] and the linear, human-organizing character of planning. Despite this, the incontestable global reality is that most terrestrial and water ecosystems are under some form of modification by humans and thus subject to management involving both natural ecosystem dynamics and planning. Even though nature conservation's original aim was the prioritized protection of pristine and near-pristine environments, and ecology seeks to understand natural processes, i.e., those undisturbed by human interventions, we have to deal every day, and in most situations, with ecosystems that are heavily influenced by human choice and action. Indeed, given the fact of global changes, we cannot just continue to talk about "untouched" or "wild" nature. The term ecosystem planning might, therefore, gain widespread use, in diverse circumstances, notwithstanding the epistemological difficulties it carries along.

Definition

In order to reconcile the nature of ecosystems with human planning reflexes and with the need for a practically useful, integrative understanding of the term "ecosystem planning," we propose a working definition: *ecosystem planning refers to the human activity of anticipating and inducing the generation of a set of ecosystem goods and services (EGS), within the limits allowed by the intrinsic dynamics of ecosystems.*

For our purposes, EGS are "the capacity of natural processes and components to provide goods and services that satisfy human needs, directly or indirectly." EGS involve the translation of ecological complexity (structures and processes) into a more restricted set of ecosystem functions that ground the provision of goods and services that are valued by humans. Admittedly, the term "ecosystem function" has been subject to conflicting interpretations, sometimes referring to internal functioning of an ecosystem (e.g., energy and matter fluxes, food chains, and food webs) and sometimes relating to the benefits derived by humans from the properties and processes of ecosystems (e.g., food production).[9,10]

Such semantic hesitations illustrate or perhaps reproduce the epistemological difficulties that tend to be encountered at the human/nature interface. Indeed ecosystem planning is implicit in the literature concerned with Coupled Human and Natural Systems (CHANS).[11] In the definition above, ecosystem planning is explicitly ascribed to, and constrained by, the limited human capacity to influence ecosystems. This attribute should be read as the crux of the concept and a key idea of this work piece.

Dynamics intrinsic to ecosystems, thresholds and nonlinearity, are explained by the laws of physics, and ecosystems can be understood as complex systems—with the support of complexity science. Ecosystem properties are subject to some limited influence, but they are not responsive to human planning imperatives. To use a somewhat less precise but more intuitive illustration, an ecosystem (as a multi-individual system, in terms of system biology) is analogous to a human body (an individual system) in that it can be trained and improved, and a certain number of its parts may be changed, but it cannot be changed as a system—any attempt to do so will cross organizational and functional thresholds that are steps towards its destruction. The system has its own character. It can be enlarged, squeezed, accelerated, or made more productive or more beautiful—but its essential characteristics as a system cannot be changed. Ecosystem planning is, therefore, like education of a human individual: it can aim at reaching the utilization of its maximum potential, but it cannot change its genetic endowment.

Term Uses

Viewed in isolation and out of context, the term ecosystem planning makes little sense. Its meaning and value become apparent only once it is considered in association with other types of planning and with attention to the concept's carrying of a specific understanding of intrinsic ecosystem dynamics.

Our working definition has several consequences and lessons. One is that the term ecosystem planning captures only partially the relation between humans and ecosystems. Employment of unduly broad or general meanings is harmful because they would allow (or inadvertently convey) the mistaken assumption that human action can compensate for ecosystem destruction by sheer planning. In reality, once destroyed (e.g., by overexploitation), the capacity of ecosystems to provide EGS (or "ecosystem carrying capacity" in the ecological economics vocabulary) cannot be simply restored by further planning. Carrying capacity is grounded in the ecosystem's intrinsic properties, and these develop during the long-term ecological history of the place. In economically equivalent terminology, the carrying capacity represents the "natural capital" (K_N), or, differently put, the ensemble of EGS extractable from a given ecosystem. Unlike the physical (K_P) and the human capital (K_H), natural capital is irreplaceable since it is dependent on ecological thresholds.

At this point, we should recall that one fundamental characteristic of biological–ecological systems dynamics is their irreversibility, meaning that once an internal threshold is crossed, an essential set of characteristics of that ecosystem are irremediably lost because passage across biological–ecological thresholds cannot be reversed. This is a consequence of the laws of thermodynamics and can be taken either as a source of ultimate ecological pessimism or simply a stark warning that the sustainability of human civilization allows no major mistake. In any case, the recognition of this reality is a foundation stone for many research threads that are bundled together in the heterodox tradition of ecological economics and the related concept of bioeconomy.[12–17] In the second half of the 19th century, Ernst Haeckel, while trying to understand the consequences of the Darwinian multifaceted struggle for survival, coined the term "ecology" to denote "the body of knowledge concerning the economy of nature." But this term only became popular in the second half of the 20th century after the introduction of the notion of "ecosystem" in 1935 by the British plant ecologist A.G. Tansley to describe the system of interactions between a biocoenosis (i.e., a community of living organisms) and their biotope (i.e., their environment), followed by the introduction of the notion of "ecosystem ecology" in 1953 by the American brother ecologists Eugene Odum and Howard T. Odum in the aftermath of the development of a slurry of mathematical models of interactions between species in the first half of the 20th century.[18–23]

Indeed, there is an even older notion which deserves renewed attention in the context of ecosystem planning and sustainability practice: that of geonomy (or geonomie), a term introduced by the Romanian biologist–ecologist and oceanographer Grigore Antipa, a student of Ernst Haeckel and the father of modern dioramas currently used in the museums of natural sciences. Antipa first used "geonomy" in 1909 to describe a system of rational management of natural resources within the watershed of Danube River and the Black Sea.[24] French juridical expert, economist, and urban planner Maurice-François Rouge in turn used the concept of geonomy to explain the organization of physical space and the structures and equilibria that determine the land uses from the triple perspective of geography, sociology, and economy.[25] This concept is known in English as "geonomics," a term which American economic geographer Ray Hugues Whitbeck used in 1926 to redefine human economy in its biophysical context of planet Earth.[26–28]

The concept of geonomics emerged initially from the holistic perspective of evolutionary ecology and then later that of economic geography. Both departure points lead to a shared insight which is now central to sustainability studies, namely that we must cease conceiving of humanity as distinct from or in opposition to nature, and instead recognize humanity as part of nature. This insight may be stated in more formal terms as the recognition that any economic system is a subsystem depending for its existence on a larger social system, in turn a subsystem of a natural (biophysical) system on which its existence depends.[29,30] The concept is roughly equivalent to—but is larger than, and includes—what is now known in the literature as the CHANS evoked in the previous subchapter. It is *prima facie* plausible to regard all of these terms as elements of the domain of sustainability studies—also known as sustainability science.[31,32] Yet when considered in light of the aim of ecosystem planning to achieve long-term sustainability, the term geonomy holds the special potential to structure a more coherent body of knowledge—i.e., more like a conception of a traditional discipline—than the idea of "sustainability studies" which stands as a broad reference to a collection of contributions to problem definition which nonetheless lack *inter alia* the internal consistency characteristic of recognized disciplines. This is a unique potential to foster systematic and comprehensive approaches to a problem domain. Use of such a unifying term would rally those ready to add to the early days of problem analysis a complementary conceptual picture of the landscape to be inhabited by an array of solutions. This is much more important than usually acknowledged in complex projects where agreements on values and knowledge are a prerequisite for project success.[33]

The three forms of capital mentioned above form together the total capital stock,[34] recognizing as a crucial constraint that natural capital cannot be replaced by the other forms of capital, and that local increases of the total capital stock available may occur while the utility of that stock decreases. Thus, when the natural capital on which human activity depends is depleted irreversibly, the value of the other two major forms of capital also decreases—they are rendered unsustainable by the destruction of the underpinning natural capital.

As argued by Costanza et al.[35] in a widely cited article, it is possible to imagine generating human welfare without natural capital/EGS in artificial "space colonies," but this possibility is still too remote and impractical for all but conceptual experimentation with the bounds of possibility. One additional, more practically relevant way to conceive the value of EGS is to determine what it would cost to replicate them in a technologically produced, artificial biosphere. Past experience with manned space missions and with Biosphere 2 (a vivarium greenhouse, i.e., a materially closed ecological system, built on 1.27 ha between 1987 and 1991) in Arizona indicates that this would be an exceedingly complex and expensive project. By contrast, Biosphere 1 (the Earth) is incomparably more efficient as least-cost provider of life support services for humans. Nevertheless, given the extent of constant human impact on biosphere, Earth's biosphere is maintained in equilibrium between its natural dynamics and the human factor (exerted through human technology), a situation which is likely to also characterize any sustainable future of humanity on Earth. To take this into account, it has been proposed that we should give great attention to the conditions required for a sustainable (or unsustainable) technobiosphere.[36] Nonetheless, greenhouse-based approaches enhanced with computer-controlled sensor systems (model laboratory terrestrial ecosystems called "ecotrons") can provide insights about impact of forcing of biogeochemical cycles (e.g., CO_2) and climate changes (e.g., temperature) on ecosystems[37–40] and thus support science-based planning of human interventions on ecosystems at planetary and local scales—aimed at mitigation of, and adaptation to, climate and other environmental changes.

Discussions on costs open, of course, the issue of potential valuation of EGS in a market. The concept of "payment for ecosystem (goods and) services" (PES/PEGS) remains controversial.[41,42] Consideration of an EGS-inclusive economy is nonetheless useful to the extent that it brings attention to the importance of incorporating into a comprehensive analysis such previously marginal concepts like "intangible values" (social and intellectual aspects—they are also connected with ecosystems) and "externalities" (ecosystem resources usually taken as "given" and not factored in by the current, neoclassical economics). In a review of this increasingly urgent matter, as current human consumption of EGS outstrips ecosystem production capacities, Baggethun et al.[42] have shown that the recent advances towards monetization of EGS indicate the slow progress of the concept. While monetization has helped draw policy and economic attention to ecosystems and EGS, it has also absorbed it into the logic of the aging yet still dominant neoclassical theory of economics in ways that deprive the concept of many of its initial virtues related to ecological and social values. Reviewers of the literature may observe that the incomplete incorporation of EGS into mainstream policy and decision-making is attributable to the prevalence of an approach that remains essentially disciplinary. EGS was repackaged or translated from ecology to current economics, along the way losing many of the virtues of EGC. Successful incorporation of EGS into policy decision-making will require a problem-driven (rather than a tool- or discipline-driven) transdisciplinary approach capable of synthesizing tools, skills, and methodologies. As their review suggests—reflecting wider opinions in the literature—valuation needs not always amount to an exclusively monetary valuation. This recommendation is naturally applicable to ecosystem planning in the sense discussed here.

Planning efficiency is nonetheless dependent on financial costs; EGS and PES represent essential advancements towards a solid grounding and meaningful use of the concept of ecosystem planning. However, as the initial concept has become diluted by disciplinary habits of subdivision and specialization, current developments and achievements are limited in their scope and practical utility. They are usefully and positively regarded as important initial forays into the conditions of sustainability.[43] On the socioeconomically transformative journey that is the transition to sustainability, ecosystem planning needs to factor in how much exploitation of EGS ecosystems can bear. In other words, how much of the carrying capacity of ecosystems can be consumed by humans without risking the collapse of the ecosystem carrying capacity. In this sense, ecosystem planning can draw support from the concept of "ecological footprint," an accounting tool for assessing the natural capital and its degree of depletion at various scales—individuals, cities, nations, or the entire planet. This approach uses estimates of consumption of natural resources for food, shelter, transportation, personal care, pollution absorption capacity, and other uses of the natural capital and compares it with the carrying capacity of ecosystems. This is one highly relevant tool for overall assessment of ecosystem planning: a value of less than 1.0 indicates that the ecological footprint remains below the carrying capacity of the ecosystems (at the scale taken into consideration), which means that ecosystem exploitation is within the limits of sustainability. On the contrary, a value greater than 1.0 indicates that a person, city, nation, or the entire humanity lives beyond the natural support capacity limits of the ecosystems/biosphere.[44–47] Values that surpass 1.0 are of utmost importance because any excess represents "eating up" the regenerative capacity of the ecosystems/biosphere, with the consequence that the overall carrying capacity decreases. At the planetary scale, it appears that humanity is already close to this tipping point or already beyond it, and the possibility of collapse is very real and a reason for accelerating and improving our efforts to understand and respond to this possibility.

The solutions for an effective transition to sustainability are still to be developed. At epistemic and moral levels, one option is to aim for a steady-state economy. Such a steady state would amount to a kind of plateau of development—as permitted by the Earth's carrying capacity—and would maintain this constant value in the future.[48] Another approach is to commit to "degrowth," meaning a collective decision of humanity to consume less, especially in those affluent countries that consume beyond the ecosystem carrying capacity available to them.[49] This idea is likely to encounter major social acceptability obstacles, certainly in developed countries, and especially in developing countries. The degrowth proposal appears to express a chosen rejection of the excessive monetization of intangible assets (social and cultural values) and ecosystem services. However, the grounds to be considered for sustainable development are first and foremost biophysical: natural limits cannot be overcome as they are thermodynamic realities already known for decades—since the origin of ecological economics.[50] The relevance of ecosystem planning relates to the immutable character of the physical laws: planning for a sustainable equilibrium of humans with ecosystems may be a matter of social decision-making and acceptance, but the consequences of those decisions are not. In other words, ecosystem planning will need to help humans accomplish sustainable development (and thus, survive). If this fails, collapse will follow. This is not science fiction: rather, it is a prediction grounded in history as civilizations have in fact overused their natural resources and faced collapse. At the planetary scale, this event is the natural outcome in the absence of a downward adjustment in the ecological footprint/carrying capacity balance.[51–53]

Taking this emergency seriously, Daily et al.[54] propose a conceptual frame for operationalizing the relation between humans and ecosystems, conceived as a never-ending circuit of five links (rendered in all caps here) and types of relations between them (rendered in italics here): ECOSYSTEMS → *biophysical models* → SERVICES → *economic and cultural models* → VALUES → *information* → INSTITUTIONS → *incentives* → DECISIONS → *actions and scenarios* → ECOSYSTEMS. Scenarios are developed for an applied case in Hawaii, called The Natural Capital Project, which tries to develop a scientific basis and connect it with policy and finance mechanisms, aiming to incorporate natural capital into resource- and land-use decisions on local and larger scales. This can be regarded as a useful example of current attempts to link ecosystem conservation with development and to render EGS concepts useful in policy and business. Yet, at the same time, we are far from the desirable situation when this would become mainstream practice. In the light of these considerations, the relevance of the term ecosystem planning remains ambiguous in the literature dedicated to the theory and applications of environmental/ecosystem management.

Mac Nally et al.[55] delimit ecosystem planning in a more cautious manner. By "ecosystem-based planning," they mean planning activities for biodiversity conservation purposes. Often, the expression "conservation planning" is used to the same effect.[5] Margules and Pressey[56] identify different stages of biodiversity conservation planning in relation to ecosystem services. Conservation biology (a term designating the aim of biodiversity and ecosystem conservation) is gradually converging with the concept of EGS.[57–59] Sometimes, an equally cautious alternative concept and expression are used, that of "ecosystem-based management," where planning activities are discussed in terms of the constraints imposed by ecosystem properties and dynamics in general and in specific contexts and case studies. In an extensive book on the matter,[60] Randolph uses terminology including "environmental protection," "land conservation," "environmental management," "environmental land use management," and "ecosystem management," as well as "land-use planning," "environmental planning," and "habitat conservation planning," to systematically describe the intricacies of human–nature interactions.

Among the rationales behind a potentially useful concept of "ecosystem planning," one can count earlier efforts to integrate environment planning and development via ecosystem approaches. Thus, the necessity to extend planning activities from human-created environment and modified environments to the natural environment arises from the expansion of human activities themselves. Therefore, the ideal situation of environmental planning would be one where it was not needed. This applies *mutatis mutandis* to ecosystem planning as well. The point we want to make here is that ecosystem planning may reveal itself to be not a goal per se, but a necessary practice towards an aspiration that is not yet concretized into a specific, readily measurable, or quantifiable goal. Implemented well, it will embody a managerial compromise between human activity expansion and the need to control, limit, and minimize the impact of human activities on the carrying capacity of biophysical systems.

One common feature is evident throughout the literature surveyed above, namely, the avoidance of a direct association between "ecosystem" and "planning." Instead, authors seem to be searching for new concepts to describe those actual situations where "ecosystem" and "planning" coincide. The authors surveyed are generally preoccupied with selection of the most apt definitions and ascription of the most appropriate meanings, hoping that the reality of human–nature interactions is being neither hastily misconceived nor ignored. For example, expressions such as "environmental planning" or "land-use planning" bear a lesser epistemological burden than "ecosystem planning." Such terms are general enough to avoid asserting an unnecessarily specific, contentious relation between planning and ecosystems, yet they clearly do include reference to sheer planning of use/occupancy of natural resources, especially in the case of water or land resources. Instead of being merely a matter of semantics, the expression ecosystem planning cannot be a useful concept unless it is associated with a clear distinction between employing knowledge about ecosystems and the effects of potential human action on ecosystems. The concept of ecosystem planning must help illuminate the border area between what humans know and can do about environment and ecosystems. Various disciplines and approaches can contribute to such a new understanding of "ecosystem planning." However, the lack of a compact body of literature makes the epistemological and technical reviewing process a highly demanding endeavor—a potential subject for future examinations.

In practice, however, understanding of the relation between humans and ecosystems may not always precede norms and decisions, as social rules and behaviors may not wait for detailed scientific clarifications. Kagan[61] examines ecosystem planning from a legal perspective, using ecosystem planning when referring to human activities related to environmental management and decision process over land/resources use, seemingly unaware of the ecological implications of putting together the words "ecosystem" and "planning." The main point of his perspective, however, is that it reflects a situation where ecosystems are being viewed, consciously or not, as something "out there," exterior to social matters. This is not very different from the currently dominant neoclassical view in economics, according to which natural resources and social matters are external to the economic processes and associated accounts, in the sense that they are "externalities"—their values or influences need not be accounted for in setting and operating a core process towards a desired outcome. All those narrow perspectives, however, are now being challenged by the widening community of practitioners for sustainable development. Nicholas Stern, the author of the homonymous report on the cost of climate changes due to greenhouse gas emissions, has arguably provided the best synthesis of the man–nature relations in a conference at the Royal Economic Society in 2007: "Climate change is a result of the greatest market failure the world has seen. The evidence on the seriousness of the risks from inaction or delayed action is now overwhelming. We risk damage on a scale larger than the two world wars of the last century. The problem is global and the response must be collaboration on a global scale." The more urgent it becomes, the great the need to reassemble disciplinary perspectives into a common understanding of the relations between natural, social, political, and economic realms.

At the borders between legislation, natural sciences, economy, and social sciences, one often-used terminology is "forest planning," meaning, in silvicultural practices, planning for forest ecosystem exploitation. The literature on forest management is among the earliest to acknowledge the tension between the deterministic approach of forest exploitation planning and the uncertainties intrinsic to ecosystem dynamics. Given the importance of forests as resource generators for human populations, uncertainty was "accommodated" in forest exploitation planning[62] in terms of managerial approaches that accounted for disturbances and other unpredictable, less deterministic phenomena. In this sense, forests represent a good case study for the relation between the management of EGS, ecosystems, and socioeconomic systems, where natural resource management planning is often seen as akin if not identical to "ecosystem planning." An extensive overview on the matter is beyond the scope of this entry. Some examples, however, may be illustrative. Exploitation of ecosystems is obviously related to the property bearing lands and waters. In Central and Eastern Europe, for example, Romania has served as a natural experiment in this regard. The recovering of the individual property rights to forests (lost at the time of military imposition of communism by the Soviet Union, when 23% of the country's forests were in private hands) in a context of a still-recovering economy and society has led to massive forest overexploitation. Large areas of forests were clear-cut in the 1990s for the immediate purpose of selling the wood (120,000 ha, almost half of the first wave of forest restitutions). Obviously, firm property rights are necessary for effective management of forests, because they provide marketability, i.e., options for future planning conservation of EGS and various uses—timber and other biomass, recreation, carbon sequestration, water retention and decontamination, and so forth. These property rights are therefore not in question, but their consequences are, in this perilous situation where the postcommunist socioeconomic transition has left a management and regulatory vacuum. Fortunately, the last decades have seen a gradual socioeconomic recovery of the country and improvements in the definition of the property rights, giving rise to remarkable improvements in forest management. Entrepreneurial activities are now related to uses of forests, based on the (1) right to access; (2) (resource) withdrawal right; (3) management right; (4) exclusion right; and (5) alienation right.[63] Along the way, a process of reforestation is taking place in the entire eastern half of the European Union. The region's forests are now recovering from some of the losses suffered during the previous years of harsh transition, with various countries at various levels of reforestation—now matching the levels of socioeconomic convergence with the more developed western European countries.[64] In such situations, ecosystem planning bears the full weight of socioeconomic contexts.

A related example that is relevant to ecosystem planning is linked to the ecological reconstruction that may follow a cycle of ecosystem overexploitation and partial ecosystem recovery. Reforestation may be difficult on highly degraded and low-accessible lands, which may become prone to soil erosion. However, knowledge of natural processes may provide the means to plan for revegetation of degraded slopes. To remain within our example from Central Europe, past experiences show how the natural vegetation succession can be used as a tool. Thus, field experiments with planting a certain shrub like the common sea-buckthorn (*Hippophae rhamnoides*) on degraded slopes in Romania have led to fast revegetation with the shrub as quasi-exclusive species. In later stages, this monospecific vegetation allows an evolution of the structure of the soil and the advent of other species (grasses and tree seedlings) to grow under its shade. In a next stage, oak (*Quercus*) and beech (*Fagus*) tree juveniles, as well as other shrubs, have grown taller and shaded the sea-buckthorn and gradually replaced it as new forest, which, even if it is characteristic of the area, would not have grown there because the land was too degraded and the conditions were suboptimal prior to the establishment of the sea-buckthorn in the first place.[65] Application of such lessons from the field, however, is only possible under favorable socioeconomic conditions. Recent advances in the country and the region may reopen the possibility of using older field ecological experiments. In such situations, ecosystem planning means planning for a desired favoring of certain natural processes, with the purpose of halting the loss of natural capital and the recovery of certain ecosystem functions and services.

A fresh question now arises: to what extent can we take advantage of our knowledge to manipulate natural processes towards recovery, albeit partial, of some initial ecosystem structures and functions? The discipline of ecological engineering is one way to explore answers to this question. Its original principles have been updated to reflect the improving understanding of the limited planning powers of humans upon ecosystems.[6,66] (1) It is based on ecosystems' self-organization capacity; (2) it can be a field test of ecological theory; (3) it relies on integrated system approaches; (4) it conserves nonrenewable energy; and (5) it supports biological conservation. Such developments seem to indicate broad acceptance that planning, and for that matter "ecosystem planning," must incorporate the idea of adaptive management, both at the scales of landscapes and those of local settlements and despite epistemological uncertainties.[67,68]

Landscape Planning

The first and most obvious application of a future-oriented, broadly accepted concept of ecosystem planning is in the area of landscape planning. However, many authors in this area may understand ecosystem planning as "the process of land-use decision-making that considers organisms and processes that characterize the ecosystem as a whole." In other words, ecosystem planning is used as shorthand for ecosystem-based planning of land uses across landscapes. Much of the literature deploys a concept that may have a certain utility in its own right, albeit narrow, yet it is often used in epistemically irregular and unstudied constructions. Musacchio et al.[69] use the expression "landscape ecological planning (LEP)." There are major challenges in integrating the concept of EGS in landscape planning and, for that matter, also in the concept of ecosystem planning as defined in this entry, simply because there is as yet no coherent and integrated approach for practical applications of EGS in planning, management, and decision-making in general.[53,70] Even in the hypothetical case where the literature will start displaying decreasing pluralism (which is not necessarily desirable) and increasing use of a shared concept (which is in principle desirable)—even a cluster concept admitting of many conceptions—it remains practically the case that there are no developments in the literature associated with substantive changes in practice. This stands in interesting contrast to other experiments regarding the place of individual human flourishing in the context of larger systems, such as the "living wage" movement's experiment in Finland with a minimum guaranteed income.[71,72] Humans are unquestionably engaged in large-scale experiments regarding new ways of living together in conditions distributing available resources with attention to the conditions of human dignity; yet those experiments are not substantially engaging the scope and scale of the sustainability challenge—which warrants special attention from researchers and managers.

Recent research programs have tried to tackle this obstacle. For example, De Groot et al.[73] have proposed a framework that involves a chain of five major links: (1) understanding and quantifying how ecosystems provide services; (2) valuing ecosystem services; (3) use of ecosystem services in trade-off analysis and decision-making; (4) use of ecosystem services in planning and management; and (5) financing sustainable use of ecosystem services. Inevitably, such a succession of actions bears the intellectual virtue of a coherent synthesis of what we can imagine to be eventually done for successfully approaching the desired equilibrium between humans and nature. But it also carries a certain naivety with respect to what may be possible—for example, it sees ecosystems as "still poorly understood" and proposes more detailed quantification as the best way to achieve a better grasp of how ecosystems function and provide EGS, as if it is only a matter of time until we get it and equally a matter which must be resolved more fully than at present if meaningful downstream action is to be taken. This way of approaching the issue, however, seems to ignore (1) the serious epistemic hurdles involved in seeking total, comprehensive understanding complex systems, especially with a reductionist mindset and (2) the practical feasibility of such an endeavor in terms of available time and resources. To give only one example, tens of thousands of chemicals exist on the market,[74] and thousands of new chemicals are introduced to the market (and released into the broader environment) every year, and there is no chance that ecotoxicological test batteries could ever be developed for each of them to "better grasp" how ecosystems function, not to mention the inherently limited relevance of each bioassay. In general, it is thought that different patterns of urbanization have a direct impact on ecosystem dynamics through feedback mechanisms and complex interactions between urban activities, land/water uses, and environmental changes.[75] Some integrative, multitier studies can be done to account for changes in ecosystem parameters in space and time, for some specific indicators, for example, water quality along a river basin, upstream and downstream from a city that is a source of water pollution.[76–78] Notably, urbanization facilitates the transition of rivers from transporters to transformers of carbon.[79]

But even those are very far from being sufficient for understanding the state of ecosystems and the quality status of EGS. What seems to be missing in the five-link type of framework proposed in the analysis cited above is the acknowledgment of the facts that we only have a limited amount of time and material resources to be allotted to advancing towards the equilibrium between humanity and the ecosystems in which it is embedded, and that those resources are themselves dependent upon our mankind–ecosystems relation that we want to address. We simply cannot plan everything we would like to. As such, the mentioned paper takes a tool-based approach rather than a problem-based approach, being concerned more with understanding than understanding sufficiently for remedial action. Apart from this difficulty, and to be fair to the mentioned authors, the framework provided by De Groot et al.[73] does appear to us to have an essentially "color-test" value for the concept of ecosystem planning proposed hereby. Under the definition of ecosystem planning employed in their paper, the chain of actions proposed by the abovementioned team at Wageningen University can actually be understood as applied to "ecosystem planning," as a useful organizer of what needs to be done by humans within the limits of the possible. Without the definition above, the same chain of actions proposed by De Groot et al. allows "everything and nothing" in a progressively increasing demand for finite. Thus, mapping landscape functions for planning the management of EGS is potentially a smart and justifiable approach, on the condition that it is integrated in a management process that leads to less destruction of EGS and, thus, interrupts the series of blind actions upon ecosystems.

A necessary feature of "ecosystem planning," as a synthetic concept, must be simplicity in the sense of operational readiness. Proposed methods should maintain sensitivity to the complexity of the phenomenon but avoid creating supplementary complications, since those would exacerbate the problem by postponing practical action. Ecosystem planning should recognize limits of human knowledge and actions and seek genuinely integrative solutions, i.e., simple yet responding to a complexity of pressures. Humanity has not managed to integrate the fragmented knowledge we have produced so far into a coherent whole, and the tension between humanity and ecosystem continues to increase. We cannot realistically hope to solve this problem by producing more piles of disparate (and mutually untranslatable disciplinary) knowledge. Ecosystem planning, if effective, will need to consist in solutions that are relevant (adaptable or instructive) to situations as various as floodplains, polders, warm and cold deserts, tropical and boreal forests, marine and fluvial ecosystems, and so forth.

Although the literature explicitly using the concept of ecosystem planning in a substantial way is scarce, there is a large and eclectic body of knowledge on implicit ecosystem planning attempts. In a study on the potential overlap between EGS and conservation policies in the coast eco-region of central California, Chan et al.[58] have extracted a set of key insights into the convergence of conservation and EGS planning: (1) both suitability of sites and demand from citizens are main drivers in what ecosystem planning can do for protecting biodiversity and EGS—near cities demand is higher but suitability is lower; (2) spatial scales may vary for optimum of biodiversity conservation or/and different types of EGS—pollination services result from a variety of small locations, while water quality from entire river basins; (3) population centers yield tensions in planning between estimated value and demand—for example, a low-value/high-demand situation can occur near cities; (4) data are usually lacking, and thorough research and analysis are necessary; (5) it must involve multidisciplinary and transdisciplinary teams, for the integration of theoretical and empirical expertise from diverse fields; (6) efficiency is conditioned by considering both trade-offs and side effects of biodiversity conservation and EGS conservation—often trade-offs are the most efficient way, and often side effects reveal points of common relevance for various goals of planning.

While the concept of EGS appears to prioritize or privilege focus on human–ecosystem relations, challenges for future applications involving the concept of ecosystem planning can be related (without being equivalent) to situations as various as land-use planning; degraded landscape management, saltmarshes and river regulation, flood prevention and management of river catchments, management of freshwater quality, silviculture (with related concepts like "ecosystem stewardship planning," "forest stewardship plans," and "forest stewardship"), and planning for carbon sequestration in terrestrial and water ecosystems. In the current context of increasing need for mitigation and adaptation to climate change, forms of ecosystem planning have been imagined at planetary scale. Thus, geo-engineering approaches propose that the planetary ocean should undergo fertilization with limiting substances (e.g., iron ions) to allow faster carbon sequestration in phytoplankton biomass. This, however, involves large-scale, unpredictable risks that require thorough investigation in a race against time.[80]

Urban Planning

In spite of some controversy, the concept of ecosystem is appropriate in the study of cities.[81] Rees and Wackernagel[44] have proposed estimations of the ecological footprint of cities and show why cities cannot be sustainable per se, even while they are actually central to sustainability. Cities can only be considered sustainable together with their hinterland, from where they draw their resources and on which they depend. In the current era of globalization, cities have become part of a planetary network of cities, with a "common hinterland," which is the Earth's biosphere. Cities play preeminent roles in the global exchanges of information and matter energy and have an immediate impact on, and are immediately affected by, the entire biosphere. Ecological footprint estimates allow cities to track the necessary resources and the plan for development according to this. Consequently, urban development planning for sustainability will require evaluations of the ecological demand of a given city (disaggregated by type of activities) and comparison with available ecosystem resources. In the same logic, ecological deficits may determine the way the city may develop, if it intends to remain sustainable.[46] Urban ecosystem services can be identified and described in urban areas just as as in nonurban areas.[82] When proposing an integrated planning tool for sustainable cities, Rotmans et al. implicitly refer to "ecosystem planning." In their paper, the concept of environmental capital seems to be equated with natural capital, as part of a wider planning for sustainable city.[83]

Niemelä describes urban ecology in the context of the relation between ecology and urban planning, where urban planning is a type of land-use planning.[84] He makes the essential observation that urban nature has been regarded in prior studies as a true field experiment about human impact on ecosystems. This resonates with the wider preoccupations with the place of urban areas within the landscapes, for example, with the degrees of vegetation cover[85] or habitat patch corridors to avoid excessive habitat fragmentation in highly urbanized areas and to allow landscape connectivity between local plant/animal populations as part of the wider metapopulations (network of local populations) within landscapes. In a previous communication concerned with the place of cities as a human social construct within local ecosystems, we have described the city in terms of an ecosystem disturbance.[86] Applying current ecological theory—the intermediate disturbance hypothesis (IDH) and island biogeography theory (IB)—we have identified an ecological taxonomy of cities and city areas as a function of disturbance intensity in a local biogeographical context: small city/city periphery (low disturbance intensity), medium-sized city/city near-center (intermediate disturbance intensity), and large city/city center (high disturbance intensity). Within this framework, any urban unit can be described on a gradient of ecological disturbance and in the local biogeographical context, with biodiversity theories and indices serving as proxies for the state and dynamics of ecosystems and ecosystems–humans dynamics.[87,88]

An abundant urban biodiversity literature has emerged providing the means for use of urban ecology-biodiversity studies in urban planning and for planning for biodiversity conservation in urban areas.[89–92] Further literature points to the transformative impact of urbanization, particularly the reduction of native habitat and the creation of new habitats, and ecosystem homogenization.[93,94] These complex aspects must be accounted for by urban/ecosystem planning. In effect, city planning emerges as a form of planning the impact (types and intensity of disturbance) of humans upon ecosystems. The management of urban areas per se and the management of city hinterlands become a matter of planning for extraction of EGS for use in cities and human settlements in general. The place of the city within the surrounding ecosystems is, therefore, a matter of "ecosystem planning."

At the level of immediate impacts, urban planning may require intra-urban or peri-urban planning, which may involve a diversity of terrestrial/water ecosystems, coastal ecosystems, and inclusion of the effects of climate changes, grazing, and agricultural land. City planners must face the concomitant emergence of new knowledge domains and a plethora of new challenges. The central feature of urban ecology is that “cities are emergent phenomena of local-scale, dynamic interactions among socioeconomic and biophysical forces” that give rise “to a distinctive ecology and to distinctive forcing functions.”[95]

The role of a city as disturbance of the local ecosystems is the result of a complex dynamic involving major concerns as disparate as urban energy systems[96] and global change,[97] solid waste and wastewater,[98,99] and infrastructure reliability engineering,[100] to cite only a few. All this requires effective community coordination, based on social multi-criteria conception and evaluation of urban sustainability policies.[101–103] In this context, the use of some multiple criteria decision aid (MCDA) methodologies seems to be unavoidable for any urban and associated ecosystem planning, and effective coordination is yet another step further. The best candidate to providing an organic integration of all these issues and perspective is the systemic view of sustainability, according to which any economic system is a subsystem of a social system, itself a subsystem of a biophysical system.[29,30] However, translation from such ecological–economic insight to management strategies, actually tried and revised, seems to be waiting.

Elsewhere, starting from the systemic conception of sustainability, we have proposed an integrative approach for problem structuring and identifying sustainable/unsustainable management scenarios for solid wastes.[104] The method consists in translating the nested inclusion relationship between economy, society, and ecosystems into an ordered set of sustainability filters to be respected in managerial practices and proposed solutions *in illo ordine:* ecological sustainability filter (EcSF), social sustainability filter (SoSF), and economic sustainability filter (EnSF). Successfully passing all filters (i.e., meeting threshold values and indicators negotiated/listed in the technical definition of each filter) indicates that a given policy or solution proposed for the stated purpose (e.g., solving the problem of an old landfill) is consistent with sustainable development. This would be considered a sustainable scenario of action, under the conditions and knowledge available at the given place and time. Under this framework, the role of ecosystem planning can be recognized at the priority level of ecosystem carrying capacity (as reflected in EcSF) prior to action being taken towards further exploitation of EGS. Alternative methods can be identified to assess sustainability of solutions proposed for urban landfills, like the so-called sustainability potential analysis (SPA), and extension of the bioecological potential analysis (BEPA) that was originally developed for local and regional landscape analyses,[105] a reminder that any urban planning is part of planning for an equilibrium between humans and the natural support systems.

Trade-offs

One idea unites all discussions about ecosystem planning, namely the need for trade-offs. For example, in the case of both landscapes and waterscapes, river drainage basins (catchment areas) are considered necessary because they represent the minimal unit by which natural forces (starting with gravity) unite to shape the surface of the planet as understood in geological and ecological terms. The European Union’s Directive 2000/60/EC, the so-called Water Framework Directive (WFD) legally requires each EU member state to have river basin management plans as a common EU-wide tool for implementing a drainage basin-based approach to integrated water resources management. Although this approach has both advantages and disadvantages, it is considered a best trade-off between the need for locally optimized performance of technical approaches to natural resource management and the need for EU-wide comparisons, which requires a common understanding and coordination, which in turn requires a commonly agreed set of procedures between over 300 methods for monitoring water quality across Europe.[106,107] Creating a common methodological body required an intercalibration exercise (which is an example of agreement on knowledge) at the scale of the European Union. So planning across large areas requires coordination which requires agreements on values and knowledge. While the WFD is an example of agreement on values achieved at political level, the intercalibration exercise is an example of agreement on knowledge achieved at the level of experts in water physics, chemistry, and biology but directed towards managerial objectives aiming at obtaining a set of EGS bundled in terms of “ecologically clean water status.”

In the case of human communities, cities can be regarded as the best candidate scale and unit for modeling and testing states and processes in the transition to sustainability, because cities present the best trade-off between system-level relevance and managerial feasibility. The city is large enough to incorporate all fundamental functions that exist in a human system, yet small enough to still allow an intelligent agent to have a holistic overview so that action can be coordinated. Lower scales, for example, city districts, are too small because they are too specialized to be representative for an entire local community (e.g., as a residential area or industrial area or commercial area). Higher scales, for example, regional or national scales, are typically too large and administered through administrative divisions like specialized departments (ministries, agencies, and offices). Systemic changes necessary in the transition to sustainability may be subject to experimentation at smaller scales, and it will be cheaper and easier than at whole-city scales, but the results will not be relevant for how whole human systems work. At scales larger then cities, experimentation is not feasible without major disruptions from which the communities may be unable to recover.

In terms of ecosystem planning, the various instances of urban green and blue infrastructure (green areas and surface water bodies) represent planning trade-offs between the natural dynamics of ecosystems and the local needs of cities, notably mitigation of urban heat island effects and flood risks.[108,109] Thus, planting trees (to create a canopy cover and dissipate heat through biological processes) can help limit the heat island effect during the day, but other factors become important for temperature relief during the night (which is important for health, as human body needs to recover during the night): reducing soil sealing (impervious surfaces).[110] At the same time, tree canopy per se and that of particular species may be part of the local culture, which adds a social component that must be taken into account in urban ecosystem planning; failing to do so can result in strong rejection, civil disobedience, and reversal of the measures. This is what happened in 2013 in the city of Iasi, Romania, where a number of lime trees (*Tilia* sp., a species common in temperate climates of Europe and with strong cultural resonance in the city and in the country) from the city's historical center have been fell for sanitary-security (related to the old age of the trees) and esthetic reasons (related to the desire to clear up facades of historic buildings and respecting the initial plans of architects), but this managerial measure was executed in a manner that was perceived as an unacceptable bureaucratic imposition—namely, without public consultation. In addition, the lime trees were replaced with Japanese pagoda tree (*Sophora japonica*)—a world-popular tree for urban forests, one that is resistant to urban pollution and heat island effect and fits with the good practice of high diversity of genera and species of urban trees[111] but which was not part of the city's *spiritus loci* (spirit of the place). Less than 2 years later, following public revolt against what was perceived as a savage massacre against a local living emblem, and after an online local referendum which showed an overwhelming support of 94% for lime trees and in spite of the large sunken cost involved, *Sophora* was dug out and replanted elsewhere in the city while the city center was replanted with lime trees as predominant species.

Such situations show that a complex balance between factors must be reached through adaptive planning of land uses and vegetation structure in each sector of the city, within the limits of what is known at a certain moment in time and, most importantly, within the local cultural frame. Often this requires combining historic and democratic traditions, certain species bearing strong symbolism codifying common cultural references and social values that reflect the local history and details of the relations between people and nature in certain biographic provinces and cultural regions of the world.

Perspectives

It is not clear yet whether the term ecosystem planning will acquire a widely recognized meaning in its own right. Nevertheless, the concept often appears to function as a convenient stylistic contraction employed in the description of complex, multilevel, multidiscipline-fed issues and topics related to environmental management. Should the term enter mainstream terminology, it will need to overcome some major epistemic difficulties presently overlooked while the term is used as an aspirational gesture unconstrained by specific operational meaning and associated specific performance measures. A variety of methodologies are expected to be developed in the future, and further redefinitions of the term are likely. No matter how methodological reflections and terminological development occur, however, it remains the case that all reflection and working terms must face the fundamental tension between human-centered planning and human-independent characteristics of ecosystems. Ecosystems are an autonomous part of the environment, with their own, conspicuously nonlinear, dynamics. Planning regarding these dynamics cannot be made fully operational, if at all, by managerial task subdelegation let alone semantic reduction. The fact that planning may work effectively in certain sectors of environmental management does not translate into effective planning at the level of ecosystems. Rather, it typically means that (1) the concept of environmental planning has been limited to engineering- and management-tractable issues; (2) it has benefitted a certain capacity of environment as a whole (i.e., ecosystem included) to absorb disturbances by human activity; and (3) environmental planning needs further refining to clarify the limitations of planning and account for the reality of nonlinear behavior of ecosystems.

In the current context of vast and fast environmental changes, which are calling for coherent responses from science and management, certain knowledge domains may assimilate the concept of ecosystem planning. Notably, conservation biology aims at more effective nature protection, going well beyond the traditional focus on biodiversity conservation, with planning emerging as a necessary component of any comprehensive approach (for a review and discussion on the matter, see Reyers et al.[112]). The imperative of a global transition to sustainable development commands a profound transformation of the economy and society, which entails effective knowledge integration and management. A recent global survey that included experts in both social and natural sciences and that was carried out by the International Council for Science and the International Social Science Council has revealed a set of five grand challenges that need to be tackled within the coming years[113] and which can be summarized in four points as follows: (1) higher management-relevant capacity to anticipate environmental changes; (2) coordinated observation of environmental changes; (3) comprehension and anticipation of disruptive environmental changes; and (4) social–institutional transformation for the transition to sustainable development. As discussed here, ecosystem planning is a focal concept for current knowledge integration and management and, despite some challenging epistemic questions, has the potential to amalgamate into a core vocabulary of sustainability. Among the multiple approaches and contributions towards sustainability, landscape and urban planning emerge as particularly effective platforms for intellectual developments involving ecosystem planning.

Natural Enemies: Conservation

Cetin Sengonca

Introduction

After the successful utilization of two methods of biological control, classical biological control (importation and establishment of exotic natural enemies against either exotic or native pests) and augmentation of natural enemies (either inundative or inoculative releases of mass reared natural enemies), the third method—conservation and enhancement—has become more and more important during recent years.[1,2] Conservation of natural enemies is probably the most important concept in the practice of biological control and, fortunately, is one of the easiest to understand and readily available to growers. Most authors consider conservation as an environmental modification to protect and enhance natural enemies.[3] This definition will be the main subject of this entry.

Natural enemies of arthropod pests, also known as biological control agents, include predators and parasitoids that occur in all production systems from commercial fields to backyards where they have adapted to the local environment and target pests. Their conservation is generally noncomplicated and cost-effective.[4] With relatively little effort the activities of these natural enemies can be observed. Natural control agents are a major factor in controlling agricultural pests and need to be considered when making pest management decisions. Today, therefore, the conservation of natural enemies is considered inseparable from enhancement and together they represent a successful biological control method.

Avoid Harmful Practices of Pesticides

Pesticides used in agriculture are not only killing target pests but they also can have direct effects on natural enemies by killing them, or indirectly by eliminating their hosts or preys and causing them to starve. In contrast, the conservation concept of natural enemies attempts to avoid the application of particularly broad-spectrum, highly disruptive pesticides. Applying selective or specific and beneficially safe pesticides may contribute much toward preserving natural enemies. Pesticide selectivity to beneficial arthropods has been broadly classified into two forms. The first of these is physiological selectivity, that is, pesticides are less toxic to natural enemies than to their target pest when applied at the recommended rate. The second form is ecological selectivity that pertains to the means and domains in which pesticides are used. Systemic pesticides killing leaf-feeding herbivores, for example, may have little or no effect on the many natural enemies that have contact only with the leaf surface. In some cases, pesticides can be successfully integrated into pest management systems with little or no detrimental effect on natural enemies, and this trend is likely to increase substantially in the future. Nowadays, the pesticide industry places increasing emphasis on the development of beneficially safe and environmentally friendly pesticides that exhibit greater selectivity for natural enemies and have minimal environmental impacts. In the same way, governmental regulatory agencies increasingly consider the adverse effects of pesticides on natural enemies in their registration process for pesticides, reflecting the growing concern over negative effects on beneficial insects. Despite these important steps and the great progress that has been made, the latent effects of pesticides and the impact of "cocktail applications" on natural enemy populations are still not fully understood. Further research and implementation of research results are urgently needed.

Alternatively, when selective pesticides are unavailable, recommended conservation tactics usually involve exact timing of pesticide applications. Careful forecasting and observation of the occurrence and growth of pest populations can substantially reduce the number of pesticide applications. Forecasting systems should be based on a defined economic threshold for each pest, considering also the presence of natural enemies.[5] Another approach is the selective placement of pesticides in agricultural fields. Limiting pesticide application only to infested parts of the field will reduce costs and also conserve natural enemies. An ideal alternative approach is the use of microbial insecticides, such as commercially available *Bacillus thuringi- ensis* and fungal and viral products that have little adverse effects on natural enemies and the environment.

Habitat and Environmental Manipulation

Another form of natural enemy conservation is habitat and environmental manipulation. The agricultural landscape is currently so intensively managed that the species diversity of many natural habitats has disappeared or become endangered. A similar reduction can be observed among natural enemies too. It has been strongly suggested by many experts that natural enemies also can be conserved by simply encouraging vegetational diversity of the agroecosystem. In this context, hedgerows, cover crops, strips inside and bordering fields, and even in-field balks provide important refuges for parasitoids and predators of many pest species. There they find and benefit from safe shelters, sources of pollen and nectar, and also alternative prey or hosts in case of food scarcity in cultivated fields. And thus, at such sites, a long-lasting and self-regulating biocoenosis will develop. A higher acceptance of weeds in agricultural crops may also increase the efficacy of natural enemies. Similarly, mixed plantings, for example, Umbelliferae, mustard, and *Phacelia tanacetifolia*,[6] growing weed strips even within fields, and providing flowering field borders significantly increase habitat diversity. *P. tanacetifolia* has been cultivated widely between crops in the production system in Germany for more than a decade. At the same time this will provide shelters and alternative food sources for natural enemies. Another important concept in conservation by habitat manipulation is that of connectivity. Natural or less disturbed habitats are often scattered and isolated within the agricultural landscape. Connecting these habitats, for example, by hedgerows and woods, will establish a continuous network of corridors allowing movement of natural enemies between fields.

Experiments have shown that a constant population of natural enemies can be established and conserved by releasing their prey or hosts during periods of scarcity, for example, releasing the red mite, *Tetranychus urticae* Koch, to support the establishment of its predatory mite, *Phytoseiulus persimilis* Athias-Henriot, in cucumber and bean cultures widely in greenhouses in middle Europe.[7] Similarly, distributing sterilized *Eupoecelia ambiguella* Hb. eggs between the two generations of this lepidopteran pest preserved its egg parasitoid *Trichogramma semblidis* (Auriv.) in the Ahr valley in Germany. A classical example is the black scale, *Saissetia oleae* (Oliv.), which interrupts its development for a short period during summer in the hot arid areas of central California. Planting irrigated oleander plants adjacent to citrus orchards allowed the black scale a continuous development. As a result, this enabled its specific parasitoid *Metaphycus helvolus* (Comp.) to maintain its population, particularly during the hot summer months.[7] In another example, it has been found that preservation of nettles, *Urtica* spp., an important host plant of *Aglais urticae* L., can enhance the efficacy of *T. semblidis* on the second generation of *E. ambiguella.* The reason is that the parasitoid maintains its population on this alternative host during the two nonoverlapping generations of *E. ambiguella.*[8]

The manipulation of some simple cultural measures can also conserve natural enemies. A famous example is strip harvesting hay alfalfa, allowing mobile natural enemies to disperse from cut strips to half-grown strips. Similarly, *Trissolcus vasilievi* (Mayr) and *T. semistriatus* Nees, two important egg-parasitoids of the sunn pest, *Eurygaster integriceps* Put., were successfully conserved in Turkey by growing shade trees in hot arid areas, providing shade and thus suitable climatic conditions for these parasitoids.

Overwintering and Shelter Sites

Natural enemies build up considerably high population densities during summer periods, but then suffer from lack of overwintering or shelter sites and unfavorable climatic conditions during winter. As a result of these detrimental environmental factors, extreme low entomophagous arthropod densities are often present the following year. This permits pest populations to explode and in consequence requires more pesticide applications. In contrast, by preserving existing or providing artificial hibernation sites or shelters, natural enemies can be conserved during overwintering periods. For example, planting of trees and perennial bunch grasses near agricultural sites, the use of burlap or cloth trees, and wrap and stones provided as hiding places at overwintering time allow coccinellid lady beetles higher survival rates during hibernation. In the same way “trunk traps” and “trap bands” can be used as artificial overwintering sites for predatory bugs and lace-wings,[9] and felt belts can be wrapped around the trunks of fruit trees and vines for the predatory mite *Typhlodromus pyri Scheuten*. The green lacewing, *Chrysoperla carnea* (Stephens), overwinters as an adult in barns, roof trusses, houses, and under the bark of trees, where mortality rates during hibernation in middle European climatic conditions may still reach 60%–90%. By using specially designed, simple wooden shelters (hibernation boxes) the overwintering mortality was reduced to only 4%–8%.[10] On this ground, these hibernation boxes are now being accepted and commonly used by farmers, gardeners, and also environmental protectionists in Germany and Switzerland.

Future Concerns

The majority of pest problems in agriculture are due to the elimination of natural enemies by the indiscriminate and intensive use of pesticides. Improper habitat manipulation and mismanagement of ecosystems have further intensified this problem by reducing the available flora and fauna. Conservation and enhancement of natural enemies is the easiest and least costly method of biological control offering solutions to most pest problems without harming and disturbing the natural ecosystem. Unfortunately, however, this field has received little attention and very little investment has been made in research. There is a serious need for research into the areas of direct conservation and enhancement of natural enemies during the vegetation period and hibernation. In a self-regulating mechanism focusing on conservation and enhancement, natural enemies can keep agricultural pests below their economic threshold and help to reduce the number and frequency of pesticide applications. Furthermore, integration of conservation and enhancement of natural enemies into existing IPM programs[11] will lead to a more sustainable and cost-effective agriculture system.

Pests: Landscape Patterns

F. Craig Stevenson

Pest and Landscape Patterns

Small Patches

Certain areas within a field may be more conducive to pest survival, establishment, and development relative to other areas. The size and proximity of localized infestations with a given field differs among the three major pest groups. Past research has shown that weed and disease patches generally have a radius of about 25 m (if you assume that they have a circular shape), but may be as large as 100 m.[1–3] In the case of wild oat *(Avena fatua* L.), the patch may be associated areas that have higher soil water and nutrient availability (see Figure 1). Weeds such as perennial sowthistle (*Sonchus arvensis* L.), with seeds adapted to wind dissemination, may occur in areas of higher elevation where seeds are trapped as they are blown across a field. Foliar disease patches generally are associated with low wet areas of fields or sheltered field margins that have higher canopy humidity and lower wind speeds. Landscape patterns for insects, however, are less persistent and harder to predict because of rapid reproductive rates and pest movement.[4] To a lesser extent, this same level of complexity also occurs for polycyclic diseases that easily become airborne. However, the overwintering phases in northern agricultural regions and

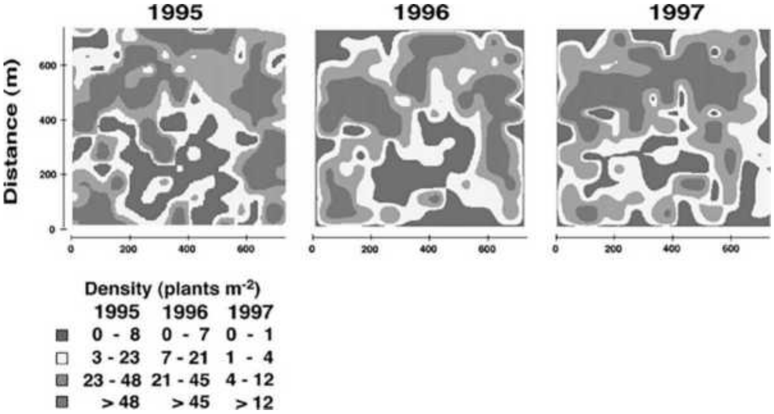

FIGURE 1 Landscape pattern of wild oat in a 65 ha field.
Source: Thomas.[6]

nonflying phases of insects may be associated with areas of a field with a more friable soil structure (e.g., grasshoppers) or other soil and microclimatic factors. In addition, for insects and to a lesser extent diseases, landscape patterns are complicated pest–predator interactions that can affect infestation of that pest in the given space in the next growing season. For example, the landscape pattern of nematodes has been shown to be partly a function of nematophagous fungi.[5] Therefore, the proximity of areas more or less conducive for the pest is ultimately dependent on the topography of the field and spatial variation of microclimatic conditions, especially for those pests with restricted mobility.

Larger Scale Landscape Patterns

These patterns are seen where larger areas of a field, or numerous fields, are being infested by a pest. These types of landscape patterns generally are dependent on external factors that move the pest from a smaller patch to adjacent areas. Climatic processes, such as wind, that blow weed seeds, disease spores, and insects can rapidly increase the area of pest infestation. Farming practices such as tillage and harvest operations also cause larger scale landscape patterns. For example, a study showed that *Polygonum* spp. of weeds tended to vary with the direction of tramlines up to distances of 635 m, a distance about 600 m more than that observed in the direction perpendicular to tramlines.[1] The spatial distribution of pests can be influenced by tillage practices and harvest operations that move crop residues and soil across a field. For example, nematodes are spread by cultivation from initial infestation foci.[5] Also, grain combine harvesters and shank-type tillage implements can move weed seeds and other reproductive structures across a field quickly.

Temporal Stability of Landscape Patterns

Time tends to complicate and/or obscure distinct landscape patterns for pests within a field. Varying climatic patterns (rainfall, temperature, etc.), within and among growing seasons can have a profound effect on the ability of pests to survive, establish, and develop. This complexity, interacting with polycyclic and multigeneration reproductive strategies within a growing season and factors moving pests across or between fields, poses a major hurdle to a holistic understanding of pests and landscape patterns. Extensive field research combined with predictive modeling may be a fruitful avenue for such a complex phenomenon.

Future Developments

The advent of global positioning systems (GPS), satellite imagery, and geographic information systems (GIS) software have heightened awareness and provided insight into landscape patterns and pests. Ultimately, these technologies may allow for the site-specific management of pests in accordance with their landscape patterns.[7] For example, spatially referenced maps could be linked to GPS on pesticide applicators to reduce the total amount of pesticide applied, thus improving economic returns and resulting in farming systems less dependent on pesticides. Our current understanding clearly shows that pest infestations often occur in patterns across a field, however, a great deal more effort will be necessary to provide information to accurately predict where pests will occur and affect crop production most extensively. These challenges will be especially difficult considering the highly variable and dynamic nature of current climatic conditions and farm management systems.

Biological Control of Vertebrates: Myxoma Virus and Rabbit Hemorrhagic Disease Virus as Biological Controls for Rabbits

Peter Kerr and
Tanja Strive

Myxomatosis

Myxomatosis is a generalized, lethal disease of European rabbits classically characterized by gross skin swellings, sometimes termed tumors or myxomas, which appear mucinous on cut sections, mucopurulent blepharoconjunctivitis, swollen face and head, thickened, edematous, often drooping ears and grossly swollen perineum. In acute infections, death occurs 8–12 days after infection or 3–5 days after development of obvious clinical signs. The case fatality rate (CFR) can approach 100%. Myxomatosis was not a disease of European rabbits in their natural range; it is caused by myxoma virus (MYXV), which originally circulated in the South American jungle rabbit or tapeti (*Sylvilagus menensis* also called

Sylvilagus brasiliensis). In this species, MYXV causes a relatively inconsequential cutaneous fibroma at the site of inoculation. Myxomatosis is an example of an emerging disease that was only seen when a susceptible host species, the European rabbit, was imported into South America where MYXV was circulating.

Myxoma Virus

MYXV is a poxvirus (family: *Poxviridae*; subfamily: *Chordopoxvirinae*; genus: *Leporipoxvirus*; species: *Myxoma virus*). Like other chordopoxviruses, MYXV is a large brick-shaped particle (286 × 230 × 75 nm). The type virus (Lausanne strain) has a double-stranded DNA genome of 161.8 kb encoding 158 unique genes, 12 of which are duplicated in terminal inverted repeats of 11.5 kb at each end of the genome. The virus replicates in the cytoplasm of infected cells and so must encode the necessary enzymes for DNA replication and RNA transcription. Like other large DNA viruses, many genes encode virulence factors which suppress host immune responses or antiviral mechanisms (Cameron et al. 1999, Kerr 2012, Kerr et al. 2015). In the natural host, these virulence factors are probably essential for local suppression of immune responses, thus maintaining virus in the fibroma for sufficient time to allow transmission. However, in European rabbits, the combination of these immune suppressive factors and the ability of the virus to replicate in lymphocytes and monocytes of this species allow the virus to disseminate from the site of initial infection and cause generalized systemic disease with lymphoid tissue destruction and profound immunosuppression (Best et al. 2000, Best and Kerr 2000, Jeklova et al. 2008). MYXV is passively transmitted on the mouthparts of biting arthropods such as mosquitoes or fleas that probe through the virus-rich skin lesions in search of a blood meal. The virus does not replicate in the arthropod vector. In European rabbits, transmission may also occur via virus in conjunctival or nasal discharges.

The Use of Myxoma Virus as a Biological Control for Rabbits in Australia

The use of MYXV to control rabbits was suggested as early as 1919 (Fenner and Ratcliffe 1965) and some early experiments were done in Australia. However, it was not until the 1930s that systematic studies were undertaken, initially in Britain and subsequently in Australia, to examine the lethality for rabbits, the host range, and the likely impact of MYXV on other Australian species (Martin 1936, Bull and Dickinson 1937). Field studies in Australia were undertaken in 1937–1939 in enclosures on Wardang Island off the coast of South Australia and subsequently, in the summer of 1940–1941, in an enclosure in low-rainfall country on the mainland where native stickfast fleas (*Echidnophaga* spp.) were present as a vector (Bull and Mules 1944). These studies were followed by field releases in the same area. The virus had a substantial impact on local rabbit populations when fleas were present and predators such as foxes were removed to prevent them from killing sick rabbits. However, it did not spread beyond the study sites and was regarded as unlikely to control rabbits on any scale (Bull and Mules 1944).

Recognizing the need for mosquitoes as vectors, experimental studies were undertaken in 1950 in higher rainfall districts in the Murray River valley near Albury on the border between New South Wales (NSW) and Victoria and near Gunbower in north-central Victoria (Myers 1954). The virus appeared to spread initially but then died out at the release sites. However, myxomatosis reappeared in December of that year at one of the sites and simultaneously at other locations along the Murray River and at locations up to 650 km away (Ratcliffe et al. 1952, Myers 1954). Transmission was driven by mosquitoes, particularly *Culex annulirostris*, which were in high numbers due to flooding in the northern Murray–Darling river system and the vast numbers of rabbits which were completely susceptible to this novel pathogen. The scale of the epizootic was unprecedented with estimates of spread covering an area of 1600 km south to north and 1750 km east to west (Ratcliffe et al. 1952). The virus trickled on in local outbreaks through the winter and then reappeared in epizootics the following summer once mosquitoes emerged. Over the next 3 years, MYXV spread, either naturally or by deliberate introduction, wherever rabbits had established and there were enough mosquitoes or other vectors to transmit the virus.

Myxomatosis reduced rabbit numbers by perhaps 90% to 99% with CFRs due to the released virus (termed the standard laboratory strain; SLS) estimated at 99.8% (Fenner et al. 1953, Myers et al. 1954). However, in some local epizootics, the estimated CFR was as low as 40% with surviving rabbits identified by scarring and the presence of serum antibodies to MYXV (Fenner et al. 1953).

Rabbits that recover from myxomatosis are probably immune for life, with immunity potentially boosted by reexposure to the virus. In addition, recovered females will transfer maternal antibodies across the placenta to kittens, which may provide limited passive protection in the early weeks of life (Fenner and Marshall 1954, Kerr 1997).

It soon became apparent that slightly attenuated strains of MYXV were occurring in the field (Fenner et al. 1953, Myers et al. 1954, Marshall et al. 1955). While still highly lethal, with CFRs of 90%–99%, these strains had a selective advantage because they allowed infected rabbits to survive for a slightly longer time, thus providing more opportunity for mosquito transmission of the virus (Marshall et al. 1955, Fenner et al. 1956).

Field strains of virus were subsequently classified into five virulence grades (1–5) based on CFR, survival times, and clinical signs of small groups of infected laboratory rabbits (Fenner and Marshall 1957). Grade 3 viruses, with CFRs of 70%–95% and survival times of 17–28 days, became the predominant strains in the field within 4 years (Figure 1) and remained so for the next 30 years after which there are no systematic data available (Fenner and Ross 1994). However, both highly virulent and highly attenuated strains can still be recovered from the field (Kerr et al. 2017, unpublished data).

With such high CFRs, MYXV was exerting very high selection pressure on the rabbit population and the emergence of somewhat attenuated viruses probably increased the frequency with which rabbits

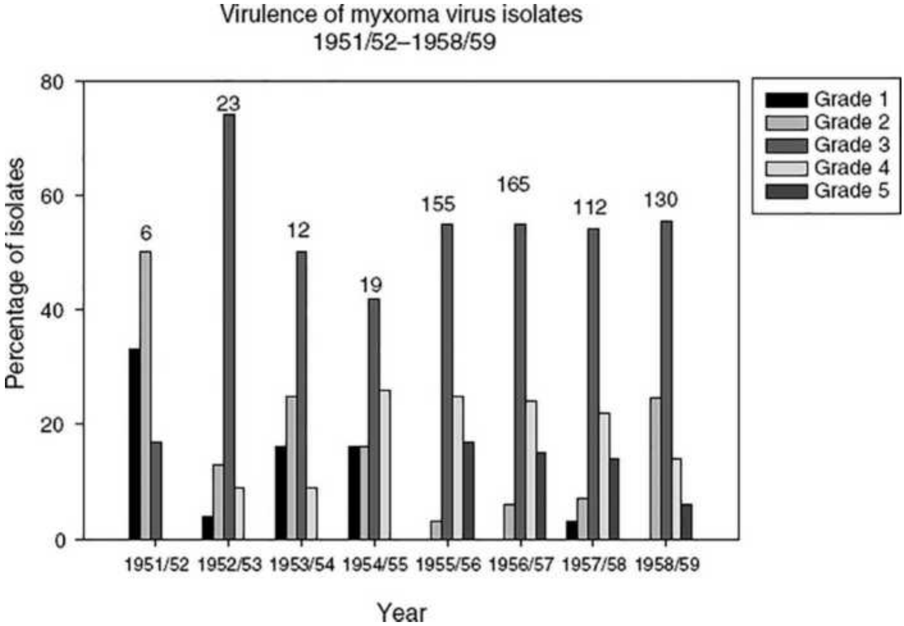

FIGURE 1 Virulence changes in Australian isolates of MYXV from 1950–1959. Virulence of MYXV field isolates is shown as the percentage of isolates made each season classified into grades 1–5. The number of isolates tested each year is shown above the bars. Data for 1951/1952–1957/1958 are from Marshall and Fenner (1960) and data for 1958/1959 are from Fenner and Woodroofe (1965). Virulence was classified as: Grade 1 average survival time (AST): ≤ 13 days; CFR: 99.5%; Grade 2 AST: > 13 ≤ 16 days; CFR: 99%; Grade 3 AST > 16 ≤ 28 days; CFR: 70%–95%; Grade 4: AST > 28 ≤ 50 days; CFR: 50%–70%; Grade 5 AST not applicable; CFR < 50%.

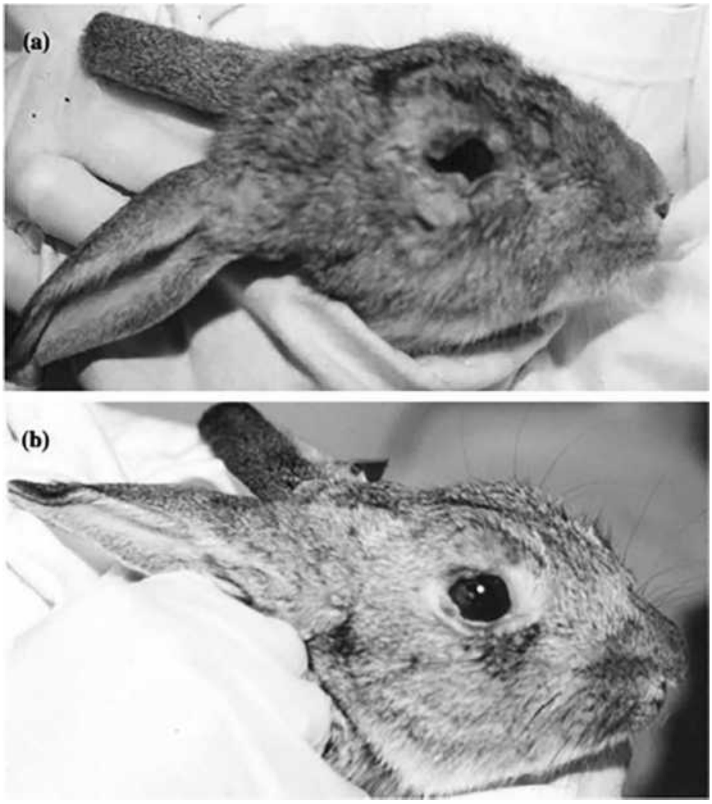

FIGURE 2 Genetic resistance to MYXV in Australian wild rabbits. (a) A wild rabbit infected 10 days previously with the grade 1 virulent SLS MYXV introduced into Australia in 1950. The rabbit shows relatively mild clinical signs of myxomatosis. (b) A wild rabbit 20 days after infection with the same virus. This rabbit has virtually fully recovered. SLS originally killed essentially 100% of infected rabbits with an average survival time of ≤13 days. (Figures are from Best SM and Kerr PJ (2000) Virology 267, 36–48, Elsevier publishing, with permission.)

with alleles conferring some resistance to myxomatosis survived infection (Figure 2) (Alves et al. 2019). In addition, high environmental temperatures enhanced survival of rabbits infected with moderately attenuated virus strains (Marshall 1959, Marshall and Douglas 1961).

A dramatic example of the selection for resistance was provided by a study on rabbits from Lake Urana in NSW. Within 7 years of natural selection by annual epizootics of myxomatosis, the CFR in these rabbits, infected under laboratory conditions with the KM13 strain of MYXV, dropped from 90% to 26% (Marshall and Fenner 1958, Marshall and Douglas 1961).

The emergence of attenuated virus strains and genetically resistant rabbits in the decade from 1950–1960 reduced the impact of myxomatosis. However, there is no doubt that the disease continued to suppress rabbit populations especially in the agricultural areas of Australia where myxomatosis, in occasional widespread epizootics and more regular local outbreaks, complemented conventional control measures. In an experiment where myxomatosis was experimentally controlled, rabbit numbers increased by 8–12 fold in a region where myxomatosis had previously been regarded as not contributing to rabbit control (Parer et al. 1985).

In the early 1990s, 40 years after the initial epizootic, it was estimated that rabbit numbers in the agricultural areas of Australia were on average fluctuating around 5% of their pre-myxomatosis numbers (Fenner and Ross 1994, Williams et al. 1995). However, in the low rainfall rangeland and semiarid areas, where conventional management was more difficult or nonexistent, populations were about 25%

of pre-1950 numbers and population irruptions were occurring (Fenner and Ross 1994, Williams et al. 1995). The rabbit breeding cycle and climatic variation means that there will be large fluctuations in population sizes particularly in the arid zones where the natural decline in rabbit populations due to drought may be as much as 99%, but it is also in these areas that rabbits have their greatest impact on preventing regeneration of vegetation (Williams et al. 1995, Cooke 2012).

Since 1995/1996, the impact of myxomatosis on rabbit numbers has been more difficult to discern because of the presence of rabbit hemorrhagic disease (RHD), which may also alter the timing of epizootics of myxomatosis by removing the seronegative young rabbits needed to sustain an outbreak (Mutze et al. 2002, 2010a). Although difficult to quantify, it is likely that myxomatosis continues to suppress rabbit numbers across Australia at essentially no economic cost.

The Introduction of Novel Insect Vectors to Australia to Enhance Biological Control by Myxomatosis

MYXV in Australia was largely vectored by mosquitoes with some local spread by direct contact and native stickfast fleas. In dry seasons or arid zones, there might be no transmission because there was little or no mosquito breeding. There were areas such as Tasmania, the northern tablelands of NSW, the western district of Victoria, or south-western West Australia where mosquito activity was low (Williams et al. 1995) with a consequent lower impact of myxomatosis.

In Britain and parts of Europe, the main vector of MYXV, following its release in 1952 (see below), was the European rabbit flea (*Spilopsyllus cuniculi*), however, this parasite had not been introduced to Australia with the rabbit. Rabbit fleas are present on rabbits all year round and move freely between rabbits, thus potentially allowing transmission of MYXV when mosquitoes are absent or in low numbers.

S. cuniculi was imported to Australia in 1966 and released from quarantine in 1968 after rather minimal testing for environmental impact (Sobey and Menzies 1969). The fleas were widely released throughout Australia, and in many regions, this produced a drop in rabbit numbers that was comparable to the earlier impact of myxomatosis (Cooke 1983, King et al.1985, Mutze et al. 2002, Cooke et al. 2013). The overall result appears to have been an increase in the efficacy of myxomatosis despite attenuated field strains of virus and genetic resistance in rabbits. In particular, fleas could drive epizootics when mosquito activity was low. *S. cuniculi* was also introduced into rabbit populations on the subantarctic Macquarie Island and the Kerguelen archipelago.

Despite its initial establishment, *S. cuniculi* tended to die out in rabbit populations in the hot dry areas of Australia (annual rainfall <200 mm) (Cooke 1984). To overcome this limitation, the Spanish rabbit flea *Xenopsylla cunicularis*, which is adapted to hot, arid conditions, was introduced (Cooke 1990). This flea was released from quarantine in 1993 after studies on species specificity showed that native animals were not a preferred host. Large-scale breeding was undertaken and over one million pupae or newly emerged fleas were subsequently released at some 500 sites (Fenner and Fantini 1999, Saunders et al. 2010). Unfortunately, due to the emergence of RHD in 1995, virtually no follow-up studies were done on the impact of this flea on the epidemiology of myxomatosis although there were reports of unseasonable outbreaks of myxomatosis (Fenner and Fantini 1999). More recent anecdotal evidence indicates that this flea remains established in rabbit populations.

Introduction of More Virulent Strains of Myxoma Virus to Australia

From the time of the first epizootic of myxomatosis in Australia, MYXV was deliberately introduced into rabbit populations. Preparations of SLS were made available for field release, and in NSW and later in other states, a field isolate derived from SLS known as the Glenfield strain was used. The distinctive

Lausanne strain of MYXV (used for release in Europe, see below) was widely used in release campaigns in Australia from the 1970s particularly in association with *S. cuniculi* release (Fenner and Ross 1994). Lausanne and Glenfield are more virulent than SLS when tested in genetically resistant wild rabbits although the virulence of the three viruses is indistinguishable in laboratory rabbits. Releases of Lausanne continued until the late 1990s even though it was recognized that released viruses were outcompeted by field strains of virus and at best might create local epizootics (Myers et al. 1954, Marshall et al. 1955, Fenner et al. 1957, Berman et al. 2006). Virulent virus is no longer produced for release in Australia, and releases of MYXV are not occurring (rabbit hemorrhagic disease virus (RHDV) is produced for release). Proposals for new introductions of virulent strains of MYXV have been made (Henzell et al. 2008, Mutze et al. 2010a), although it is difficult to see how these would compete in the field based on previous releases of virulent virus. For example, despite its widespread release in Australia, no circulating strains of MYXV derived from the Lausanne strain have been identified (Saint et al. 2001, Kerr et al. 2019).

Myxomatosis in Europe and Other Regions

The Lausanne strain of MYXV was released in France in June 1952 by a landholder seeking to control rabbits. The virus established and spread, killing an estimated 90% of wild rabbits in France (Fenner and Ross 1994). From France, MYXV spread to the rest of Europe wherever rabbits were present in the wild and into domestic rabbitries. It was illegally introduced into Britain in 1953 and spread through the British wild rabbit population with estimates of population reduction as high as 99% (Fenner and Ross 1994). As in Australia, there was emergence of both attenuated virus strains and genetically resistant rabbits as the virus and its new host coevolved, although this seems to have happened more slowly in Britain (Fenner and Ross 1994).

In Europe, the rabbit is a keystone species in some ecosystems and a valued game animal for hunting. Collapse of rabbit populations, initially due to myxomatosis and later due to RHD, has added to pressure on endangered predators such as the Spanish imperial eagle (*Aquila adalberti*) and Iberian lynx (*Lynx pardinus*) (Rogers et al. 1994). In 2018, a widespread epizootic of myxomatosis occurred in hares (*Lepus granatensis*) in the Iberian Peninsula potentially signaling a species shift (Dalton et al. 2019).

MYXV was also introduced into Chile in 1954 (and later into Argentina) to control feral rabbit populations. It has also been released onto the subantarctic Macquarie Island and Kerguelen Archipelago.

Rabbit Hemorrhagic Disease as a Biological Control for European Rabbits

RHD was first described in 1984 as a novel disease outbreak in domestic Angora rabbits imported into China from Germany. It subsequently spread to, or emerged in, Europe, the Americas, Korea, and other parts of the world causing substantial losses in domestic and wild rabbit populations (Cooke and Fenner 2002).

In its original form, RHD typically presented as a sudden onset of high mortality in subadult and adult rabbits. Kittens less than 4–6 weeks of age were generally unaffected. In the peracute form of RHD, rabbits often died with no premonitory signs and some still had food in their mouths. More normally, the disease manifested as a short period of malaise with fever and elevated respiratory rate for up to 24 hours prior to death, which might be accompanied by ataxia, posterior paresis, convulsions and coma, hematuria, and a bloody discharge from the nostrils. Death is due to fulminant hepatitis complicated by disseminated intravascular coagulation with hemorrhages in lungs, kidneys, and other tissues. Subacutely affected rabbits that survive for a few days may show signs of jaundice.

Rabbit Hemorrhagic Disease Virus

RHD is caused by a calicivirus (Family: *Caliciviridae*; genus: *Lagovirus*; species: *Rabbit hemorrhagic disease virus*; RHDV). RHDV is a small non-enveloped virus approximately 40 nm in diameter with icosahedral symmetry. It has a single-stranded positive-sense RNA genome of 7.4 kb and replicates in the cytoplasm of infected cells; it cannot be routinely isolated in cell culture.

Two distinct genotypes of the virus now circulate: viruses derived from the original RHDV (here referred to as RHDV1) and a more recently emerged genotype, which will be referred to as RHDV2. A new nomenclature for the lagoviruses has been proposed with a single species *Lagovirus europaeus* that subsumes RHDV and the related *European brown hare syndrome virus* (EBHSV) each of which would become a genogroup. Genogroups are then further subdivided into genotypes and variants based on phylogenetic relationships. In this proposal, RHDV1 is genotype G1.1 and RHDV2 becomes genotype G1.2 (Le Pendu et al. 2017).

RHDV probably evolved from an apathogenic or mildly pathogenic rabbit calicivirus (RCV). These viruses replicate in the small intestine (Hoehn et al. 2013) and are widely distributed in domestic and wild rabbits in Europe and Australia and probably other parts of the world where farmed, feral, or wild European rabbits occur (Capucci et al. 1996, Cooke et al. 2004, Marchandeau et al. 2005, Forrester et al. 2007, Strive et al. 2009, Bergin et al. 2009, Jahnke et al. 2010, Strive et al. 2010, Marchandeau et al. 2010, Le Gall Reculé et al. 2011b, Nicholson et al. 2017). RCVs are closely related to RHDV, induce cross-reactive antibodies and, in some cases, appear to provide cross-protection to RHDV.

Following the initial spread of RHDV1, an antigenic variant termed RHDVa emerged in Europe (Capucci et al. 1998) and appeared to outcompete RHDV. The more divergent RHDV2 emerged in 2010 and appears to have evolved independently (Le Gall Reculé et al. 2011a, Silvério et al. 2018). RHDV2 overcomes the age resistance to disease in young kittens (Dalton et al. 2014, Neimanis et al. 2018) and has a broader host range spilling over from rabbits to cause disease in multiple species with some evidence of circulation in hares (Puggioni et al. 2013, Camarda et al. 2014, Hall et al. 2017, Neimanis et al. 2018). RHDV1 and a recombinant of RHDV1 have also been retrospectively demonstrated in Iberian hares with clinical signs of RHD (Lopes et al. 2014, Lopes et al. 2017).

Recombination of RHDV1, RHDV2, and low virulence RCVs is a significant feature of the ongoing evolution of these viruses (Lopes et al. 2015, Silvério et al. 2018, Hall et al. 2018).

Infection with RHDV can occur by most routes of inoculation, but infection via the oropharynx is probably most common in the field. RHDV replicates to very high titres in the liver causing massive hepatic necrosis. Virus RNA is present in liver, spleen, mesenteric lymph nodes, bile, thymus, urine, blood, and feces (Shien et al. 2000). In experimental studies, where relatively high doses of virus are used, death generally occurs within 2–3 days of infection. The CFR in susceptible rabbits following infection with RHDV1 is over 90%.

Kittens less than 4 weeks of age inoculated with RHDV1 support virus replication and can transmit virus (Lenghaus et al. 1994, Mikami et al. 1999, Matthaei et al. 2014) but generally do not develop clinical disease and are subsequently immune to reinfection. This age-related resistance is gradually lost between 4 and 9 weeks of age (Robinson et al. 2002b). However, kittens infected with RHDV2 succumb to disease with high CFRs.

The titres of RHDV in the blood are sufficiently high for fleas and mosquitoes to passively transmit the virus; it does not replicate in these insects (Lenghaus et al. 1994). However, the duration of viremia prior to death is very short so it is unlikely that biting insects play a significant role in transmission. In contrast, carrion-feeding flies play a major role in transmission by feeding on carcasses and passively shedding virus in feces and regurgita (Asgari et al. 1998, McColl et al. 2002a, Schwensow et al. 2014).

Rabbits that have recovered from RHD are probably immune for life to the infecting antigenic type with potential boosting by natural reexposure to the virus (Cooke et al. 2002). Immune females will transfer protective antibodies across the placenta to their kittens. These passive maternal antibodies can protect kittens for up to 11 weeks after birth depending on the titre of antibody in the doe. Importantly, kittens that are challenged with RHDV while passive antibody titres are waning may become infected but survive and be subsequently immune (Robinson et al. 2002b). It is uncertain how much immunological cross-protection occurs between RHDV1 and RHDV2. Anecdotally, vaccination against RHDV1 seems poorly protective against RHDV2 (Dalton et al. 2012) and limited field studies showed little cross-protection (Peacock et al. 2017). However, in a study with experimentally infected rabbits, some cross-protection appeared to occur (Calvete et al. 2018).

RHDV is relatively resistant to environmental degradation, and infective virus can persist in carcasses for at least 20 days at 22°C and perhaps as long as 3 months, although this would be affected by the climatic conditions (McColl et al. 2002b, Henning et al. 2005). Thus, RHDV has two modes of transmission: direct contact between susceptible and infected animals shedding virus and environmental contamination from carcasses and flies that feed on infected carcasses. Predators such as foxes that feed on infected rabbits or scavenge carcasses do not support virus replication but may also pass infectious RHDV in their feces and potentially spread the virus.

Introduction of RHDV to Australia as a Biological Control Agent

The potential of RHDV as a biological control for European rabbits was quickly recognized following epizootics in wild rabbits in Spain (Cooke and Fenner 2002), and in 1991, the Czech 351 strain of RHDV was imported into the high-security Australian Animal Health Laboratory at Geelong for evaluation. Studies of virulence, pathogenesis, and transmission in laboratory and wild rabbits of different ages were undertaken (Lenghaus et al. 1994). Species-specificity testing indicated that rabbits were the only susceptible species of those tested. Approval was then given for the virus to be evaluated in pens on Wardang Island 5 km off the coast of South Australia; the same location that had been used nearly 60 years earlier for trials with MYXV.

Testing on Wardang Island commenced in March 1995. Despite careful security, including insecticide treatments, RHDV escaped from the island and appeared in rabbit populations on the adjacent mainland in October 1995 (Cooke and Fenner 2002). It was probably transmitted by blowflies (*Calliphora* spp.) or bushflies (*Musca vetustissima*), which had not been previously suspected as vectors. Contingency plans to contain the virus by eradicating rabbits in the area were put into action, but it quickly became obvious that the virus was not just spreading between warrens but was making large jumps to new populations hundreds of kilometres away (Cooke and Fenner 2002). This long-distance spread, together with the escape from Wardang Island, clearly implicated flying insects in dissemination of the virus (Cooke 2002).

Following this accidental release of RHDV, regulatory inquiries, including public submissions, and further species-specificity testing suggested that the virus was unlikely to infect other species and it was registered as a pest control agent (Cooke and Fenner 2002). This allowed government agencies to produce virus for deliberate release as an inoculation for rabbits or for distribution on carrot baits.

Impact of RHDV as a Biological Control

Within 12 months of its escape, RHDV was reported in all the mainland states of Australia. As with myxomatosis 45 years earlier, the impact on rabbit populations was dramatic with some populations being reduced by 95% (Mutze et al. 1998, Saunders et al. 1999, Story et al. 2004, Bruce and Twigg 2004). This was particularly so in the low rainfall regions of Australia. In the more temperate regions, the impact was mixed. Generally, populations were considerably reduced, but at some sites, there was little or no impact following RHD (Saunders et al. 1999, Henzell et al. 2002, Bruce and Twigg 2005, Richardson et al. 2007).

In the subsequent years, there was a gradual reduction in the impact of RHDV on rabbit populations but numbers were still at lower levels than pre-RHD (Mutze et al. 2002, 2014). In southern West Australia, RHDV disappeared and was successfully reintroduced (Bruce and Twigg 2005). Reduction in rabbit populations in some arid regions was strongly associated with recovery of endangered mammals (Pedler et al. 2016). RHDV was also released on Macquarie Island in 2011 as part of a successful rabbit eradication campaign.

Emergence and Release of Novel RHDV Strains

In 2014, an exotic RHDVa strain was detected in south-eastern Australia (Mahar et al. 2018b); it is not known how this virus entered Australia. The virus is a recombinant between an RCV-like and an RHDVa virus most closely related to a virus from China. In 2015, routine surveillance detected an exotic RHDV2 strain in south-eastern Australia (Hall et al. 2015). Phylogenetic studies indicated that it had been circulating for some months prior to detection; this virus spread across the rabbit-infested areas of Australia largely replacing RHDV1 (Mahar et al. 2018a). A novel recombinant between this virus and RCV has also been reported (Hall et al. 2018). These RHDV2 strains also spill over into introduced European hares causing some lethal infections (Hall et al. 2017). Studies with the originally isolated Australian RHDV2 virus showed that it caused similar disease processes in kittens and adults, as had already been shown in Europe and, in this way, was quite distinct from RHDV1 (Neave et al. 2018, Neimanis et al. 2018). It appears to have substantially reduced rabbit populations (Mutze et al. 2018, Ramsey et al. 2020) and, as of 2019, was the dominant virus in the environment. It is possible that the ability of RHDV2 to kill very young rabbits has interfered with the spread of RHDV1 by removing a susceptible cohort from the population. Combined with the ability to overcome immunity to RHDV1, this has likely given RHDV2 a selective advantage, which may wane as the breeding female population becomes dominated by survivors of RHDV2, which will pass passive antibody protection to their offspring.

From 2010 onwards, a large research program in Australia examined other globally occurring variants of RHDV for their potential to augment the impact of circulating RHDV and slow the growth in rabbit populations. An RHDVa strain from Korea was selected because it overcame partial cross-protection conferred by recent infection with benign RCV (see below) and had a better ability to infect genetically resistant wild rabbits than other strains. This virus (termed K5) was released in a nationwide campaign in March 2017 (Strive and Cox 2019).

Although K5 achieved a local reduction in rabbit populations at some release sites, there is so far no evidence that it has established in the rabbit population. This is likely due to the competing RHDV2. K5 remains available as a commercial product for rabbit control but probably only has impact as a local biocide rather than disseminating widely. Whether it provides additional genetic potential for recombination with other strains remains to be seen.

Adult wild rabbits are likely to have survived RHD and, therefore, be immune to further challenge with the same antigenic type (McPhee et al. 2009). This means that the virus will have its main impact on the susceptible kittens and subadults each breeding season. However, depending on the timing of epizootics, the impact of RHD may be reduced by age resistance, passively transferred maternal antibodies, and potentially by cross-protection from apathogenic caliciviruses (see below) (McPhee et al. 2009, Mutze et al. 2010a, 2010b, Cox et al. 2017, Cooke et al. 2018). The co-circulation of two antigenic types of RHDV that can at least partially overcome existing immunity may be altering the epidemiology in complex ways (Dalton et al. 2012, Peacock et al. 2017).

Interference with RHDV by Rabbit Caliciviruses

The impact of RHD was substantially less in the higher rainfall, more temperate areas of Australia (Henzell et al. 2002, Cooke 2002, McPhee et al. 2002). This may be due, at least in part, to an apathogenic RCV (Rabbit Calicivirus Australia-1; RCV-A1) (Strive et al. 2009, Strive et al. 2010). Infection with RCV-A1 induces antibodies that cross-react with RHDV (Nagesha et al. 2000, Cooke et al. 2002, Robinson et al. 2002a). Recent infection with RCV-A1 provides some protection from experimental challenge with

RHDV (Strive et al. 2013). However, this protection is relatively short-lived and appears to be independent of the titres of cross-reacting antibody. In addition to attenuating RHDV infection, previous exposure to RCV has been suggested to reduce the rate of RHDV transmission at a population level (Cooke et al. 2018).

As already noted, similar caliciviruses are widely distributed in farmed and wild European rabbits around the world. Recombination between RCV and RHDV, in particular exchange of the nonstructural and structural genes, generating new variants appears to be relatively common (Lopes et al. 2015, Hall et al. 2018).

Impact of RHDV in New Zealand

RHDV was illegally imported into New Zealand from Australia and released into rabbit populations in October 1997. Following its release, RHDV spread over the rabbit infested areas of New Zealand. Decrease in rabbit populations ranged from 90% in some areas to less than 20%, essentially no effect, in others (Sanson et al. 2000, Parkes et al. 2002, Norbury et al. 2002, Henning et al. 2006). Cross-reacting antibodies to RCV and possible protection from RHDV were also observed in New Zealand wild rabbits (O'Keefe et al. 1999, Nicholson et al. 2017). As in Australia, once the initial impact on the naïve population had passed, there was a gradual recovery in some rabbit populations. However, the rate of increase has been much slower in the presence of RHD than occurred following conventional controls (Parkes et al. 2008). Predation, particularly by cats, may be locally important in maintaining suppression in low density populations in the presence of RHD (Reddiex et al. 2002, Henning et al. 2008). In 2018, RHDV2 emerged in New Zealand via an unknown entry pathway. In the same year, New Zealand also released K5 as an additional tool for rabbit control. However, the effects of RHDV2 and K5 on New Zealand rabbit populations have yet to be quantified.

What Is the Future for Biological Control with RHDV?

Adult rabbits experimentally infected with RHDV1 generally only survive for 2–3 days. Based on the myxomatosis model, it might be expected that selection would occur for virus that allowed the rabbit to survive for longer and shed virus for longer. There has been no systematic study of RHDV virulence in the way MYXV was studied. However, there is no compelling epidemiological evidence to suggest that the virus is attenuating either in Australia or Europe and some data showing the emergence of strains of higher virulence compared to the released virus (Elsworth et al. 2014). The avirulent RCVs identified so far are clearly not derived from RHDV (Capucci et al. 1996, Strive et al. 2009, Jahnke et al. 2010, Mahar et al. 2016).

It is probable that RHDV is not attenuating because high virulence, leaving carcasses with extremely high titres of virus as a source of contamination for insect vectors or for direct transmission, is an effective transmission strategy that offsets the advantages of shedding for longer (Elsworth et al. 2014, Schwensow et al. 2014). By causing such rapid death, the virus almost completely avoids the adaptive immune response (Cooke and Berman 2000), which may also reduce selective pressure. In addition, very young rabbits can be infected but are resistant to disease caused by RHDV1 and, thus, could maintain virulent virus without selection pressure. However, this may be of limited importance since in most populations kittens will have passive maternal antibodies which would prevent infection or limit shedding during this period of age resistance (Robinson et al. 2002b). The emergence of RHDV2 has also considerably altered the role of kittens in RHDV epidemiology.

It has been reported that some populations of wild rabbits in Australia exhibit resistance to infection with RHDV (Saunders et al. 2010, Elsworth et al. 2012, Schwensow et al. 2017). Similar observations have been made in Europe (Fouchet et al. 2009). Studies on the mechanism of resistance have focused on the expression of complex carbohydrate molecules called histo-blood group antigens (HBGAs) on the surface of epithelial cells (Guillon et al. 2009). Binding of RHDV to these molecules appears important in the infection process although other cell-surface receptors must also be utilized since HBGAs are not expressed on hepatocytes.

Rabbits that do not express particular HGBAs on intestinal epithelium are significantly overrepresented in populations following epizootics of RHDV suggesting a strong selection advantage (Guillon et al. 2009, Nyström et al. 2011). Experimentally, such rabbits were significantly more likely to survive oral challenge with low doses of virus although they still became infected, and challenge with higher doses of virus was lethal (Nyström et al. 2011). Regulation of HBGA expression in rabbits is complex and not fully understood (Nyström et al. 2015).

Different strains of RHDV utilize different HGBAs for attachment suggesting that there is likely to be a complex and ongoing selection in rabbit populations for expression of particular HBGAs (and potentially other receptors) and in virus populations for recognition of different HBGAs. It should not be assumed that this is the only mechanism of resistance that might emerge. Indeed, other factors such as major histocompatibility molecules type I (MHC-I) have been implicated in genetic studies (Schwensow et al. 2017). This ongoing host–pathogen coevolution may have unpredictable consequences for viral virulence and biological control (Fouchet et al. 2009).

The emergence of RHDV2 may also be altering the ongoing host–pathogen dynamic in unpredictable ways. One could envisage a scenario of alternating dominance of RHDV1 and RHDV2 variants depending on the degree of immunological cross-protection. As with myxomatosis, RHD is likely to continue to suppress rabbit populations at essentially no economic cost but with gradually diminishing impact. Economic modeling has suggested that the combined impact of myxomatosis and RHD has accrued benefits to agriculture of 70 billion Australian dollars (at 2011 values) (Cooke et al. 2013). Population suppression also means that other natural processes such as predation, parasitism, and other disease agents have more impact.

Cabbage Disease Ecology and Management

Anthony P. Keinath,
Marc A. Cubeta,
and David B.
Langston, Jr.

Introduction

Cabbage (*Brassica oleracea* 'Capitata Group') has long been cultivated as an important vegetable crop and a source of fiber, minerals, and vitamins, particularly during cold seasons in temperate climates. More recently, cabbage and other cruciferous vegetables (members of the Brassicaceae) have been recognized as important sources of dietary chemoprotective phytochemicals. Cabbage and other brassica vegetables were grown on 2.4 million hectares worldwide in 2018 (Food and Agriculture Organization, 2020). Cabbage is a productive vegetable based on biomass per area of cultivation, which averaged 28.7 ton/ha in 2018. However, many diseases, particularly those caused by bacteria and fungi, affect the production of this crop. This chapter focuses on six diseases of worldwide importance in cabbage production. These diseases also affect other cole crops, i.e., vegetables derived from *B. oleracea*, including broccoli, Brussels sprouts, cauliflower, collard, kale, and kohlrabi, and other genetically related cruciferous vegetables, such as Chinese cabbage, mustard, rutabaga, and turnip. Emphasis will be placed on pathogen life cycle stages susceptible to management techniques. Control measures will be presented in an integrated pest management (IPM) framework.

Major Diseases and Pathogen Ecology

Black Rot

Black rot is caused by the bacterium *Xanthomonas campestris* pathovar *campestris*. *X. campestris* pv. *raphani* also has been isolated from necrotic spots on cabbage seedlings (Lange et al. 2016). Because this bacterium can be seedborne, black rot occurs in most areas of the world where cabbage and other crucifers are grown. The pathogen produces V-shaped chlorotic and necrotic lesions starting at the margins of leaves, but it also causes wilting of plants if it reaches the vascular system in the stem (systemic infection). Blackening of the leaf veins is a helpful diagnostic symptom. The pathogen survives in infested crop debris and usually survives only for a few months in soil in the absence of host debris.

Clubroot

Clubroot is caused by the protozoan-like organism *Plasmodiophora brassicae*. This soilborne organism is an obligate biotroph, completing its unique life cycle within the root cells of crucifers. Infected root cells enlarge and divide to produce the diagnostic swollen, club-like roots. The pathogen produces resting spores in the clubs that persist in soil for at least 10 years after they decay. Isolates of *P. brassicae* differ in host range, and races have been found that are pathogenic on the few resistant cultivars of cabbage. Resting spores are extremely resistant to desiccation and easily spread with wind-blown soil and irrigation water.

Black Spot, Dark Leaf Spot

Five species of *Alternaria*, but primarily *A. brassicae* and *A. brassicicola*, infect cabbage and other crucifers. *A. brassicicola* has a higher optimal temperature for growth, sporulation, and spore germination (20°C–30°C) than *A. brassicae* (18°C–24°C). Both fungi can be seedborne and airborne but do not survive apart from infested host debris in soil. Infested debris left on the soil surface can be a significant source of pathogen spores for up to 12 weeks after harvest (Humpherson-Jones 1989). Seedborne inoculum can lower seed germination and vigor but usually is not damaging to seedlings.

Downy Mildew

Crucifer downy mildew is caused by the oomycete *Hyaloperonospora parasitica*. This biotroph produces airborne sporangia on the underside of leaves and oospores inside infected leaves, roots, and stems. The pathogen is believed to survive as dormant oospores in roots and stems and on living hosts in frost-free regions. Cabbage is affected by downy mildew particularly during the seedling and heading growth stages. High relative humidity, dew, and fog are favorable for infection.

Watery Soft Rot, Sclerotinia Stem Rot, White Mold

Sclerotinia sclerotiorum has a wide host range but is especially damaging to cabbage, because it not only infects the head in the field but also can cause decay in transit and storage. Infection occurs primarily at head maturity when wrapper leaves shade the soil, providing a cool, moist environment that favors the pathogen. This fungus produces airborne sexual spores (ascospores) that infect plants, and soilborne survival structures (sclerotia) cause infection when they germinate near a plant. The closely related species *Sclerotinia minor* also has been reported on brassica vegetables.

Wirestem

Wirestem, a postemergence disease, is caused by the soilborne fungus *Rhizoctonia solani* anastomosis groups (AGs) 2-1 and 4 (Budge and Shaw 2009). In soils cropped repeatedly to crucifers, AG 2-1 predominates. At low pathogen levels, wirestem is more prevalent or severe than preemergence damping-off. Seedlings may be killed by wirestem when lesions girdle stems. Older plants may be killed later or be stunted and fail to produce a marketable-sized head. Root rot also occurs when infection is severe but is absent when discrete stem lesions are the only symptoms.

Control

General Control Principles

Exclusion. It is extremely important to prevent contamination of clubroot-free land by excluding the pathogen. Movement of field-grown transplants, soil, and equipment from clubroot-infested fields or farms should be avoided (Hwang et al. 2014). Growers in clubroot-free areas should avoid purchasing field-grown transplants or equipment from infested areas. Before purchase, greenhouse-grown transplants should be inspected for symptoms of downy mildew, black rot, and black spot.

Eradication. Testing seed for the fungal pathogen *Plenodomus* (=*Phoma*) *lingam* has greatly reduced outbreaks of black leg disease of crucifers. Cruciferous weeds should be eradicated to eliminate sources of the pathogens causing black rot, downy mildew, and clubroot (Table 1). Cruciferous ornamentals also can be infected by the same species of *Alternaria*, *Hyaloperonospora*, *Plasmodiophora,* and *Xanthomonas* that infect cabbage. The parasitic fungus *Paraconiothyrium minitans*, the active ingredient in the biofungicide Contans®, infects and destroys sclerotia of *S. sclerotiorum* and *S. minor.*

Avoidance. Cabbage crops should be rotated to a different field or plot each season to avoid contact with infested debris remaining from previous crops. Using a shallow planting depth for transplants reduces wirestem incidence, because the susceptible hypocotyl is not directly in contact with *Rhizoctonia*-infested soil. Avoid wounding plants to prevent black rot, bacterial soft rot, and watery soft rot.

Resistance. Host plant resistance is widely available in green (white) and red cabbage for yellows (caused by *Fusarium oxysporum* f. sp. *conglutinans*). Some hybrid cultivars have partial resistance to black rot that restricts lesions to the wrapper leaves. A few cabbage cultivars (mostly red cabbage) have moderate resistance to *Alternaria*. Cabbage cultivars available in the United States are susceptible to clubroot, downy mildew, white mold, and wirestem.

Protection. Seed treatment with fungicides is very effective in preventing damping-off caused by species of *Pythium* and *R. solani*. Protectant fungicides are effective against black spot and downy mildew and used for managing black rot, clubroot, and wirestem with varying degrees of success. Potassium phosphite is an alternative fungicide that is effective against downy mildew. The fungicides boscalid and penthiopyrad are registered in the United States to control *Sclerotinia* on cole crops.

TABLE 1 Management Practices for Common Diseases of Cabbage

Disease	Plant-Resistant Cultivars	Use Healthy Seed or Transplants	Eliminate Weeds	Avoid Wounding	Bury Crop Residue	Rotate with Nonhosts	Apply Protectant Fungicide or Bactericide
Black spot	+	+	+	–	+	+	+
Bacterial soft rot	–	–	–	+	–	–	–
Black leg	–	+	–	–	+	+	+
Black rot	+	+	+	+	+	+	–
Clubroot	–	+*	+	–	–	–	+/–
Downy mildew	–	+	+	–	+	+	+
Yellows	+	–	–	–	–	–	–
Sclerotinia stem rot	–	–	+	+	+	–	+/–
Damping-off	–	–	–	–	–	–	+
Wirestem	–	+*	–	–	+	–	+

+ = Practice can be used to manage the disease; – = Practice is ineffective or inappropriate, based on pathogen life cycle; +/– = Practice may be useful under certain conditions.

* The pathogen is not seedborne but can be spread on infected, field-grown transplants.

Therapy. The only measure to control cabbage diseases postinfection is the application of systemic fungicides for downy mildew.

Examples of Integrated Disease Management

Cabbage scouting guides have been developed and are useful for surveying production fields for diseases, insects, and weeds. Controlling weeds, especially ragweed (*Ambrosia artemisiifolia*), can reduce the incidence of watery soft rot. Ascospores of *Sclerotinia* can also infect ragweed flowers that fall onto cabbage leaves and heads because flower parts provide nutrients for the pathogen (Dillard and Hunter 1986). Lastly, it is important to control flea beetles (*Phyllotreta cruciferae*), which carry spores of *Alternaria brassisicola* on their bodies and in their frass and transmit conidia while feeding.

Managing Seedborne Pathogens

Seed should originate from seedlots that have tested negative for the presence of the black leg and black rot pathogens. Hot water seed treatment is useful to control seedborne black rot bacteria, provided the water temperature is monitored carefully so it remains at 50°C for 25 minutes to avoid reducing seed germination and quality. Minimize leaf wetness periods when producing transplants in glasshouses, because of the ease of spreading pathogens. Apply protectant fungicides to seed crops to prevent infection of seed by *Alternaria*.

Managing Soilborne Pathogens

Soil fumigants generally are not used against soilborne pathogens in cabbage production because of the high cost, although they may be used to disinfest seedbeds and suppress clubroot. Field-grown transplants may be sources of the clubroot and wirestem pathogens and spread them to noninfested fields. Because of this risk, transplants should be produced in soilless mixes in greenhouses when possible. Do not plant any cruciferous cover crops or vegetables in fields before or after cropping to cabbage. Use monocots as rotation crops, because *R. solani* AG-4 and *S. sclerotiorum* have wide host ranges among dicotyledonous crops. The resting spores of the clubroot organism cannot be eradicated by rotation. Instead, liming soil to raise the pH above 7.2 with calcium oxide or hydrated lime prevents infection of roots.

Managing Foliar Pathogens

Diseases caused by foliar pathogens, such as *Alternaria* and *Xanthomonas*, can be managed with crop rotation during the period when infested host debris is decaying in affected fields, because these foliar pathogens of cabbage do not survive longer than 1 or 2 years in soil, respectively. Disk and bury or compost unmarketable cabbage heads. Apply protectant fungicides as needed based on environmental conditions and host susceptibility. Black spot can be reduced by increasing row width and plant spacing to promote air circulation that dries leaves, because *Alternaria* spp. require relatively long periods of leaf wetness for infection (a minimum of 5–9 hours).

Conclusion

The diseases dark spot, downy mildew, watery soft rot, and wirestem often can be managed successfully using a combination of biological, chemical, and cultural control measures. The biological and cultural methods listed in Table 1 are amenable to organic production systems. Management of black rot and clubroot remains challenging. In the future, resistance to downy mildew and improved resistance to black rot may be available in cabbage cultivars. It may be possible to transfer downy mildew resistance from broccoli to cabbage using molecular genetics methods. Additional molecular genetics research is needed to clarify the identity of races of the downy mildew and clubroot organisms.

Natural Enemies and Biocontrol: Artificial Diets

Simon Grenier and
Patrick De Clerq

Introduction

Arthropod parasitoids and predators used in biological control strategies are at present mainly produced on natural or alternative hosts or prey. However, their large-scale production may be more convenient and cost-effective when using artificial diets/media. Studies aiming at the successful development of arthropod parasitoids and predators under artificial conditions have started a long time ago, but the practical use of insects and mites grown on artificial diets is still in its infancy. Besides their use for the production of natural enemies, artificial media may be valuable tools for physiological and behavioral studies of entomophagous arthropods due to a simplification of their environment. Different types of artificial diets with or without insect additives can support the development and/ or reproduction of natural enemies. Successes have been achieved for several species of parasitoids and predators but these have mainly been restricted to an experimental level. Comparisons of the performances of artificially vs. naturally reared natural enemies (as quality control) have primarily been conducted in the laboratory, and only very rarely in the field. The promising results achieved in recent years open up new prospects for natural enemy producers.

Artificial Diets for Predators and Parasitoids

The culture of entomophagous insects and mites involves rearing not only of the host/prey, but often also of the host's/prey's plant food, and thus requires a tritrophic level system. Different steps were taken to try to reduce the production line for entomophagous arthropods. The complete line comprises plant growing, host/prey rearing, and parasitoid/predator rearing. The simplified line includes the use of artificial diets instead of plants for the phytophagous host/prey, or of factitious hosts/prey that are easier to rear in the laboratory than the natural food (e.g., eggs of *Ephestia kuehniella* or *Sitotroga cerealella*, larvae of *Galleria mellonella* or *Tenebrio molitor*). The ultimate reduction of the production line consists only of an artificial diet for direct parasitoid/predator rearing. Mass rearing entomophagous insects on artificial media, first suggested 60 years ago, holds the promise to increase the ease and flexibility of insect production, including automation of procedures, and to reduce cost. The early and subsequent efforts at developing artificial diets have extensively been reviewed.[1–3] The basic qualitative nutritional requirements of parasitoids and predators are similar to those of free-living insects. But the very fast growth of some parasitoids such as tachinid larvae requires a perfectly well-balanced diet[4] to minimize intermediate metabolism and toxic waste product accumulation.

Essentially, two types of artificial diets can be distinguished: Those including and those excluding insect components. The availability of media without insect components offers a greater independence from insect hosts/prey, even if in some countries insect components are cheap and easily available by-products, e.g., from silk production in Asia or South America.[5] In diets containing insect additives, such varied components as hemolymph, body tissue extract, bee brood extract or powder, egg juice, or homogenate of the natural host have been used. Products of insect cell culture have also been incorporated into diets as host factors. The composition of most media for in vitro rearing of *Trichogramma* egg parasitoids is based on lepidopterous hemolymph.[6] Media for the tachinid fly *Exorista larvarum*, the chalcid wasp *Brachymeria intermedia*, and the ichneumonid wasp *Diapetimorpha introita* contain various insect components. Bee extracts or bee brood have been commonly added in diets for predatory coccinellids.[1,5] Only few diets devoid of insect additives are composed of ingredients that are fully chemically defined in their composition and structure. Besides proteins or protein hydrolysates, most of such diets contain crude or complex components, e.g., hen's egg yolk, chicken embryo extract, calf serum, cow's milk, yeast extract or hydrolysate, meat or liver extract, or plant oils. Beef or pork meat and liver have extensively been used as basic components of diets for feeding coccinellids and several predatory heteropterans.[1,5]

Successes and Failures with Artificial Diets

Both biochemical and physical aspects determine the success of an artificial diet. Artificial diets should be nutritionally adequate to support development and reproduction of an insect and should be formulated in such a manner that the medium is easily recognized and accepted for feeding or oviposition; the food should be readily ingested, digested, and absorbed.[7] For parasitoids, the diet must also allow the growing larvae to satisfy other physiological needs like respiration and excretion without diet spoiling. The best results on artificial media were obtained with idiobiontic parasitoids such as egg or pupal parasitoids and with polyphagous predators. Different tachinid species were also successfully grown in vitro, but the koinobiontic Hymenoptera appear the most difficult group to be reared in vitro, probably because of a close relationship with their living host that supplies them with crucial growth factors. Ectoparasitoids are generally easier to culture in vitro than endoparasitoids for which the diet is also the living environment of the immature stages.[2] Several predatory insects have been reared for successive generations on artificial diets, including heteropterans (e.g., *Geocoris punctipes, Orius laevigatus, Podisus maculiventris*), coccinellids (e.g., *Coleomegilla maculata, Harmonia axyridis),* and chrysopids (e.g., *Chrysoperla carnea, Chrysoperla rufilabris*).[3]

Artificial rearing of natural enemies has mostly remained at an experimental level, and the practical experience with natural enemies produced in artificial conditions has remained quite limited. Wasps of the genus *Trichogramma* reared on factitious host eggs are the most common agents used worldwide in biological control in many field crops and forests. In China, *Trichogramma* spp. and *Anastatus* spp. produced on a large scale in artificial host eggs have been released on thousands of hectares of different crops with a parasitization rate above 80%, leading to an effective pest control level equal to that of naturally reared parasitoids.[5] In the U.S.A., field tests with encouraging first results were conducted using the pteromalid parasitoid *Catolaccus grandis* reared for successive generations on artificial diet for the control of the cotton boll weevil *Anthonomus* grandis.[5] Since the late 1990s, biocontrol companies in the U.S.A. and Europe have started producing a number of natural enemies (partially) on artificial diets.

Quality Control of Natural Enemies Produced on Artificial Diets

Long-term rearing on artificial diets could lead to genetic bottleneck effects inducing high selection pressure on the entomophages and possible reduction of their effectiveness. Periodic population renewals from nature may circumvent this drawback. The use of natural enemies in augmentative biological control requires a reliable mass production of good quality insects. Therefore, quality control is a key element for the efficiency and the long-term viability of biological control. The quality control procedures developed for in vivo production of entomophages could be recommended as a first approach for in vitro production.[8] Many parameters can be used as quality criteria. Size, weight, life cycle duration, survival rate, and especially fecundity, longevity, and predation/parasitization efficiency are the most relevant characters.[5] Besides its value as a quality criterion, the biochemical composition (based upon carcass analyses) of the insects produced on artificial diets may be a powerful tool for improving the composition and performance of the diets through the detection of excess or deficiency of some nutrients. Often, different criteria are closely linked; hence, the quality control process may be simplified if one easily measured parameter can be used to predict another one that is more complex or time consuming to determine (e.g., fecundity). Arguably, excellent field performance of the artificially produced natural enemy against the target pest remains the ultimate quality criterion. However, quality assessments of artificially reared natural enemies have mostly been performed at a laboratory scale or in semifield conditions, and only rarely so in practical field conditions.

Conclusions

At present, rearing systems using natural or factitious foods remain the only effective way for industrial production of most entomophagous insects and mites. However, success achieved for a restricted number of species of parasitoids (e.g., *Trichogramma* spp., *Exorista larvarum, Catolaccus grandis)* and predators (e.g., *Orius* spp., *Geocoris punctipes, Chrysoperla* spp., *Harmonia axyridis)* has prompted producers to increasingly incorporate artificial diets into their mass rearing systems. Further behavioral and physiological investigations may lead to significant improvements in artificial rearing through a better knowledge of the host-parasitoid and predator-prey relationships. Besides an easier mechanization of the production line, the use of artificial diets opens new possibilities for preimaginal conditioning of parasitoids/predators to targeted hosts/prey by adding specific chemicals in their food. Artificial diets also seem the only way of mass rearing for some middle-sized egg parasitoids (Encyrtidae, Eulophidae, Eupelmidae, Scelionidae to name a few) that are promising pest control agents but are unable to develop normally in the small lepidopteran substitution host eggs commonly used nowadays *(Ephestia kuehniella, Sitotroga cerealella).*

Animals: Toxicological Evaluation

Vera Lucia S.S.
de Castro

Introduction

Developmental toxicants may be a chemical, microorganism, physical agent, or deficiency state that alters the morphology or a physiological process of a developing organism, both before and after birth. Exposure of the developing embryo or fetus to some environmental agents like gamma irradiation and thalidomide is known to produce anatomical anomalies leading to in utero death or structural birth defects. Developmental toxicology studies the causes, mechanisms, manifestation, and prevention of developmental deviations produced by developmental toxicants. Several environmental agents are established as causing developmental toxicity in humans, while many others are suspected of causing developmental toxicity in humans on the basis of data from experimental animal studies.

Nowadays, all the possible manifestations of developmental toxicity (death, structural abnormalities, growth alterations, and behavioral and functional deficits) are of concern, while in the past there has been a tendency to consider only malformations and death as end points of concern. Developmental toxicity usually results from prenatal exposures to toxicants experienced by the mother, but it can also result from paternal exposures, e.g., in rural workers exposed to pesticides. Effects can include birth defects, reduced body weight at birth, growth and developmental retardation, organ toxicity, death, abortion, and functional dysfunctions. It can also lead to behavioral deficits that become manifest as the organism develops since the chemicals can impair postnatal development up to pubertal development. Further considerations related to the efforts to assemble an internationally harmonized source of common nomenclature for use in describing observations of fetal and neonatal external, visceral, and skeletal abnormalities can be found in Makris.[1]

In May 2001, more than 90 nations adopted the Stockholm Convention on Persistent Organic Pollutants (POPs), with significant contributions from non-governmental organizations, trade unions, and private companies. The Stockholm Convention is a global treaty created to protect human health and the environment from chemicals that remain intact in the environment for long periods, become widely distributed geographically, accumulate in the fatty tissue of humans and wildlife, and have adverse effects to human health or to the environment. Exposure to POPs can lead to serious health effects, including certain cancers, birth defects, dysfunctional immune and reproductive systems, greater susceptibility to disease, and even diminished intelligence. Given their long-range transport, no one government acting alone can protect is citizens or its environment from POPs. In response to this global problem, the Stockholm Convention entered into force in 2004, requiring parties to take measures to eliminate or reduce the release of POPs into the environment. The convention is administered by the United Nations Environment Programme and is based in Geneva, Switzerland. The substances covered initially are eight pesticides (aldrin, chlordane, DDT, dieldrin, endrin, heptachlor, mirex, and toxaphene), two industrial chemicals (hexachlorobenzene and polychlorinated biphenyls), and two POP by-products (dioxins and furans). In 2009, the Conference of the Parties decided to undertake a work program to provide guidance to parties on how best to restrict and eliminate nine newly listed POPs and invited parties to support work on the evaluation of alternatives and other work related to the restriction and elimination of these new POPs [α-hexachlorocyclohexane, ß-hexachlorocyclohexane, lindane, pentachlorobenzene, perfluorooctane sulfonic acid (PFOS), PFOS salts, perfluorooctane sulfonyl fluoride, tetrabromodiphenyl ether, and pentabromodiphenyl ether (commercial pentabromodiphenyl ether)] (http://chm.pops.int/default.aspx).[2]

Exposure of the developing embryo or fetus to some environmental agents like gamma irradiation and thalidomide is known to produce anatomical anomalies leading to in utero death or structural birth defects, commonly termed teratogenesis. Perhaps less well appreciated is that such environmental exposures also can cause functional disorders that persist postnatally and into adult life. The spectrum of such postnatal consequences is growing, and more recently is thought to include disorders of the immune system, brain function, obesity, and diseases such as diabetes and cancer, to name a few.[3]

Importance of Oxidative Stress

Xenobiotics such as phenytoin and benzo[*a*]pyrene can be bioactivated by enzymes like the cytochromes P450 (CYPs); however, the developing embryo and fetus have relatively low levels of most CYP isozymes. The xenobiotic bioactivation to a free radical intermediate by enzymes associated with peroxidase activities within the embryo or fetus can be a critical determinant of teratogenesis. In the developing embryo and fetus, enhanced formation of reactive oxygen species by xenobiotics may adversely alter development by oxidatively damaging cellular lipids, proteins, and DNA, and/or by altering signal transduction. The postnatal consequences may include an array of birth defects, postnatal functional deficits, and diseases.[3]

Also, estrogen-like substances, such as several organochlorine pesticides, have been demonstrated to induce defeminization, miscarriages, malformations, and transplacental carcinogenesis. This variety of effects results from the interference of these substances with the metabolism of steroid and protein hormones, therefore altering a whole spectrum of complex developmental functions.[4]

Importance of Toxic Effects on Nervous System Development

Only about 200 chemicals out of more than 80,000 registered with the U.S. Environmental Protection Agency (EPA) have undergone extensive neurotoxicity testing, and many chemicals found in consumer goods are not required to undergo any neurodevelopmental testing. The cumulative effects of co-contaminants and the difficulties in analyzing biomarkers of exposure in human tissues have complicated comprehensive risk assessment. Furthermore, population-based studies that measure subtle effects on neurobehavioral outcomes are challenging to interpret and costly to conduct.[5]

The effects observed following developmental exposure may be different both quantitatively and qualitatively from adult exposure because of the potential to affect processes in the developing child that have no parallel process in adults. Central nervous system development consists of a series of processes that occur in sequence and are dependent on each other, such that interference with one stage may also affect later stages of development. This makes the timing of a potential environmental neurotoxicant a critical parameter in the risk for subsequent neurologic effects. The sequence includes proliferation, migration, differentiation, synaptogenesis, apoptosis, and myelination.

There are multiple windows of vulnerability during which environmental exposures can interfere with normal development. For many developmental toxicants, there is a spectrum of adverse outcome depending on dose timing of exposure, maternal and fetal susceptibility, and interactions with other environmental factors.[6]

Therefore, environmental exposure to a toxic agent that affects synaptogenesis, such as lead, may affect brain areas differentially depending on timing of exposure. Since different brain areas develop on different time lines during prenatal and postnatal life, an environmental neurotoxic agent may produce impairment in different functional domains depending on the time of exposure. For example, the same exposure at different points in development could result in an adverse effect on motor systems versus memory or executive functions. Similarly, exposures at different concentrations or for different lengths of time could potentially produce differential effects. Therefore, the constellation of observed effects should not be expected to be the same in different children exposed to the same neurotoxic agent.[7]

Concern on Developmental Impairment in Children

The findings of the some studies imply that children's exposure to pesticides may bring about impairments in their neurobehavioral development. The long-term neurotoxicity risks caused by prenatal exposures to pesticides are sometimes unclear. Effective control of exposure is complicated by variable exposure sources and variable contaminant levels in food and environment. This awareness has also been extended to effect(s) of toxic contaminants on breastfeeding women and their children.[8]

The information deriving from epidemiological studies indicate a need to increase awareness among people and children exposed to pesticides about the association between the use of pesticides and neurodevelopmental impairments. There are modest epidemiological evidence on occupational exposures of female workers to industrial chemicals and the consequences in regard to the child's neurodevelopment. The majority of the occupational studies identified aimed to assess organic solvents and organophosphate pesticide effects in the offspring, and neurobehavioral impairments were reported. In some reports, however, the evidence suffers from a variety of shortcomings and sources of imprecision. These problems would tend to cause an underestimation of the true extent of the risks. Due to the vulnerability of the brain during early development, a precautionary approach to neurodevelopmental toxicity needs to be applied in occupational health.[9,10]

With increasing evidence of the high prevalence of pesticide use and the considerable risk it poses to children, it is of concern that there has been little research into the health implications of household pesticide use. Children are exposed to pesticides in various ways, not only environmentally, but also through food and through use of pesticides at home and in public areas. The exposure depends on a large variety of factors related to chemical characteristics and use, and children's activities. In spite of its potential health and environmental risks and contribution to agribusiness, the use of agricultural chemicals for yard care has not been well studied. The probability that a household chooses a mix of do-it-yourself and hired applications of synthetic chemicals increases with income, age, and the presence of preschoolers.[11]

Also, children who live in farming communities are furthermore exposed to both agricultural and household pesticides. Farmworkers bring home pesticide residues on their clothing, boots, and skin, placing other household members at risk, particularly children.[12] Recent studies on in utero exposure to the organochlorine pesticide dichlorodiphenyltrichloroethane and its breakdown product, dichlorodiphenyltrichloroethane, indicate that exposure is associated with poorer infant (6 mo and older) and child neurodevelopment depending on the end point evaluated. Research on organophosphate pesticide exposure and neurodevelopment also suggests some negative association of exposure and neurodevelopment at certain ages. About abnormal reflexes in neonates and in young children (2–3 years), two separate studies observed an increase in maternally reported pervasive developmental disorder with increased levels of organophosphate exposure.[13]

For example, children whose mothers worked in the flower industry during pregnancy scored lower on communication and fine motor skills, and had higher odds of having poor visual acuity, compared with children whose mothers did not work in the flower industry during pregnancy, after adjusting for potential confounders. These facts showed that maternal occupation in the cut-flower industry during pregnancy may be associated with delayed neurobehavioral development of children aged 3–23 mo. However, possible hazards associated with working in the flower industry during pregnancy include pesticide exposure, exhaustion, and job stress.[14]

The increased emphasis on children's exposures to pesticides and other organic pollutants has led to a surge in recent years in the number of research studies aimed at this specific susceptible population. Continuous strong investment in research plus strong preventive action by the government is required for further progress in environmental pediatrics and for better control of the diseases caused in children by environmental toxic exposures. This research will have high costs and demanding long-term multiyear studies.[15]

Developmental Animal Experimental Studies

Before 1960, governmental recommendations for the assessment of chemical effects on the reproductive cycle involved limited animal testing. During the early 1960s, the thalidomide disaster evidenced, on the one hand, the greater vulnerability of the embryo and fetus, and on the other, that the complexity of the mother-child unity warranted special consideration. Thalidomide was used as a sedative drug in the 1950s, also in pregnant women. Later, it was found that it could cause malformations in newborns of mothers who ingested the drug during the sensitive period.[16] This disaster fostered the establishment of formal laboratory animal-testing procedures for assessing fetal development.

In contrast to most other toxicological tests, developmental studies are usually required in rodent and nonrodent subjects. One of the reasons for this requirement is the thalidomide disaster. When the developmental toxicity of thalidomide was studied in experimental animals, large interspecies differences were found in effective doses and in the types of effects. However, the discrimination between direct and indirect (i.e., as a consequence of maternal toxicity) developmental effects was often doubtful, and is one of the factors that could explain the apparent differences between species.[16]

Despite the limitations, animals can be useful predictors of chemical hazards to humans. A specific animal model might be chosen for any conjunction of widely varying reasons. Accessibility of embryos, cost of acquiring or maintaining animals, availability of genomic analyses or probes, and/or close similarity to human physiology might factor in the design of a laboratory experiment. Growth and development are compressed into a shorter period in animals, which makes interpretation of animal testing inherently more difficult. Each experimental species has its own advantages and the use of laboratory animal models is based on diverse practical grounds arising from an assumption of generalizability across species. The conjunction of evolutionary and developmental biology shows that the timing and sequence of early events in brain development are remarkably conserved across mammals.[17] During mammalian development, the fetal organism is exposed to its own gonadal hormones, placental steroids, and maternal hormones that may cross the placental barrier.[18]

Manifestations of developmental toxicity observed in humans are not always reproduced in experimental animals, and in general there is at least one experimental species that mimics the types of effects seen in humans. The fact that every species may not react in the same way could be due to species-specific differences in critical periods, differences in timing of exposure, metabolism, developmental patterns, placentation, or mechanisms of action.[6]

The vast majority of the laboratory studies on the developmental effects of environmental contaminants use the pregnant or lactating animal as the conduit to deliver the contaminant to the developing offspring. The traditional approach in developmental toxicology adopts a linear perspective for the interpretation of the effects of contaminants on the offspring as a particular one is given to the mother in order to expose the fetus in utero or postnatally via lactation. Variations of this approach may manipulate time of exposure or use cross-fostering strategies to separate the effects of in utero from those of lactational exposure.

Maternal behavior is not always monitored during the treatment period, even though there is evidence of the effects of these compounds on adult behaviors, particularly on behaviors that are sensitive to hormonal manipulations. As is the case with all mammals, maternal care in female rodents comprises very specific behaviors that help ensure the survival of the offspring by providing nourishment, warmth, sensory stimulation, cleaning, and protection. Maternal behavior begins even before parturition as the dam builds a nest in order to provide warmth and protection for the coming offspring. The fact that many developmental outcomes are determined or modulated by the amount and quality of maternal care raises the question of the importance of possible changes in maternal behavior in determining the consequences of their exposure during early development.[19] There are some guidelines proposed in the literature in order to evaluate the maternal behavior and its effects on litter development.[20,21]

Reproductive and Developmental Protocols

Developmental toxicology bioassays are designed to identify agents with the potential to induce adverse effects and include dose levels that induce maternal toxicity. In reproduction toxicity studies, the determination of the high dose is important since changes in body weight are often used as an index of toxicity. The highest dose level should be chosen with the aim to induce some parental toxicity (e.g., clinical signs, decreased body weight gain, not more than 10%) and/or evidence of toxicity in a target organ. Consequently, the knowledge on maternal (and to some degree, paternal) toxicity is important as a natural limiter to prevent underdosing. A comparison between doses causing effects in adults and offspring can also be used, although a direct comparison is difficult since the level of observation applied in offspring is often much higher than in adults. It is also useful in order to obtain information on the influence of pregnancy and/or lactation on the susceptibility to a test compound. However, if dosing was high enough to cause maternal toxicity, these doses often also cause some effects in the offspring.[22]

Prenatal developmental toxicity studies are designed to provide general information concerning the effects of exposure to the pregnant test animal on the developing organism. Although exposures during a typical guideline prenatal developmental toxicity study are designed to include either the entire period of gestation or limited species-specific gestation periods, developmental end points are considered to be an integral concern in the assessment of potential health effects from continuous lifetime exposures to a toxicant. Pregnancy and fetal development are thus considered to represent a potentially susceptible life stage that should be considered in lifetime or chronic assessments. If studies and information on reproductive or developmental toxicity are absent in a health-effect assessment, specific uncertainty factors (e.g., database) may be applied to the final point of departure used in risk calculations. It is also well established, however, that developmental toxicity may occur in response to single exposure, such as during specific developmental windows of susceptibility. Whereas this circumstance does not influence the relevance of typical guideline developmental studies to the evaluation of chronic or lifetime assessments of health effects, it does signify that developmental end points observed in these repeated dose studies are relevant in health-effect assessments of shorter-term exposures, including acute exposures.[23] Results from developmental toxicology bioassays have significant predictive value in identifying potential health risks to the human embryo/fetus.[24]

Data Quality Control of Experimental Studies

To accomplish good experimental planning, some points before the beginning of the study should be observed for adequate data interpretation in view of the experimental delineation.[25,26] Animals to be used in laboratory research should experience an acceptable welfare (for ethical reasons) and show normal behavioral and physiological reaction patterns to guarantee the quality of research.[27] In this sense, the performing laboratory should maintain a historical control database to track any changes in the data over time in the animals and/or in the equipment. The value of historical data depends on its quality and its reliability at the side of contemporary controls.

International Protocols

Different international organizations have developed protocols for testing the reproductive and developmental toxicity of chemicals. The information produced by them, related to toxic effects produced by environmental pollutants, is very useful worldwide. Besides, new protocols are being evaluated viewing to reduce the number of animals used and to improve the predictability for human health hazards identification.

Developmental study methodology has been extensively reviewed and evaluated over the last 25 years. This has included the conduct of a number of meetings and collaborative studies involving experts from academic, industry, regulatory, and public interest groups. For example, in recent years, the International Life Sciences Institute (ILSI), under a cooperative agreement with the EPA, established a working group of scientists from government, industry, and academia, to discuss developmental neurotoxicity test protocol ending with a public workshop in which occasion the conclusions of the working group were presented.[28]

Food Quality Protection Act

Developmental and reproductive toxicity testing protocols such as those recommended by the EPA, Food and Drug Administration, and Organization for Economic Cooperation and Development are useful for characterizing toxicity in developing animals and for assessing risks to children that might arise from in utero and postnatal exposures.[7] However, there is a global interest in reducing, refining, and replacing (3Rs) the use of animals in research.[29]

The Food Quality Protection Act (FQPA) of 1996 enactment by U.S. Congress amended the Federal Insecticide, Fungicide, and Rodenticide Act and the Federal Food, Drug, and Cosmetic Act by fundamentally changing the way the EPA regulates pesticides. The major requirements of the FQPA include stricter safety standards, especially for infants and children, and a complete reassessment of all existing pesticide tolerances. They include an additional safety factor to account for developmental risks and incomplete data when considering a pesticide's effect on infants and children, and any special sensitivity and exposure to pesticide chemicals that infants and children may have (http://www.epa.gov/opp00001/regulating/laws/fqpa/).

The FQPA mandated that all pesticides in the United States undergo re-registration with a focus on reducing cumulative risk of exposure to pesticides sharing a common mode of action. Enforcement of FQPA has resulted in the modification of use patterns and removal (or pending removal) of many organophosphate insecticides that had previously seen wide use.[30]

The FQPA also requires the EPA to consider the cumulative effects of exposure to pesticides having a common mechanism of toxicity, considering for a cumulative risk assessment the exposure to all chemicals that act by a common mechanism of toxicity, as well as the exposure to each chemical via various routes and sources in an aggregate risk assessment. To support the grouping of different chemicals together for purposes of cumulative risk assessment, there must be sufficient evidence to support a common adverse effect that is associated with a common mechanism of action in specific target tissues. However, the criteria that are required to establish a common mechanism of toxicity with a specific toxic effect have not always been achieved for various pesticides as the common mechanism of toxicity of organophosphorus and carbamate insecticides (inhibition of acetylcholinesterase activity) that can be associated with adverse effects (cholinergic signs of intoxication). For example, a determination of common mechanism of toxicity in mammals is complicated by the number of potential biological target sites and effects expressed by various pyrethroid insecticides on these targets. Probably, the differences of action on neuronal ion channels among the pyrethroid insecticides contribute to the diversity of neurologic and behavioral manifestations of acute toxicity that are evident in the whole animal.[31]

European Union's Reach Legislation

REACH is the European Community Regulation on chemicals and their safe use. It deals with the Registration, Evaluation, Authorization, and Restriction of Chemicals. The law entered into force on June 1, 2007. The REACH regulation places greater responsibility on industry to manage the risks from chemicals and to provide safety information on the substances. Manufacturers and importers are required to gather information on the properties of their chemical substances, which will allow their safe handling, and to register the information in a central database in Helsinki (http://ec.europa.eu/environment/chemicals/reach/reach_intro.htm). It transfers responsibility for risk assessment from government to the manufacturers and importers, and includes downstream uses in the registration and management process. It introduces authorization and restriction procedures for the most hazardous chemicals and creates a new European Chemicals Agency. The legal permission to market products is conditional on the firms testing them for toxicity. If firms do not provide data required by the program, their products will not be permitted to enter (or remain in) the market. This program holds some promise for detecting developmental toxicants before they enter commerce and cause adverse effects. Whether this will work for subclinical neurotoxic and other developmental effects depends on tests the European Union requires. The REACH testing strategy is to require fewer tests for products produced in lesser amounts and to require more tests and more detailed tests as the production volume increases.[32]

In particular, large numbers of industrial chemicals are unlikely to be tested under this paradigm, and there is no specific requirement for developmental neurotoxicological testing under the new European Union law governing chemical regulation (REACH), which was passed in 2006 and went into effect in 2007. In response to the need for broader screening for developmental neurotoxicity, efforts are under way to develop additional developmental neurotoxicity screening paradigms. Additional efforts will be needed to focus on identifying possible chemical class- specific targets and biomarkers of effect, and on ways to differentiate normal variability in response from changes that are adverse.[33]

Perspectives

There is a need to expand risk assessment paradigms to evaluate exposures relevant to children from preconception to adolescence, taking into account the specific susceptibilities at each developmental stage. Risk assessment approaches for exposures in children must be linked to life stages. Establishing causal links between specific environmental exposures and complex, multifactorial health outcomes is difficult and challenging, particularly in children. For children, the stage in their development when the exposure occurs may be just as important as the magnitude of exposure. Very few studies have characterized exposures during different developmental stages. Some examples of health effects resulting from developmental exposures include those observed prenatally and at birth (e.g., miscarriage, stillbirth, low birth weight, birth defects), in young children (e.g., infant mortality, asthma, neurobehavioral and immune impairment), and in adolescents (e.g., precocious or delayed puberty). Emerging evidence suggests that an increased risk of certain diseases in adults (e.g., cancer, heart disease) can result in part from exposures to certain environmental chemicals during childhood. Advancing technology and new methodologies now offer promise for capturing exposures during these critical windows. This will enable investigators to detect conceptions early and estimate the potential competing risk of early embryonic mortality when considering children's health outcomes that are conditional on survival during the embryonic and fetal periods.[34]

Furthermore, emerging technologies such as gene expression, electrical activity measurements, and meta-bonomics have been identified as promising tools for evaluating neurotoxicity. In a combination with other assays, the in vitro approach could be included into a developmental neurotoxicological intelligent testing strategy to speed up the process of developmental neurotoxicity evaluation mainly by initial prioritization of chemicals with developmental neurotoxicity potential for further testing. Also, emerging nano/microtechnologies (piezoelectric spotting and microcontact printing of different biomolecules to create protein microarrays) can be used to promote cell differentiation and make the model suitable for developmental neurotoxicity screening.[35]

Developmental Toxic Effects on Nontarget Organisms in Environment

In addition to their potential role as human reproductive toxicants, pesticides are also implicated in reproductive failure of wildlife species exposed to pesticide sprays and residues. One main example of the ecological consequences of teratogenic pesticides is related to the organochlorines, which, besides inducing malformations in embryos, cause calcification problems in eggshells and impair reproduction in several wild bird species. This problem still remains in numerous areas, due to organochlorine residue accumulation through food chains and to wild populations exposed to organochlorine-contaminated sites.[36] Also, organochlorine pesticides can be maternally transferred to the developing eggs of alligators. This maternal exposure is associated with reduced clutch success and increased embryonic mortality.[37]

Toxicity assays are available for the evaluation of pesticide impact on wildlife or their surrogates, and many compounds have been shown to cause teratogenesis in fish, amphibian, avian, and mammalian species. Some chemicals that have been detected in the environment may be disrupting of both target and non-target systems in exposed populations of wildlife and fish.[38] Environmental compounds can also interfere with the endocrine systems of wildlife. Surface waters are the main sinks of endocrine disrupters, which are mainly of anthropogenic origin. Thus, aquatic organisms, especially lower vertebrates such as fish and amphibians, are the main potential targets for endocrine disrupters at direct or indirect risk via ingestion and accumulation of endocrine disrupters, direct exposure, or via the food chain. The impact of these compounds on reproductive biology can be mediated through four principal mechanisms of action: estrogenic, anti-estrogenic, androgenic, and anti-androgenic.[39]

Furthermore, population studies have revealed disruptions in crustacean growth, molting, sexual development, and recruitment that are indicative of environmental endocrine disruption. However, environmental factors other than pollution (i.e., temperature, parasitism) also can elicit these effects, and definitive causal relationships between endocrine disruption in field populations of crustaceans and chemical pollution is generally lacking.[40]

Amphibians are considered reliable indicators of environmental quality, in particular due to their biphasic life (aquatic and terrestrial) and semipermeable skin. These vertebrates are sensitive to a great number of pollutants dispersed in the environment, such as pesticides, heavy metals, and polychlorinated biphenyls. Field studies on frogs from polluted and reference sites have provided information on the effects of chronic exposure to contaminants.[41]

Despite the fact that almost all environmental chemical exposure is to mixtures, the current understanding of environmental health risks is based almost entirely on the evaluation of chemicals studied in isolation. Consequently, it is essential to develop and validate methods to accurately predict effects of endocrine-disrupting mixtures beyond the individual exposure to a single chemical, in order to protect humans and wildlife from the risk associated with potentially cumulative effects of these mixtures.[36,42] Its focus should be on the biological system or the target tissue rather than on the mechanism of toxicity or even a single signaling pathway.[43]

Although the importance of multiple stressors is widely recognized in aquatic ecotoxicology, pesticide mixture studies pose some major challenges such as experimental design difficulties (e.g., near-insurmountable factorial complexity for large numbers of chemicals), poorly understood pathways for chemical interaction, potential differences in response among species, and the need for more sophisticated statistical tools for analyzing complex data.[44]

Conclusion

The ability of a species to reproduce successfully requires the careful orchestration of developmental processes during critical time points, particularly the late embryonic and early postnatal periods. Standard developmental toxicology bioassays are designed to identify agents with the potential to induce adverse effects. Government agencies that regulate the use of pesticides and various industrial chemicals evaluate the toxicity of these agents to the developing embryo/fetus as an integral part of the testing protocol used to assess potential dangers to the public. However, an adequate experimental delineation is important to the data interpretation.

Humans and other non-target organisms are exposed to a mixture of chemicals. Various chemicals may target the organism's development during the same critical developmental period. Although developmental studies have been historically conducted on a chemical-by-chemical basis, the interest on considering cumulative risks of chemicals is growing. Chemicals as pesticides represent a risk for the reproduction and development of children and non-target organisms of terrestrial and aquatic ecosystems.

Bioindicators for Sustainable Agroecosystems

Joji Muramoto
and Stephen
R. Gliessman

Introduction

The growth of larger-scale monocultures that heavily depend on use of synthetic pesticides, chemical fertilizers, and fossil fuel-based agricultural machinery has significantly increased crop yield. However, this has also brought about both direct and indirect negative consequences on ecological (e.g., soil erosion, nitrate and pesticide contamination of groundwater, loss of agrobiodiversity), economic (e.g., increase of production and marketing costs and decrease of the net income of farmers), and social (e.g., loss of agricultural communities due to farm consolidations) sustainability of agriculture.[1,2] Especially, agricultural intensification is one of the major drivers of global biodiversity loss as a result of associated habitat fragmentation, land conversion, and agrochemical applications.[3,4] Since the 1970s, and more so after the 1980s, therefore, various alternative farming practices have been developed in pursuit of sustainable agriculture.[5–12] Farmers around the world have adopted these practices to varying degrees, but evaluation of their success needs to be conducted locally. To implement sustainable agricultural practices and policies, managers and policy makers need tools for assessing changes in agroecosystems in various time and spatial scales. Numerous indicators for agricultural sustainability including physicochemical, socioeconomic, and biological indicators, or bioindicators, have been developed.[13–17] Bioindicators are important because they are direct measures of the desired outcome, i.e., sustained or increased biodiversity. They also are living, dynamic, and active indicators, often responding quickly to the way farming is carried out. As evidence regarding the role of biodiversity in maintaining agroecosystem structure and function accumulates, its role as a bioindicator increases.

This chapter will first briefly review the background, definitions, concepts, and history of bioindicators. Then, we discuss the current status of developing bioindicators with two case studies: Europe and Latin America (shaded coffee systems). The former case represents temperate agroecosystems with 4000 years of farming history. The second case characterizes upland tropical agroecosystems known to occur in regions of the world with some of the highest, yet most threatened, biodiversity. Furthermore, examples of recent studies on use of aquatic organisms as bioindicators for agricultural sustainability and an example of the participatory approach in implementing agrobiodiversity policy in Japan are presented.

Agricultural Sustainability and Agrobiodiversity

Although many definitions of sustainable agriculture exist, most of them address ecological, economic, and social goals.[18,19] From an ecological perspective, sustainable farming practices (1) maintain their natural resource base; (2) rely on minimal artificial inputs from outside the farm system; (3) manage pests and diseases through internal regulating mechanisms; and (4) allow the recovery from the disturbances caused by cultivation and harvest.[20] Ecological characteristics of an agroecosystem, such as diversity, trophic structure, energy flow, nutrient cycles, population-regulating mechanisms, stability, and resilience, are metrics to help determine if a particular farming practice, input, or management decision is sustainable.[2]

Functions of biodiversity in agroecosystems, or agrobiodiversity, are foundations of sustainable farming practices. Ever since agriculture began some 10,000–12,000 years ago, biodiversity has allowed farming systems to evolve by providing genetic resources including edible plants, crop species, and livestock species.[21] However, diversities of crops and livestock have been decreasing rapidly since the introduction of monocultures of high-yielding cultivars and industrialization.[22] Insect and plant biodiversity in an agroecosystem provide multiple ecological services for agriculture. Examples include pollination,[23,24] insect pest management by intercropping,[25] and disease control by mixed planting of multiple cultivars.[26] Soil biodiversity, even though perhaps fewer than 10% of the species have been identified, is vital to soil fertility, decomposition of organic matter, soil structure, and soil health.[27,28] With higher diversity, there is greater microhabitat differentiation; there are more opportunities for coexistence and beneficial interference between species; there are more possible kinds of beneficial interactions between herbivores and their predators; there is more efficient use of resources of soil, water, and light; and there is reduced risk for the farmer. Examples of farming practices that can enhance agrobiodiversity and agroecosystem sustainability are listed in Table 1. Studies show that species and taxonomic groups respond to varying degrees to environmentally friendly management.[29,30]

Bioindicators

Heink and Kowarik[31] proposed an all-encompassing definition of indicators: "An indicator in ecology and environmental planning is a component or a measure of environmentally relevant phenomena used to depict or evaluate environmental conditions or changes or to set environmental goals. Environmentally relevant phenomena are pressures, states, and responses as defined by OECD (2003)"[32] (see Figure 1).

Bioindicators are based on biota that serve as indicators of the quality of the environment, the biotic component, or human impacts within an ecosystem.[34] The concept of bioindicators has been around for a long time—for example, the use of canaries to detect deadly carbon monoxide and methane gas buildup in mines has a long history. In the United Kingdom, it had been used since 1911 until it was completely replaced with gas detectors in 1986.[35] Other early uses of bioindicators include aquatic organisms to evaluate water quality in the United States[36] and the melanic form of moths to detect air pollution in the United Kingdom.[37,38] The number of publications about environmental indicators including bioindicators has been increasing since the 1980s.[39] The inaugural issues of the journals *Ecological Indicators* and *Environmental Bioindicators* (changed to *Environmental Indicators* in 2010) were published in 2001 and 2006, respectively. At the 2002 Johannesburg World Summit on Sustainable Development, representatives from 190 countries committed to achieving a significant reduction of the

TABLE 1 Farming Practices That Can Enhance Agrobiodiversity and Agroecosystem Sustainability

Habitat diversification	
Spatial	Temporal
Intercropping	Rotations
Trap crops	Fallow
Hedgerows	Cover crops
Shelterbelts	
Windbreaks	
Agroforestry	
Mosaic landscape	
Organic amendment applications	
Compost, organic mulch	
Green manure	
Conservation or minimum tillage	
Biological pest management	
No or reduced use of pesticides, fungicides, herbicides, and fumigants	
Use of beneficial insects	
Anaerobic soil disinfestation[a]	
Physical pest management	
Solarization	
Flooding	
Plant resistance

current rate of biodiversity loss at the global, regional, and national levels by 2010.[40] Since then, the use of bioindicators for evaluating the status and functions of ecosystems and sustainability of agroecosystems has risen considerably,[41,42] yet the majority of recent studies of bioindicators has focused on the detection of pollution.[39]

Successful bioindicators should not only have biological and methodological relevance but also societal relevance because indicators require long-term monitoring to separate real change from natural fluctuations. Features of bioindicators are listed in Table 2. Inventory and classification are the foundations for developing indicators.[43] Developing an indicator then involves several steps: define objectives; determine end uses; construct indicators; determine norms and thresholds; and test sensitivity, probability, and usefulness.[44] Compared to abiotic indicators, however, developing a bioindicator has greater challenges for several reasons. First, biotic parameters are highly variable both temporally and spatially. There is a paucity of information on temporal and spatial variability of most natural species populations. Second, due to high variability, it costs more to collect additional replications to achieve the same statistical power in data. Standardized sampling methods for bioindicators are often lacking. Databases for bioindicators are critically limited especially in developing countries[45] although number of such studies are increasing.[46,47] Finally, it is more difficult with bioindicators to define background levels, norms, and thresholds.[42]

Nevertheless, demand for bioindicators as evaluative tools at diverse levels is increasing. Some of these are policy driven and others are market driven. For example, international organizations, such as the Organisation for Economic Co-operation and Development (OECD)[48–50] and the

TABLE 2 Features of Bioindicators for Environmental and Ecological Health Assessment

Biological relevance	• Provides early warning • Exhibits changes in response to stress • Changes are measured on appropriate time scale • Intensity of changes related to intensity of stressors • Change occurs when effect is real • Changes are biologically important and occur early enough to prevent catastrophic effects • Changes can be attributed to a cause • Changes indicate effects on ecosystem services • Can be used as sentinels for humans
Methodological relevance	• Easy to use in the field • Can be used by nonspecialists • Easy to analyze and interpret data • Measures what it is supposed to measure • Useful to test management questions • Can be used for hypothesis testing • Can be conducted in a reasonable time • Does not require expensive or complicated equipment • Easily repeatable with little training
Societal relevance	• Of interest to the public • Of interest to regulators and public policy makers • Easily understood by the public • Methods transparent to the public • Measures related to environment, ecological integrity, and human health • Cost-effective • Adds measurably to other indicators • Complements other indicators

Source: Modified from Burger.[34]

European Union (EU),[51] promote development of standardized bioindicators as a policy to compare biodiversity worldwide. Among commercial sectors, bioindicators have been used to certify "environmentally sound" products, such as migratory birds for shade-grown coffee.[52] Ecologists are using bioindicators and various other indicators at different levels of organization to evaluate the health of ecosystems (Table 3) and make recommendations for future management.[53,54] Bioindicators are often integrated into the frameworks of sustainability indicators of agroecosystems.[55,56]

TABLE 3 Usefulness of Indicators at Different Biological Levels of Organization to Ecological Health

Ecological Level	Type of Indicator	Ecological Health
Individual	Contaminant levels	Used to evaluate health of individuals For evaluation of risk to higher-level consumers As an indicator of health of its foods, including prey
	Lesions	
	Disease	
	Tumors	
	Infertility	
	Growth	
	Longevity	
	Reproduction	
	Age of reproduction	
	Hormonal balance	
	Proper development and maturation	
Population	Reproductive rates	Used to evaluate health of populations of species, particularly endangered or threatened species
	Growth rates	
	Survival rates	For comparison among populations
	Movements	For temporal comparisons
	Population genetics related to the breadth of the gene bank	Sources of resistance and pressure of natural selection
Community	Foraging guilds	Measures health of species using the same niche, such as colonial birds nesting in a colony or foraging animals such as dolphins and tuna
	Breeding guilds (groups of related species)	
	Predator–prey interactions	Indicates relationship among different species within guilds or assemblages
	Competitive interactions	
	Pathogen–host, pest–host relationships	For spatial and temporal comparisons
	Species richness	For evaluating efficacy of management options
Ecosystem	Decomposition rates	Measure changes in relative presence of species, how fast nutrients and energy will become available, how fast nutrients in soil will no longer be available, how much photosynthesis is occurring
	Erosion rates	
	Primary productivity	
	Energy transfer	Examines overall structure of the ecosystem in terms of the relationships among trophic levels
	Nutrient flow	
	Relationship among different trophic levels	For evaluating efficacy of management options
	Biomass	
	Energy flow	
Landscape	Relative amounts of different habitats	Measures dispersion of different habitat types, indicates relative species diversity values
	Patch size	Measures the difference among habitats
	Corridors between habitat types or different ecosystems	Measures distribution of corridors and refugia within the landscape
	The extent of uniform genetics	Also can measure the relationship between developed and natural areas for evaluating the importance of specific ecosystems within the landscape

Bioindicator Development in European Union Agroecosystems

The importance of agro-environmental indicators has been highlighted by the EU[51] where current agricultural policies aim to increase multifunctionality of agricultural production. Intensive studies on bioindicators have been conducted in European countries. Bioindicators demonstrated to be sensitive to farm management intensities in European and some other agroecosystems are listed in Table 4. Generally, it is observed among invertebrate species that with less intensive management, there are more specialists and less generalists (as a result of ecological succession), greater biodiversity, and greater resilience.[42] An example of a bioindicator based on these correlations is European spiders; habitat preferences of spiders, particularly the ratio of "pioneer species (mostly Linyphiidae)" versus "wolf spiders (Araneae: Lycosidae)," can be a sensitive indicator for the assessment of farming intensity.[56] Many bioindicators listed in Table 4, however, have critical use limitations due to technically complex sampling methods and greater temporal and spatial variability. Although special instruments are required, recent advancements in molecular techniques may make some highly sensitive bioindicators such as nematodes much more accessible.[57,58]

TABLE 4 Examples of Potential Bioindicators for Sustainability of Farming Practices in European and Other Agroecosystems

Bioindicator	Parameter	Comments	References
		Arthropods	
Ground beetles (Carabidae)	Abundance	• Sensitive to management intensity but needs intensive data collection	[91–96]
Spiders (Araneae)	Habitat preferences Percent pioneer species	• Highly sensitive to management intensity and database is available on ecological characteristics of central European spiders	[97–105]
Hoverflies (Syrphidae)	Percent stenotopic species	• Diversity of landscape structure adjacent to the field enhances species numbers	[106–111]
Pollinators	Individuals Populations Ecological guilds	• Environmental stress brought about by pesticides and habitat modification reduce pollinators	[112–114]
Arthropod community	Abundance of key species	• Diverse arthropod communities are affected by landscape diversity and environmental stress	[98,115–116]
		Soil fauna	
Ants	Diversity Community composition	• Good indicator for rangeland monitoring and land-use changes	[117–122]
Earthworm	Biomass Species number Ecological guilds	• Suitable indicator for soil structure or compaction, tillage practice, pesticides, and other toxic chemicals	[123–131]
Collembola Protozoa Nematode Micro-arthropods Mites Soil animal	Physiotype Biodiversity Trophic index Maturity index Food web	• Highly sensitive to management intensity but time consuming and special skills are required for identification. Recent advancement in molecular approach makes these more accessible	[58,132–157]
		Soil microbiota	
Soil enzymes (e.g., glucosinases for cellulose decomposition, phenol oxidases for lignin decomposition)	Activities	• Moderately sensitive to management intensity and relatively easy to measure but moderately variable both temporally and spatially	[58,158–160]

(*Continued*)

TABLE 4 (*Continued*) Examples of Potential Bioindicators for Sustainability of Farming Practices in European and Other Agroecosystems

Bioindicator	Parameter	Comments	References
Soil protists (e.g., algae, amoeba, diatom)	Species diversity Photosynthetic activity	• Less studied but sensitive to tillage, pesticides, and fertilizers	[161–163]
Microbial communities	Composition Functional diversity PLFA[a] profiles qPCR[b]	• Moderately sensitive to management intensity, but special skills and equipment are required and difficult to interpret	[58,164–166]
Functional groups	Mycorrhizae Nitrification Root pathogens	• Highly sensitive to management intensity, but special skills and instruments are required. DNA-based approaches (e.g., TRFLP[C], qPCR) became popular	[58,167–171]
Microbial activity	Soil respiration Mineralization Multiple substrate-induced respiration (MSIR)	• Relatively easy to measure but highly variable both temporally and spatially	[58,159,160,171]
Microbial biomass	C, N, and P biomass	• Relatively easy to measure but highly variable both temporally and spatially	[159,160]
		Birds	
Terrestrial birds Farmland birds	Species abundance of focal species and taxonomic composition at landscape scales	• Bird communities can be used to evaluate the effect of agriculture on surrounding ecosystems and hydrology and to explore sustainable land-use scenarios at regional scales	[62,172–175]
		Plants	
Higher plants	Numbers of "characteristic" species, weeds, functional groups, and endangered species Cover of litter in vegetation Diversity Evenness indices Habitat age	• Capable of being integrated into sophisticated floristic diversity at the habitat scale but requires intensive data collection	[176–180]

[a] PLFA, phospholipid fatty acid.

[b] qPCR, quantitative polymerase chain reaction.

[c] TRFLP, terminal restriction fragment length polymorphism.

To practically implement agro-environmental policy in the EU, efforts have been made to develop relatively easy-to-measure surrogate indicators (e.g., length of borders, farm size, area managed with organic farming).[42] Another practical bioindicator is a list of indicator plant species to evaluate species richness of a farm. A total of 28 indicator flower species for meadows and pastures that can be easily identified by local farmers were selected in Baden-Württemberg, Germany. Agro-environmental payments are granted to farms that have at least 4 of these 28 indicator species in all of the meadows and pastures on the farm.[59] In designing more efficient agro-environmental schemes, advantages of result-oriented remuneration (e.g., payment towards species-rich meadows) over action-oriented remuneration (e.g., payment towards manuring and mowing once per year) have been discussed.[60] It has been further recognized that the preservation of biodiversity is only possible through the (re)establishment of a mosaic of habitat patches at the landscape level. To meet this need, Geographical Information System

(GIS)-based landscape-oriented indicators have been examined.[61] GIS approaches are powerful tools for special analysis of bioindicators such as studies on correlations of bioindicator distributions (e.g., birds) and environmental and social factors at a landscape level.[62] Landscape context can have significant effect on biodiversity.[63,64]

To select objective, broad-scale, and unbiased indicators, conceptual frameworks for agro-environmental indicators have been proposed. Varying causal chain frameworks such as pressure–state–response (PSR), driving force–state–response (DSR),[65] and driving force–pressure–state–impact–response (DPSIR)[66] have been developed (Figure 1). Enhanced DPSIR (eDPSIR) was proposed as a way to provide improved conceptual guidance in indicator selection based upon the DPSIR approach, systems analysis, and causal networks.[54] Sustainability Assessment of Farming and the Environment (SAFE), a hierarchical framework for assessing the sustainability of agricultural systems in Belgium, was created as a consistent and comprehensive framework of principles, criteria, and indicators.[55] These frameworks integrate bioindicators as a component of sustainability indicators of agroecosystems.

Biodiversity has multiple dimensions, and it is difficult to measure by a single indicator. Feest et al. proposed the "biodiversity quality" approach using multiple indicators (e.g., species richness, evenness/dominance, density/population, relative biomass, and species conservation value index) in combination to assess the balance between a range of indices and their relative magnitude.[67,68] Four different types of indicators of biodiversity change were suggested as a tool to facilitate indicator development (Figure 2).[69] With a goal of stable or increasing populations in all species associated with agricultural landscapes, Butler et al. developed a cross-taxonomic index for quantifying the health of farmland biodiversity by which the detrimental impacts of agricultural change to a broad range of taxonomic groupings can be assessed.[70]

For nationwide soil monitoring in the United Kingdom, a framework in selecting soil bioindicators for balancing scientific and technical opinion to assist policy development was established.[58]

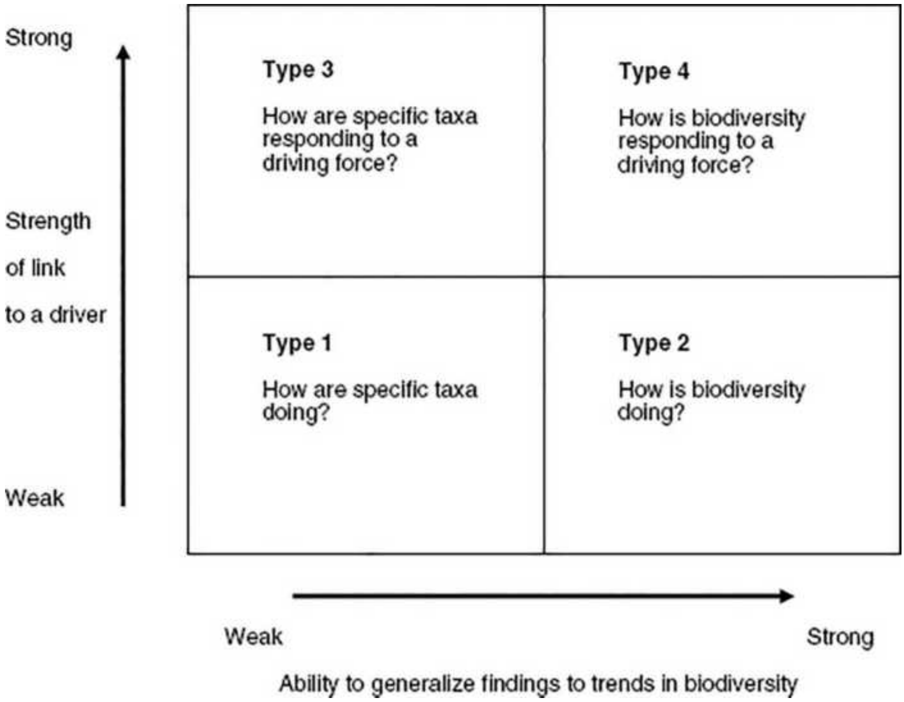

FIGURE 2 Typology of biodiversity change indicators. (van Strien et al.[69])

This semi-objective approach using "logical sieve" yielded 17 bioindicators that cover a range of genotypic-, phenotypic-, and functional-based indicators for different trophic groups out of 183 candidate bioindicators. This framework allows transparency in the decision-making process in selecting soil bioindicators as well as flexibility in including other indicators depending on priorities of the monitoring. The need for unambiguous and broad definitions of terms such as *indicators* and *biodiversity* was addressed for improving communication among interdisciplinary researchers, policy makers, and stakeholders.[71] To make indicators relevant to potential users and have long-term public support, the necessity of stakeholder participation in developing ecological indicators was also emphasized.[72]

Bioindicator Development in Shaded Coffee in Latin America

Coffee is the second most traded commodity in the world after petroleum and forms the principal economic activity of more than 20 million people in farming communities throughout much of the developing world.[73] Traditionally grown in the understory of forest cover or planted shade trees, throughout the 1970s and 1980s, many coffee farmers adopted more modern production practices, planting higher-yielding varieties in full sun, eliminating shade trees, and increasing pesticide and fertilizer applications.[74] The loss of shade cover, and associated biodiversity, has led to many environmental problems such as soil erosion, loss of water capture and recharge ability, and contamination from the excessive fertilizer and pesticide use associated with sun-grown coffee.

Recent research has documented the high levels of agrobiodiversity and ecosystem services (such as pollination, soil conservation, and natural pest control) associated with diverse shade coffee production.[75,76] From this research, several very important bioindicators are being developed. The number of tree species in the shade canopy is an important indicator of both conservation potential of coffee plantations and increased options for farmer livelihood alternatives.[77–79] The species richness of ants and insect feeding birds are greater in shade coffee than in sun coffee, especially ground-foraging ants that act as important predators and birds that are bark gleaners and leaf surface foragers. It also appears that the higher diversity of predaceous ants restricts the development of pest ants such as the fire ant *Solenopsis* sp. (Hymenoptera), a very common pest in open landscapes and sun-grown coffee. Associated species such as orchids in the shade tree canopy can also be important bioindicators. Local farmers can be trained to recognize orchids, demonstrating how the development of bioindicators of sustainability can be an accessible and local methodology that adds value to more sustainable farming practices. Orchids have an intrinsic value from a conservation perspective and, at the same time in this region of northern Nicaragua, have added an attractive value for an emerging agro-ecotourism industry associated with shade-grown coffee landscapes.[80]

Aquatic Organisms as Bioindicators

Recent studies showed that a range of aquatic organisms that inhabit water bodies in agroecosystems or in watersheds including agroecosystems can be used as bioindicators for evaluating sustainability of agroecosystems or their impacts on the environment. A study in organic and conventional paddy fields in Costa Rica found that some aquatic macroinvertebrates (*Baetis* sp., *Fallceon* sp., *Leptohyphes* sp., *Tricorythodes* sp., *Farrodes* sp., *Phyllogomphoides* sp., *Hydroptila* sp., *Mayatrichia* sp., *Neotrichia* sp., *Oxyethira* sp., *Nectopsyche* sp.1, *Nectopsyche* sp.2, and *Oecetis* sp.) were found only in organic paddy fields and can be used as sensitive bioindicators of water quality in these agroecosystems.[81]

Rhinella arenarum, a toad species, inhabiting ponds associated with agroecosystems, showed a smaller egg diameter, a higher frequency of abnormal eggs, and a higher mortality of oviposition compared to those inhabiting a reference pond without agricultural influences.[82] The δ15N signature of large, long-lived, freshwater mussels (Mollusca: Bivalvia: Unionidae) was successfully used as an integrated bioassessment tool for tracking agricultural nitrogen inputs into watersheds.[83]

Improving Awareness of Farmers and Consumers

Often, farmers themselves are not fully aware of the biodiversity in their farms. Moreover, to economically sustain environmentally friendly farming practices, recognition and support from consumers are necessary. To implement sustainable agricultural policy, therefore, improved awareness of both farmers and consumers on agrobiodiversity is required.

An example of such activity is the participatory biodiversity inventory in paddy rice ecosystems in Japan, where paddy fields occupy ~50% of the cultivated lands of the country. Japanese paddy agroecosystems contain a diverse group of organisms: Recent inventory found 5668 species including birds (189 spp.), fish (143 spp.), reptiles and amphibian (61 spp.), arthropods (1726 spp.), and plants (2075 spp.).[84] Since the 1960s, however, many native species inhabiting paddy fields have decreased in abundance mainly due to nontarget effects of pesticide applications and the construction of concrete ditches. Consequently, 3 mammal species, 15 insect species, 5 bird species, 27 species of fish, 3 amphibian species, 3 mollusks, and 26 plant species are listed as endangered species inhabiting paddy fields.[84] Nongovernmental organizations (NGOs), scientists, farmers, the general public, and administrators collaborated to create nationwide inventories of biodiversity in paddy agroecosystems and proposed a broad range of bioindicators (237 animal species[85] and 223 plant species[86]) to enhance the awareness of both farmers and consumers on paddy field biodiversity (Figure 3).

FIGURE 3 A portion of Japanese poster for improving farmer and consumer awareness of agrobiodiversity in paddy fields. Central figure indicates a bowl of rice being equivalent to 3000–4000 grains of rice, 3 stubs of rice plants, and 35 tadpoles in a paddy. This can be interpreted as eating a bowl of rice supports 35 tadpoles in a paddy. Numbers of species are averages from the national survey of agrobiodiversity in paddy fields in Japan. Clockwise from the upper left, the species listed are *Daphnia pulex* (water flea), *Pantala flavescens* (Globe Skimmer), *Sympetrum frequens* (Autumn Darter), *Triops longicaudatus* (longtail tadpole shrimp), *Branchinella kugenumaensis* (fairy shrimp), *Hyla japonica* (Japanese tree frog), *Rhabdophis tigrinus* (tiger keelback), *Misgurnus anguillicaudatus* (Dojo Loach), *Oryzias latipes* (Medaka), *Rana nigromaculata* (Dark-spotted frog), *Rana rugosa* (Japanese wrinkled frog), and *Ceriagrion melanurum* (damselfly). (Une.[181])

Conclusions

Indicators represent a compromise between scientific knowledge of the moment and simplicity of use.[44] Compared to assessment systems for natural ecosystems,[43,87] the current status of developing bioindicators for sustainability of farming practices appears to still be in its early stages but is making good progress as seen in increased number of studies from places outside of Europe. For using bioindicators to implement sustainable agricultural policy, however, we need not only more research on the science of bioindicators but also better awareness on agrobiodiversity among farmers and consumers.

Future studies on bioindicators for sustainable farming practices should address the following: (1) the importance of stability and reproductive potential of not only pest and beneficial species but also other species typical of agroecosystems;[42,70,88] (2) standardization of sampling methods;[42] (3) expansion of databases and improvement of the statistical techniques to minimize potential bias of indicators;[68,89] (4) improved understanding of the mechanisms linking the status of biodiversity, Earth system processes, human decisions, and ecosystem services impacting human welfare through interdisciplinary studies;[52,89] (5) use of participatory approaches in the processes of developing bioindicators;[72,90] (6) development of multiple sets of bioindicators tailored to different end users (general public, farmers, policy makers, and scientists);[42] and (7) constructing a hierarchical system that integrates different types of bioindicators and ecological, social, cultural, and economic indicators to evaluate sustainability of farming practices.[55].

Ecological Indicators: Eco-Exergy to Emergy Flow

Simone Bastianoni,
Luca Coscieme, and
Federico M. Pulselli

Introduction

Living systems can be viewed as dissipative structures, self-organizing systems that dissipate energy for the maintenance of organization.[1] They exist by the transforming available energy potentials, building new structures as a consequence of the process.[2] To study the ecosystem in this view, we need proper tools able to take into account the biological time[3] that has been necessary for the "creative" planning and construction of dissipative structures in the system, through the concentration of energies and matter.

The study of the behavior of a single species in a system provides knowledge of the system's parts. Similar to a jigsaw puzzle, we need to know the single drawing on each piece, as well as the boundaries/shapes of the pieces, in order to properly choose where each piece must be placed, so that we can reconstruct the entire drawing. However, in a very complex context, we are not capable of reconstructing the whole drawing if we do not have a reference, a picture of the whole system that can guide us, e.g., the drawing on the box of the puzzle. Holistic indicators, orientors, or goal functions give us this kind of information, guiding the disciplinary research in a conjunction of efforts, in order to have the best description of the system. In fact, extending the study from a "simple" description of the system in a given time to a description of the system evolving through various states, the holistic indicators allow us to understand if the system under study is globally following a path that will take the system to a "better" or to a "worse" state.[4]

As maintained by Müller and Leupelt,[5] goal functions and orientors have been developed as holistic measures of the global performance of ecosystems, of what we could call, in a broad sense, complexity. Fath, Patten, and Choi[6] showed that 10 extremal principles involving orientors (power, storage, empower, emergy, ascendency, dissipation, cycling, residence time, specific dissipation, and empower/exergy ratio) can be unified by ecological network notation.

In its evolution, a system changes properties and behaviors, like human beings or other organisms change their "reactions" to the surrounding "signals" during their evolution. Every different holistic indicator is appropriate to describe the system in a particular state or phase of its evolution or a particular characteristic of the same system. When studying a dynamic system in evolution, holistic indicators (and the joint use of them) seem to be more powerful than nonsystemic indicators. Only this approach seems to be truly useful to describe the system and its dynamics, i.e., from a "young system" state, through intermediate states (i.e., of reorganization after possible perturbations), toward a climax mature stage.

This holistic approach is relatively new, but it is very efficacious and promising for ecosystem investigation and management.

In this entry, we describe the combined use of two holistic indicators, eco-exergy and emergy, composing a ratio that is able to describe the system during its evolution. Moreover, it adds information to that obtained from the use of the two orientors separately. This kind of approach is in line with the book *A New Ecology: Systems Perspective* proposed by Sven Jørgensen and coauthors[4] and with what Fath, Patten, and Choi[6] maintained in their fundamental paper on the use of a plurality of "goal functions," highlighting their complementarity and interdependency.

A Description of the System Using Emergy

A class of indicators, based on the concept of emergy, are able to evaluate the convergence of matter and energy (several inputs) to a system. On the basis of a thermodynamic hierarchy of energy, and starting from solar energy input to the earth, emergy provides a measure of the environmental work necessary to generate an item or a flow (which could be, for example, an input to any system).

The concept of emergy derives from a reflection about the concept of energy quality.[7] The second principle of thermodynamics states that energy transformations imply an irreversible degradation of energy. In living systems and ecosystems, inputs of energy are transformed, and the energy quality changes. A portion of diluted sunlight is lost as heat, and a portion is concentrated into forms that are more able to do work, and/or more flexible to be used. According to Odum, many joules of low quality are needed for a few joules of high quality. In the case of a typical web of connections, like the food chain, "at each stage, energy is degraded as a necessary part of transforming a lower quality energy to a higher quality one in lesser quantity. The energy flows decrease as one goes up the food chain."[7] "A joule of sunlight, a joule of coal, a joule of human effort are of different quality and represent vastly different convergences of energy in their making."[8] Therefore, in many cases, it is not correct to use energy to describe the dynamics and behavior of systems. Solar energy can be considered the basis upon which energy transformations in the biosphere occur. Emergy, expressed in solar emergy joule (seJ or, according to a recent proposal, semj) is defined as the quantity of solar energy directly or indirectly necessary to produce a flow or a product. In the case of ecosystems, the emergy flow (empower) is considered, which is the quantity of solar energy directly or indirectly necessary to support the system and its level of organization.[9–11]

To compare all kinds of energy on the common basis of solar energy, solar transformity has been utilized, defined as the solar energy directly and indirectly required to generate 1 J of a product. It is a conversion factor that takes into account the position of one energy form in a sort of thermodynamic hierarchy in the biosphere. The solar transformity of the sunlight absorbed by the earth is 1 seJ/J by definition.[12]

To quantify the emergy of a product or system, all the inputs to the system or production process must be quantified and expressed in seJ by means of suitable transformities, which are used to convert different flows of energy into equivalent solar energy.[9] In case of matter inputs, the specific emergy (expressed in seJ/g or another unit) is used to convert mass into equivalent solar energy. Recently, the concept of unit emergy value has been used, independently of the unit in which the flows are expressed (energy or mass). The total emergy of a system (EmS) is given, approximately, by the sum of the energy content (*Ei*) of the *i*th input to the system multiplied by the corresponding transformity (Tr*i*), while avoiding double counting any inputs (see Bastianoni[13] for a thorough analysis of this calculation method):

$$\mathrm{Em_S} = \Sigma E_i \cdot \mathrm{Tr}_i \tag{1}$$

Every flow can be expressed by means of its solar equivalent, and a system of environmental accounting based on emergy can be implemented.[14]

Emergy represents the convergence of different kinds of energy to a system (E_i) times the quantity of solar energy that has been necessary to make available one unit (Tr_i,). It is not a state function because it depends on the kinds of energy and the process that is used to obtain a certain item (that can be a product or a given state of the system). Therefore, emergy enables us to identify, quantify, and weigh the inputs that feed an ecosystem. If natural selection has been given time to operate, the higher the emergy flux necessary to sustain a system, component, or a process, the higher the hierarchical level and the usefulness that can be expected for that entity (maximum empower principle[7]).

In a pristine natural system, self-organizing from young states, this maximum empower principle (derived from the maximum power principle[15]) is realized, and the continuous increase of emergy is an indication of a proper evolution toward a mature system (climax stage).[16] Therefore, empower has been proposed as an ecosystem health indicator.[17]

In "real-world" cases, where natural systems interact with human systems and dynamics, the increase of emergy (as a consequence of the increase in energetic inputs that reach the ecosystem) is not always "good" in the sense that it will support the evolution of the system toward a climax stage. In fact, a portion of the inputs that the ecosystem receives is not used to build structures in order to maintain the nonequilibrium state (e.g., nutrient overflow, pollutants). Emergy flow alone cannot be used as a "reference direction" indicator[18] if the system is not a pure pristine system.

A Description of the System Using Eco-Exergy

The usable energy input to a system is converted into genetic information, biomass storages, and a relation network.[7,19,20] Structural complexity and biodiversity influence the possible evolutions of the system toward another (more or less) stable state.[21]

Eco-exergy expresses the development of ecosystems by the increase in the work capacity,[4] considering the biomass stored in a system and its genetic information.[22–25]

According to Jørgensen,[26,27] we can distinguish between technological exergy and eco-exergy: the former uses the environment as a reference state and is able to measure the useful energy provided by a production process; the latter uses as a reference state the same ecosystem at thermodynamic equilibrium. Eco-exergy thus estimates the distance of an ecosystem from thermodynamic equilibrium and is given by the formula

$$\mathrm{Eco-Ex} = \Sigma \beta_i \cdot c_i \tag{2}$$

where c_i is the concentration of the ith component of the ecosystem and β_i is the weighting factor that accounts for the genetic information that the component carries (for a list of β values.[28]

When the available inputs to the system are used to build up new biomass and/or complexity, the system is tending to its climax stage (maximum exergy principle[4]). Eco-exergy is a state-based descriptor of a system's structure (and functions, networks, interactions) based on usable energy and information. It has also been used as an ecosystem health indicator.[24,25,29]

Ratio of Eco-Exergy to Emergy Flow

Emergy and eco-exergy can be considered as complementary entities, with the former accounting for the amount of basic energy (solar) required to support a process or an ecosystem and the latter being the level of organization reached by a system.

The need to compare the emergy flow that supports an ecosystem with the consequent ecosystem reaction was already clear to Odum, who tried to assess the ecosystem response using the emergy-to-information ratio[7] as a measure of information hierarchy. Odum used the mass of DNA as information carrier and looked at the ratio of emergy to information measured in bits, considering that the emergy required per bit may give an indication on the usefulness of the information in an adapted system.[7,30] The emergy-to-information ratio, also used by Keitt,[31] has a problem that consists in the arbitrariness of the choice of the system's basic element: an atom or an individual of a species, a letter of an alphabet, or a gene as the basic "symbol." Bastianoni and Marchettini[30] have proposed joining emergy with eco-exergy in order to measure the ecosystem structure. The ratio between eco-exergy and emergy flow indicates the organization or structure of an ecosystem per unit of solar emergy flow required to produce or maintain it.[30] Bastianoni and Marchettini[30] first introduced this- relation as the ratio of emergy (flow) to eco-exergy. This choice was made in order to maintain coherence with the definition of transformity (i.e., the emergy that contributes to a production system divided by the energy content of a product). In fact, the ratio of emergy flow to eco-exergy represents an empower converging to a certain system divided by the eco-exergy of the whole system. Actually, the inverse seems more comprehensible, where the effect (eco-exergy) is at the numerator and the requirement is at the denominator, as in any efficiency indicator.

The role of information and structure is fundamental when we approach the study of complex systems, such as an ecosystem. The use of eco-exergy adds something to the classical exergy approach (for an overview, see Jørgensen and Mejer,[22] Jørgensen,[27] and Sciubba and Wall[32]), which does not take into account information content. For instance, the difference between a living organism and a dead one is not related to the classical exergetic content that is in fact the same, but is related to the capability of the living system to use the information content in its DNA.[33]

The ratio of eco-exergy to emergy flow has also been considered as an indicator of the efficiency[30] in transforming available inputs, evaluated in emergy terms, into the structure, information, and ecosystem organization, evaluated in eco-exergy terms. In fact, it represents the state of the system (as eco-exergy) per unit input (as empower). Strictly speaking, its unit is JyrseJ^{-1} (we maintain this representation even if β values may influence the pure thermodynamic nature of eco-exergy and its unit). Since the dimensions are those of time, it cannot be regarded as a real efficiency (which is dimensionless) but more as a proxy of efficiency. The higher its value, the higher the efficiency of the system; if the eco-exergy/empower ratio tends to increase (apart from oscillations due to normal biological cycles), it means that natural selection is making the system follow a thermodynamic path that will bring the system to a higher organizational level.[33,34] As an efficiency indicator, the ratio of eco-exergy to empower enlarges the viewpoint of a pure exergetic approach, where the exergy degraded and the eco-exergy stored for various ecosystems are compared: using emergy, there is a recognition of the fact that solar radiation is the driving force of all the energy (and exergy) flows on the biosphere, which is essential when important "indirect" inputs (of solar energy) are also present in a process, and must be identified, weighted, and finally, taken into account.

Fath, Patten, and Choi[6] have identified the ratio of eco-exergy to emergy flow as one of the possible orientors of an ecosystem: they link the emergy flow to the total system throughput and eco-exergy to the total system storage, therefore connecting the maximization of the ratio of eco-exergy to emergy flow with the maximization of residence time.

Applications in Environmental Investigation and Management

A Definition of Ecosystem Development

Ecological orientors and goal functions can indicate some aspects of the degree of naturalness of ecosystems; they provide a good basis for finding usable indicators for ecosystem health, ecological integrity, and sustainability;[5] they can also be used to evaluate the strength of human impact and an ecosystem's structural carrying capacity.

The ratio of eco-exergy to empower has often been applied in order to assess ecosystem health: in fact, ecosystems with different empower and eco-exergy can be compared with each other, also regarding their behavior and performance. In general, we can say that in natural systems, where selection has acted undisturbed for a long time, the ratio of eco-exergy to empower is higher and decreases with the progressive introduction of artificial inputs and stress factors that make the emergy flow higher and lower the eco-exergy content of the ecosystem. In the evolutionary process, close to the steady state (climax), the ratio of eco-exergy to empower tends to increase, which means that the system uses all the materials and energy available to reach a higher eco-exergy content. The same systems, once the climax has been reached, will remain in such a state for some time and can then grow/develop again only if further energy and/or materials are available. In the latter case, new sources of energy (or better emergy) can be used to build up new biomass and/or complexity of the ecosystem (stored eco-exergy). In terms of the ratio of eco-exergy to empower, when a system is relatively young and acquires new inputs, the ratio tends to be lower; when the system is developing toward the climax stage, the ratio tends to rise.[2,35]

This approach is helpful when different kinds of ecosystems are compared, natural and artificial. The former might have different quantities and qualities of available inputs, while the latter cannot be compared only on the basis of its "state" but also considering its requirements to develop and sustain the state itself. The results of a study on eight different aquatic ecosystems[30,35–37] demonstrated that the highest level of efficiency (in the exergy/empower sense) is obtained by a seminatural system within the lagoon of Venice, a farming basin developed over several centuries. Its efficiency is of the same order of magnitude as natural systems, but it is higher than systems with limited human input. Furthermore, the efficiency of the seminatural system is two orders of magnitude greater than artificial ecosystems by virtue of a higher level of organization and less need for external input.[36,38] Application to agroecosystems can be found in Bastianoni et al.[39] The ratios of eco- exergy to emergy and eco-exergy to empower have been also proposed to assess the self-organization efficiency of forest ecosystems.[40]

A Definition of Ecosystem Health and Pollution

A qualitative or quantitative change in the set of inputs can contribute to a change in a system's self-organization pattern and a system's different responses. Moreover, controlled human intervention can make a positive contribution to the system in terms of organization, information complexity, etc., (the eco-exergy of the system) that more than offset the environmental cost of the same intervention (the emergy flow corresponding to the human-induced inputs to the system).

If we consider the emergy flow to a system to vary between two equal and contiguous intervals, we will indicate the variation of emergy flow with ΔEM. Consequent changes in system organization can be measured by the variation of the exergy content of the system ΔEX. The quantity $\sigma = \Delta EX/\Delta EM$, with the dimensions of $J{\cdot}s{\cdot}seJ^{-1}$, represents the change of level of organization (exergy) of the system under study, when it is related to a change of the emergy flow. It is a quantity that is specific to the inputs that are subtracted or added. If σ is positive, the addition of emergy input gives rise to further organization (increasing eco-exergy), whereas a lowering of emergy has a negative effect on the system (decreasing eco-exergy). On the other hand, when σ is negative, a higher emergy flow implies a decrease in organization, whereas a lower quantity of one or more inputs causes increasing organization. In these two last cases, the inputs can generally be viewed as pollutants: in an evolutionary perspective, if they are removed, the system self-organizes; if they are added, the system is damaged. This provides a definition of pollution based on two holistic orientors representing system dynamics. A first-level observation of the behavior of σ (and of the system as a whole) gives information on the existence of pollutants; a deeper analysis can identify the intensity of pollution that is given by the sensibility of eco-exergy relative to a change in emergy flow.[41]

Holistic Interpretation of Ecosystem Services

Emergy and eco-exergy can be related to the concept of "ecosystem services." Ecosystem services are the benefits human populations derive, directly or indirectly, from ecosystem functions (e.g., food provision or waste assimilation).[42] This concept derives from a reconceptualization of ecosystem functioning from an anthropocentric viewpoint.[43]

In general, ecosystems utilize flows of energy and matter from the environment to maintain themselves as far as possible from thermodynamic equilibrium and to survive, grow, and/or develop. The degree of development and the efficacy with which these flows are used up and processed depend on the state/structure/organization of the ecosystem, which is a particular configuration of the abiotic–biotic system components, characterized by specific relationships between living organisms and nonliving surroundings. The outputs of an ecosystem are all flows of energy and matter moving from the system to the environment, as well as all goods and services useful for humans.

A relationship between the inflows of energy and matter supporting the ecosystem and the services it provides has been investigated by Pulselli, Coscieme, and Bastianoni,[21] who noted that in this input–output representation of ecosystems, the emergy flow (input) supporting an ecosystem and the value of the services (output) it provides are rather independent from each other, because the former depends on natural dynamics and the latter on the utility humans (decide to) draw from nature, which may vary from case to case. Despite this, at the global level, it has been calculated that nature contributes to humans not only more (as Costanza et al.[42] demonstrated) but also in a more efficient way than do all the world economic infrastructures. In fact, if we divide the world ecosystem service value by the emergy flow to the biosphere, we obtain the amount of money that is, on average, produced by 1 seJ of solar emergy feeding the global ecosystem. This ratio combines an amount of money that is not really circulating in the global economy and the flow of all renewable resources that feed the planet (sunlight, geothermal heat, rain, wind, etc.). It can be considered as a potential efficiency of the entire biosphere in providing a kind of economic wealth for humans (since at least a portion of it can be converted into real economic utility/benefit) based only on its natural functioning.[21]

The reciprocal of the above relation, i.e., the ratio of the global emergy flow to the total value of ecosystem services, is between 5.09×10^{11} and 1.51×10^{n} seJ/€ (depending on the minimum and maximum values calculated by Costanza et al.[42]). Both the maximum and minimum values are lower than values traditionally calculated for national economies, which in emergy theory are known as the emergy-to-money ratio (EMR). The EMR is given by the ratio of the emergy flow of a country (including both natural and commercial man-induced flows) to its GDP, and its order of magnitude is, in general, 10^{12} seJ/€ or more (for an overview of national values.[44] This means that the global ecosystem uses, on average, less emergy than a national economy per unit money provided to humans.

Jørgensen[26] proposed an approach to connect an ecosystem's structure and organization descriptor (eco-exergy) to a user-side measure (the value of ecosystem services), highlighting a relation between a biophysical and an economic evaluation of the environment. The calculation of ecosystem services through eco-exergy resulted in values higher than those proposed by Costanza et al.,[42] because eco-exergy represents the annual work capacity increase of an ecosystem that can be translated into the set of the possible services it can offer (not only the services that anthropic systems actually utilize) and can be compared with the actual flow of services utilized.

Ecosystem dynamics can be represented through a generic and complete input–state–output scheme. In this sense, we can imagine a kind of 3-D diagram, with the inflows of resources, measured in terms of solar emergy, on the x axis; the work capacity embodied in the system biota, expressed in terms of eco-exergy, on the y axis; and the useful services for humans, valuable in economic terms, on the z axis.[45] This multidimensional holistic approach makes it clear that inputs are used up, directly or indirectly, to produce services in output and/or to develop the system, and enables us to have an indication of changes in ecosystem dynamics, structure, and services. Within this framework, a thermodynamic/

socio-ecological evolutionary time path can be acknowledged: from young systems, to climax-stage systems, to socio-ecological integrated systems.

Conclusion

The ratio of eco-exergy to emergy flow is the combination of two thermodynamics-based orientors: emergy flow, which quantifies the amount of resources necessary for the system to survive, and eco-exergy, which represents the actual state of the ecosystem in terms of work capacity and distance from thermodynamic equilibrium. The joint use of these two entities adds information that is useful for the investigation of the behavior of the system during its evolution. It is a measure of the ability of a system to reach and maintain a given structure (as eco-exergy) per unit input (as emergy); it is therefore a measure of the efficiency of the system in transforming available resources into organization. The use of the ratio of eco-exergy to emergy flow is important when investigating the evolution of an ecosystem or the effects on ecosystem dynamics of human intervention and infrastructures. Two further applications of this entity have been described too, which can be useful in the field of environmental management: according to the change in exergy due to a change in emergy flow, we can identify potential pollutants and define the intensity of pollution; the combined use of eco-exergy and emergy can also help in assessing the role of ecosystem services in human well-being.

Ecological Indicators: Ecosystem Health

Felix Müller,
Benjamin Burkhard,
Marion Kandziora,
Claus Schimming,
and Wilhelm
Windhorst

Introduction

Environmental management has to operate in an extremely complex framework, which can be characterized by a multitude of different components and an even higher number of interrelations between these parts.[1] Ecological as well as human and societal influences have to be taken into account, and the dominant role of indirect effects has to be realized.[2] Consequently, there is a very high demand for holistic management concepts, which approach the management object from an ecosystem-based starting point. The biggest challenge of such concepts arises from the enormous complexity of human–environmental systems.[3,4] To cope with this challenge, indicators can be suitable tools. They enable quantitative statements in spite of the complex environment, but this potential is attained due to simplification, aggregation, modeling, and abstraction. Therefore, indicators often are correlated with a high uncertainty, i.e., whether the indicated object is really well represented by the indicator.[5]

Ecosystem health is an environmental management concept that directly meets these problems.[6] It follows the important demand to manage the environment from a system-based viewpoint, acknowledging inherent complexities. Therefore, the selection of suitable indicators plays a major role for quantitative applications of the health concept.[7] In the following text, some focal approaches on how these challenging demands are met are documented. The leading questions are the following:

- What are the basic features and requirements for ecosystem-based indicators, and how are they related to the concept of ecosystem health?
- What are the focal ideas of ecosystem health, and how can they be translated into ecological indication concepts?

- What are the problems and experiences of health indication in different ecosystem types?
- How do recent indicator approaches cope with the challenging demands for ecosystem-based indication?

The entry starts with a short statement on the general requirements for ecological indicators. Thereafter, the actual indicandum—ecosystem health—is sketched, and a literature survey of established ecosystem health indicators is presented. In the final sections, indicator applications and aggregations are discussed, and demands for future development are formulated based on a comparison of identified requirements and the state of the art.

Basic Features of Ecological Indicators

Environmental management should be based upon qualitative or quantitative key variables that can be used to demonstrate the demand for management actions and the outcomes of the respective activities. Such indicators provide aggregated information on certain complex phenomena,[8–10] which often are not directly accessible.[11–13] Indicators are developed on the basis of specific management purposes; they often include an integrating, synoptical value, and they should be capable of showing the differences between an existing situation and an aspired-to target state.[14,15] Thus, indicators are signals for attracting attention on changes in complex humanenvironmental systems. Heink and Kowarik[16] propose the following indicator definition: "An indicator in ecology and environmental planning is a component or a measure of environmentally relevant phenomena used to depict or evaluate environmental conditions or changes or to set environmental goals."

Being applied for the management of human–environmental systems, indicators have to satisfy very different and challenging demands: On the one hand, scientific correctness is a major requirement, and on the other, transparency and public utility in the decision making processes are significant demands (see Tables 1 and 2). Therefore, indicator applications should be based on satisfying scientific hypotheses and relevant cause–effect relations, while they also have to translate the high complexity of ecosystems in a scientifically sound way to meet the needs of politicians and decision makers for common acceptance. Furthermore, the indicator should comprise an optimal sensitivity for the related disturbance, and it should be characterized by a clear representation of the indicandum by the indicator—in this case, it should represent the challenging properties of ecosystem health.

Basic Components of Ecosystem Health

The pioneering ecologist Aldo Leopold's writings about land sickness[17] created the basic ideas for the ecosystem health concept. In the following decades, definitions of ecosystem health have been constantly evolving toward an increasing integration of human and societal contexts in order to understand what is

TABLE 1 Scientific Demands on Good Indicators

Good indicator sets should provide scientific correctness basing upon the following:

- A clear representation of the indicandum by the indicator.
- Clear proof of relevant cause–effect relations.
- An optimal sensitivity of the representation.
- Information for adequate spatio-temporal scales.
- A very high transparency of the derivation strategy.
- A high degree of validity and representativeness of the available data sources.
- A high degree of comparability in and with indicator sets.
- An optimal degree of aggregation.
- Good fulfillment of statistical requirements concerning verification, reproduction, representativity, and validity.

Source: Wiggering an Müller.[9]

TABLE 2 Applied Demands on Good Indicators

Good indicator sets should provide practical applicability basing upon the following:

- Information and estimations of the normative loadings.
- High political relevance concerning the decision process.
- High comprehensibility and public transparency.
- Direct relations to management actions.
- An orientation toward environmental targets.
- A high utility for early warning purposes.
- A satisfying measurability.
- A high degree of data availability.
- Information on long-term trends of development.

Source: Wiggering an Müller.[9]

considered to be a healthy ecosystem.[18,19] The concept has gained special popularity in the United States and in Canada, where ecosystem health has been integrated in legislation. Today, ecosystem health is part of various international political programs, like the Rio convention on sustainable development.[20] Here, it has been demanded in principle 7 that "states shall cooperate in a spirit of global partnership to conserve, protect and restore the health and integrity of the Earth's ecosystem." Ecosystem health does not only take into account ecological components but also requires a linkage with social, economic, and cultural dimensions (see Table 3).

De Kruijf and Van Vuuren[25] analyzed that "the present definitions of ecosystem health contain several of the following elements:

- Healthy ecosystems are free from ecosystem distress syndrome …;
- Healthy ecosystems are resilient … they recover from natural perturbations and disturbances;
- Healthy ecosystems are self-sustaining and can be perpetuated without subsidies or drawing down natural capital;
- Healthy ecosystems do not impair adjacent ecosystems …;
- Healthy ecosystems are free from risk factors;
- Healthy ecosystems are economically viable;
- Healthy ecosystems sustain healthy human communities."

Summarizing the different approaches, a working definition of ecosystem health can be given as follows: Ecosystem health refers to the ability of an ecosystem to maintain its structure and function over time under external stress, safeguarding a sustainable provision of ecosystem goods and services contributing to human well-being.

The facts mentioned above have to be reflected while defining appropriate sets of indicators that can be applied for environmental management.[16] Suitable ecosystem health indicator sets have to consider ecological structures as well as ecological functions on different spatial and temporal scales. As shown by the Millennium Ecosystem Assessment,[26] most ecosystems on our planet have already been

TABLE 3 Different Approaches Defining Ecosystem Health

Haskell et al.[21]: An ecological system is healthy and free from "distress syndrome" if it is stable and sustainable—that is, if it is active and maintains its organization and autonomy over time and is resilient to stress.'

Karr[22]: Ecosystem health is related to "the condition in which a system realizes its inherent potential, maintains a stable condition, preserves its capacity for self-repair when perturbed, and needs minimal external support for management."

Rapport et al.[23]: Ecosystem health refers to a "condition where the parts and functions of an ecosystem are sustained over time and where the system's capacity for self-repair is maintained, such that goals for uses, values, and services of the ecosystem are met."

Xu and Mage[24]: Ecosystem health refers to "the system's ability to realize its functions desired by society and to maintain its structure needed both by its functions and by society over a long time."

degraded under the pressure of increasing human demands. If ecosystem health shall be achieved on a long-term perspective, preventative and restorative environmental management strategies are needed. When looking at different typical ecosystem health indicators, like species diversity or water quality, many of the ecosystems on our planet can be considered unhealthy.[18] As a consequence, many ecosystem functions needed for the provision of ecosystem services have been altered. Ecosystem health refers to systems that are manipulated to satisfy human needs.[17] Therefore, ecosystem health provides a suitable conceptual framework describing the linkages between ecosystem functions, services, and human well-being.

The explicit integration of societal components makes it different from other ecosystem management concepts, for example, ecological integrity. Ecological integrity refers to the functioning of ecosystems based on self-organized processes, while ecosystem health also includes resilience and sustainability with regard to the provision of ecosystem services. Therefore, different ecological concepts like homeostasis, diversity, complexity, emergent properties, or hierarchy principles are closely related to the health concept.[19]

Basic Requirements for the Indication of Ecosystem Health

A focal problem of these concepts is the complexity of ecosystems that arises from the high number of components, relations, and interactions. Hence, for environmental practice and decision making, this complexity has to be reduced. Ecosystem theories provide an applicable basis for such a reduction. Some of the respective theoretical fundamentals of the ecosystem health concept are listed in Table 4.

These requirements are summarized in the "V-O-R model,"[21] describing the ecosystem vigor, organization, and resilience. Vigor is indicated by activity, metabolism, or primary productivity, while organization represents the diversity and number of interactions between the system components. Resilience is understood as a system's capacity to maintain structure and function in the presence of (external) stress. When resilience is exceeded, the system can shift to an alternate state. By including this approach, ecosystem health is closely related to the concepts of stress ecology, where vigor, system organization, resilience, and the absence of ecosystem distress are the main factors for a system's condition.

This model is correlated with a very high demand for comprehensive data sets and long-time series to determine resilience. Additionally, linkages of environmental and social–economic attributes and attributes representing structures as well as functions and organization have to be included. All these demands can hardly be fulfilled. Therefore, quantification deficits have to be expected as one of the main problems of the ecosystem health approach.

Utilized Indicators of Ecosystem Health

In the following paragraphs, a short literature survey of health indicators is presented, whereby different approaches have been distinguished: In the beginning, community-based indicators are listed, followed by aggregated theoretical indicators and indicators based on ecosystem analysis. Finally, a link will be developed toward the indication of ecosystem services.

TABLE 4 Axioms of Ecosystem Health

Dynamism: Nature is a set of processes, more than a composition of structures.
Relatedness: Nature is a network of interactions.
Hierarchy: Nature is built up by complex hierarchies of spatio-temporal scales.
Creativity: Nature consists of self-organizing systems.
Different fragilities: Nature includes various sets of different resiliences.

Source: Wiggering an Müller.[9]

Species- and Community-Based Indicators and Indices

Biodiversity loss is one of the characteristic signs for ecosystems under stress[18] and thus is a major issue in environmental management.[26] Consequently, there are many initiatives and concepts to describe and assess biodiversity.[27] Biodiversity indicators and indices are based on the abundance, absence, or composition of selected species or communities. They vary from single-species indicators to complex composite indicators. Suitable indicator species have to be selected in order to be representative for certain phenomena or sensitive to particular environmental changes.[28] Therefore, the appearance and dominance of certain communities can be associated with states of ecosystem health.[7]

The parameters used to quantify respective indicators can be derived from direct measurements and observations of selected species' abundance. Species- and community- based indicators can be linked to numerous international and national policy instruments, for which biodiversity indicators need to be derived (e.g., Bern Convention 1979; Bonn Convention 1979; Convention on Biological Diversity CBD 1992; the Millennium Development Goals to be achieved by 2015). Most policy and decision makers rely on indices that aggregate biodiversity data across large numbers of species,[29] but also, a limited number of key taxa are frequently used to indicate ecosystem health.[30] Some of these biodiversity indicator concepts—mainly related to the indicator collections of Marquez et al.[31] and Joergensen et al.[6]—are presented in the following.

Species Richness

The most established way to indicate biodiversity is based on species counts and composite indices. One advantage is that the number of species in a certain area is a measure that is easily established and understood by a broad range of people. The Shannon–Wiener index and the Simpson index are the most commonly applied indicators.[29] The Shannon-Wiener index H' originates in information theory and integrates species' number and evenness:

$$H' = -\sum p_i \log 2 p_i \tag{1}$$

p_i is the proportion of individuals found in species i. The values of this index can vary between 0 and 5. H' has a maximum value if the individuals of all species occur with the same density. The Simpson index refers to the number of species present and the relative abundance of each species.[32] Species richness provides important information on ecosystem conditions. However, its application in ecosystem health assessments can be misleading, for example, concerning nonnative (exotic or "invasive") species. Their abundance will increase the value of standard biodiversity indicators, but their increased dominance in biotic communities can be a typical sign of ecosystem stress.[18]

Indicator Taxa

Indicator taxa (or bioindicators, indicator species) are species or higher taxonomic groups whose properties can be used as proxies for assessments of ecosystem health.[33,34] Respective species have to be selected in order to react on ecosystem alterations by changing their abundance, density, conditions, or activities. Therefore, indicator species have to be selected objectively and must represent clear indicator-indicandum relationships. Pollinators have been suggested as useful bioindicators for ecosystem health by Kevan[35] as they are crucial for the functioning of almost all terrestrial ecosystems. Moreover, pollinators are needed for the provision of manifold ecosystem services. Further indicators based on the abundance of selected species have been suggested by Jørgensen et al.[6,36] and Burkhard et al.[7]

- Saprobic Classification: The saprobe index gives information about the degree of water pollution.[37] The different saprogenic stages are related to certain indicator organisms like bacteria, fungi, algae, amoeba, mussels, worms, insect larvae, or fishes. The stages range from polysaprobic (very highly polluted), α-mesosaprobic (highly polluted), β-mesosaprobic (medium polluted), to oligosaprobic (rather clean and clear water).

- Bellan's Pollution Index: Aquatic species like *Platynereis dumerilii*, *Theosthema oerstedi*, *Cirratulus cirratus,* and *Dodecaria concharum* are used as indicators for water pollution, whereas species like *Syllis gracillis* and *Typosyllis prolifera* indicate clear water conditions.[38] Bellan's pollution index equation is

$$\mathrm{IP} = \sum \text{dominance of pollution indicator species/clear water indicator} \tag{2}$$

  Index values higher than 1 indicate a pollution-based disturbance in the community.
- AZTI Marine Biotic Index: AZTI Marine Biotic Index (AMBI) distinguishes the soft bottom macrofauna into five groups in accordance with their sensitivity to increasing stres[39]:
  I. Species very sensitive to organic enrichment and eutrophication, present only under unpolluted conditions.
  II. Species indifferent to organic enrichment, occurring in low densities only and with no significant variations over time.
  III. Species tolerant to excess organic matter enrichment, usually supported by organic enrichment, that can also be found under normal conditions.
  IV. Second-order opportunist species.
  V. First-order opportunist species (deposit feeders).
  The coefficient is calculated as follows:

$$\mathrm{AMBI} = \left\{(0\times\%\mathrm{I})+(1.5\times\%\mathrm{II})+(3\times\%\mathrm{III})+(4.5\times\%\mathrm{IV})+(6\times\%\mathrm{V})\right\}/100 \tag{3}$$

  The AMBI values vary among the following: normal (0.0–1.2), slightly polluted (1.2–3.2), moderately polluted (3.2–5.0), highly polluted (5.0–6.0), or very highly polluted (6.0–7.0).
- BENTIX
  BENTIX is based on the AMBI but uses three groups only[40]:
  I. Species generally sensitive to disturbances.
  II. Species tolerant to stress or disturbance. Populations may respond to organic enrichment or other pollution sources.
  III. First-order opportunistic species (pioneer, colonizers, or species that are tolerant to hypoxia).
  The indicator values are calculated as follows:

$$\mathrm{Benix} = \left\{(6\times\%\ \mathrm{I})+2(\%\ \mathrm{II}+\%\ \mathrm{III})\right\}/100 \tag{4}$$

  The results represent different states of aquatic ecosystems: normal (4.5–6.0), slightly polluted (3.5–4.5), moderately polluted (2.5–3.5), highly polluted (2.0–2.5), or very highly polluted (Bentix = 0).

- Macrofauna Monitoring Index: Twelve indicator species are included in the macrofauna monitoring index. Each indicator species is assigned a score, based on the ratio of its abundance. The actual index value is the average score of species that are present in the sample.[41]
- Umbrella, Flagship, and Keystone Species: Umbrella species have high demands for their habitat conditions with regard to habitat size and quality. When protecting these species, many other species will be supported automatically. Flagship (or charismatic) species are organisms whose necessity for protection can be easily communicated. Keystone species provide an extraordinary importance for the maintenance of ecosystem structures and functions as well as for other species in the same ecosystem. Therefore, the identification and protection of keystone species can be crucial for the management of ecosystem health.[42]

Examples for the utilization of these indicator types are the Species Trend Index,[43] Red Lists,[44] or the Living Planet Index (LPI), which has been developed for land, freshwater, and marine vertebrate species. The average population trends over time are documented in the LPI. The actual calculations are based on a data set of more than 2500 species and 8000 population time series over the past 30 years. Three indices are calculated: 1) terrestrial species population index; 2) freshwater species population index, and 3) marine species population index. Each of these indices is set to a baseline of 100 in 1970, and all are given an equal weighting.[45,46]

Ratios between Different Classes of Organisms or Elements

The increase or decrease of one species in relation to others provides information about changes in ecosystems, for example, Nygard's algal index[36] or the diatoms/nondiatoms ratio.[47]

Indicators Based on Ecological Strategies

Different ecological strategies are altered by human activities or during different stages of natural development. Hence, indicators for the distinct behavior of different taxonomic groups under environmental stress situations were developed, e.g., the nematodes/copepods index, the polychaetes/ amphipods ratio, and the index of *r*/*k* strategists, which considers different taxa: Most communities in ecosystems in rather late developmental stages show dominance of *k*- selected or conservative species with large body sizes and long life spans. *R*-selected or opportunistic species have shorter life spans and are often numerically dominant. After a significant disturbance and during the following reorganization, the opportunistic species can become dominant in biomass as well as in number, whereas the conservative species are usually less favored.[36,48] Another strategy-related indicator is the trophic infaunal index, which refers to organisms' different feeding strategies (distinction of macrobenthos species into suspension feeders, interface feeders, surface deposit feeders, and subsurface deposit feeders).[49]

Additionally, there are several attempts aiming at harmonizing existing biodiversity indicator initiatives. Two examples are sketched here.

- Streamlining European 2010 Biodiversity Indicators: The Streamlining European Biodiversity Indicators (SEBI) were established in 2005 under the umbrella of the Convention on Biological Diversity (CBD). It is a process to select a set of biodiversity indicators to monitor progress toward the 2010 target of halting biodiversity loss and help achieve progress toward the target.[50,51] The SEBI is a regionally coordinated program that has been initiated in Europe as collaboration between the European Environment Agency and other European and United Nations institutions. The SEBI proposes a list of 26 indicators within the 7 CBD focal areas: status and trends of the components of biological diversity, threats to biodiversity, ecosystem integrity and ecosystem goods and services, sustainable use, status of access and benefit sharing, status of resource transfers, and public opinion.[50,51]
- Group on Earth Observations Biodiversity Observation Network: The Group on Earth Observations Biodiversity Observation Network (GEO BON) is a global partnership helping to collect, manage, analyze, and report biodiversity data.[52] It is a voluntary partnership of 73 national governments and 46 participating organizations and was launched in 2002. The GEO BON aims at providing a framework to coordinate data and observations within the Global Earth Observation System of Systems (GEOSS). Biodiversity has been named as one of nine GEOSS priority societal benefit areas. The GEO BON will integrate key ecosystem functional parameters into a Terrestrial Ecosystem Function Index (TEFI). The TEFI will integrate data of measurements of the energy, carbon, and nutrient balance.[52]

Aggregated Theory-Based Indicators and Indices

In contrast to the biotic approaches, which mainly can be used as structural indicators, the health component "vigor" is included in ecosystem theory based-indicators and indicator sets. The following four aggregations stem from thermodynamics, network, and information theories. Their basic target is a holistic aggregation of ecosystem properties into one guiding variable.

- Exergy and Exergy Indices: Exergy is that energy fraction that can be transformed into useful mechanical work. In ecological terms, it can, for example, be measured by the total biomass of the system. Eco-exergy is a refinement of the exergy concept in which biomass is weighted by the genetic complexity of the species observed.[4,36] Further holistic indicators are the exergy index and the specific exergy.[4] In ecosystems, the captured exergy is used to build up biomass and structures during successions.[48] Therefore, more complex systems also have more built-in exergy than simpler ones. Both exergy and specific exergy have been used as indicators for ecosystem health.[6] Relations between the exergy values and other ecosystem health characteristics like diversity, structure, or resilience can be found. For example, a very eutrophic ecosystem has a very high exergy due to the high biomass, but the specific exergy is low as the biomass is dominated by algae with low β values. The combination of exergy index and specific exergy provides a satisfactory structural and holistic description of ecosystem health.
- Entropy: Entropy production is one result of any metabolic activity. It can be measured by the system's respiration or the total system's export. As life is a very effective producer of entropy, this indicator has been proposed as an ecological orientor to represent maturity as well as ecosystem stress.[53,54]
- Emergy: Emergy (embodied energy) accounts for the differences between distinct biomass fractions in ecosystems basing upon the energy that has been used to build up the respective structure.[55] Conversion values, called transformities, have been derived to allow the calculation of emergy values for many ecological entities as well as socio-ecological products.[56]
- Ascendency: Ascendency is a holistic indicator that is based upon the energy flows in ecological systems and the information associated with the particular network configuration.[57,58] It represents the total system throughput and the flow diversity as a result of the food web structure. The respective network configuration is indicated by the average mutual information. Ascendency is measured by the total system throughput times the average mutual information, providing helpful information on an ecosystem's energy flow schemes and efficiencies.

Ecosystem Analytical Indicators and Indices

While most of the approaches mentioned before are aiming at one focal dimension and one value to characterize the state of an ecosystem, the following indicators have been constructed as multidimensional approaches. They try to represent ecosystem structures (biotic and abiotic structures), functions (water, matter, energy flows), and (in some cases) their relevance for human systems.

- Integrity Indicators and Orientors: Several ecosystem assessments are based on the concept of ecosystem integrity, which is closely related to ecosystem health.[18,59] The focal difference can be found in the origins of the concepts: While integrity was related to wilderness as a target function, health has been referring to ecosystems under human pressures from the beginning.[60] Meanwhile, the core conceptions have become rather similar. Therefore, one approach of integrity indication will be included in the following paragraphs.

  Taking into account the focal ideas of the sustainable development concept, "meet the needs of future generations "means "keep available ecosystem services on a long-term, intergenerational and broad scale, intragenerational level." From a synoptic viewpoint, all ecosystem services are strongly dependent on the performance of the system's regulation capacity (see the section on "Ecosystem Service Indicators"). Taking into account that the integral of regulating ecosystem services represents self-organized processes,[61] it becomes clear that the respective benefits are dependent on the degrees and potentials of self-organization. To maintain these services, the ability for future self-organizing processes has to be preserved.[53,62] Under this viewpoint, Barkmann et al.[63] have defined ecological integrity as a "management target for the preservation against

> nonspecific ecological risks, that are general disturbances of the self-organising capacity of ecological systems. Thus, the goal should be a support and preservation of those processes and structures which are essential prerequisites of the ecological ability for self-organisation".

In ecosystem theory, many different approaches (see Joergensen[4]) are highly compatible with the theory of self-organization. The consequences have been condensed within the orientor approach,[64–66] a system-based theory about ecosystem development, which is founded on the ideas of nonequilibrium thermodynamics,[54,62] and network development on the one hand and succession theory on the other.[67,68] The basic idea is that throughout the undisturbed complexifying development of ecosystems, certain characteristics are increasing steadily, developing toward an attractor state, which is restricted by the specific site conditions. For instance, the food web will become more and more complex; heterogeneity, species richness, and connectedness will be rising; and many other attributes will follow a similar long-term trajectory.

Many of these orientors cannot be easily measured or modeled under usual circumstances. Therefore, the selected indicators have to be represented by variables that are accessible by "traditional" methods of ecosystem quantification. Furthermore, it has to be reflected that the number of indicators should be reduced as far as possible, providing a small set consisting of the most important items that can be calculated or measured in many local instances. The focal subsystems that should be taken into account to represent ecosystem organization are ecosystem structures with the biotic and abiotic diversity and functions, represented by the energy, water, and matter balances (for a detailed justification, see Müller[61]).

On the basis of these features, a general indicator set to describe the ecosystem or landscape state in terrestrial environments has been derived. It is shown in Table 5. The basic hypothesis concerning this set is that a holistic representation of the degree of and the capacity for complexifying ecological processes on the basis of an accessible number of indicators can be fulfilled by these variables. They also represent the basic trends of ecosystem development; thus, they show the developmental stage of an ecosystem or a landscape. As a whole, this variable set represents the degree of self-organization in the investigated system. For quantifications, see Müller[69] or Müller and Burkhard.[70]

- The holistic ecosystem health indicator: An expansion toward an integration of human items is provided by the holistic ecosystem heath indicator (HEHI) system. It was developed in 1999 in Costa Rica as an integrative indicator that might be an appropriate tool for assessing and

TABLE 5 Proposed Indicators to Represent the Organizational State of Ecosystems and Landscapes

Orientor Group	Indicator	Potential Key Variable
Biotic structure	Biodiversity	Number of species
Abiotic structures	Biotope heterogeneity	Index of heterogeneity
Energy balance	Exergy capture	Gross or net primary production
	Entropy production	Entropy production[71] Entropy production[72] Output by evapotranspiration and respiration
	Metabolic efficiency	Respiration per biomass
Water balance	Biotic water flows	Transpiration per evapotranspiration
Matter balance	Nutrient loss	Nitrate leaching
	Storage capacity	Intrabiotic nitrogen
	Soil organic carbon	Soil organic matter

evaluating health of managed ecosystems.[73] The HEHI follows a hierarchical structure starting with three main branches: ecological, social, and interactive. The interactive branch includes measures relating to land use and management decisions that characterize the interactions between the human communities and the ecosystem. Furthermore, each branch is subdivided into categories or criteria (see Table 6). Each category is given a target or a benchmark, which is based on references available in scientific literature, policies, etc.

Ecosystem Service Indicators

As the explicit target figure of ecosystem health indicators has more and more been moved toward human wellbeing, the respective indicanda—ecosystem goods and services—are mentioned here. Their implementation seems to be very significant as a criterion of success in ecosystem health management. Ecosystem services are the benefits people obtain from natural structures and functions. Since ecosystems are dynamic and complex units, the assessment of their services is strongly facilitated by the categorization into functional groups, which are exemplarily listed in Table 7, referring to the following:

- Provisioning services: products obtained from ecosystems, e.g., food, water.
- Regulating services: benefits from regulating ecosystem processes, e.g., flood regulation, disease regulation.
- Cultural services: nonmaterial benefits, e.g., recreation, spiritual benefits, information.

Ecosystem structures and functions can be indicated by ecological integrity, as described above. Regulating ecosystem services is strongly related to ecosystem functions, and some regulating services are even overlapping with ecological integrity processes (e.g., processes related to nutrient or water regulation.[74] Thus, clear definitions of ecological integrity variables and regulating ecosystem service indicators are mandatory. Most ecosystem functions are difficult to quantify under natural conditions, but the application of ecological models can help. Perhaps the best data are available for provisioning ecosystem services. Normally, production and trade quantities and their market prices are used. Cultural ecosystem services again are rather difficult to quantify due to each individual's subjective and situation-dependent appreciation of related values.[26]

Ecosystem services are not a linear chain from means to ends because ecosystems as well as societal systems are complex, dynamic, and adaptive.[3] There exist multiscale relationships between services and benefits. When ecosystems are stressed and degraded, their service provision is affected too, which in turn has impacts on human activities and health.[75] The fact that there is a high correlation between decline in ecosystem health and service provision leads to the suggestion that ecosystem services are good integrative and aggregate measures, showing the consequences of the respective ecosystem health conditions.[76]

TABLE 7 List of Ecosystem Services

	Regulating Ecosystem Services
Local climate regulation	Effects on temperature, wind, radiation, precipitation
Global climate regulation	For example, carbon sequestration, greenhouse gas emission
Flood protection	Extreme flood event dampening
Groundwater recharge	Runoff, flooding, aquifer recharge
Air quality regulation	Removal of toxic and other elements from the atmosphere
Erosion regulation	Soil retention and prevention of landslides
Nutrient regulation	(Re)cycling of, e.g., N, P, or other elements
Water purification	Removal of impurities from fresh water
Pollination	For example, by wind and bees
	Provisioning Ecosystem Services
Crops	Edible plants
Livestock	Edible animals
Fodder	Animal fodder
Capture fisheries	Fish accessible for fishermen
Aquaculture	Terrestrial or marine aquaculture
Wild foods	For example, berries, mushrooms, hunting, fishing
Timber	Trees or plants for construction
Wood fuel	Trees or plants for heating, cooking
Energy (biomass)	Trees or plants for energy generation
Biochemicals and medicine	Production of biochemicals, medicines
Freshwater	For example. for drinking, irrigation
	Cultural Ecosystem Services (selection)
Recreation and aesthetic values	Landscape and visual qualities
Intrinsic value of biodiversity	Value of nature and species themselves

Health Indicators in Different Ecosystem Types

To illuminate the wide field of health indicators, in the following sections, some utilizations of the concept in different ecosystem types are presented.

Agroecosystem Health

An agroecosystem can be defined as "a socio-ecological system, managed primarily for the purpose of producing food, fiber and other agricultural products, comprising domesticated plants and animals, biotic and abiotic elements of the underlying soils, drainage networks, and natural vegetation and wildlife."[77–79] The health status of agro ecosystems has been described by Rapport,[80] and Rapport et al.[81] In this entry, a valuable overview about various approaches to indicate agroecosystem health on various spatial scales is provided. For example, Zhang et al.[82] merge geographical information systems (GIS)-based land use analysis data with the use of pesticides and their pathways through the environment. This approach allows the assessment of ecosystem health as a ratio between the amounts of pesticides applied in one grid to the maximum dose applied in the study area. Kaffka et al.[83] suggest that the capacity to retain nutrients like N and P might be useful to evaluate the ecosystem health of a catchment area, while Mitchell et al.[84] consider the content of soil organic matter (SOM) of agricultural areas as a focal indicator to assess ecosystem health in the foreground.

Hopkins[85] indicates ecosystem health via the number and size of wildlife patches in an area dominated by intensive agriculture.

In comparison to the aforementioned authors, Altieri and Nicholls[86] base their suggestions to achieve healthy agroecosystems on the avoidance capacity of diseases—indicated by optimal recycling of nutrients, closed energy flows, water and soil conservation, and biological pest regulation. Belcher and Boehm[87] use yield, soil N and P, soil water, SOM, soil erosion, and CO_2 emissions as major attributes in their sustainable agroecosystem model. However, the assessments of agroecosystem health regularly focus on resources that have to be classified as internal to the system.[88] Hence, the options to assess the health of an agroecosystem in relation to its ability to adapt to variations in its changing socio-economic and ecological context are rarely realized according to Waltner-Toews[79] or Ikerd.[89]

Forest Ecosystem Health

In the United States, 20 years ago, a sound definition of forest health had already been derived to sustain healthy conditions of ecosystem development and productivity in a long-term perspective.[90] The term "forest health" increasingly found evidence in mandates concerning environmental management and protection, mostly supported by the idea that the conventional measures for describing forest states (e.g., crown conditions, tree growth, loss of nutrients, soil potentials, biodiversity) can also be used to indicate forest ecosystem health. Regarding forests, only recently in Europe, Ecosystem Health has been advertised in the context of deposition of air pollutants[91] and the consequent change of chemical states, particularly the degree of eutrophication and acidification which relate to the holistic aspects of productivity and biogeochemical cycling. Information on nutrient recycling, imbalance with the inputs and outputs and on energy use are the essentials of the Ecosystem Assessment Health concept and the adequate indicators proposed by Jørgensen.[6] This kind of concept, basically productivity related and holistic, does greatly comply with ecosystem theories and opens on for indicating Forest Ecosystem Health combing both, utilitarian and ecosystem perspectives[92] respecting the conditions under which selforganization of forest ecosystems can take place.[50]

Whereas atmospheric deposition of acidifying air pollutants and eutrophic nitrogen is identified as one of the major environmental problems, an ecosystem process-orientated indicator has been demanded for quantifying marginal loads for damaging structures and for interference with ecosystem functions.[93–95] Since the respective concept of critical loads is a stoichiometric approach and a function of the load quantity on chemical effects on ecosystems, intensity criteria are needed to provide adequate threshold values.[96–98] The conduction of the concept depends on combined balances of mass and charge provided by mineral elements, nitrogen, and free acidity completing the ion composition of internal transfers and the matter–flux relationship with the abiotic environment. Imbalance between input and recycling respecting mass and ionic charge indicates the efficiency of nutrient use while the quantities can be related with the intensities of effective concentrations and free acidity. In this regard soil chemistry is a function of the extensity of production on the intensities of nutrient availability, free acidity and effectiveness of toxic concentrations under influence of ecosystem self-organization.

The performance of cycling and imbalance between input rates and the degree of recycling provide useful information on the Ecosystem Health aspect. Moreover, as imbalance of mineral element cycling and related losses from the ecosystem are irreversible processes for terrestrial ecosystems, decreasing alkalinity in combination with increasing free acidity are directing to maturity of ecosystems. Regarding abiotic structures, maturity emerges by development of soil structures, which is related to loss of potentials. Based on these principles, Ulrich[99] suggested the indication of stages of forest ecosystems, for instance, by the structural properties of soil constituents providing acid neutralization and buffer capacity.

Aquatic Ecosystem Health

Aquatic ecosystems (wetlands, marine and estuarine zones, lakes, groundwater, lagoons, and rivers) consist of complex structures and fulfill important functions for the provision of numerous ecosystem services.[26] Some of these aquatic ecosystems are heavily endangered, e.g., wetlands were turned into agricultural land with dramatic consequences due to the loss of the buffer capacity for pesticides, nutrients, and floods as well as the loss of habitat functions. Marine and estuarine ecosystems are heavily influenced by humans due to population growth and the associated consequences such as pollution, growing demands for resources, eutrophication, overfishing, and habitat modification (e.g., mangrove clearing). Estuarine and marine ecosystems are interdependent as estuarine areas are the nursery grounds for many species, which are then provided as successful functioning marine commercial stocks. Probably the most important function of lakes is the freshwater storage, which provides ecosystem services for society and economy, but these systems also are heavily endangered.

Aquatic ecosystems are focal areas of ecosystem health assessments. Therefore, many of the previously mentioned indicator concepts mainly provide information on aquatic ecosystem health (see Utilized indicators of ecosystem health or Joergensen et al.[6]). Besides these long indicator listings, Boesch and Paul[100] highlight the following traditional indicators: contaminant levels, material input (e.g., nutrients, sediments), water quality (e.g., dissolved oxygen), fish catch, extent of certain habitats (e.g., wetlands), community structure, toxicity biomarkers, and indicators of human pathogens).

Urban Ecosystem Health

A very special aspect is provided by the health concept in urban systems, i.e., because the human factor plays a dominant role in the relevant literature.[101–105] For instance, Su et al.[101] state that “an urban ecosystem consists of residents and their environment in certain time and space scales, in which, ecologically-speaking, consumers are the dominant component lacking producers and decomposers.”

Therefore, urban ecosystem health must be assessed by very comprehensive, integrative indicator sets, which also include variables of human health. Consequently, Hancock[104] has determined six basic elements for healthy cities:

1. Population health and distribution.
2. Societal well-being.
3. Government, management, and social equity.
4. Human habitat quality and convenience.
5. Natural environment quality.
6. Impact of the urban ecosystem on the larger-scale natural ecosystem.

A similar approach can be found in the indicator sets of Su et al.,[101] who generally distinguish human and environmental subsystems (see Table 8).

TABLE 8 Some Indicanda for Urban Health

Human Subsystem	Environmental Subsystem
Public health	Provisioning services
Health expenditure	Environmental quality
Nutrition	Atmospheric quality
Budget and finance situation	Water quality
Urban infrastructure	Forest coverage
Human housing conditions	Farmland area
Education	Emergy density
Employment	Carrying capacity

Source: Su et al.[101]

Indicator Application and Aggregation in Management

Management toward ecosystem health is directed to improve human well-being. However, in order to environmentally manage, alternatives to achieve higher levels of human well-being and ecosystem health or to stabilize the present level in a changing world have to be identified. Hence, indicators have to facilitate the comparability of states in space and time, in order to allow informed decisions based on assessments of the present state and the state achievable by management options in respect to the power and competences in the hands of the manager. Concerning ecosystem health, at least, decision makers acting on the following levels have to be equipped with indicators:

1. Site management, e.g., field, forest, lake
2. Unit management, e.g., farm, forest district, catchment, nature sanctuary
3. Public management, e.g., community, county, nation
4. Public, e.g., citizens, interest groups (nongovernmental organizations)

All levels are interrelated. For example, 1) different kinds of pest management on the site level change not only the local ecosystem but also the food quality and availability. 2) The fodder quality available on the farm level depends on the productivity of the fields and impacts the economic efficiency of the farm. 3) The socio-economic state on the community level depends, on the one hand, on the economic viability of the hosted unit (item 2), but the provision of public services likewise constrains the range of activities of the units. 4) Adaptation to changing global constraints of public (item 3), unit (item 2), and site (item 1) management largely depends on the public awareness and level of satisfaction, e.g., human well-being realized at present and achievable in the future.

To account for all levels requires a nested approach in indication of ecosystem health plus mirroring the mutual synergistic and antagonistic interactions between the different levels. The need for such an approach has been articulated by Walter-Toewe and Wall[88] and Rapport and Singh.[106] However, a broadly accepted scheme meeting these requirements is not in place yet.[107] The present state of the art is largely influenced by the concept of ecosystem services and human well-being presented by the Millennium Assessment[26] and the TEEB Study.[108] With respect to "management," the further development of indicators should be constrained by the range of management options in space and time available to decision makers on the indicated levels (1–4) and be limited to parameters relatable to indicators of human well-being.

The need for indicator aggregation evolves out of the definition of ecosystem health. According to Waltner-Toews and Wall,[88] a nested approach is required in this context also. Another constraining aspect to be considered is societal interests, which are embedded in the definition as well. In addition, in case that the state of ecosystem health is considered to be poor, new or changed management activities have to be initiated and monitored by indicators. Thus, the goal of indicator aggregation is to transfer the information about the ecosystem state to those spatiotemporal scales on which management is possible and performed. The respective levels range from site management via communities, counties, states, nations up to the international institutions. Hence, a satisfying overlap between the spatial extent of the ecosystems at stake and the respective management unit is required. Systems theory and hierarchy theory provide a theoretical background to facilitate indicator aggregation for such nested systems.

To practically deal with this means to accept generalizations, including losses of information, as never can all interactions causing emergent properties relevant for human well-being be known. Hence, bottom-up aggregation is normally severely restricted. Furthermore, the focus on ecosystems enforces the integration of components, which are measured with parameters that cannot be aggregated on the base of concise units, e.g., the mortality rate of a specific species in forests of a watershed is already challenging to determine but analytically impossible to fuse with the number of pathogens endangering the fish population in a lake of the same catchment. A feasible approach to deal with this challenge is to work with relative indicator values, i.e., to indicate relative changes of the selected variables. A suitable option to facilitate spatiotemporal comparisons is to define a particular ecosystem state as reference state and to study the relative alterations from this reference state. Examples harnessing this approach have been presented by Windhorst et al.[109,110] A suitable method to facilitate aggregation and to deal with spatiotemporal interactions is to use simulation models (Belcher and Boehm,[87] Schönthaler et al.[111] and Reuter et al.[112]).

In any case, all ecosystem health indicators and respective aggregation approaches should be connectable to the different components of human well-being. The Millennium Assessment's[26] categories were "security, basic material for good life, health, good social relations and freedom of choice and action." They can be indicated for the management units at stake. Hence, multiple interactions to be considered take place and further are conceivable for future situations, creating a fuzzy environment, obstructing the development of generally applicable aggregation procedures. However, progress in identifying suitable aggregation procedures can be achieved by answering the following questions for each management unit at stake:

- Can the aggregated indicator of ecosystem health be addressed and modified by at least one management action?
- Are changed values of the aggregated indicator indicative for different ecosystem states of the management unit at stake?
- Do changed values of the aggregated indicator indicate betterment of at least one category of human well-being?

Conclusions

The previous paragraphs have shown that there is an enormous variety of indicators proposed to represent ecosystem health. Many of these indicators have been used to assess ecosystem health in different ecosystem types, and in many of those cases, the indicators have been useful tools for environmental management. On the other hand, these applications illuminate some general problems of health indicators that should be solved in the future:

- The health approach is very challenging, i.e., due to its comprehensive character. Therefore, health status can hardly be represented by one variable alone. Instead, comprehensive indicator sets are necessary to include the basic elements of vigor, organization, and resilience.
- Indicators or sets selected have often failed in fulfilling the comprehensive criteria of ecosystem health assessments because they are mostly specific for one particular environmental problem to be solved[6] and do not adequately represent ecosystem complexity. Thus, there are difficulties in satisfying the original ecosystem health idea advertised.
- Consequently, the meaningfulness of solely structural indicators is limited, as they do not reflect processes of ecosystem functions. Therefore, many of the listed indicators should be understood as elements of indicator sets, not as single indicators of ecosystem health.
- As the health concept has been outlined in strict contact with human systems, the linkage between man and environment should be included, at least in indicator selection. That linkage up to now can hardly be found in the literature.
- Due to the metaphoric character of the "health" approach, it has been very successful in some areas, while in other nations, it has not been applicable due to critical viewpoints on the concept's theoretical or even philosophical character.
- Furthermore, the indication of ecosystem health also covers the health status of the human population, as well as socio-economic and cultural dimensions in relation to the vigor, organization, and resilience of ecosystems.[18] Hence, parameters to indicate security, basic material for good life, health, and good social relations are indispensable to analyze overall ecosystem health, which is in line with the assessment of Rapport et al.[75] An integrative approach to bundle a suite of indicators and to attach meaningful values is the concept of ecosystem distress syndromes,[113]

which can be seen as a forerunner of the environmental degradation syndromes elaborated by the German Advisory Council on Global Change (WBGU). The three major syndromes have been named by WBGU[105]: 1) utilization, which includes the overexploitation of marginal land; 2) development which includes the destruction of ecosystems as a result of large-scale projects; and 3) sink, comprising environmental degradation resulting from large-scale diffusion of long-lived substances.

Coming back to our initial questions, we can summarize the following:

- The basic features and requirements of the ecosystem health approach demand for comprehensive and integrative indicator sets, which is a big scientific and practical challenge.
- Therefore, several proposals exist, and the health concept is used as a reference in several cases, but very often, the interdisciplinary demands of the approach are not fulfilled.
- Applications can be found mainly in aquatic ecosystems, mostly being quite distant from the involvement of human factors.
- Good chances for future development can be seen by enhancing the integration with integrity and ecosystem services.

Sustainable Fisheries: Models and Management

Fabian Zimmermann and Katja Enberg

Introduction: Population Dynamics and Fisheries

Population dynamics models are a key component of fisheries sciences to describe the changes in populations over time and their responses to fishing. The need for modeling approaches originates from the difficulties to observe fish directly. Together with the large socioeconomic relevance of fisheries, this has put fisheries models at the forefront of modeling biological systems. The focus has traditionally been on describing changes in population biomass through the growth and decay of a population's biomass. Historically, models have been divided into biomass models that lump entire populations into one biomass and models that are structured by age or size, allowing for more specific dynamics such as growth of body size, maturation, reproduction, recruitment and mortality. In this section, we will contrast biomass models with their structured counterparts, present models of growth, stock-recruitment and mortality, and outline current applications in a fisheries context.

Biomass, Age and Size Structure

In the 1950s, progress in industrial fishing triggered an increasing need to analytically describe the dynamics of fish populations in response to fishing, serving as basis to estimate the productivity of populations and maximize the yield of fisheries. Some of the first models to address these questions were the surplus production models, notably the Schaefer model by Milner B. Schaefer. These types of models describe a population as undifferentiated biomass that grows in response to the population size. Specifically, the Schaefer model (Schaefer 1954) assumes that changes in biomass are governed by population growth rate r, the carrying capacity K and the fisheries catch C:

$$\frac{dB}{dt} = rB\left(1 - \frac{B}{K}\right) - C \tag{1}$$

C can be defined in different ways, most typically it is introduced as a product of B and a fishing rate (which in turn is usually fishing effort times a catchability coefficient). The core of the equation is, however, the logistic growth of the population, which levels out to zero at $B = K$ (and at $B = 0$) and reaches a maximum of $\frac{rK}{4}$ at $B=\frac{K}{2}$. Consequently, in this model, B remains in perpetuity at $\frac{K}{2}$ if $C=\frac{rK}{4}$, which therefore maximizes the sustainable yield of a fishery. This idea builds the foundation of the concept of a maximum sustainable yield (MSY) that to date dominates global fisheries policies (Hey 2012).

There are various modifications of the Schaefer model (Haddon 2010), such as, for instance, the Fox model:

$$\frac{dB}{dt}=rB\left(1-\frac{\log(\mathrm{B})}{\log(K)}\right) \tag{2}$$

which accounts for the fact that productivity in many fish species is assumed to be not a symmetric parabola but exhibit a maximum at $B<\frac{K}{2}$. An attempt to integrate different functional forms into one generalized surplus production model is the Pella and Tomlinson model:

$$\frac{dB}{dt}=\frac{r}{s}B\left(1-\left(\frac{B}{K}\right)^{s}\right) \tag{3}$$

Here the parameter s defines the shape of the relationship between biomass and productivity, corresponding to the Schaefer model $s=1$ and displaying a left- or right-skewed parabola when $s<1$ or $s>1$, respectively.

Surplus production models can be considered as the first analytical models that have been applied systematically in fisheries science, both to assess the state of fish stocks as well as to determine reference points for management or explore conceptual questions. The biggest advantage of this class of models is their simplicity that requires comparatively little information or input data to generate (somewhat) meaningful predictions. It is for this reason why biomass-based models are still widely in use today, mostly in data-poor fisheries where the lack of information prevents the use of more sophisticated models. However, the simplicity is also the biggest caveat since omitting largely the biology and ecology of a population tends to oversimplify true dynamics. The demographic composition of a population and traits linked to demographics such as growth, maturity and fecundity are important factors of population dynamics. Ignoring these will, therefore, often result in biased or even completely wrong predictions. In the following sections, we will therefore focus on structured models of fisheries dynamics and their different components.

Growth

Besides the recruitment of new individuals to the population, increases in population biomass are caused by increasing body size of individual fish, making individual growth one of two major factors of a population's production. Fish typically grow from millimeter-sized eggs to adults that can reach up to several meters in some species while undergoing dramatic changes in their ecology and morphology. By constraining the available food and potential predation, the size of a fish is a major determinant of its ecological niche and habitat choice, while food acquisition and environmental conditions drive changes in size. Growth is a trait that is shaped by the entire life history and ecology of a species (Enberg et al. 2012), such that, typically, short-lived species tend to grow faster than long-lived ones. Furthermore, the size of fish commonly determines their fecundity and reproductive potential, and thus, the size composition of a population may be important for its productivity (Hixon Johnson, and Sogard 2014). Understanding growth is, therefore, essential to model population dynamics.

Based on the model design and their application, growth models in fish can be separated into two groups: process-based growth models and statistical growth models (Enberg, Dunlop, and Jørgensen 2008).

The former type of models defines growth through the underlying biology of an organism and the environment it experiences, shaping the processes that govern growth. Typically, process-based growth models use insights from bioenergetics to predict growth as a product of energy acquisition and transformation, accounting for metabolic processes, behavior, food intake, temperature or life-history trade-offs, as for instance between growth and reproductive investment. Process-based growth models aim at a fundamental understanding of growth, providing an approximation to the mechanisms that determine growth and enabling them to predict more accurately growth and how it may change in response to environmental and anthropogenic disturbances. In contrast, the second group of growth models focuses on a statistical description of observed sizes with little to none of the underlying biology of growth included. These models contain often fewer parameters and assume a direct relationship between age or size of an organism with growth. Examples are the logistic growth model

$$G_t = K\left(1 - \frac{W_t}{W_\infty}\right) \tag{4}$$

or the Gompertz growth model

$$G_t = K\left(\log\left(W_\infty\right) - \log\left(W_t\right)\right) \tag{5}$$

that assume that the growth rate G_t is a linear function of absolute or log-transformed weight W at time t subject to growth parameter K and an asymptotic maximum weight W_∞. While ignoring the biology of growth processes, statistical growth models can be applied to size-at-age data that is readily available for many commercially harvested fish populations. Process-based growth models, on the other hand, require more knowledge of the growth processes and data to fully parameterize the model. Particularly the necessary data on bioenergetic processes is often missing, turning the larger flexibility and predictive power of such models into a disadvantage in a practical context. Consequently, statistical growth models tend to be more common in many areas of fisheries science such as stock assessment, as they are sufficient to describe the observed size compositions of a population.

There is, however, an overlap between the two groups of growth models. Statistical growth models can be extended with additional physical or biological parameters, approximating better the actual drivers behind growth. On the other hand, process-based growth models are often used in purely statistical approaches. A good example for such applications is the von Bertalanffy growth model (VBGM), which stems from a model that includes anabolic and catabolic processes but is commonly fitted to size data like a statistical model.

Ludwig von Bertalanffy originally proposed a general growth model describing the change in length as a differential equation of length at time t, the maximum length L_∞, and a growth parameter r:

$$\frac{dL}{dt} = r\left(L_\infty - L_t\right). \tag{6}$$

Mechanistically, this is founded on the differences in how anabolic and catabolic processes scale with body weight W:

$$\frac{dW}{dt} = aW_t^{m_1} - cW_t^{m_2} \tag{7}$$

where a and c are the proportionality coefficients for anabolism and catabolism, respectively, and m_1 and m_2 the corresponding scaling exponents. Assuming that the acquisition and thus anabolic processes are proportional to body mass by $m_1 = \frac{2}{3}$ and catabolic processes (metabolism and maintenance) by $m_1 = 1$, this results with increasing body size in a higher proportion of available resources spent on catabolic processes, leaving less for growth.

The VBGM has later been introduced by Beverton and Holt into fisheries, where it has become and remained the dominating model for fish growth, mainly because it provides typically good fits to length or weight data of most fish species for both individuals and population averages. The standard form of the model is used to calculate the length or weight at time t and results in an asymptotic shape, i.e., size approaches a maximum while growth increments decrease over time:

$$L_t = L_\infty \left(1 - e^{-k(t-t_0)}\right) \tag{8}$$

$$W_t = aW_\infty \left(1 - e^{-k(t-t_0)}\right)^b \tag{9}$$

Length or weight are, therefore, determined by the growth coefficient k and an asymptotic (maximum) length L_∞ or weight W_∞. The exponent b is derived from the age–length relationship $L_t = aW_t^b$ (and in most applications simplified to a cubic relationship), and t_0 is an (hypothetical, negative) age when size is zero. The latter is included to avoid that length or weight equal to zero at hatching ($t = 0$).

The VBGM assumes discrete time steps that correspond in most applications to years. However, this may be inadequate from a biological perspective since temperate and boreal species typically do not grow equally throughout the year but show distinct intra-annual growth patterns that align with the seasonal food availability. To account for such dynamics, the standard VGBM can be modified by introducing cyclical growth patterns:

$$L_t = L_\infty \left(1 - e^{-\left(s_1 sin\left(\frac{2\pi(t-s_2)}{s_3}\right)+k(t-t_0)\right)}\right), \tag{10}$$

with s_1 and s_2 determining the shape of the oscillation and s_3 the frequency by subdividing the time step, e.g., in the most common case of annual time steps into months ($s_3 = 12$) or weeks ($s_3 = 52$).

Such modifications also reveal the main limitation of the standard VBGM: lacking functional flexibility and very simplified or erroneous biology. Specifically, the underlying scaling of anabolic and catabolic processes with size has been empirically shown as very similar, with values ranging between 0.7 and 0.8 for both exponents in most fish species. Furthermore, the VBGM neglects crucial insights from life-history theory and, therefore, captures juvenile growth less accurately than adult growth. The reason for this is that the model does not account for maturation and reproduction. Reproductive investment is very energy-demanding and, thus, requires organisms to allocate a major share of the acquired energy to it. Since resources for basic maintenance processes can only be reduced to a very limited extent, reproductive investment mainly comes at the expense of growth. Consequently, there is a trade-off between growth and reproduction, resulting in different growth trajectories before and after maturation. The VBGM does not incorporate these dynamics and, therefore, tends to underestimate the growth rates of juvenile fish, which typically approximates linear growth. The following two models attempt to address these limitations by allowing for more functional flexibility or specifically incorporating life-history considerations.

Generalized models serve the purpose of aggregating different models into one equation that can take different functional forms depending on the parameter values. The model developed by Schnute and Richards generalizes several of the growth models used in fisheries, including the VBGM and logistic model as well as models previously proposed by Gompertz, Chapman, Richards, or Schnute:

$$L_t = L_\infty \left(1 - ae^{-bt^c}\right)^{-\frac{1}{d}} \tag{11}$$

Setting parameters c and d equal to one, for instance, reduces the model to the VBGM. A generalized model such as the one from Schnute and Richards allows therefore for a better representation of observed data and biology of a population. Nevertheless, this presents a statistical approach rather than a processed-based one, possibly explaining data well but without biological understanding. Additionally, the large number of parameters may make the fitting process challenging, particularly if no prior (mechanistic) knowledge is included.

A different approach has been taken by biphasic growth models that build explicitly on life-history theory and incorporate the trade-off between growth and reproduction. These build on bioenergetics and the assumption that the change in somatic weight W depends on the acquired energy E_t and the energy invested in gonadal weight G_{t+1}:

$$W_{t+1} = W_t + E_t - G_{t+1} \tag{12}$$

Provided that weight is a cubic function of length, $W = L^3$, this can be used to model the growth in length. The model by Roff (1983) is one application of this idea, assuming a linear growth for juvenile fish, i.e., when age a is lower than the maturation age a_{mat}, whereas growth will depend on the gonado-somatic index (GSI) from the onset of maturation:

$$L_{t+1} = \begin{cases} L_t + l_0 \\ L_t + l_0 \Big/ (1 + R_{t+1})^{\frac{1}{3}} \end{cases} \text{for} \begin{cases} a < a_{mat} \\ a \geq a_{mat} \end{cases} \tag{13}$$

GSI is gonad mass divided by somatic mass, which means the larger the investment in R_{t+1}, the more will growth in length be reduced.

A very similar approach has been taken by the modified model based on Quince et al. (2008) in which the growth is also shaped by the reproductive investment R_{t+1} from of the GSI (Boukal et al 2014):

$$L_{t+1} = \sqrt[(1-\alpha)\beta]{\frac{L_t^{(1-\beta)\alpha} + (1-\beta)cb^{-(1-\beta)}}{1 + q^{-1}(1-\beta)R_{t+1}}} \tag{14}$$

For fish below a_{mat}, R_{t+1} equals zero, whereas from a_{mat} onward $R_{t+1} > 0$. The modified Quince et al. model resolves some limitations of Roff's model and incorporates a larger functional flexibility. This includes a less constrained length–weight relationship than Roff's model by assuming $W_t = aL_t^{\alpha}$, a conversion factor between somatic and gonadic investment q, and by not enforcing strictly linear growth for juvenile individuals. Both models, however, incorporate the same key feature that results in biphasic growth trajectories, separating quasi-linear growth prior to maturation from a decreased growth after the onset of maturation that depends on the reproductive investment. These models illustrate how our understanding of life-history processes can be included in growth models to represent better how growth can vary between different life stages and achieve better fits to empirical data.

Besides the trade-off between growth and reproduction, there are other trade-offs that may directly or indirectly affect growth. A major driver is survival and, therefore, everything that affects mortality, most notably predation and fishing. For instance, very size-selective mortality can increase survival for fish that invest more into growth (instead into basic maintenance processes such as the immune system) to grow faster through the size range of increased mortality. Similarly, behavioral adaptations may result in decreased or increased growth. For instance, passive behavior such as hiding can be used to reduce predation risks at the expense of reduced foraging, reducing the resources available for growth and reproduction. In contrast, growth may be increased through more active foraging and a bolder behavior; however, this may also expose fish to higher predation and reduce the probability of survival (Claireaux, Jørgensen, and Enberg 2018).

Essential life-history traits such as growth, reproductive investment, survival, and behavior are to a large part determined by an individual's inherited genotype. This means that traits are shaped by evolution and subject to evolutionary change that depends on the reproductive success of a specific life history within a given environment. Consequently, how resources are acquired and allocated into growth or reproduction is less of an individual decision than the result of an inherited life-history strategy. The trade-offs between growth, reproductive investment, and survival are key to this process and determine the success of a specific strategy under the current environmental conditions in reproducing and thus inheriting the same strategy to the next generation. Because mortality is a major driver of natural selection, changes in the degree or selectivity of mortality may affect the selection landscape and result in evolutionary adaptations in growth or traits that influence growth. This means growth trajectories within a population are not stationary over time but may change in response to environmental change and anthropogenic perturbation such as fishing or increasing sea water temperatures.

Although the growth of an organism is fundamentally shaped by life-history evolution, most observed changes in growth and thus size-at-age occur in the short term as a result of phenotypic plasticity. The most important driver is environmental variability, specifically physical and ecological conditions that influence metabolism and food availability. The latter is particularly relevant, since it determines directly the available energy that can be acquired by an organism and invested into processes such as growth. Food availability per capita is the combined result of food production through the food web and the competition for the available food sources. On a seasonal or annual time scale, growth of an organism can therefore be determined by bottom-up effects through variation in the ecosystem productivity, e.g., through varying nutrient inflow or temperatures, as well as through the abundance of its own population and other competing species. Feedbacks occur between the environmental variability and density dependence, for instance, when high food availability leads to increasing population abundance(s) and thus to competition in the future. Although the causes of environmental variability are often difficult to determine and parametrize in models, density-dependent growth has been empirically established (Zimmermann, Ricard, and Heino 2018) and may affect the sustainability of fisheries (van Gemert and Andersen 2018). A simple approach to implement density dependence in growth models is the use of an asymptotic length $L_{\infty,t}$ that decreases as a function of a density dependence coefficient d and the population biomass B_t in each year: $L_{\infty,t} = L_\infty - dB_t$ (Lorenzen and Enberg 2002). This example illustrates that not only insights from bioenergetics, physiology, and life-history theory are important to modeling growth but also insights from population ecology.

Recruitment

Recruitment is a key component of population dynamics and contributes together with body growth to the increase in biomass within a population. Because of the enormous reproductive potential of most fish species, recruitment tends to be the most important factor for the overall productivity of a population and the major driver of fluctuation in population size. Recruitment as such is the combined result of the total number of eggs produced by the mature part of a population and the survival throughout the early life stages from egg to juveniles, which explains the large variation in number of recruits observed in most fish. Typically, fish produce very large numbers of eggs per individuals, reaching millions per spawning event. At the same time, the early life stages are very vulnerable to unsuitable physical conditions, predation or insufficient food, causing large inter-annual variation in survival. Consequently, recruitment can result in favorable years in very large cohorts that sustain a population for many years during which recruitment may be average or fail completely. This variability in recruitment, however, poses also a challenge for any attempt to model and predict recruitment. Nevertheless, because recruitment is fundamental for population dynamics and thus fisheries, various recruitment models have been established. Most of these models rely on the basic assumption that recruitment must be related to the mature part of the population and is subject to some form of density-dependent reduction. The two models that remain most widely used until today are the stock-recruitment models developed by Ricker (1954) and Beverton and Holt (1957).

The Beverton–Holt model assumes a stock–recruitment relationship that increases with increasing biomass of mature fish B at time t, however, with decreasing number of recruits per spawning individual and thus approaching an asymptotic maximum of recruitment:

$$R_t = \frac{\alpha B_t}{\beta + B_t} \tag{15}$$

with α representing the asymptotic maximum for a given B_t and β the population biomass where $\alpha/2$ is reached, defining the steepness of the curve. Biologically, α stands for the maximum spawning output that linearly increases with population biomass, whereas β defines the density-dependent regulation in recruitment and therefore the productivity of a population at specific biomass levels. The underlying mechanism is the density-dependent survival of early life stages, which is assumed to decrease with increasing amount of eggs spawned by a larger population biomass due to intra-cohort competition for resources, particularly food (Van Poorten, Korman, and Walters 2018), and stronger predation pressure.

The Ricker model takes a similar approach as the Beverton–Holt model, except that it assumes an overcompensatory effect of increasing population biomass on recruitment. This implies that the Ricker stock-recruitment curve reaches a peak recruitment after which the realized number of recruits decreases again, instead of simply approaching an asymptotic maximum. The typical equation to describe this relationship is denoted as:

$$R_t = \alpha B_t e^{-\beta B_t} \tag{16}$$

Here, α defines the recruitment at a low biomass of the spawning population and scales the total number of recruits, whereas β determines the density-dependent decrease in recruits per spawning biomass. As in the Beverton–Holt model, α represents the reproductive output of the mature population and β the density-dependent mortality experienced by early life stages after spawning. The key difference between the two models is that the recruits per spawning biomass in the Ricker model do not remain at a value larger than zero but approach zero, suggesting that a population biomass above a certain level has such detrimental effects on recruitment that it overcompensates the marginal increase in spawning output. Such effects can occur through substantial negative inter-cohort interactions through cannibalism or competition (Ricard, Zimmermann, and Heino 2016), i.e., older cohorts that deplete the resources of following cohorts or prey directly on them, or other negative feedbacks, for instance when growth at early life stages is density-dependent while predation is size-dependent. This may add up to a substantially increased mortality when cohort density decreases growth rates.

It is noteworthy that the Ricker curve can take an almost identical shape as the Beverton–Holt curve for an observed range of population biomass and number of recruits, making the Ricker model more flexible in representing populations with different recruitment patterns. A step further in this direction is taken by generalized recruitment models that allow for a large functional flexibility with other models as special cases. One example for such an approach is a model suggested by Deriso and later modified by Schnute:

$$R_t = \alpha B_t (1 - \beta \gamma B_t)^{\frac{1}{\gamma}} \tag{17}$$

Here α and β take equivalent roles as in the Beverton–Holt or Ricker models, while parameter γ determines the form of the recruitment curve. For instance, when γ goes to 0, the Deriso model corresponds to the Ricker model, and $\gamma = -1$ transforms it into a Beverton–Holt-type model. A generalized model of this kind avoids the need for prior assumptions on the type of relationship, enabling better fits to data or to test effects of gradual changes in the functional form. The downside of such an approach is, however, that it takes mainly a statistical and not a process-orientated approach to incorporate biological knowledge. Furthermore, recruitment data typically turns out to be very noisy, which may make it very difficult to find reasonable parameter estimates for a model with a high degree of functional freedom.

Empirically, the biomass of the spawning population is in most cases an insufficient predictor of recruitment. As a consequence, models such as Beverton–Holt or Ricker typically fit poorly to data.

Recruitment data is in general very noisy and shows a lot of variation. Because survival at early life stages tends to be much more important than the total reproductive output of the mature individuals, other factors such as environmental conditions, food availability and predation that directly or indirectly affect mortality of eggs, larvae and juveniles are key drivers of recruitment (Zimmermann, Claireaux, and Enberg 2019). Especially large-scale atmospheric and oceanographic processes with cyclical patterns have been identified as important forcing factors. A simple approach to model such cyclical patterns in recruitment is to include an autoregressive term in a stock-recruitment model:

$$R = \alpha B_t e^{-\beta B_t} + u_t \tag{18}$$

representing a Ricker model that includes a $AR(1)$ process defined as $u_t = \varphi u_{t-1}$ with φ as autocorrelation coefficient. This allows for capturing temporal autocorrelation in recruitment time series and simulating inter-annual cyclical patterns.

A different approach to extend a Ricker model is to include explicitly an additional variable that is related with recruitment:

$$R = \alpha B_t e^{-\beta B_t} e^{-\gamma X_t} \tag{19}$$

Here X is the second variable besides mature biomass B and γ is the corresponding coefficient. Examples for X could include any environmental or ecological factor that is expected to affect the recruitment of a specific population, such as annual sea surface temperature, zooplankton indices or the biomass of a predator. This approach can be further extended with additional, equally defined terms.

Classic stock-recruitment models assume that the relationship between mature population biomass and recruitment remains stationary over time. However, this assumption may often not hold because the reproductive potential of a population as well as the mechanisms of density regulation can change over time due to external factors, both anthropogenic and natural. Regime shifts can, for instance, occur when changes in the environment or anthropogenic impacts alter the ecosystem productivity with implications on the reproductive success of a population and thus the relationship between the mature population and recruitment (Vert-pre et al. 2013). To incorporate two different regimes, a Ricker model can be modified:

$$R_t = \alpha_i B_t e^{-\beta_i B_t} \tag{20}$$

α and β depend now on $i = 1,2$ which can be defined as two different periods in a time series.

The number of regimes can be extended further if required. This comes, however, with an equally increasing number of parameters as caveat. Considering that time series of recruitment data usually only cover a few decades, the number of parameters can become easily disproportional compared to the number of data points. A solution to this problem is to introduce a time-invariant parameter that captures gradual changes in the relationship between population and recruitment over time (Perälä and Kuparinen 2015). For instance, if we assume that the productivity of the mature biomass varies with time, time-variant α_t can be introduced:

$$R_t = \alpha_t B_t e^{-\beta B_t} \tag{21}$$

where parameter α follows a random walk process $\alpha_t = \alpha_{t-1} + \sigma_t$, with σ assumed to be normally distributed. This enables the productivity term in the stock-recruitment relationship to vary gradually over time, representing changes in the population's reproductive output for instance through changes in the population's demographic structure due to fishing or because of increasing temperatures, as well as subsequent evolutionary adaptation (Enberg et al 2010).

Mortality and Population Dynamics

Whereas individual growth and recruitment represent the increase in biomass of a population, mortality constitutes the loss term in the equation. Survival is therefore a crucial component in fisheries models, making them very sensitive to the underlying assumptions and specifications of mortality. Mortality is typically given in rates that define the survival of individual fish over time. Two main sources of mortality are distinguished: mortality from natural causes, most notably predation and diseases, commonly denominated as natural mortality M, and mortality from anthropogenic harvesting, commonly termed fishing mortality F. These instantaneous rates of mortality can be summed to total mortality $Z = F + M$, which translates into proportional survival after a given time step as e^{-Z} and, reciprocally, relative mortality as $1 - e^{-Z}$. In an age-structured population, the abundance reduces in one time step t by:

$$N_t = N_{t-1}e^{-Z} \tag{22}$$

or alternatively an abundance at a given age a of:

$$N_a = N_0 e^{-Za}, \tag{23}$$

with N_0 as initial abundance of a cohort, typically corresponding to recruitment R_t.

Mortality is, however, in most fish species dependent on size and, thus, age of an individual. This applies both for F and M. While other sources of mortality such as diseases, parasite or starvation can be relevant as well, M is to a large degree shaped by predation. Vulnerability to predation is influenced by various traits, including the individual behavior, but most importantly body size because most predators have a size window for prey based on limitations in perception and handling. For a given stock, smaller and younger fishes tend to be much more vulnerable to predation than bigger and older ones, which means that mortality decreases substantially with increasing size and age.

F is subject to similar size selectivity, indirectly because parts of populations such as pre-recruits often do not share the same habitat as the ones targeted by fisheries and directly through size-selective fishing gear. In contrast to M, F increases in most cases with age and size: while small, young fishes are usually excluded from fisheries and experience very low fishing, the F for the targeted age and size classes can be substantial and outweigh M. These dynamics can be captured by using age-specific mortality rates F_a and M_a, leading to

$$N_{a,t} = N_{a,t-1}e^{-(F_a + M_a)} \tag{24}$$

This model can be further extended by allowing F and M also to vary in time:

$$N_{a,t} = N_{a,t-1}e^{-(F_{a,t} + M_{a,t})} \tag{25}$$

The two-dimensional mortality matrices here are age- and time-specific, which is common for stock assessment models where annual F_a's are estimated.

Stock Assessment

Managing fish stocks depends on knowing the state of the stock and its trajectory. Because fish are typically numerous, mobile and difficult to observe, this can be much more difficult than for classic terrestrial resources such as forests. Finding methods to assess a fish stock and use this information as the basis for regulative decisions is therefore at the core of sustainable fisheries management. This so-called stock assessment process relies commonly on observations, notably from commercial catches or standardized scientific sampling, and mathematical models to transform these often nonrepresentative, biased or snapshot-like observations into information on changes in the stock. The type and complexity of the model used is determined by the quantity, quality and structure of the available data.

The main distinction follows our previous differentiation of model complexity: biomass or age-/length-structured models. The latter require consistent information on the age or size of individual fish in the catch or scientific samples, which implies comparatively large and costly efforts in data collection over many years. Consequently, only a minority of global fish stocks are assessed in such a framework, mostly in commercially valuable fisheries in industrialized countries. All other fish stocks are classified as data-limited and are assessed with a wide range of methods (Chrysafi and Kuparinen 2015). Typically, these produce time series of absolute or relative biomass based on combining data on fisheries catch and effort with life-history information. However, to inform on the key parameters of population growth r and K (see Eq. 1), data of stock sizes at very high and low levels are necessary to give good indications on maximum growth rate and carrying capacity, respectively, which typically requires relatively long time series that ought to include unfished and overfished periods, what is rarely available. Alternatively, life-history parameters can act as predictors of stock productivity and resilience and therefore indicate adequate catch levels. This comes with the benefit that information gaps even in cases with very little or no data can be bridged by tapping into existing knowledge on ecology and life-history theory to incorporate it as priors into Bayesian assessment models (Kindsvater et al. 2018).

Age- or length-structured models can be divided into two major categories: statistical methods and cohort dynamics models. Both are based on the population dynamics detailed before in Eqs. 10 and 24 and, most importantly, the catch equation that relates total catch to age- or size-specific abundance and mortality:

$$C_{a,t} = \frac{F_a}{F_a + M_a} N_{a,t} \left(1 - e^{-(F_a + M_a)}\right) \tag{26}$$

In stock assessment, this equation provides an approach to determine the unknown variables F_a and N_a from catch data. Because time series of catch exist in essentially all commercial fisheries where assessments are conducted, the catch equation represents the core of almost all assessment models.

The main difference between statistical methods and cohort dynamics is the way these variables and other parameters are derived. Cohort dynamics, most commonly known as virtual population analysis (VPA) or more advanced derivatives such as extended survivor analysis (XSA), do not estimate their parameters but are instead based on an iterative process where the size of each cohort is calculated backwards in time and the result reseeded until the values of $N_{a,t}$ and $F_{a,t}$ approximate the observed $C_{a,t}$ sufficiently well. For this approach to work, other parameters, especially M_a, need to be given as fixed values. Later versions such as XSA were mostly developed to allow for the inclusion of catch indices from commercial or scientific surveys. VPA-type assessment models were particularly widespread in the assessments of European fisheries but have been increasingly replaced by statistical models in recent years.

Statistical catch-at-age models estimate their parameters directly by fitting Eq. 26 and other underlying equations to data by optimizing a given objective function. This offers greater flexibility and actual statistical evaluation compared to cohort dynamics models, yet comes with risks of over-parametrization and over-fitting when using ill-defined models. This can easily be illustrated with a model that assumes all $N_{a,t}$ and $F_{a,t}$ as independent parameters, which would result with, e.g., 10 age classes and a time series of only 20 years in 200 parameters alone, twice as many as data point. The problem is typically circumvented by linking parameters such as $F_{a,t}$ among each other through, e.g., a selectivity-at-age function or restricting changes over time. Together with increasing computational power and efficient optimization algorithms, this has elevated the utility of these models considerably and therefore also the number of stocks assessed with such, even though limitations remain (Subbey 2018).

Two of the most common frameworks for statistical assessment models are Stock Synthesis (Methot and Wetzel 2013) and, in recent years, State-space Assessment Model (SAM, Nielsen and Berg 2014). The strength of Stock Synthesis and reason for its popularity is mainly its flexible adjustment to a range of data situations, from relatively data-limited stocks to such with many data series and process knowledge available. SAM on the other hand is a state-space model framework which allows, thus, for a separation of observation and process error and the estimation of the development in F_a over time. Benefits include that time-varying selectivity can be directly estimated and uncertainty incorporated, representing possible solutions for two major problems in stock assessment. Both Stock Synthesis and SAM utilize comparable automatic differentiation algorithms that can estimate a large number of parameters efficiently based on maximum likelihood (or, in case of stock synthesis, also Bayesian inference).

Despite technical advances in assessment methods and increasing data availability, major challenges persist in stock assessment. Generally, there's a widespread lack of process knowledge and true mechanistic understanding that leads to biased or erroneous estimates (Maunder and Piner 2015). This includes insufficient knowledge on key biological processes, notably natural mortality, which are often described and parametrized in highly simplified ways that build a stark contrast to the increasing wealth of data and complexity when it comes to commercial and scientific catch indices. Natural mortality is in the large majority of assessed stocks kept constant over all age classes and over time. Similarly, maturity at age and growth are often described with time-invariant equations, despite existing knowledge that all these traits and the underlying processes can show large variation over time with significant impacts on stock dynamics. Ultimately, this is also reflected in the fact that most stock assessments maintain an isolated perspective on one specific stock and ignore its ecological context (Skern-Mauritzen et al. 2016), even though this excludes important information on drivers of dynamics and stock productivity. Incorporating ecosystem dynamics, for instance, by integrating them into natural mortality and growth in assessment models and their forecasts may therefore provide an important step forward in improving the prediction power and subsequently also the management of fisheries. Currently, the downside is the required data and effort that adds to an already work-intensive assessment process. One potential solution to this problem could be reduced assessment frequencies to free up capacities (Zimmermann and Enberg 2017) and focus on collecting the necessary ecosystem data to improve the quality of assessments.

Advice and Management

A key goal of modeling fish stocks and assessing them is to inform management strategies and shape regulative fisheries policies. The main outputs of the assessment process are therefore indicators of a stock's current state to evaluate them against reference points, forming the basis of the management advice. Reference points are important targets or thresholds in the state of a stock or the catch levels, which are typically linked to desirable objectives (notably, the stock size or fishing mortality that produces MSY) or unwanted situation (e.g., the stock size below which the risk of collapse exceeds a predefined limit). These thresholds are estimated from the available information, i.e., the specific approach depends again on data availability. If a complete analytical assessment exists, the estimated parameters (such as stock–recruitment relationship, length-at-age, natural mortality, fisheries selectivity-at-age, uncertainty) can be applied in stochastic simulation models of the population dynamics to calculate the desired reference points. In data-limited situations, there is often the need for different approaches due to the lack of a full assessment model. These utilize either catch and effort data or qualitative measurements of stock status (Froese et al. 2017) or are derived from biological information (Brooks, Powers, and Cortés 2009). It is noteworthy that in data-limited stocks, methods that rely on time series of catches tend to not perform better than simpler methods with lower data requirements (Carruthers et al. 2014).

Management advice to the regulatory agents is provided as management strategies and their outcomes, often with clear recommendations accompanied by a decision table that lists different options and how they perform in respect to reference points or policy objectives. Risk assessment is an important part of management advice, typically focusing on estimated probabilities of falling below limit thresholds of stock size or yield. Ideally, this translates into risk management that implements a precautionary approach to mitigate harmful impacts on fish stocks or fisheries (Hilborn et al. 2001). To develop and test management strategies, the most common framework today are management strategy evaluations (MSEs) that apply a suite of management strategies in simulation models to evaluate their long-term performance. These can include a broad range of (generic) management strategies or specifically developed ones. Main challenges hereby are the representation of uncertainty and the comprehensive transfer of results to managers and decision makers (Punt et al. 2016). The dimensions of a MSE increase with each management strategy or reference point considered, easily resulting in very large and complex outputs. It is therefore crucial that the results of MSE are summarized and presented in the best possible way, otherwise they may fail to convey the necessary information to managers and lead to suboptimal decision-making.

Ultimately, the key to successful fisheries management is the clear definition of objectives. A common reason for management failure is ill-specified or conflicting objectives (Hilborn 2007). Many objectives in fisheries management do not align or are even mutually exclusive. Classic trade-offs among objectives include food production and conservation or economic benefits and employment in the fisheries sector. It is, therefore, crucial that stakeholders such as policy makers, managers, fishermen, scientists and the public agree on the objectives that fisheries ought to achieve, to facilitate the design of suitable management strategies and their evaluation. Nevertheless, the success also hinges on the entire process of assessing stocks and, therefore, the adequate use of models to represent and predict stock dynamics sufficiently well. The major challenge of fisheries science remains therefore to collect the necessary information, use data efficiently and maximize the knowledge gain through suitable model choices.

The ecosystem approach to fisheries management has increasingly been recognized as a next step towards a more holistic and sustainable use of marine resources. Fish stocks are part of an ecosystem that is shaped by its environment, species composition and anthropogenic pressures. Climatic and oceanographic processes and trophic interactions among fish stocks and their prey and predators are important sources of variation in population dynamics that need to be accounted for if these dynamics ought to be accurately explained or predicted. Interactions between stocks are, for instance, important for management strategies because they not only affect recruitment and natural mortality but also result in trade-offs in reference points such as MSY (Voss et al. 2014) and rebuilding strategies of overfished stocks (Zimmermann and Yamazaki 2017). Furthermore, adaptations to selective harvesting (Heino et al. 2013), density effects (van Gemert and Andersen 2018) or climate change (Britten, Dowd, and Worm 2016) can affect the productivity of fish stocks and, thus, shift reference points. Ignoring such dynamics may therefore result in flawed reference points that increase the risk stock collapse and overfishing or underfishing, that is managing a fish stock suboptimally in respect to the biological or economic objectives. Finding robust and beneficial ways of increasingly integrating ecological information into assessment and management is therefore a major goal in our quest towards sustainable fisheries.

Currently, ecological interactions and the variation caused by them are still rarely included in stock assessment and management (Skern-Mauritzen et al. 2016). A major obstacle in the process towards ecosystem-based management has been that higher model complexity results in the curse of dimensionality and increasing uncertainty (Collie et al. 2016). Models that were meant to build the basis for ecosystem-based management by replicating entire food webs or ecosystems have turned out too complex, lack uncertainty quantification and are difficult to parametrize on a year-to-year basis, particularly for the many fisheries where data or knowledge are limited. For tactical fisheries management, current ecosystem models are therefore too data hungry and, most importantly, show poor estimation and prediction capabilities (Planque 2016). This is problematic because for management, the short-term prediction skills are crucial (Dietze et al. 2018) and there is no gain from incorporating ecosystem dynamics into management without sufficient prediction power (Basson 1999). A way forward is, therefore, an approach that focuses on integrating specific ecological or environmental interactions that can be effectively monitored, have high predictive power and significantly impact the dynamics of a population. Future research will subsequently focus on how such ecological interactions can in a systematic way be identified and incorporated into fisheries management processes.

Bioremediation: Contaminated Soil Restoration

Sven Erik Jørgensen

Introduction

Contaminated soil is an increasing problem in industrialized countries, and the high cost of remediation has driven the interest in the direction of ecological engineering applications of bioremediation technologies. They apply biological processes, mainly microorganisms or plants. It is often possible to solve the pollution problem satisfactorily by this ecotechnologically based methodology without the hazard and expense involved in removing polluted materials for treatment elsewhere for the use of traditional environmental technological methods.

Ecotechnological bioremediation may be applied for both organic waste and heavy metals, although the methods applied in practice may differ and they are therefore treated below in two different sections, on organic compounds and heavy metals. The success of any bioremediation technology depends on a number of factors including site characteristics, environmental factors such as temperature, pH, redox potential, concentrations of nutrients, the contaminant, the presence of microorganisms, and bioavailability. It is therefore necessary to look into these factors to comprehend the applicability of these methods.

Bioavailability of Toxic Organic Compounds

Bioavailability is a crucial factor for the application of bioremediation. It is defined as the amount of contaminant present that can be readily taken up by organisms. The bioavailability controls the biodegradation rates for organic contaminants because microbial cells must expend energy to induce the catabolic processes used in biodegradation. If the contaminant concentration is too low, induction will not occur. Soil microbial populations are typically slow-growing organisms and often exposed to nutrient-poor environments.[1] Bioavailability also determines the toxicity of both organic and inorganic contaminants to organisms other than those applied for bioremediation. There is therefore an increased need for bioremediation when bioavailability is high, which fortunately makes bioremediation more attractive. Three cases can be envisioned that would result from different bioavailabilities of contaminants:[2]

1. Biodegradation will not occur because the concentration of the bioavailable contaminant is insufficient and/or the biodegradation rate for the contaminant is too low to justify the energy expenditure to induce biodegradation.
2. Microbial cells may degrade the contaminant at low bioavailable concentrations and/or low biodegradation rates, but in a resting or maintenance stage rather than in a growing stage.
3. At a sufficient bioavailability and biodegradation rate, there is enough bioavailable contaminant to induce biodegradation in a growing stage. That will allow for optimal rates of remediation.

The biodegradability of organic contaminants is highly dependent on the physical and chemical structure[3] of the contaminant and the soil. The section on "Biodegradation" will discuss this topic. A coarse but still applicable rule for a very first estimation of the biodegradability of organic compounds is given in the entry entitled "Biodegradation." Moreover, the software EEP (Estimation of Ecotoxicological Parameters) is able to give some first estimation of biodegradability.

The bioavailability of heavy metals is also a significant factor for the applicability of bioremediation. Heavy metals are of course not degraded but removed, mainly by plant uptake. The uptake by organisms of heavy metals, which determines the overall removal efficiency, is entirely controlled by the bioavailable amount of heavy metals. An ecological model presented in the section on *Uptake of Heavy Metals by Plants* will illustrate the strong dependence of the bioavailability of heavy metals.[4]

Bioavailability is influenced by a number of factors:

1. Low water solubility
2. Sorption on the solid phase of soil
3. Physical makeup of the soil (pore size distribution)
4. Microbial adaptations

Low water solubility can limit availability of the substrate to bacterial cells and hence constrain biodegradation.[5,6] Microbial cells are 70%–90% water, and the food they utilize comes from the water surrounding the cells. Plants take up water to cover the evapotranspiration needed for the maintenance of their life functions. Therefore, uptake and transport are only feasible for water-soluble material. If first-order biodegradation kinetics is presumed, the biodegradation rate becomes proportional to the concentration in the water phase. It means for components with low water solubility that they are biodegraded very slowly. There are clear relationships between the water solubility of an organic compound and the chemical structure that can be utilized to estimate the water solubility.[3] EEP (a software containing many equations to estimate ecotoxicological parameters) and other estimation equations utilize these relationships to make estimation of the water solubility and of K_{ow}. Side reactions may change the water solubility. This is of particular interest for heavy metal ions, which can increase the solubility by the formation of complexes either with organic or with inorganic compounds. The formation of complexes with humic acid and fluvic acid plays a major role for the solubility of metal ions in soil water. Hydrocarbons that are frequently found as soil contaminant have a low water solubility: 2–6 μg/L for pentacyclic aromatic hydrocarbons and *n*-alkanes of chain length 18–30. The solubility decreases with increasing molecular weight.[3]

The state of the contaminant in combination with the water solubility is also of importance. There is evidence that liquid-phase hydrocarbons are more bioavailable than solid-phase hydrocarbons.[7] In practical terms, this means that the maximum growth rate occurs in different solubility ranges for liquid-phase (0.01–1 mg/L) and solid-phase (1–10 mg/L) components. Degradation can be described by a Michaelis–Menten expression. Water solubility increases with increasing temperature and usually an Arrhenius expression can be applied with the temperature coefficient 1.06 or 1.07.

Many authors have found that surfactants increase mineralization rate due to increased dissolution. Also, surfactants may provide an additional carbon source, which is preferentially utilized by the bacteria. There may, how-ever, also be a negative effect by surfactants due to their toxicity to the bacterial population.

Sorption on the solid phase of soil may be a limiting factor for biodegradation of microorganisms and uptake by plants. There are several reports that suggest that organic chemicals are not mineralized while associated with solid phases.[8,9] Experiments by Robinson et al.[10] show that sorbed-phase substrate was not degraded and that longterm biodegradation was limited by the slowly desorbing fraction of substrate. These results suggest that rate-limited mass transfer processes (primary desorption) may significantly affect the rate at which a compound is degraded in the presence of a solid phase.

The model presented in the section on "Uptake of Heavy Metals by Plants" uses the fraction soluble in the soil water of heavy metal ions to determine the uptake. The sorption is dependent of pH, redox potential, and humus, clay, and sand fractions in the soil. The relationship between these factors and the sorption is included in the model. If the sorption of organic compounds to soil is not known, the soil–water partition coefficient, K_{oc}, can be estimated from the octanol–water partition coefficient by the following equations:

$$\log K_{oc} = -0.006 + 0.937 \log K_{ow} \tag{1}$$

$$\log K_{oc} = -0.35 + 0.99 \log K_{ow} \tag{2}$$

In the case that the carbon fraction of organic carbon in soil is f, the distribution coefficient, K_D, for the ratio of the concentration in soil and in water can be found as $K_D = K_{oc} f$.

It has been suggested that there are different stages of sorption processes and that newly sorbed material is more labile and therefore more bioavailable than aged sorbed material. Numerous experiments have demonstrated that aging affects bioavailability in soil due to changes in the soil structure, resulting in slower desorption processes. The sorption can frequently be described by either Freundlich or Langmuir adsorption isotherm, expressed respectively by the following equations:

$$a = kc^b \tag{3}$$

$$a = k'c/(c + b') \tag{4}$$

where a is the concentration in soil, c is the concentration in water, and k, k', b, and b' are constants. Equation 3, corresponding to Freundlich adsorption isotherm, is a straight line with slope b in a log–log diagram, since $\log a = \log k + b \log c$.[11] The Langmuir adsorption isotherm is an expression similar to the Michaelis–Menten equation. If $1/a$ is plotted versus $1/c$,[11] we obtain a straight line, Lineweaver-Burk's plot, as $1/a = 1/k' + b'/k'c$. When $1/a = 0$, $1/c = -1/b'$ and when $1/c = 0$, $1/a = 1/k'$. This plot can be applied to assess the expression of the type used in Michaelis–Menten's equation and in Langmuir's adsorption isotherm; it is observed that b is often close to 1 and c is for most environmental problems small. This implies that the two adsorption isotherms get close to $a/c = k$, and k becomes a distribution coefficient. k for 100% organic carbon is usually denoted K_{oc} (see above).

The sorption determines the uptake of organic contaminants by plants as it is expressed in the following equation:[11]

$$\mathrm{BCF} = f_{\mathrm{lipid}} K_{ow}{}^{b} / hfK_{ow}{}^{a}, \tag{5}$$

where BCF, the biological concentration factor, expresses the ratio between the concentration in soil and in the plant (or the microorganisms); f_{lipid} is the lipid fraction in the plant; f is, as shown above, the fraction of organic carbon in the soil; and a, b, and h are constants. The denominator expresses the fraction of the organic matter that is dissolved in the soil water. h is therefore the constant determined by Equations 1 and 2. If we use Equation 1, Equation 5 may be reformulated to the following equation:

$$\mathrm{BCF} = 1.01 f_{\mathrm{lipid}} K_{\mathrm{ow}}{}^{0.063} / f \tag{6}$$

As it is seen, BCF becomes almost independent of K_{ow} and mainly dependent on the ratio between f_{lipid} and f. A high BCF means that the concentration in the plants (eventual microorganisms) is high and a significant amount of the toxic compound is removed; the lipid fraction in the plants has to be high and the carbon content of the soil has to be low.

Physical makeup of the soil (*pore size distribution*) is of importance for bioavailability. Bacteria may be excluded from the microporous domain since most bacteria range from 0.5 to 2 μm. If such an exclusion occurs, biodegradation cannot take place in the microporous domain. The degradation rate is therefore limited by the diffusion of solute from the microporous to the macroporous domain. This is obviously of particular importance for organic contaminants with a high molecular weight. In a field situation, it is difficult to separate the effects of sorption and micropore exclusion, as some residues are protected from biodegradation by both mechanisms.

Microbial adaptations: Microorganisms have developed several strategies to increase the bioavailability of organic contaminant. One strategy is the development of increased cell affinity for hydrophobic surfaces. It allows the microorganisms to attach to the hydrophobic substrate and directly adsorb it. A second strategy is the production and release of surface active agents or biosurfactants.[12,13]

The biological adaptation is a current change of the properties of the microbial population by a selection of the microorganisms that are best fitted to survive and grow under the prevailing conditions. They are determined by the properties of the environment including the concentrations and characteristics of the contaminants. A biological adaptation is widely used to prepare a microorganism population for bioremediation. It is often possible, although not general, that a 10 times faster decomposition can be achieved by the use of adapted microorganisms.[2]

Biodegradation

See the entry entitled "Biodegradation," where a general presentation of this process included methods for estimation of the biodegradation rate from the chemical structure of the toxic organic compounds.

The usual applied procedure to follow for the utilization of microbiological biodegradation to reduce the concentration of a toxic organic matter in contaminated soil has six steps:

1. Spatial mapping of quantitative distribution: the contaminant is developed by analytical chemistry intensively. Analyses of pore water are often applied to evaluate the extent of environmental risks.
2. Laboratory test/treatability studies to verify the applicability of bioremediation.
3. Calculation (often by development of a model) to assess the feasibility of the method in situ.
4. Production of an adapted strain of the microorganisms in sufficient amount.
5. Implementation in situ. If the groundwater table is high, it is usually lowered. Injection pits are introduced into the soil, and air is blown into the soil to reinforce the decomposition of organic matter. In case of chlorinated compounds, a mixture of methane and air may be applied.
6. The results are followed by use of a wide spectrum of analytical methods including radioactive tracers, detection of intermediary metabolites, and respiration rate.

Uptake of Heavy Metals by Plants

Plants are contaminated by heavy metals originating from deposition of heavy metals (waste sites), air pollution, the application of sludge from municipal wastewater plant as a soil conditioner, and the use of fertilizers. The uptake of heavy metals from municipal sludge by plants has previously been modeled.[4] The model is based on a mass balance for cadmium in a typical Danish soil (see Figure 1).

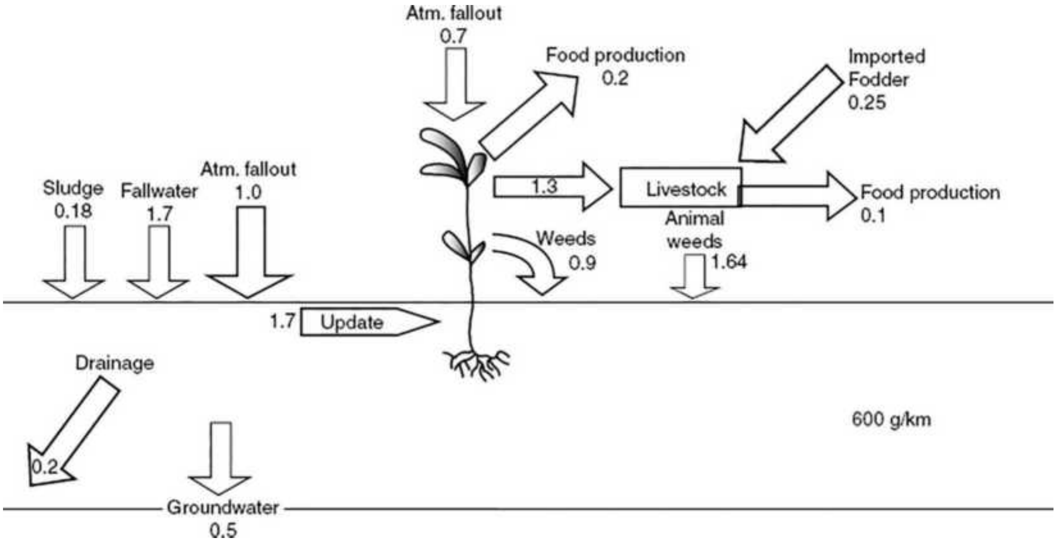

FIGURE 1 Cadmium balance of 1 ha of an average Danish agriculture land. All rates are expressed as grams of Cd per hectare per day.

The model can briefly be described as follows: Depending on the soil composition, it is possible to find for various heavy metal ions a distribution coefficient, i.e., the fraction of the heavy metal that is dissolved in the soil water relative to the total amount. The distribution coefficient was found by examination of the dissolved heavy metals relative to the total amount for several different types of soil. Correlation between pH, the concentration of humic substances, clay, and sand in the soil on the one hand, and the distribution coefficient on the other, was also determined. The uptake of heavy metals was considered a first-order reaction of the dissolved heavy metal. It is, how-ever, also possible to test acid volatile sulfide and organic carbon to describe the metal binding capacity of sediment in constructed wetlands. This will give approximately the same ratio "bound" to "bioavailable" heavy metals as the above-mentioned correlation. The basic idea is the same, namely, to find easily measurable soil properties that determine the metal binding capacity, which is crucial for the uptake of heavy metals by plants.

In addition to the uptake from soil water, the model presented below considers the following:

1. Direct uptake from atmospheric fallout onto the plants.
2. Other sources of contamination such as fertilizers and the long-term release of heavy metal bound to the soil and the non-harvested parts of the plants.

Published data on lead and cadmium contamination in agriculture are used to calibrate and validate the model that is intended to be used for the following:

1. Risk assessment for the use of fertilizers and sludge that contain heavy metals as contaminants.
2. A risk involved in the use of plants harvested from a waste site.
3. Determining the possibilities of removal of heavy metals by plants that have a particular ability to take up heavy metals. This last intended application of the model makes it useful for determination of the result of application of bioremediation.

Figure 2 shows a conceptual diagram of the Cd version of the model. The STELLA software was applied. As can be seen, it has four state variables: Cd-bound, Cd-soil, Cd- detritus, and Cd-plant. An attempt was made to use one or two state variables for cadmium in the soil, but to get acceptable accordance between data and model output, three state variables were needed. This can be explained by the presence of several soil components that bind the heavy metal differently.

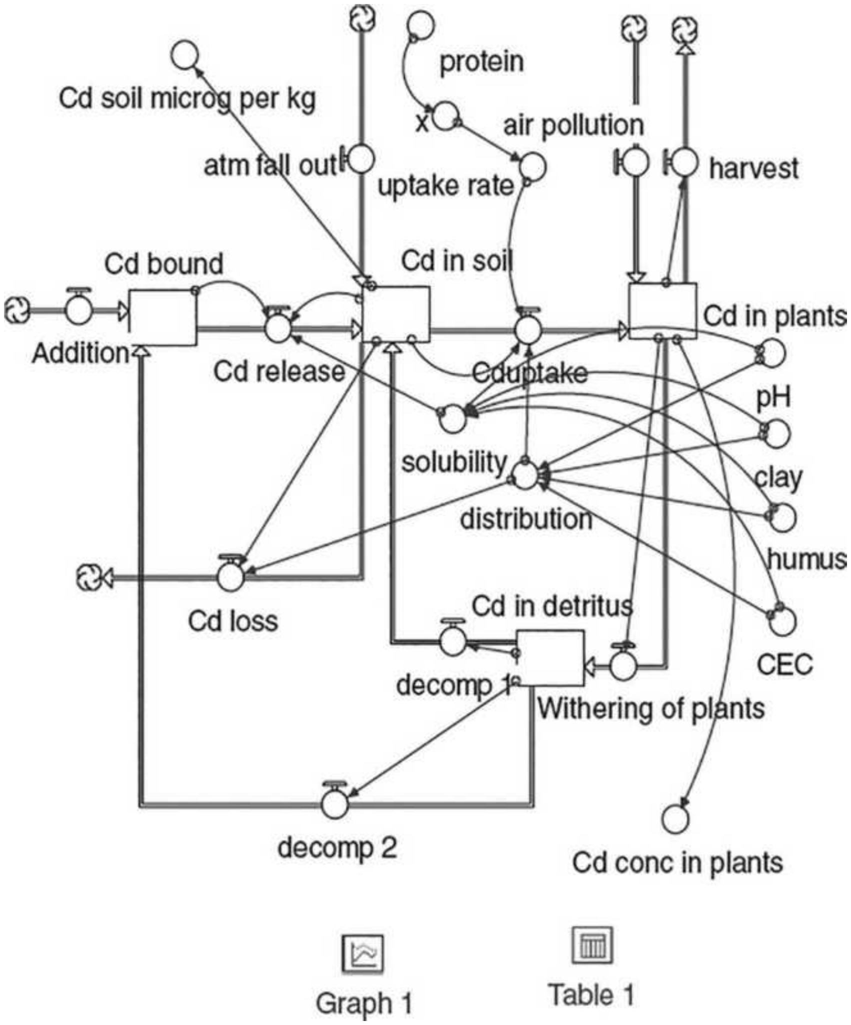

FIGURE 2 Conceptual diagram of the model. Boxes show state variables, double-line arrows denote flows, circles show functions, and single-line arrows show feedback mechanisms.

The loss covers transfer to the soil and groundwater below the root zone. It is expressed as a first-order reaction with a rate coefficient dependent on the distribution coefficient that is found from the soil composition and pH, according to the correlation found by Jørgensen.[14] The transfer from Cd-bound to Cd-soil indicates the slow release of cadmium due to a slow decomposition of the more or less refractory material to which cadmium is bound. The cadmium uptake by plants is expressed as a first-order reaction, where the rate is dependent on the distribution coefficient, as only dissolved cadmium can be taken up. It is furthermore dependent on the plant species. As will be seen, the uptake is a step function that, here (grass), is 0.0005 during the growing season, and, of course, zero after the harvest and until the next growing season starts. Cd-waste covers the transfer of plant residues to detritus after harvest. It is therefore a pulse function, which here is 60% of the plant biomass, as the remaining 40% has been harvested. Cd-detritus covers a wide range of biodegradable matter and the mineralization and is therefore accounted for in the model by use of two mineralization processes: one to Cd-soil and one to Cd-bound. The first one is rapid and is given a higher rate for the first 180 days as the addition of municipal sludge in this case is at day 0. The second one is at about the same rate, but as the cadmium is transferred to the Cd-bound, the slow release rate is considered by the very slow transfer from Cd-bound to Cd-soil. Similar models can be erected for other heavy metals, but the distribution coefficient is of course different for the other heavy metals.[14]

Plants with a high protein content will generally take up heavy metals with a higher efficiency. Several applications of plants with a high uptake efficiency have been reported in the literature; see Tongbin et al.,[15] where a very effective uptake of arsenic is reported, and Feng et al.,[16] where simultaneous removal of arsenic and antimony is reported. The use of algae for removal of heavy metals has also been successfully tested.[17]

Models are used increasingly to solve the problems of contaminated soil (see UNEP-EITC and Copenhagen University[18]). Spatial models have been developed to consider the distribution of the contaminants in eco-spatial time scale. These models are very useful in setting up and optimizing time-bound action plans of bioremediating the contaminated soil.

Biotechnology: Pest Management

Maurizio G. Paoletti

Benefits of Genetic Engineering in Pest Control

Since 1987, many crops have been genetically modified for features such as resistance to insects, resistance to pathogens (including viruses) and herbicides, and for improved features such as longer-lasting ripening, higher nutritional status, protein content, seedless fruit, and sweetness. Up to 34 new genetically engineered crops have been approved to enter into the market.

In 1998, 27.8 million ha of engineered crops were planted in countries such as the United States, Argentina, Canada, and Australia. The United States alone contains 74% of the modified crop land-planted. Globally, 19.8% of this area has been planted with herbicide-tolerant crops, 7.7% with insect-resistant crops, and 0.3% with insect and HRCs. Five crops—soybean, corn, cotton, canola, and potato—cover the largest acreage of engineered crops.[1,2]

Disease Resistance in Crops

The crops currently on the market that have been engineered for resistance to plant pathogens are listed in Table 1. Disease-resistant engineered crops have some potential advantages because few current pesticides can control bacterial and viral diseases of crops. In addition, these engineered plants help reduce problems from pesticides.

The large-scale cultivation of plants expressing viral and bacterial genes might lead to adverse ecological consequences. The most significant risk is the potential for gene transfer of disease resistance from cultivated crops to weed relatives. For example, it has been postulated that a virus-resistant squash could transfer its newly acquired virus-resistant genes to wild squash *(Cucurbita pepo),* which is native to the southern United States. If the virus- resistant genes spread, newly disease-resistant weed squash could become a hardier, more abundant weed. Moreover, because the United States is the origin for squash, changes in the genetic make-up of wild squash could conceivably lessen its value to squash breeders.

TABLE 1 Plants Genetically-Engineered for Virus Resistance That Have Been Approved for Field Tests in the United States from 1987 to July 1995

Crop	Disease(s)	Research Organization
Alfalfa	Alfalfa mosaic virus, Tobacco mosaic virus (TMV), Cucumber mosaic virus (CMV)	Pioneer Hi-Bred
Barley	Barley yellow dwarf virus (BYDV)	USDA
Beets	Beet necrotic yellow vein virus	Betaseed
Cantelope and/or squash	CMV, papaya ringspot virus (PRV) Zucchini yellow mosaic virus (ZYMV), Watermelon mosaic virus II (WMVII)	Upjohn
	CMV	Harris Moran Seed
	ZYMV	Michigan State University
	ZYMV	Rogers NK Seed
	Soybean mosaic virus (SMV)	Cornell University
	SMV, CMV	New York State Experiment Station
Corn	Maize dwarf mosaic virus (MDMV) Maize chlorotic mottle virus (MCMV), Maize chlorotic dwarf virus (MCDV)	Pioneer Hi-Bred
	MDMV	Northup King
	MDMV	DeKalb
	MDMV	Rogers NK Seed
Cucumbers	CMV	New York State Experiment Station
Lettuce	Tomato spotted wilt virus (TSWV)	Upjohn
Papayas	PRV	University of Hawaii
Peanuts	TSWV	Agracetus
Plum Trees	PRV, plum pox virus	USDA
Potatoes	Potato leaf roll virus (PLRV), Potato virus X (PVX), Potato virus Y (PVY)	Monsanto
	PLRV, PVY, late blight of potatoes	Frito-Lay
	PLRV	Calgene
	PLRV, PRY	University of Idaho
Potatoes	PLRV, PVY	USDA
	PYV	Oregon State University
Soybeans	SMV	Pioneer Hi-Bred
Tobacco	ALMV, tobacco etch virus (TEV), Tobacco vein mottling virus	
	TEV, PVY	University of Florida
	TEV, PVY	North Carolina State University
	TMV	Oklahoma State University
	TEV	USDA
Tomatoes	TMV, tomato mosaic virus (TMV) CMV, tomato yellow leafcurl virus	Monsanto
	TMV, ToMV	Upjohn
	ToMV	Rogers NK Seed
	CMV	PetoSeed
	CMV	Asgrow
	CMV	Harris Moran Seeds
	CMV	New York State Experiment Station
	CMV	USDA

Some plant pathologists have also suggested that development of virus-resistant crops could allow viruses to infect new hosts through transencapsidation. This may be especially important for certain viruses, e.g., luteoviruses, where possible heterologus encapsidation of other viral RNAs with the expressed coat protein is known to occur naturally. With other viruses, such as the PRV that infects papaya, the risk of heteroencapsidation is thought to be minimal because the papaya crop itself is infected by very few viruses.

Virus-resistant crops may also lead to the creation of new viruses through an exchange of genetic material or recombination between RNA virus genomes. Recombination between RNA virus genomes requires infection of the same host cell with two or more viruses. Several authors have pointed out that recombination could also occur in genetically engineered plants expressing viral sequences of infection with a single virus, and that large-scale cultivation of such crops could lead to increased possibilities of combinations. It has recently been shown that RNA transcribed from a transgene can recombine with an infecting virus to produce highly virulent new viruses.

A strategy for reduced risk would include: 1) identification of potential hazards; 2) determination of frequency of recombination between homologous, but nonidentical sequences in crops and weeds; and 3) determination of whether or not such recombinants can have selective advantage.

Assessment of Transgenic Virus-Resistant Potatoes in Mexico

An in-depth assessment of potential socioeconomic implications related to the introduction of some genetically modified varieties of virus-resistant potatoes (PVY, PVX, PIRV) in Mexico underscores the importance of this technology. This type of genetic modification could prove especially beneficial to large-scale farmers, but only marginally beneficial to small-scale farmers, because most small farmers use red potato varieties that are not considered suitable for transformation. In addition, 77% of the seeds that small farmers use come from informal sources, not from the seed providers that could sell the new resistant varieties.

The mycoplasma and virus diseases in Mexico are not currently controlled with pesticides, and rank second and third in economic damages. The major pest, the fungus *Phytophtora infestans,* ranks first in economic damages and requires, in some cases, up to 30 fungicide applications. Thus, the interesting new genetically altered varieties of potatoes are of little benefit to crop production for small farmers.

HRCS

Several engineered crops that include herbicide resistance are commercially available; 13 other key crops in the world are ready for field trials (Table 2). In addition, some crops (e.g., corn) are being engineered to contain both herbicide (glyphosate) and biotic insecticide resistance (BT α-endotoxin).

Herbicides adopted for herbicide-resistant crops employ lower doses when compared with atrazine, 2,4-D, and alachlor. However, the resistance of the crop to the target herbicide would, in practice, suggest to the farmer to apply dosages higher than recommended. In addition, costs for this new technology of HRCs are about 2-times higher in corn than the recommended herbicide use and cultivation weed control program.

Integrated pest management (IPM) could benefit from some HRCs, if alternative non-chemical methods can be applied first to control weeds and the target herbicide could be used later, only when and where the economic threshold of weeds is surpassed. Generally, though, the use of herbicide resistant crops will lead to increased use of herbicides and environmental and economic problems. Most HRCs were developed for Western agriculture. For example, in Northern African countries, most crops, such as sorghum, wheat, and canola (oilseed rape), have wild weed relatives, thereby increasing the risk that genes from the herbicide- resistant crop varieties could be transferred to wild weed relatives.

The risk of herbicide-resistant genes from a transgenic crop variety being transferred to weed relatives has been demonstrated for canola (oilseed rape) and sugar beet.

TABLE 2 Herbicide-Resistant Crops (HRCs) Approved for Field Tests in the United States from 1987 to July 1995

Crop	Herbicide	Research Organization
Alfalfa	Glyphosate	Northrup King

Repeated use of herbicides in the same area creates problems of weed herbicide resistance. For instance, if glyphosate is used with HRCs crops on about 70 million ha, this might accelerate pressure on weeds to evolve herbicide resistant biotypes. Sulfonylureas and imidazolinones in HRCs are particularly prone to rapid evolution of resistant weeds. Extensive adoption of HRCs will increase the hectarage and surface treated, thereby exacerbating the resistance problems and environmental pollution problems.

Bromoxynil has been targeted in herbicide resistant cotton by Calgene and Monsanto (Table 2). This herbicide has been used on winter cereals, cotton, corn, sugarbeets, and onions to control broad leaf weeds. Drift of bromoxynil has been observed to damage nearby grapes, cherries, alfalfa, and roses. In addition, legumious plants can be sensitive to this herbicide, and potatoes can be damaged by it. Herbicide residues above the accepted standards have been detected in soil and groundwater, and as drift fallout. Rodents demonstrate some mutagenic responses to bro- moxynil. Beneficial *Stafilinid* beetles show reduced survival and egg production, even at recommended dosages of bromoxynil. Crustaceans *(Daphnia magna)* have also been severely affected by this herbicide.

Toxicity of Herbicides and HRCs

Toxic effects of herbicides to humans and animals also have been reported. For example, the Basta surfactant (sodium polyoxyethylene alklether sulfate) has been shown to have strong vasodialatative effects in humans and cardio- stimulative effects in rats. Treated mice embryos exhibited specific morphological defects.

Most HRCs have been engineered for glyphosate resistance. Although adverse effects of herbicide-resistant soybeans have not been observed when fed to animals such as cows, chickens, and catfish, genotoxic effects have been demonstrated on other non-target organisms. Earthworms have been shown to be severely injured by the glyphosate herbicide at 2.5–10.1/ha. For example, *Allolobophora caliginosa*, the most common earthworm in European, North American, and New Zealand fields, is killed by this herbicide. In addition, aquatic organisms, including fish, can be severely injured or killed when exposed to glyphosate. The beneficial nematode, *Steinerema feltiae*, a useful biological control organism, is reduced by 19%–30% by the use of glyphosate.

There are also unknown health risks associated with the use of low doses of herbicides. Due to the common research focus on cancer risk, little research has been focused on neurological, immunological, developmental, and reproductive effects of herbicide exposures. Much of this problem is due to the fact that scientists may lack the methodologies and/or the diagnostic tests necessary to properly evaluate the risks caused by exposure to many toxic chemicals, including herbicides.

While industry often stresses the desirable characteristics of their HRCS, environmental and agricultural groups, and other scientists, have indicated the risks. For example, research has shown that the application of glyphosate can increase the level of plant estrogens in the bean, *Vicia faba*. Feeding experiments have shown that cows fed transgenic glyphosate-resistant soybeans had a statistically significant difference in daily milk-fat production as compared to control groups. Some scientists are concerned that the increased milk-fat production by cows fed these transgenic soybeans may be a direct consequence of higher estrogen levels in these transgenic soybeans.

Economic Impacts of HRCs

Some analysts project that switching to bromoxynil for broadleaf weed control in cotton could result in savings of 37 million dollars each year. Furthermore, recent problems with use of glyphosate-resistant cotton in the Mississippi Delta region—crop losses resulting in up to $500,000 of this year's cotton crop—suggest that this technology needs to be further developed before some farmers will reap economic benefits. In addition, a recent study of herbicide- resistant corn suggests that the costs of weed control might be about two times more expensive than normal herbicide and cultivation weed control in corn.

While some scientists suggest that use of HRCs will cause a shift to fewer broad spectrum herbicides, most scientists conclude that the use of HRCs will actually increase herbicide use.

BT for Insect Control

More than 40 BT crystal protein genes have been sequenced, and 14 distinct genes have been identified and classified into six major groups based on amino acids and insecticidal activity. Many crop plants have been engineered with the BT α-endotoxin, including alfalfa, corn, cotton, potatoes, rice, tomatoes, and tobacco (Table 3). The amount of toxic protein expressed in the modified plant is 0.01%–0.02% of the total soluble proteins.

Some trials with corn demonstrate a high level of efficacy in controlling corn borers. Corn engineered with BT endotoxin has the potential to reduce corn borer damage by 5%–15% over 28 million ha in the US, with a potential economic benefit of $50 million annually. Some suggest that corn engineered with BT toxin will increase yields by 7% over similar varieties. However, it is too early to tell if all these benefits will be realized consistently. Potential negative environmental effects also exist because the pollen of engineered plants contains BT, which is toxic to bees, beneficial predators, and endangered butterflies like the Karka Blue and Monarch Butterflies.

Cotton was the first crop plant engineered with the BT α-endotoxin. Caterpillar pests, including the cotton boll- worm and budworm, cost U.S. farmers about $171 million/ yr as measured in yield losses and insecticide costs. Benedict et al.[3] predict that the widespread use of BT cotton could reduce insecticide use and thereby reduce costs by as much as 50% to 90%, saving farmers $86 to $186 million/yr.

The development of insect resistance to transgenic crop varieties is one highly possible risk associated with the use of BT D-endotoxin in genetically engineered crop varieties. Resistance to BT has already been demonstrated in the cotton budworm and bollworm. If BT- engineered plants become resistant, a key insecticide that has been utilized successfully in IPM programs could be lost. Therefore, proper resistance management strategies with use of this new technology are imperative. Another potential risk is that the BT a-endotoxin could be harmful to non-target organisms. For example, it is not clear what potential effect the BT D-endotoxin residues that are incorporated into soils will have against an array of non-target useful invertebrates living in the rural landscape. It has also been demonstrated that predators, such as the lacewing larvae (*Crysoperla carnea*) that feed on corn borers (*Ostrinia nubilalis*), grown on engineered BT corn have consistently higher mortality rates when compared to specimens fed with non-engineered corn borers. In addition, the treated larvae need three more days to reach adulthood than lacewings fed on prey from non-BT corn.

Discussion

Both pesticides and biotechnology have definite advantages in reducing crop losses to pests. At present, pesticides are used more widely than biotechnology, and thus are playing a greater role in protecting world food supplies. In terms of environmental and public health impacts, pesticides probably have a greater negative impact at present because of this more widespread use.

Genetically engineered crops for resistance to insect pests and plant pathogens could, in most cases, be environmentally beneficial, because these more resistant crops could allow a reduction in the use of hazardous insecticides and fungicides in crop production. In time, there may also be economic benefits to farmers who use genetically engineered crops; this will depend, however, on the prices charged by the biotechnology firms for these modified, transgenic crops.

There are, however, some environmental problems associated with the use of genetically engineered crops in agriculture. For example, adding BT to crops like corn for insect control can result in any of the following negative environmental consequences: 1) development of resistance to BT by pests species in corn and other crops; 2) health risks from exposure to the BT toxin to humans in their food and to livestock in feed; 3) the toxicity of the pollen from the BT-treated corn to honey bees, beneficial natural enemies, and endangered species of insects that feed on the modified corn plants or come into contact with the drifting pollen; engineered plant residues incorporated into soil can produce undesirable effects on soil micros and mesofauna.

A major environmental and economic concern associated with genetically engineered crops is the development of HRCs. Although in rare instances HRCs may result in a beneficial reduction of toxic herbicide use, it is more likely that the use of HRCs will increase herbicide use and environmental pollution. In addition, farmers will suffer because of the high costs of employing HRCs—in some instances, weed control with HRCs may increase weed control costs for the farmer threefold.

More than 40% of the research by biotechnology firms is focused on the development of HRCs. This is not surprising, because most of the biotechnology firms are also chemical companies who stand to profit if herbicide resistance in crops result in greater pesticide sales. Theoretically, the acceptance and use of engineered plants in sustainable and integrated agriculture should consistently reduce current use of pesticides, but this is not the current trend. In addition, most products and new technologies are designed for Western agriculture systems, not for poor or developing countries. For instance, if terminator genes enter into the seed market, there will be no possibility of traditional and small farmers using their plants to produce their seeds. Thus, genetic engineering could promote improvements for the environment; however, the current products—especially the herbicide-resistant plants and the BT-resistant crops—do have serious environmental impacts, similar to the consequences of pesticide use.

Plant Pathogens (Fungi): Biological Control

Timothy Paulitz

Introduction

In the classical definition of biological control, certain fungi, termed biocontrol agents (BCAs), can reduce the amount of inoculum or disease-producing activity of a plant pathogen, usually another fungus.[1] The net result is a reduction of plant disease and crop loss. This section will cover mechanisms of how these fungi antagonize the pathogen, what part of the pathogen life cycle can be targeted, how the BCAs can be applied, and examples of commercially available products. Within the past 20 years, there has been a tremendous increase in interest and research on the subject, spurred by a search for more environmentally benign methods of disease control. But fungal BCAs have limitations that have restricted the number of products that are currently on the market. Table 1 shows some products used against soilborne pathogens on the market as of January 1999.

Mechanisms of Biological Control by Fungi

The strategy behind managing pathogens is to target or interrupt part of the pathogen life cycle.[1,2] Like any microbe, pathogens start from inoculum in the environment, which can be spores, mycelia, or other dormant survival structures. These germinate on the plant surface, penetrate and infect the plant, and reproduce and sporulate on the plant to produce new inoculum. Many pathogens can also grow saprophytically on dead organic matter and plant debris. In biological control, the pathogen can be targeted in three ways.[1,2] First, the inoculum of the pathogen can be reduced or destroyed. This is most effective for soilborne pathogens, where the inoculum is dormant in the soil and the monocyclic disease is determined by the initial inoculum present in the field. BCAs can also interfere with inoculum formation by pathogens growing saprophytically on organic matter and plant debris. However, this strategy is not very effective for foliar polycyclic diseases, where inoculum comes from outside the field and the initial inoculum has little effect on the final outcome of the disease. Another strategy is one of protection, where a population of the BCA is established on the infection site of the plant before the pathogen attacks, thus preventing the pathogen's entry. These infection sites can be on seeds, bulbs, roots, leaves, fruit, flowers, or wounds. Finally, nonpathogenic or avirulent fungi can stimulate the plant to a higher level of resistance to a later-attacking pathogen, a concept termed induced resistance.

TABLE 1 Some Commercial Biocontrol Products for Use against Soilbome Crop Diseases

Biocontrol Fungus	Trade Name	Target Pathogen/Disease	Crop	Manufacturer
Ampelomyces quisqualis M-10	AQ10 Biofungicide	Powdery mildew	Cucurbits, grapes, ornamentals, strawberries, tomatoes	Ecogen Inc., Langhorne, Pennsylvania
Candida oleophila I-182	Aspire	Botrytis, Penicillium	Citrus, pome fruit	Ecogen Inc., Langhorne, Pennsylvania
Fusarium oxysporum (nonpathogenic)	Biofox C	Fusarium oxysporum	Basil, carnation, cyclamen, tomato	S.I.A.P.A., Galliera, Bologna, Italy
Trichoderma harzianum and *T. polysporum*	Binab T	Wilt and root rot pathogens, wood decay pathogens	Fruit, flowers, ornamentals, turf, vegetables	Bio-innovation, Algaras, Sweden
Coniothyrium minitans	Contans	Sclerotinia sclerotiorum and S. minor	Canola, sunflower, peanut, soybean, lettuce, bean, tomato	Prophyta Biologischer Pflanzenschutz, Malchow/Poel, Germany
Fusarium Oxysporum (nonpathogenic)	Fusaclean	Fusarium oxysporum	Basil, carnation, cyclamen, gerbera, tomato	Natural Plant Protection, Nogueres, France
Pythium oligandrum	Polygandron	Pythium ultimum	Sugar beet	Plant Protection Institute, Bratislavsk, Slovak Republic
Trichoderma harzianum and *T. viride*	Promote	Pythium, Rhizoctonia, Fusarium	Greenhouse, nursery transplants, seedlings	JH Biotech, Ventura, California
Trichoderma harzianum	RootShield, Bio-Trek T-22G, Planter Box	Pythium, Rhizoctonia, Fusarium, Sclerotinia homeocarpa	Trees, shrubs, transplants, ornamentals, cabbage, tomato, cucumber, bean, corn, cotton, potato, soybean, turf	Bioworks, Geneva, New York
Phlebia gigantea	Rotstop	Heterobasidium annosum	Trees	Kemira Agro Oy, Helsinki, Finland
Gliocladium virens GL-21	SoilGard (formerly GlioGard)	Damping-off and root pathogens, Pythium, Rhizoctonia	Ornamentals and food crops grown in greenhouses, nurseries, homes, interiorscapes	Thermo Triology, Columbia, Maryland
Trichoderma harzianum	Trichodex	Botrytis cinerea, Colletotrichum, Monilinia laxa, Plasmopara viticola, Rhizopus stolonifer, Sclerotinia sclerotiorum	Cucumber, grape, nectarine, soybean, strawberry, sunflower, tomato	Makhteshim Chemical Works, Beer Sheva, Israel
Trichoderma Harzianum and *T. viride*	Trichopel, Trichoject	Armillaria, Botryosphaeria, Fusarium, Nectria, Phytophthora, Pythium, Rhizoctonia		Agrimm Technologies, Christchurch, New Zealand

The most direct way a fungus can attack a fungal pathogen is by mycoparasitism, where the BCA uses the pathogen as a source of food.[3] The hyphae of the mycoparasite contact, penetrate, and colonize the hyphae, spores, or survival structures of the host fungus. Many of these mycoparasites produce enzymes that degrade the cell walls of the fungal host, including β-1–3 glucanase and chitinase. Most mycoparasites are necrotrophic and eventually kill their fungal host. Much of this research has focused on reducing the inoculum of soilborne pathogens. Classic examples include *Trichoderma* and *Gliocladium* spp. parasitizing *Rhizoctonia solani* and *Pythium* spp., which cause seed, seedling, and root rots.[4–6] *Pythium* spp. such as *Pythium oligandrum* and *P. nunn* parasitize pathogenic species of *Pythium. Coniothyrium minitans* and *Sporodesmium sclerotivorum* parasitize sclerotia of *Sclerotinia* spp., such as the white mold pathogen *S. sclerotiorum*, which attacks hundreds of plant species (57). *Ampelomyces quisqualis* parasitizes cleistothecia of powdery mildews. Major limitations to this strategy are that mycoparasites are slow acting and large amounts of mycoparasite inoculum must be added to the soil to ensure it will encounter the propagules of the pathogen. However, a promising strategy demonstrated with *S. sclerotivorum* is to render a soil suppressive to the pathogen by an inoculative release at a lower inoculum density, and allowing the mycoparasite to build up over successive seasons, using the pathogen as a food source. This is similar to the classic predator–prey relationship found in insect biocontrol.

Some fungi can produce antibiotic compounds that are toxic to other microbes, including plant pathogens. *Trichoderma* spp. produce volatile and nonvolatile antifungal compounds, including peptiabols, pyrones, and terpenoid antibiotics.[4] *Gliocladium virens* produces glioviren and gliotoxin that inhibit *R. solani* and *Pythium ultimum*. This mechanism is most effective when the BCA can grow to high populations and has an energy source to produce the antibiotic. An example would be *Trichoderma* or *Gliocladium* spp. applied to seeds or where a food base is added to the inoculum.[4,5]

Plant pathogens require carbon, nitrogen, iron, and other nutrients to grow. Many spores have an exogenous requirement for these nutrients, supplied by the plant rhizosphere or phyllosphere, in order to germinate. BCAs can compete with the pathogen for these limiting nutrients. For example, nonpathogenic species of *Fusarium oxysporum* can compete with pathogenic forma speciales for these limiting nutrients, resulting in control of wilt diseases. Competition by yeasts or hyphal fungi may protect flowers and foliage against nectotrophic pathogens such as *Botrytis cinerea* by colonizing the senescent tissue or nutrient-rich flower petals.[8,9] This mechanism, although difficult to prove experimentally, is probably one of the primary ways BCAs can protect a plant surface through preemptive exclusion of the pathogen.

Fungal biocontrol agents can also affect the pathogen by acting indirectly on the plant to make it more resistant to pathogen attack. Nonpathogenic microbes can induce a systemic resistance in plants (79). When the plant recognizes the inducing BCA, a signal is transduced systemically to the entire plant, bringing the defenses to a "high state of alert," so that a subsequent challenge by a pathogen is reduced. Nonpathogenic isolates of *F. oxysporum* induce a defense reaction against pathogenic isolates of *F. oxysporum*. This mechanism has several advantages. Once induced, the resistance is systemic, the entire plant becomes more resistant, and high populations of the BCA do not need to be maintained. It can also protect parts of the plant that cannot be protected directly by the BCA, including new growth of shoots and roots. However, more research is needed to investigate the applicability of this technology under greenhouse and field conditions.

Application of Fungal Biocontrol Agents

How are fungal BCAs applied? Most are applied in an inundative strategy in large amounts to build up the population of the BCA high enough to overwhelm and have an effect on the pathogen.[1,5] Most are also targeted toward soilborne pathogens. However, one limitation of this strategy is the large amount of inoculum that must be applied and the high cost of production of spores, conidia, biomass, or chlamydospores.[5,9] Another problem is the erratic performance of many biocontrol agents under field conditions, due to unfavorable environmental conditions for the BCA, and the problem of establishing the BCA in a niche already occupied by competing microflora. Therefore most of the commercially available products have targeted applications that avoid these problems. For example, the greenhouse and nursery markets are prime targets because of the controlled environmental conditions and the high economic value of the crops. Another method is to use a protective strategy and apply the BCA directly to the infection court when it is small. For example, high populations of *Trichoderma* or *Gliocladium* conidia can be coated onto seeds to protect against damping-off pathogens such as *R. solani* and *P. ultimum*. Transplant cuttings and bulbs can be treated with liquid suspensions of products before planting in the greenhouse or field. Products such as formulations of *G. virens* can be mixed directly into the soil or soilless mixes in the greenhouse. Granules of *Trichoderma* spp. can be added to seed furrows, mixed with seeds in a planter box, or added to a commercial seed slurry.[4]

Since many pathogens gain access to plants through wounds, biocontrol agents can also be applied to transplant or pruning wounds. A classic example, and one of the first commercially used fungal biocontrol agents, is the application of *Phlebia* (= *Peniophora*) *gigantea* to cut pine stumps to prevent the stumps from being colonized by the pathogen *Heterobasidium annosum*. The pathogen can spread from these stumps to the entire plantation via the root system.

Postharvest pathogens are weak pathogens that require wounds on fruit to gain access. Yeast-like organisms such as *Candida* spp. can be applied to fruit during processing to exclude rot pathogens such as *Penicillium* spp. from colonizing wounds.[8] However, these applications require more stringent testing for registration, since they are applied directly to a food product. Competition is preferable to antibiosis for this application, since antifungal compounds would also have to be tested for animal and human toxicity.

Roots are a difficult infection court to protect, since the susceptible tips are constantly growing and moving through space encountering new inoculum. One strategy is to treat the entire rooting medium in the greenhouse or nursery. Another approach is to use a fungus that can colonize the root system from a seed or furrow treatment and protect the expanding root surface. This characteristic, called rhizosphere competence, has been demonstrated in some strains of *Trichoderma* spp.

Foliar applications of fungi are the least common, although this is the most common method of fungicide application. One example is *Pseudozyma* (= *Sporothrix*) *flocculosa,* a yeast-like fungus which is being developed for control of powdery mildews on greenhouse roses and cucumbers in Canada. *Trichoderma* and *Gliocladium* spp. can be applied to foliage and flowers and can prevent infection by necrotrophic fungi such as *B. cinerea* and *S. sclerotiorum*.

Future of Biological Control by Fungi

In conclusion, the full potential of controlling plant diseases with fungi still has not been realized. Only a small number of products are on the market, but this is a vast improvement compared to only five years ago. There are still many economic constraints in terms of the cost of development and registration of products and the low cost production of organisms in liquid fermentation or solid on substrates.[5,9] Like chemicals, the risks of fungal BCAs need to be addressed, including the displacement of nontarget microbes, allergenicity to humans and other animals, and toxigenicity and pathogenicity to nontarget organisms.[10] However, there are no existing chemical controls for many diseases, because of deregistration of pesticides, pathogen resistance to pesticides, and environmental concerns. These diseases may be the niches for fungal biocontrol agents. It is unlikely that biological control will succeed alone, but it needs to be integrated with other disease management strategies, including cultural control and genetic disease resistance.

Plant Pathogens (Viruses): Biological Control

Hei-Ti Hsu

Economic Loss

Damage to crop plants due to virus and viroid infections is difficult to assess. The actual figures for global crop loss are not available. Plant disease losses are estimated at $60 billion annually. Losses due to virus and viroids have been considered second to those caused by fungi. Unlike diseases caused by fungi, bacteria, and nematodes, where control measures using chemical, biological, and integrated pest management approaches have been effective, diseases caused by viruses or viroids are far more difficult to manage.

Economic crop loss resulting from virus and viroid disease is due to the reduced growth and vigor of infected plants which, in turn, causes a reduction in yield. In some instances, a virus infection may kill a plant. Apart from yield reduction, the quality and market value of commercial end products may be affected. There are also costs of attempting to maintain crop health such as vector control, production of pathogen-free propagation materials, and quarantine and eradication programs. In addition, resources are being diverted to research, extension, and education as well as toward breeding for resistance to virus or viroid infection.

World Impact

No single country is exempt from crop losses. Production of food, fiber, and horticultural crops are seriously affected worldwide by virus or viroid infection of plants.[1] This is even more so in developing countries that depend on one or a few major crops; for example, *Cassava mosaic virus* in cassava plants in Kenya, *Citrus tristeza virus* in citrus trees in Africa and South America, and *Cacao swollen shoot virus* in cacao trees in Ghana. Recently, *Papaya ringspot virus* (PRV) infection has affected every region where papaya plants are grown. The virus induces a lethal disease in papaya. The widespread aphid-transmitted PRV has changed the way papayas are grown in many parts of the world. Normally, papayas are produced annually for a number of years over the life of the papaya plant. For proper management of the disease due to PRV infection, papaya has now become an annual crop in which healthy seedlings are planted each year. Even so, productivity is still below the average yield obtained before PRV became a problem. Viroids infect a limited number of crops when compared with viruses. However, they can cause severe problems in specific crops, for instance, cadang-cadang disease of coconuts, potato spindle tuber disease, and chrysanthemum stunt disease.

Control Measures

No direct chemical control means are available to combat virus infections in plants. Control of viral diseases is achieved primarily by sanitary practices that involve reducing sources of inoculum from outside, preventing spreading within the crop, and limiting the population of insects, mites, nematodes, and fungi that may serve as vectors for many plant viruses.[1] Virus disease testing programs are now common in many parts of the world where the economic importance of growing virus-free plants is recognized. Although seeds and seedlings certified as virus-free are more expensive than those that have not been tested for certain viruses, testing provides assurance of virus-free production materials. Early detection of virus in a field and removal of the infected plants minimizes spread of the virus.

Plants may be protected from development of severe disease symptoms by first introducing a mild strain of virus into a healthy plant. A plant systemically infected with a mild strain of virus is protected from infection by a severe strain of the same virus. This phenomenon in called “cross protection” and has been observed for many plant viruses.[2] It is also observed to occur between viroids or plant virus satellites. In practice, cross protection is of great interest since it has been utilized to protect plants against severe virus strains (*Citrus tristeza virus, Papaya ringspot virus, Zucchini yellow mosaic virus, Tomato mosaic virus,* etc.), in the field.

Another approach toward controlling plant virus diseases is to develop resistant or tolerant plants.[3] Historically, long-term manipulation of crop plants through breeding has produced many valuable commercial varieties resistant to plant viruses. Breeding plants resistant to vectors may also offer control of the virus they transmit. Conventional breeding of crossing and back crossing commercial varieties with plants bearing virus resistance traits takes years to develop. In order for a new variety to be commercially acceptable, undesirable traits from the resistant parent breeding line must be selected out. The process is labor intensive and time consuming. Advances in science have allowed new technology to precisely manipulate resistance genes at the molecular level.[4] Biotechnology represents the fastest growing area of biological research. The application of biotechnology in breeding for resistance to virus infection is a major area of research. Successful control of viral disease through resistance breeding will undoubtedly reduce the use of synthetic pesticides for vector control.[5]

Introducing virus resistance and vector resistance into a cultivar by gene transfer technology (genetic engineering) has been successful in combating plant viruses.[6] The technology has several major advantages over conventional cross breeding. It is a relatively fast procedure. Desirable genes can be introduced without disturbing the balanced genome of target plants. Furthermore, there is no restriction on the source of the transgenes allowing the use of genes from other plant species or even from outside the plant kingdom (Table 1).[1,7]

Several approaches for producing transgenic virus- resistant plants have been explored. Among these, plants expressing virus coat protein genes, parts of other viral genes, or virus satellite ribonucleic acids (RNAs) have been shown to offer the best control.[2,8,9] Plants expressing antisense viral RNAs, ribozymes, pathogen-related proteins, or virus-specific antibody genes may also confer resistance to virus infection. Control of virus vectors by introducing insect toxins such as trypsin inhibitor, lectin, and *Bacillus thuringiensis* (Bt) toxin genes into plants would undoubtedly contribute toward achieving the goal of controlling plant virus diseases.

Prospects

Use of resistant cultivars is considered the best approach to combat virus infection in plants. Biotechnology, no doubt, will play a significant role in the economic growth of many countries. Molecular breeding, however, will not replace but complement the efforts of conventional cross breeding. Much attention has been given to engineering resistance to plant viruses. Recently, genetic engineering of crop plants has been closely scrutinized and criticized due to increasing public concerns regarding human health and environmental impact. Careful assessment of the benefits and potential risks involving the release of

Stored-Product Pests: Biological Control

Lise Stengård
Hansen

Introduction

Stored grain and other durables of plant origin, raw and processed, can become infested by insect and mite pests. As the environment in storage facilities in general is conducive to rapid pest development, this often results in substantial quantitative and qualitative losses. Many stored-product pests are internal feeders developing inside whole-grain cereals and legumes in storage. Another group of pests are external feeders developing on broken kernels, flour, etc., and are mainly found in processing facilities, stores of processed cereals and bulk grain, and packaged foodstuffs (Table 1).

TABLE 1 Examples of Pests and Natural Enemies in Stored Products

Pest Type	Commodity	Examples of Pest Species	Examples of Natural Enemies
Internal feeders or primary pests	Whole-grain cereals	*Sitophilus spp.* (C) *Rhyzopertha dominica* (C) *Sitotroga cerealella* (L) *Prostephanus truncatus* (C)	*Lariophagus distinguendus* (l) *Theocolax elegans* (l) *Anisopteromalus calandrae* (l) *Teretrius nigrescens* (p)
	Whole legumes	*Bruchus* spp. (C) *Callosobruchus* spp. (C)	*Dinarmus* spp. (1)
External feeders or secondary pests	Broken kernels, flour, milled rice, dried fruit, spices, nuts	*Tribolium* spp. (C) *Cryptolestes* spp. (C) *Oryzaephilus* spp. (C)	*Trichogramma spp.* (e) *Holepyris silvanidis* (l) *Cephalonomia spp.* (1) *Xylocoris flavipes* (p)
		Ephestia kuehniella (L) *Cadra cautella* (L) *Plodia interpunctella* (L)	*Trichogramma spp.* (e) *Venturia canescens* (1) *Habrobracon hebetor* (l) *Xylocoris flavipes* (p)
		Storage mites (Acarina)	*Cheyletus eruditus* (p)

Source: Schöller,[2] Subramanyam and Hagstrum.[3,4]
C, Coleoptera; e, egg parasitoid; L, Lepidoptera; l, larval parasitoid; p, predator.

Beneficial insects are often found in storage facilities and may prevent or delay pest development. The internal feeders are attacked by a range of parasitoids specialized in detecting infested kernels and placing their progeny on the larvae within the kernel. The external feeders are more freely exposed to the activities of natural enemies and are attacked by both predators and parasitoids (Table 1).

Although the concept is not new, biological control of stored-product pests is still not widely used. The following description gives some examples of the recent development within biological control of stored-product pests using beneficial insects and mites.

For general reviews on stored-product pest species and biological control of stored-product pests.[1–4]

Factors that Promote Successful Biocontrol in Storage

Storage facilities are ideally suited for development and reproduction of pests. However, these factors are also conducive to successful biocontrol: 1) Climatic conditions are relatively stable and, at least during part of the year, favorable for insect development; 2) the storage structure provides protection from temperature extremes and precipitation as well as a physical barrier to dispersal; and 3) in many storage situations, time is not a limiting factor and thus often sufficient for natural enemies to establish and exert their control. These factors can be manipulated to be more favorable to the natural enemies, e.g., grain temperature can be reduced by aeration to a level that offers a greater advantage to the activities of the beneficial insect than to the pest.[5]

"Classical" Biological Control

In "classical" biological control, a natural enemy is imported and released for establishment to control an introduced (exotic) pest. An example of this among stored-product pests is the larger grain borer, *Prostephanus truncatus,* which was accidentally introduced from Central America into Africa, where it has become a serious pest of many products, e.g., stored maize and cassava chips. A predator, *Teretrius nigrescens,* was introduced from Central America and, after large scale releases, established successfully in many locations in Africa. *T. nigrescens* has been credited with reducing losses of stored maize to *P. truncatus.* However, despite the presence of the predator, *P. truncatus* densities often reach outbreak levels in many countries. An analysis in Holst and Meikle[6] led to the conclusion that *T. nigrescens* alone is unable to exert control to an acceptable level inside a store due to the predator's intraspecific density-dependence and low growth rate compared with its prey. In this case, biocontrol must be supplemented with other integrated control measures.[7]

Biocontrol of Internally Feeding Pests

The larvae of internally feeding insect pests develop within whole-grain cereals and legumes. These species are important primary pests in stores of bulk grain. Several species of parasitoids are specialized to live on these pests. The adult parasitoids enter the bulk of grain and find infested kernels, probably by means of acoustic or olfactory cues. They then drill into the kernel, paralyze the host, and deposit an egg from which the parasitoid larva emerges. After consuming the host, the parasitoid exits the kernel as an adult. The ability of the parasitoid to locate its host within grain varies among species: *Anisopteromalus calandrae* is primarily active at the grain surface whereas *Theocolax elegans* and *Lariophagus distinguendus* are able to find infested kernels down to a depth of 2.2 and 4 m, respectively.[8,9] Great differences in life history parameters occur among different parasitoid strains.[8] These factors as well as grain characteristics such as kernel size and grain variety all affect the ability of the natural enemy to exert effective control of the pest.

A constraint against biocontrol in stored products is a reluctance to increase the amount of insects by releasing natural enemies. However, these minute parasitoids (<2 mm) can easily be removed by grain cleaning procedures. In a study using *T. elegans* against *Rhyzopertha dominica* in wheat, the number of insect fragments in the resulting flour was reduced by 89%.[10]

Biocontrol of Externally Feeding Pests

Both beetles and moths are represented among external pests that feed on broken kernels and debris as well as flour. They are important pests in grain stores, in cereal processing facilities such as flourmills, and in warehouses storing cereal products.

Many species of parasitoids, particularly Trichogram-matidae, attack the egg stage of external pests. The impact of these species is increased by their host feeding behavior, which can account for half of the mortality of host eggs.[11] These egg parasitoids are able to parasitize a wide range of species, but in nature they generally show affinity to a specific habitat; it is thus important to select strains that are adapted to the stored-product environment. *Trichogramma* species have been successfully released against pyralid moth pests in experimental peanut storages in the U.S.A.[12] and in wholesale stores and industrial bakeries in Germany.[13] These egg parasitoids do not establish within the premises and must be released on a regular basis.

Larvae of moth pests are attacked by both ectoparasitoids, e.g., *Habrobracon hebetor* and endoparasitoids, e.g., *Venturia canescens*. Both species are cosmopolitan, often occurring together in flourmills and both species show potential for biocontrol of moth pests.[12] However, *H. hebetor* may affect populations of *V. canescens* negatively by feeding on hosts parasitized by this species.

The predatory bug *Xylocoris flavipes* is a generalist living on eggs and larvae of a wide range of beetles and moths. Almost 30 species of stored-product pests have been reported as prey of *X. flavipes*.[12] In residues in empty maize stores in the U.S.A., many of these species occur together in the same store. A single introduction of *X. flavipes* led to population reductions of 70%-100% of externally feeding beetle pests, whereas internal feeders and late instar moth larvae were less affected. It was suggested that releases of predatory bugs combined with parasitoids for the moths and internal feeders might eliminate or greatly reduce residual pests before the next storage season.[12]

This strategy of introducing predators in empty stores was widely practiced to control storage mites (Acarina) in the Czech Republic. The predatory mite *Cheyletus eruditus* led to reductions in storage mite populations of 88%, compared with the 18% reduction obtained with a pesticide treatment.[14]

Conclusions

The above-mentioned examples show the great potential of biological control of stored-product pests. This research field benefits from extensive international collaboration and applicability, as the pest species as well as their natural enemies have a cosmopolitan distribution as a result of international grain trade. A great amount of faunistic surveys and laboratory research on the natural enemies has been carried out, but very few field trials have been conducted. Application of natural enemies to control pests in bulk grain as well as in empty grain stores prior to introduction of newly harvested grain is considered to hold potential in the near future. However, widespread use depends on crucial experience to be obtained from field trails. The next step is ensuring reliable supplies of natural enemies, designing introduction strategies, and establishing quality control during mass rearing and shipment of beneficials. From these starting points, other pest species and other storage situations can be covered. These activities can contribute to satisfying public demands of more environmentally friendly pest control methods and food production that is focused on consumer safety.

Weeds (Insects and Mites): Biological Control

Peter Harris

Introduction

The usual targets for classical biocontrol are introduced weeds of uncultivated land that lack enemies and have spread to dominate large areas. Such weeds cause huge habitat and forage losses, reduce diversity of the native flora and fauna, and displace rare species.[1] The concern about establishing their natural enemies is that desirable plants might also be attacked. Testing to ensure that this does not happen costs about two scientist years per agent ($900,000). About a third of the agents fail to establish, a third remain scarce, and nearly half of those that become abundant do not achieve control. On the other hand, costs of biocontrol increase little with infestation size and the same agent may achieve control in climates as different as Australia and Canada. Thus, the cost per ha can be small and biocontrol is less damaging to nontarget plants than most alternatives. Release approval for the agents in North America rests with Animal and Plant Health Inspections Service-United States Drug Administration and the Canadian Food Inspection Agency who consult advisory groups.

History and Impact of Classical Weed Biocontrol

Classical weed biocontrol was the serendipitous result of introducing the mealybug (*Dactylopus ceylonicus* thinking it was *D. coccus*), to India in 1795.[2] The purpose was to start a dye industry on the impenetrable stands of the South American prickly pear cactus, *Opuntia vulgaris.* The result was rapid cactus kill and little dye production. After 68 years and several eradication attempts the government distributed the insect for *O. vulgaris* control.

Hawaii took the ball in 1902 by importing 23 insect species to control the introduced shrub *Lantana camara*.[2] Their intention was to establish a complex to attack all parts of the plant. Only 12 species arrived alive in sufficient numbers for release and eight established. Success was claimed for a fly that destroyed 86% of the seed, but none of the criteria for success were demonstrated: that the weed is reduced to a low density in several locations, it remains at a low density, or it returns to a high density when protected from the agent.[3]

The mealy bug *D. ceylonicus* practically eliminated *O. vulgaris* in Australia but did not affect two more abundant cacti, which by 1925 had infested 60 million acres. Concerns that introduced insects might attack cultivated plants were met with the "no-choice" test in which only species that starve on representative crop plants were released. They tested 49 insect species, released 24, of which 12 established. Control was attributed to just two: the mealy bug *D. opuntia* and the cladode-boring moth *Cactoblastis cactorum*, which, two years after increase, caused a crash of cactus from 5000 to 11 plants/acre.[4]

Australia then tackled St. John's wort *(Hypericum perforatum)*.[1] Eight insect species were released, four established and, up to seven years after release, the leaf-feeding beetle *Chrysolina quadrigemina* increased to control the weed. The four established insects were then released in California, where 40,500 ha of open range that were infested in northern California in 1929 had increased to almost 2 million ha in western North America by 1940. Increases of *C. quadrigemina* returned most of the infested area to a native bunch grass community with fair to good productivity and an increased diversity of plant species, and the weed stabilized at about 1% of its former density.[5] The two beetle species were released in Canada in 1952. Up to 13 years later, *C. quadrigemina* increased to control the weed on summer-dry sites and *C. hyperici* on summer moist sites, but both failed above 900 m elevation.[6] This program terminated chemical control of the weed in British Columbia and removed it from the Ontario noxious weed list.

Both *Chrysolina* spp. developed on Canadian *Hypericum* spp. in no-choice tests, but in the field they have not been attacked.[6] The plant genus contains photosensitizing compounds lethal to sun exposed larvae. In nature the larvae feed at dawn and dusk on a winter mat of foliage, which is absent in the Canadian species. Two nontarget species are attacked, but are poor hosts: the introduced evergreen ornamental *H. calycinum,* which has hard mature foliage, and in California the native *H. concinnum*, which has diffuse foliage (presumably shading is reduced and the need for climbing by inactive larvae is increased).

It is more predictive to use the no-choice tests to show that the larval host range is restricted to a taxonomic group of plants rather than that individual crop plants are unacceptable. Some reviewers felt that tests of crop plants were still necessary for public confidence, but gradually these tests have been eliminated. The laboratory larval host range limit exaggerates the field host range, since congeners not attacked in nature usually support development in the test. The larva role is to stay on the plant on which it hatched and eat, which may involve distinguishing the host from intermingled vegetation, but not host finding. Host finding is done by the adult female using habitat and plant cues.[7] The larval host range limit was a satisfactory measure of risk as long as native congeners were not an issue. This changed in 1997 when the attack of native *Cirsium* spp. by the seed-head weevil *Rhinocyllus conicus* was deplored.[8] The 1967 petition for release of the weevil against the introduced thistle *Carduus nutans* stated that its host range included *Cirsium*, but this caused no concern. Today the view is mixed. Some deplore the weevil, but to many a reduction of native thistles is not a concern and the control of most stands of *C. nutans* with increased forage production, makes it an eminent success.

Three Current Issues

Host-Specificity Tests

Most introduced weeds in North America have native congeners. A total of 23 of 27 insect species established in Canada developed on congeners in laboratory no-choice tests, but only one species in Canada and three in the United States have attacked the North American relatives of the weed in the field. Exclusion of species with larvae that develop on native congeners in the laboratory will practically end weed biocontrol. A scientifically sound alternative is to base release approval on the adult host range. The larval no-choice test does not distinguish between species with adults that oviposit on the weed's relatives in the field from those that exclude them. However, adult tests in large field cages or open releases allow assessment of this choice. Thus, although the beetle *Altica carduorum* develops on all *Cirsium* spp., the adult only "sees" *C. arvense* in large arenas. This combined with a low suitability of other *Cirsium* spp. for the immature stages means there is selection pressure against host plant shifts and accounts for the field specificity of the beetle in Eurasia.[9] However, the development of new host screening procedures are currently at an impasse because some reviewers still feel larval ability to complete development in the laboratory is an unacceptable risk even if the adult does not recognize the plant as a host.

Costs and Agent Success

Past cost increases of weed biocontrol have been partly compensated for by using fewer agents and by improving establishment success. The first Hawaiian and first two Australian projects tried to release 55 insect species of which 44% established and three reduced weed density. The current world establishment rate is 65% with the release of 4.1 species against each successfully controlled weed.[10] The idea that all parts of the plant need to be attacked is not supported by the fact that 81% of the successes result from single species. Where several agents contributed, they tend to do so in different habitats such as *C. quadrigemina* and *C. hyperici.*

New host tests are likely to increase costs. An obvious solution is to eliminate the approximately 80% of agents released that contribute little. Present practice is to be more discriminating with expensive agents than those that are cheap simply because testing was done by another country (Table 1). However, establishing any agent may have ecological effects. Thus, it is prudent to reduce the number released to the necessary minimum. No agent trait associated with effectiveness has been found, although establishment is broadly correlated with a high rate of increase, long adult life, the number of generations a year, and small size. However, effectiveness may be plant related. For example, root feeders have been more effective on tansy ragwort, *Senecio jacobaea*, and leafy spurge, *Euphorbia esula*, than defoliators and seed feeders, which have been effective on other plants. If this were determined in preliminary studies, host specificity tests could be restricted to insects in the relevant feeding guild. This combined with studies of the insect's ecological requirements could halve the number of failures.

Legislation

The enabling legislation used for classical weed biocontrol is the Federal Plant Pest Act of 1957 in the United States and the Plant Protection Act of 1990 in Canada. The purpose of both is to prevent pest establishment and spread, so release of nonpests is allowed by reverse logic. However, with no explicit mention of biocontrol, other acts, with various purposes, come into play. For example, the U.S. Endangered Species Act of 1973 requires federal agencies to ensure their actions are not likely to jeopardize the continued existence of endangered or threatened species. The ability of larvae to develop on an endangered plant may indicate jeopardy, but the issue is complicated. The act can save habitat from human destruction, but it cannot stop invading weeds, such as leafy spurge, which are displacing the

threatened northern prairie skink in Canada and the endangered western prairie fringed orchid in both countries. Biocontrol is the best hope for their survival; however, there are rare Florida spurges that will support larval development of leafy spurge agents. It is not possible under the act to weigh the benefits against the risks, although the risks are small if the agent has an obligatory winter diapause that prevents survival in Florida. Nevertheless, the approval of agents for the major North American leafy spurge problem is currently stalled. The Australian Biocontrol Act of 1984 solves the issue by instructing reviewers to approve the release of agents when the expected benefits outweigh the risks. A further need is to judge risk on a holistic assessment of adult and immature needs and habits. It would also be helpful to make weed biocontrol more open to public input and have procedures for resolving conflicts of interest.

NEC: Natural Elements and Chemicals Found in Nature

27

Antagonistic Plants

Philip Oduor-Owino

Introduction

Plant parasitic nematodes cause significant crop losses in Africa and other parts of the world. Infected plants suffer from water deficiency and low yields, and have necrotic and/or galled roots. Control of nematodes has been mainly through the use of chemicals and host resistance. However, the existence of physiological races in the pathogen's population has complicated efforts to breed for resistant cultivars. Chemical control is effective but difficult to sustain for long-term benefits. The high cost of nematicides and their toxic effects also make them less attractive. Some nematicides such as Nemagon and Fumazon have now been banned from the world market and this has placed severe constraints on strategies for nematode control. Interest in developing alternative control measures that are safe and economically attractive has now intensified worldwide. The use of antagonistic plants is viewed as a viable nematode management option.[1–3]

Nature of Antagonistic Plants

Antagonistic plants are defined as plants that produce chemicals in their roots that are toxic and/or repellant to phytonematodes in the soil ecosytem.[4] These plants include *Tagetes erecta* L; *Tagetes patula* L; *Datura stramonium* L; *Ricinus communis* L; and *Asparagus officinalis*. Fresh roots of asparagus produce asparaguric acid glycoside that is toxic, even when diluted, to most plant parasitic nematodes. Root exudates from *Tagetes, Datura,* and *Ricinus* spp. induces premature hatching of nematode eggs, blocks the processes of mitosis and meoisis, and reduces galling intensity on roots of susceptible plants. This has been attributed, in part, to the toxic effects of the alkaloids terthienyl, hyosine, and ricinine present in *Tagetes, Datura,* and *Ricinis* spp., respectively. These compounds may also disrupt female taxis to roots or male taxis to female.[4] Other plants with antagonistic properties include some crucifers and citrus. Root diffusates from crucifers reduce the pathogenicity of nematodes on potato, while a compound in citrus roots is toxic to *Tylechulus semipenetrans*.[1]

Antagonistic Plants in Cultural Pest Control

Antagonistic plants may have a great nematode-control potential in agriculture if properly utilized in crop rotation and intercropping systems.[2] For example, intercropping food crops with nematicidal plants is now a nematode management strategy in Tanzania, India, and Zimbabwe and has also been

recommended for Pakistan.[5] Field trials with *T. minuta*, *D. stramonium*, and *R. communis* are promising.[2,5,6] These plants reduce galling intensity and enhance tomato performance significantly. In India, a rotation of *D. stramonium*, maize, tomato, and pepper reduced the population of root-knot nematodes by 30% but the level of nutrient depletion by the antagonistic plant was 15%.[4] Integration of these plants with the biological agent, *Paecilomyces lilacinus* Thom (Sam), gave better results in Kenya.[3,7,8] Tomato plants grown in soils planted with the various antagonistic plants in combination with *P. lilacinus* develop significantly heavy shoots and roots and relatively fever root galls compared to controls (Table 1). Cases where antagonistic plants are used in crop rotation or intercropping systems are now increasing.[4] For instance, in Indonesia, *Tagetes* sp. *Crotalaria usaramoensis,* corn, and sweet potato (*Ipomea batatas*) are used to reduce *Meloidogyne* spp. density in the soil. For cereal-based cropping systems, the following crop sequences for root-knot nematode control are recommended in the Philippines: rice-mung bean *(Phaseolus* aureus)-corn-cabbage-rice, rice-tobacco *(Nicotiana tobacum)-rice* and rice-tobacco and *Tagetes* spp. There is also considerably less galling by *Meloidogyne* spp. on potato *(Solanum tuberosum)* roots intercropped with onion (*Allium* sp.), corn, and marigold compared with galling found on potatoes alone. Although antagonistic plants are gaining popularity as pest management tools, their benefits and risks must be understood thoroughly before one can exploit their potential in pest control.

Benefits and Risks of Antagonistic Plants

Benefits and risks associated with the utilization of antagonistic plants in agriculture are varied. Phytonematoxic plants such as *R. communis, D. stramonium, Tagetes* spp. *Crotalaria* spp. *A. najus,* and *Datura metel* L. are traditionally gaining popularity due to their medicinal significance.[9] The flowers of *D. metel* are used against asthma, while *Crotalaria* spp. is a nitrogen-fixing legume. Castor oil from *R. communis* is used for making soaps and waxes: rinolecic acid from castor seeds is a valuable laxative.[9] Despite these attributes, antagonistic plants may pose a serious threat to food production if not well utilized. They may compete with economically important crops for space and nutrients.

In addition they are slow in action, an attribute that makes them less attractive for use in a commercial setting. Because of this scenario, it is important that scientific disciplines work together in order to develop a viable pest control system. What is good for the nematologist may not be good for either the agronomist or economist.

Future Concerns

There is increasing internal awareness of the value of natural plants and their products in the development of new drugs and formulation of materials that can be used for pest control. Since some of the antagonistic plants can also be used to treat human ailments,[9] they may attract intensive scientific evaluation, recognition, and funding. However, more work should be done to reexamine the future of antagonistic plants in nematode control and in the drug industry. Efficacy of these plants against nematodes and their utilization in the pharmaceutical industry will depend highly on the concentrations of the active ingredients in their tissues.[10] It will also depend on whether they can stimulate activity of most biocontrol fungi and plant growth consistently. They have so far enhanced tomato growth in the greenhouse and in the field significantly[2,7] (Tables 2 and 3), but more trials are needed in order to understand the relationship between antagonistic plants, natural enemies, and crop performance.

Arthropod Host-Plant Resistant Crops

Gerald E. Wilde

Introduction

Because of the many advantages plant resistance offers, virtually every cultivated crop has been evaluated for this trait and one or more resistant sources have been identified. The challenge has been to incorporate these resistant sources into agronomically adapted and consumer acceptable, high-yielding cultivars. In addition to traditional breeding methods, the use of modern breeding techniques and genetic transformation of crops has opened the door to other ways of identifying, incorporating, and employing pest-resistance genes to effectively and economically manage arthropod pest populations. The use of resistant cultivars contributes significant economic and social benefits and sustainable agricultural systems to the world's farmers. The positive effects of resistant cultivars have been demonstrated repeatedly in crops as diverse as wheat, alfalfa, grape, sorghum, maize, rice, apple, and cotton.

Percentage of Crops That Have Some Degree of Pest Resistance

Plant resistance has been employed to a greater or lesser degree in practically all of the major food, feed, and fiber crops. Table 1 lists a number of major crops grown in the world and the number of pests for which resistance has been employed to at least some extent in the field. Hectarage planted to resistant cultivars varies for each pest and crop and over time as new varieties and hybrids (both susceptible and resistant) are grown and, in some instances, as new pest biotypes (pest populations that are capable of damaging previously resistant sources) develop. For example, most of the modern rice varieties and hybrids grown in China, India, and other countries are resistant to one or more major pests. Resistant American grape rootstocks have been used extensively over the world to control *Phylloxera vittifolae* (Fitch). A large percentage of the alfalfa planted in the United States is comprised of varieties resistant to aphid species. Sorghum hybrids with resistance to the greenbug have occupied up to 80% of the hectarage in the United States. Significant hectarages of wheat and barley in the United States, Canada, and North and South Africa have resistance to at least one pest. Most commercial soybean

varieties are resistant to the potato leafhopper. Several cotton varieties carrying genes for resistance to jassids (*Empoasca* sp) are grown widely in Africa, India, and the Philippines. In the United States, more than 65% of commercial maize hybrids have some resistance to corn leaf aphid, >90% have some resistance to first generation European corn borer, and >75% have some resistance to second generation corn borer.

However, many more resistance genes have been identified in all crops than have been used in modern commercial varieties and hybrids, because incorporating them into high yielding cultivars acceptable to growers has been difficult. Recently, transgenic crops have been utilized to combat major insect pests. Hybrids or varieties with insect-resistance genes have been developed in cotton, maize, and potato. An estimated 6.7 million hectares of transgenic corn resistant to the European corn borer, 2.5 million hectares of transgenic cotton resistant to several pests, and 20,000 hectares of transgenic potato resistant to Colorado potato beetle were grown in the world in 1998. The hectares planted to transgenic crops are likely to increase as additional countries register these products and this technology is used on additional crops. For example, specific biotechnology applications are being field tested for rice and wheat, which together occupy 400 million hectares globally.

Effect of Plant Resistance on Pest Populations

The growing of pest-resistant cultivars can be used as a major control tactic or adjunct to other measures. Historically, the use of resistant cultivars combined with other tactics has resulted in a reduction of many pest species to subeconomic levels. Even small increases in resistance enhance the effectiveness of cultural, biological, and insecticidal controls. The extent to which growing resistant plants affects pest populations is dependent upon the level of resistance expressed, the mechanisms of resistance involved, and the number of hectares grown. The growing of resistant wheat on 50% of the hectarage in Kansas has been shown to reduce Hessian fly populations to extremely low levels. Resistance in wheat to wheat curl mite (ca. 25% of the hectarage) was effective in limiting the spread of wheat streak mosaic virus, which the mite transmits. The incorporation of leaf and stem pubescence into most commercial soybean varieties has resulted in population suppression of the potato leafhopper over the past 60 years. As the hectarage of sorghum resistant to the greenbug increased to >50%, the area of sorghum treated with insecticide was reduced by 50%. Tenfold reductions in pest populations have been observed where insect-resistant rice cultivars have been grown widely.

Economic and Social Benefits

Assessing the economic benefits of plant resistance is difficult in the context of integrated pest management programs and is likely to be underestimated frequently and substantially. Even determining the obvious advantages (yield benefits and reduced production costs) may be difficult over a large area where pest populations vary from locality to locality and year to year. Other environmental benefits, such as cleaner water and food, reduced risks to farmers, more flexibility in planting and cropping systems, reduced disease transmission, and reduced secondary pest outbreaks, also are difficult to quantify. Nevertheless, some specific estimates are available. In the United States alone the estimated valued of using arthropod-resistant alfalfa, barley, corn, sorghum, and wheat cultivars is more than $1.4 billion each year. The net economic benefit of greenbug resistance in U.S. sorghum production is estimated at close to $400 million annually. The global economic value of arthropod-resistant wheat has been estimated at $250 million annually. The value of resistance to aphids in alfalfa in the major alfalfa-producing states of the United States is estimated at more than $100 million annually. Breeding for pest resistance in rice has been estimated to be responsible for one-third of recent yield increases and $1 billion of additional annual income to rice producers. The net return of insect-resistant Bt maize in the United States and Canada has been estimated in some studies at $42.00–$67.30 per hectare, but other studies have indicated less of an economic return. The average net economic return of insect-resistant Bt cotton in 1997 was $133 per hectare.

Biomass

Alberto Traverso
and David Tucker

Introduction

This work is organized into seven main sections. The first section provides the reader with a general overview on biomass, including definition, environmental benefits, energetic properties, and a short list of biomass types that can be used as energy sources. The second section illustrates the mechanical processes to produce standardized solid biomass fuels. The third section describes one of the major technologies for converting biomass into energy, combustion. The fourth section analyzes pyrolysis and gasification as promising techniques for efficient exploitation of biomass, still in a precommercial phase. The fifth section is concerned with biochemical processes for producing biogas and biofuels for transportation. The sixth section outlines the major benefits from biomass exploitation for energy purposes. The seventh section reports about the potential carbon dioxide (CO_2) emission reduction due to extensive use of biomass as a renewable energy resource. The eighth section concludes this entry.

Generalities about Biomass

In general, biomass is whatever substance produced or by-produced by biological processes. Commonly, biomass refers to the organic matter derived from plants and generated through photosynthesis. Biomass provides not only food but also construction materials, textiles, paper, medicines, and energy. In particular, biomass can be regarded as solar energy stored in the chemical bonds of the organic material or as a reduced state of carbon. CO_2 from the atmosphere and water absorbed by the plant roots are combined in the photosynthetic process to produce carbohydrates (or sugars) that form the biomass.

TABLE 1 Typical Types of Biomass for Energy Use

Supply Sector	Type	Example
Forestry	Dedicated forestry	Short rotation plantations (e.g., willow, poplar, eucalyptus)
	Forestry by-products	Wood blocks, wood chips from thinnings
Agriculture	Dry lignocellulosic energy crops	Herbaceous crops (e.g., miscanthus, reed canary-grass, giant reed)
	Oil, sugar and starch energy crops	Oil seeds for methylesters (e.g., rape seed, sunflower)
		Sugar crops for ethanol (e.g., sugar cane, sweet sorghum)
		Starch crops for ethanol (e.g., maize, wheat)
	Agricultural residues	Straw, prunings from vineyards and fruit trees
	Livestock waste	Wet and dry manure
Industry	Industrial residues	Industrial waste wood, sawdust from sawmills
		Fibrous vegetable waste from paper industries
Waste	Dry lignocellulosic	Residues from parks and gardens (e.g., prunings, grass)
	Contaminated waste	Demolition wood
		Organic fraction of municipal solid waste
		Biodegradable landfilled waste, landfill gas
		Sewage sludge

Source: Adapted from European Biomass Industry Association[1] and DOE Biomass Research and Development Initiative.[2]

The solar energy that drives photosynthesis is stored in the chemical bonds of the biomass structural components. During biomass combustion, oxygen from the atmosphere combines with the carbon and hydrogen in biomass to produce CO_2 and water. The process is therefore cyclic because the carbon dioxide is then available to produce new biomass. This is also the reason why bioenergy is potentially considered as carbon- neutral, although some non-recoverable CO_2 emissions occur due to the use of fossil fuels during the production and transport of biofuels.

Biomass resources can be classified according to the supply sector, as shown in Table 1.

The chemical composition of plant biomass varies among species. Yet, in general terms, plants are made of approximately 25% lignin and 75% carbohydrates or sugars. The carbohydrate fraction consists of many sugar molecules linked together in long chains or polymers. Two categories are distinguished: cellulose and hemi- cellulose. The lignin fraction consists of non-sugar-type molecules that act as a glue holding together the cellulose fibers.

Energy Content of Biomass

Bioenergy is energy of biological and renewable origin, normally derived from purpose-grown energy crops or by-products of agriculture and forestry. Examples of bioenergy resources are wood, straw, bagasse, and organic waste. The term *bioenergy* encompasses the overall technical means through which biomass is produced, converted, and used. Figure 1 summarizes the variety of processes for energy production from biomass.

The calorific value of a fuel is usually expressed as higher heating value (HHV) and/or lower heating value (LHV). The difference results from the vaporization of water formed from the combustion of hydrogen in the material and the original moisture.

The most important property of biomass feedstocks with regard to combustion—and to the other thermochemical processes—is the moisture content, which influences the energy content of the fuel. Wood, just after falling, has a typical 55% water content and an LHV of approximately 7.1 MJ/kg; logwood after 2–3 years of air-drying may present a 20% water content and an LHV of 14.4 MJ/kg; pellets show a quite constant humidity content of about 8% with an LHV equal to 17 MJ/kg.

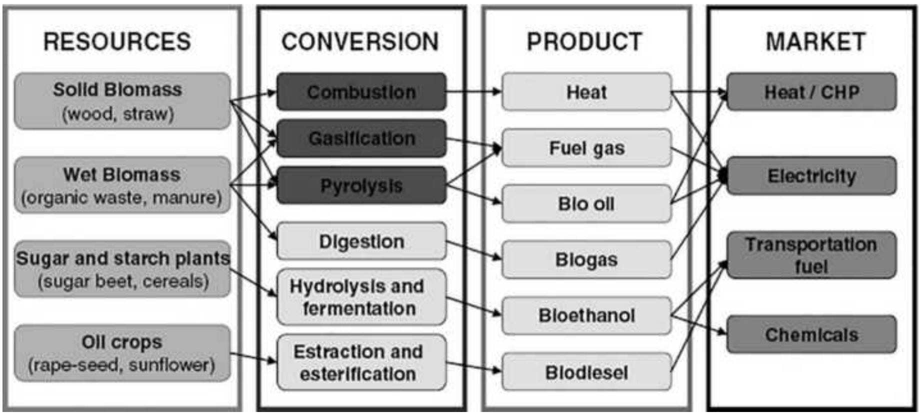

FIGURE 1 Processes to convert biomass into useful energy, i.e., bioenergy.
Source: European Biomass Industry Association,[1] Overend et al.[3] and Risoe National Laboratory.[6]

Mechanical Processes for Energy Densification

Some practical problems are associated with the use of biomass material (sawdust, wood chips, or agricultural residues) as fuel. Those problems are mainly related to the high bulk volume, which results in high transportation costs and requires large storage capacities, and to the high moisture content, which can result in biological degradation as well as in freezing and blocking the in-plant transportation systems. In addition, variations in moisture content make difficult the optimal plant operation and process control. All those problems may be overcome by standardization and densification. The former consists in processing the original biomass in order to obtain fuels with standard size and heating properties, while the latter consists in compressing the material, which needs to be available in the sawdust size, to give it more uniform properties.

Table 2 reports the main features of pellets, briquettes, and chips.

TABLE 2 Comparison of Different Solid Wood Fuels

	Pellets	Briquettes	Chips
Appearance			Raw material	Dry and ground wood or agricultural residues	Dry and ground wood or agricultural residues. Raw material can be more coarse than for pelleting, due to the larger dimensions of final product	Dry wood logs
Shape	Cylindrical (generally Ø 6 to 12 mm, with a length 4 to 5 times the Ø).	Cylindrical (generally Ø 80 to 90 mm) or parallelepiped (150 × 70 × 60 mm)	Irregularly parallelepiped (70 × 30 × 3 mm)

Biomass Combustion

The burning of wood and other solid biomass is the oldest energy technology used by man. Combustion is a well- established commercial technology with applications in most industrialized and developing countries, and development is concentrated on resolving environmental problems, improving the overall performance with multifuel operation, and increasing the efficiency of the power and heat cycles (combined heat and power, CHP).

The devices used for direct combustion of solid biomass fuels range from small domestic stoves (1 to 10 kW) to the large boilers used in power and CHP plants (>5 MW). Intermediate devices cover small boilers (10 to 50 kW) used in single family houses heating, medium-sized boilers (50 to 150 kW) used for multifamily house or building heating, and large boilers (150 kW to more than 1 MW) used for district heating. Cofiring in fossil-fired power stations enables the advantages of large-sized plants (>100 MWe) that are not applicable for dedicated biomass combustion due to limited local biomass availability.

To achieve complete burnout and high efficiencies in small-scale combustion, downdraft boilers with inverse flow have been introduced, applying the two-stage combustion principle. An operation at very low load should be avoided as it can lead to high emissions. Hence, it is recommended to couple log wood boilers to a heat storage tank. Since wood pellets are well suited for automatic heating at small heat outputs, as needed for buildings nowadays, pellet furnaces are an interesting application with increasing propagation. Thanks to the well-defined fuel at low water content, pellet furnaces can easily achieve high combustion quality. They are applied both as stoves and as boilers and find increased acceptance in urban areas, due to the high efficiency of modern pellet stoves now used for home heating. While a conventional fireplace is less than 10% efficient at delivering heat to a house, an average modern pellet stove achieves 80%–90% efficiency. Technology development has led to the application of strongly improved heating systems, which are automated and have catalytic gas cleaning equipment. Such systems significantly reduce the emissions from fireplaces and older systems while at the same time significantly improving the efficiency.

Understoker furnaces are mostly used for wood chips and similar fuel with relatively low ash content, while grate furnaces can also be applied for high ash and water content. Special types of furnaces have been developed for straw, a very low density material that is usually stored in bales. Beside conventional grate furnaces operated with whole bales, cigar burners and other specific furnaces are in operation. Stationary or bubbling fluidized bed (SFB) as well as circulating fluidized bed (CFB) boilers are applied for large-scale applications and often used for waste wood or mixtures of wood and industrial wastes, e.g., from the pulp and paper industry.

Co-Combustion

Bioenergy production might be hampered by limitations in the supply and/or fuel quality. In those cases, cofiring of several types of biomass or of biomass with coal ensures flexibility in operation, both technically and economically. Several concepts have been developed:

- Co-combustion or direct cofiring. The biomass is directly fed to the boiler furnace, if needed after physical preprocessing of the biomass such as drying, grinding, torrefaction, or metal removal is applied. This typically takes place in SFB or CFB combustors. Such technologies can be applied to a wide range of fuels, even for very wet fuels like bark or sludge. Multifuel fluidized bed boilers achieve efficiencies of more than 90%, while flue gas emissions are lower than for conventional grate combustion due to lower combustion temperatures.
- Indirect cofiring. Biomass is first gasified and the fuel gas is then cofired in the main boiler. Sometimes, the gas has to be cooled and cleaned, which is more challenging and implies higher operation costs.
- Parallel combustion. The biomass is burnt in a separate boiler for steam generation. The steam is used in a power plant together with the main fuel.

Problems in Biomass Combustion

Biomass has a number of characteristics that makes it more difficult to handle and combust than fossil fuels. The low energy density, the high water content, and the tendency to "bridge" in tanks or pipes are the main problems in handling and transport of the biomass, while the difficulty in using biomass as fuel relates to its content of inorganic constituents. Some types of biomass used contain significant amounts of chlorine, sulfur, and potassium. The salts, KCl and K_2SO_4, are quite volatile, and the release of these components may lead to heavy deposition on heat transfer surfaces, resulting in reduced heat transfer and enhanced corrosion rates. Severe deposits may interfere with operation and cause unscheduled shutdowns.

In order to minimize these problems, various fuel pretreatment processes have been considered, including washing the biomass with hot water or using a combination of pyrolysis and char treatment.

Thermochemical Conversion of Biomass

Pyrolysis and gasification are the two most typical thermochemical processes because they convert the original bioenergy feedstock into more convenient energy carriers such as producer gas, oil, methanol, and char,[3] instead of producing useful energy directly.

Pyrolysis

Pyrolysis is a process for thermal conversion of solid fuels, like biomass or wastes, in the complete absence of oxidizing agent (air/oxygen) or with such limited supply that gasification does not occur to any appreciable extent. Commercial applications are focused on either the production of charcoal or the production of a liquid product, the bio-oil, and pyro-gas. Charcoal is a very ancient product. Traditional processes (partial combustion of wood covered by a layer of earth) were very inefficient and polluting, but modern processes presently used in industry such as rotary kiln carbonization have been optimized to maximize efficiency and minimize environmental impact. Bio-oil production (or wood liquefaction) is potentially very interesting as a substitute for fuel oil and as a feedstock for production of synthetic gasoline or diesel fuel. Pyro-gas has higher energy density than gasification gas (syngas) because it has been created without oxygen (and nitrogen, if air is employed); hence, it does not contain the gaseous products of partial combustion.

Pyrolysis takes place at temperatures in the range 400–800°C, and during this process, most of the cellulose and hemicellulose and part of the lignin will disintegrate to form smaller and lighter molecules, which are gases at the pyrolysis temperature. As these gases cool, some of the vapors condense to form a liquid, which is the bio-oil and tar. The remaining part of the biomass, mainly parts of the lignin, is left as a solid, i.e., the charcoal. It is possible to influence the product mix through a control of heating rate, residence time, pressure, and maximum reaction temperature, so that either gases, condensable vapors, or the solid charcoal is promoted.

Gasification

Modern gasification technology has been developed since the 18th century (first historical hints about gasification date from the Chinese Han Dynasty, between 206 BC and AD 220), but it is still at a development phase.[4,5] Gasification is a conversion process that involves partial oxidation at elevated temperature. It is intermediate between combustion and pyrolysis: in fact, oxygen (or air) is present but it is not enough for complete combustion. This process can start from carbonaceous feedstock such as biomass or coal and convert them into a gaseous energy carrier. The overall gasification process may be split into two main stages: the first is the pyrolysis stage, i.e., where oxygen is not present but temperature is high; typical pyrolysis reactions take place here; the second stage is the partial combustion, where

TABLE 3 Qualitative Comparison of Technology for Energy Conversion of Biomass

Process	Technology	Economics	Environment	Market Potential	Present Deployment
Combustion—heat	+++	€	+++	+++	+++
Combustion—electricity	++(+)	€€	++(+)	+++	++
Gasification	+(+)	€€€	+(++)	+++	(+)
Pyrolysis	(+)	€€€	(+++)	+++	(+)

Note: +, low; +++, high; €, cheap; €€€, expensive.

oxygen is present and reacts with the pyrolysed biomass to release heat necessary for the process. In the latter stage, the actual gasification reactions take place, which consist of almost complete charcoal conversion into lighter gaseous products (e.g., carbon monoxide and hydrogen), through the chemical oxidizing action of oxygen, steam, and carbon dioxide: such gases are injected into the reactor near the partial combustion zone (normally, steam and carbon dioxide are mutually exclusive). Gasification reactions require temperature in excess of 800°C to minimize tar and maximize gas production. The gasification output gas, called "producer gas," is composed of hydrogen (18%–20%), carbon monoxide (18%–20%), carbon dioxide (8%–10%), methane (2%–3%), trace amounts of higher hydrocarbons like ethane and ethene, water, nitrogen (if air is used as oxidant agent), and various contaminants such as small char particles, ash, tars, and oils. The incondensable part of producer gas is called "syngas," and it represents the useful product of gasification. If air is used, syngas has a high heating value in the order of 4–7 MJ/m^3, which is exploitable for boiler, engine, and turbine operation, but, due to its low energy density, it is not suitable for pipeline transportation. If pure oxygen is used, the syngas high heating value almost doubles (approximately 10–18 MJ/m^3 high heating value). Such a syngas is suitable for limited pipeline distribution as well as for conversion to liquid fuels (e.g., methanol and gasoline). However, the most common technology is air gasification because it avoids the costs and the hazards of oxygen production and usage. With air gasification, the syngas efficiency, describing the energy content of the cold gas stream in relation to that of the input biomass stream, is on the order of 55%–85%, and typically 70%.

Comparison of Thermal Conversion Methods of Biomass

Table 3 reports a general overview on specific features of the conversion technologies analyzed here, showing the related advantages and drawbacks.

Biochemical Conversion of Biomass

Biochemical conversion of biomass refers to processes that decompose the original biomass into useful products. Commonly, the energy product is either in the liquid or in the gaseous form; hence, it is called "biofuel" or "biogas," respectively. Biofuels are very promising for the transportation sector, while biogas is used for electricity and heat production. Normally, biofuels are obtained from dedicated crops (e.g., biodiesel from seed oil), while biogas production results from concerns over environmental issues such as elimination of pollution, treatment of waste, and control of landfill greenhouse gas (GHG) emissions.

Biogas from Anaerobic Digestion

Biogas is produced most commonly by anaerobic digestion of biomass. Anaerobic digestion refers to the bacterial breakdown of organic materials in the absence of oxygen. This biochemical process produces a gas called biogas, principally composed of methane (30%–60% in volume) and carbon dioxide. Such a biogas can be converted to energy in the following ways:

- Biogas converted by conventional boilers for heating purposes at the production plant (house heating, district heating, industrial purposes).
- Biogas for CHP generation.
- Biogas and natural gas combinations and integration in the natural gas grid.
- Biogas upgraded and used as vehicle fuel in the transportation sector.
- Biogas utilization for hydrogen production and fuel cells.

An important production of biogas comes from landfills. Anaerobic digestion in landfills is brought about by the microbial decomposition of the organic matter in refuse. Landfill gas is, on average, 55% methane and 45% carbon dioxide. With waste generation increasing at a faster rate than economic growth, it makes sense to recover the energy from that stream, through thermal or fermentation processes.

Biofuels for Transport

A wide range of chemical processes may be employed to produce liquid fuels from biomass. Such fuels can find a very high level of acceptance by the market, thanks to the relatively easy adaptation to existing technologies (i.e., gasoline and diesel engines). The main potential biofuels are outlined below.

- Biodiesel is a methyl-ester produced from vegetable or animal oil to be used as alternative to conventional petroleum-derived diesel fuel. Compared to pure vegetable or animal oil, which can be used in adapted diesel engines as well, biodiesel presents lower viscosity and slightly HHV.
- Pure vegetable oil is produced from oil plants through pressing, extraction, or comparable procedures, crude or refined but chemically unmodified. Usually, it is compatible with existing diesel engines only if blended with conventional diesel fuel, at rates not higher than 5%–10% in volume. Higher rates may lead to emission and engine durability problems.
- Bioethanol is ethanol produced from biomass and/or the biodegradable fraction of waste. Bioethanol can be produced from any biological feedstock that contains appreciable amounts of sugar or other matter that can be converted into sugar, such as starch or cellulose. Also, lignocellulosic materials (wood and straw) can be used, but their processing into bioethanol is more expensive. Application to modified spark ignition engines is possible.
- Bio-ETBE (ethyl-tertio-butyl-ether) is ETBE produced on the basis of bioethanol. Bio-ETBE may be effectively used for enhancing the octane number of gasoline (blends with petrol gasoline).
- Biomethanol is methanol produced from biomass. Methanol can be produced from gasification syngas (a mixture of carbon monoxide and hydrogen) or wood dry distillation (old method with low methanol yields). Virtually all syngas for conventional methanol production is produced by steam reforming of natural gas into syngas. In the case of biomethanol, a biomass is gasified first to produce a syngas from which the biomethanol is produced. Application to spark ignition engines and fuel cells is possible. Compared to ethanol, methanol presents more serious handling issues, because it is corrosive and poisonous for human beings.
- Bio-MTBE (methyl-tertio-butyl-ether) is a fuel produced on the basis of biomethanol. It is suitable for blends with petrol gasoline.
- Biodimethylether (DME) is dimethylether produced from biomass. Bio-DME can be formed from syngas by means of oxygenate synthesis. It has emerged only recently as an automotive fuel option. Storage capabilities are similar to those of LPG. Application to spark ignition engines is possible.

Benefits from Biomass Energy

There is quite a wide consensus that, over the coming decades, modern biofuels will provide a substantial source of alternative energy. Nowadays, biomass already provides approximately 11%–14% of the world's primary energy consumption (data vary according to sources).

TABLE 4 Benefits in Reduction of GHG Emissions

+	Avoided fossil fuel transport (from producer to user)
–	Emission from biomass fuel transport (from producer to user)
+	Avoided fossil fuel utilization

Source: Risoe National Laboratory.[6]
Note: +, positive; –, neutral.

There are significant differences between industrialized and developing countries; in particular, in many developing countries, bioenergy is the main energy source, even if it is used in very low efficient applications (e.g., cooking stoves have an efficiency of about 5%–15%). Furthermore, inefficient biomass utilization is often associated with the increasing scarcity of hand-gathered wood, nutrient depletion, and the problems of deforestation and desertification.

One of the key drivers to bioenergy deployment is its positive environmental benefit regarding the global balance of GHG emissions. This is not a trivial matter, because biomass production and use are not entirely GHG neutral. In general terms, the GHG emission reduction as a result of employing biomass for energy is as reported in Table 4.

Since the energy cost associated with collection and transport of biomass is a significant portion, bioenergy is a decentralized energy option whose implementation presents positive impacts on rural development by creating business and employment opportunities. Jobs are created all along the bioenergy chain, from biomass production or procurement, to its transport, conversion, distribution, and marketing.

Bioenergy is a key factor for the transition to a more sustainable development.

Potential for CO_2 Emission Reduction

When biomass is used for energy production, the carbon contained in it is ultimately transformed into CO_2. In fact, such a biomass-derived CO_2 does not contribute to global warming, as it equals the CO_2 absorbed by the biomass during its growth; the relatively short time of such carbon cycle makes the biomass a carbon-neutral energy resource.

Abundant resources and favorable policies[7] enable bio-power to expand in Northern Europe (mostly cogeneration from wood residues), in the United States, and in countries producing sugar cane bagasse (e.g., Brazil).

In the short term, cofiring remains the most cost- effective use of biomass for power generation, along with small-scale, off-grid use. In the mid-long term, gasification plants and biorefineries for biofuel production could expand significantly (mainly ethanol, lignocellulosic ethanol, biodiesel). International Energy Agency projections suggest that the biomass share in electricity production may increase from the current 1.3% to some 3%–5% by 2050, depending on assumptions.[8] This is a small contribution compared to the estimated total biomass potential, but biomass are also used for heat generation and to produce fuels for transport.

Today, biomass supplies some 50 EJ/yr (1 EJ = 10^{18} joules [J] = 10^{15} kilojoules [kJ] = 24 million tons of oil equivalent [Mtoe]) globally, which represents 10% of global annual primary energy consumption (Figure 2). This is mostly traditional biomass used for cooking and heating.

Based on this diverse range of feedstocks, the technical potential for biomass is estimated in the literature to be possibly as high as 1500 EJ/yr by 2050, although most biomass supply scenarios that take into account sustainability constraints indicate an annual potential of between 200 and 500 EJ/yr (excluding aquatic biomass). Forestry and agricultural residues and other organic wastes (including municipal solid waste) would provide between 50 and 150 EJ/yr, while the remainder would come from energy crops, surplus forest growth, and increased agricultural productivity.

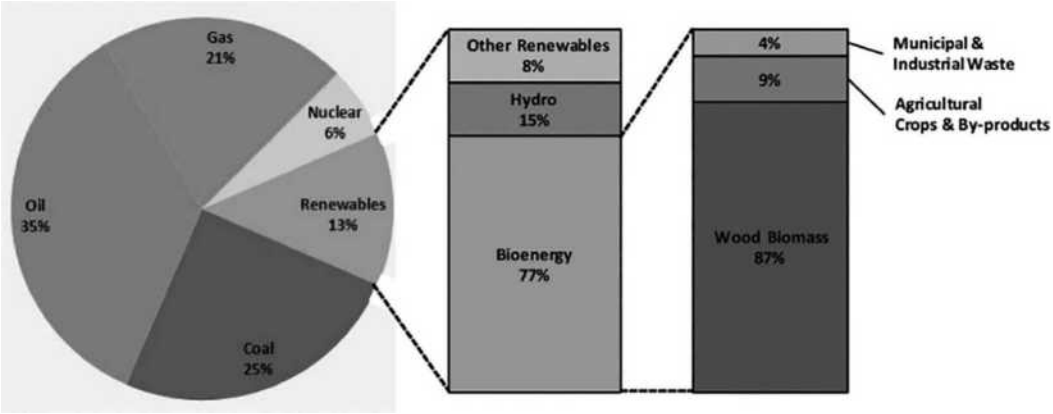

FIGURE 2 Share of bioenergy in the world primary energy mix. (*Source:* International Energy Agency.[9])

Projected world primary energy demand by 2050 is expected to be in the range of 600 to 1000 EJ, compared to about 500 EJ in 2008.[9] Scenarios looking at the penetration of different low-carbon energy sources indicate that future demand for bioenergy could be up to 250 EJ/yr. This projected demand falls well within the sustainable supply potential estimate, so it is reasonable to assume that biomass could sustainably contribute between a quarter and a third of the future global energy mix. Whatever is actually realized will depend on the cost competitiveness of bioenergy and on future policy frameworks, such as GHG emission reduction targets.

Given the CO_2-neutral nature of biomass, and assuming that biomass will primarily substitute fossil fuels, the potential for reduction in CO_2 emission in 2050 can then be estimated as the same figure (i.e., around 20%–30% of anthropogenic CO_2), compared to a business-as-usual scenario. Definitely, biomass will play a determinant role towards a CO_2-free development.

Conclusions

Biomass refers to a very wide range of substances produced by biological processes. In the energy field, special focus has been and will be placed on vegetable biomass, such as wood and agricultural by-products, because of the energy potential as well as economic and environmental benefits. Size and humidity standardization of biomass is a necessary step to make it suitable for effective domestic and industrial exploitation: chips, briquettes, and pellets are modern examples of standard solid fuels.

Biomass can be converted into energy in three pathways: combustion, thermochemical processing, and biochemical processing. The combustion of solid biomass for the production of heat or electricity and heat is the most viable technology, while pyrolysis and gasification still face economic and reliability issues. Among biochemical processes, anaerobic digestion is often used to reduce the environmental impact of hazardous waste and landfills. Biochemical processes are also concerned with the conversion of biomass into useful fuels for transportation, such as biodiesel, bioethanol, and biomethanol. All of them can effectively contribute to the transition to a more sustainable transportation system at zero GHG emissions.

Biomass represents a viable option for green energy resources of the 21st century.

Nematodes: Biological Control

Simon Gowen

Introduction

Many pathogens and predators of nematodes are known but few have the necessary characteristics of specificity, mobility, or speed of colonization to have a significant influence on a pest population. Attempts at their commercial exploitation as field treatments have not been successful largely because of their inconsistency. Understanding the subtleties associated with the deployment of biocontrol agents will require considerable research effort. Additionally, the recommended rates of application and the formulation on suitable carriers and nutrient sources poses a problem in practicability and in the interpretation of the biological processes involved.

Contemporary research has shown that natural control does exist and that in certain crop/nematode/pathogen situations nematode populations will decline as they are attacked by components of the soil microflora. Soils where this occurs are known as suppressive, but well-documented examples of naturally occurring suppressiveness to particular nematode pests are uncommon.

During the life of a crop the population densities of many of the serious nematode pests can increase by 1000fold. Economic damage may result from initial population densities of one nematode per gram of soil. To be effective therefore a biocontrol agent must have an impact on the numbers of nematodes that would invade a host and not simply eliminate the surplus individuals that may never locate or invade a root. This being so, those pathogens and predators that are relatively unspecific (trapping, ingesting, or parasitizing all types of free-living nematodes in soil) may be considered less promising than those that parasitize specific pests.

Significant progress has been made in the recognition and deployment of such microorganisms parasitic on some of the species of sedentary nematodes such as the root-knot nematodes, *Meloidogyne* spp., and some of the cyst nematodes, *Heterodera* spp., and *Globodera* spp.

Root-knot and cyst nematodes produce eggs either in clusters on roots or contained within or attached to the cuticle of the female nematode. Biocontrol agents that prevent these nematodes from reproducing may have more impact from an epidemiological point of view than those that kill the free-living individuals in the soil.

Biocontrol Agents Specific to Certain Nematode Pests

Verticillium chlamydosporium is a facultative, soil-dwelling fungus that parasitizes eggs in egg masses exposed on the root surface. Under the right conditions, such fungi will have a significant effect on nematode populations. The efficacy of *V. chlamydosporium* is partly dependent on its root colonizing ability; this can vary according to the plant host. Skill is required in selecting crops that support and/or increase the root colonization by the fungus but are also less favored hosts of root-knot nematodes. *V. chlamydosporium* may be less effective when it is deployed with plants that are highly susceptible and large galls are produced in response to the nematode infection. In such cases, many egg masses may not be exposed on the root surface and so escape infection.

Paecilomyces lilacinus is another fungus commonly found infecting the eggs of sedentary nematodes such as the root-knot and the cyst nematodes, and, like *V. chlamydosporium* being relatively easy to produce on defined growth media, has good potential for commercial development.

Pasteuria penetrans, an obligate bacterial parasite of root-knot nematodes begins its life cycle on free-living juveniles in the soil. Spores attach to the juveniles as they move in search of host roots. Parasitic development begins after the nematode enters a root and continues in synchrony with that of its host. The nematode eventually is overcome by its parasite; it fails to produce eggs; and its body, filled with the spores of the bacterium, eventually ruptures releasing spores into the soil.

The efficiency of *P. penetrans* as a biocontrol agent of root-knot nematodes depends on the concentrations of spores in the soil, the chances of contact with the juvenile stage, and the specificity of the particular *P. penetrans* population. Commercial success will depend therefore on finding techniques for mass-producing the bacterium and on developing populations with a broad spectrum of pathogenicity.

Other *Pastearia* species parasitic on some sedentary *(Heterodera)* and migratory *(Pratylenchus)* species have been described.

Biological control agents such as *V. chlamydosporium, P. lilacinus*, and *P. penetrans* could provide an adequate replacement for nematicides in some cropping systems but the lack of immediate effects, such as are provided by nematicide or fumigant treatments, is a disadvantage. Protection is normally needed in the early stages of plant growth such as in nursery beds. In this situation, integration with other practices such as nematicides, rotation, solarization, and mulches is necessary.

There are several reports of the successful deployment of these biocontrol agents. Small field plots treated once with *P. penetrans* spores (produced by an in vivo system) caused a decline in numbers of root-knot nematodes and increases in yield over a series of crop cycles using root-knot nematode susceptible crops. In other locations, where treatments with *P. penetrans* were combined with *V. chlamydosporium*, organic manures and grass mulches showed similar declines in nematode populations. These two organisms acted against root-knot nematodes in a complementary fashion. As part of this strategy, root systems containing spore-filled cadavers were deliberately left to disintegrate in the soil after each crop. No field treatments were effective after only one crop indicating that some crop loss must be expected during the development of suppressiveness. *P. penetrans* was also effective when used in combination with a nematicide in permanent beds within a plastic polytunnel. Better control of root-knot nematodes was achieved if the biocontrol agent was combined with other control strategies. With such treatments, beneficial effects may develop over one crop cycle.

The chlamydospores of *V. chlamydosporium* do not have the persistence of the spores of *P. penetrans*, which can remain viable for many years.

Nonspecific Biocontrol Agents

There is a long history of interest in the fungi that trap nematodes in soil such as species of *Arthrobotrys*. These are commonly found in all soils but despite much research effort the problems of the unreliability of soil applications have not been solved and none have become established as successful commercial products.

There are several rhizosphere colonists that have potential for alleviating nematode damage. The precise mechanisms are not clear. Some produce toxins but others may affect root exudation and thus indirectly the attractiveness of roots to nematodes. Experiments have shown that strains of *Pseudomonas fluorescens* can reduce root invasion by different plant parasites but as with the trapping fungi, poor consistency hinders successful development of these microorganisms as commercial products.

Future Prospects

Recently, the nematicidal (and insecticidal) effects of the toxins produced by the bacteria associated with entomopathogenic nematodes (*Photorhabdus* spp., *Xenorhabdus* spp., and *Pseudomonas oryzihabitans*) have been demonstrated.

Success in the commercial development of biocontrol agents does appear promising with those microorganisms that can be formulated as a standard product with proven reliability; others may have a future as single treatment introductions in the more intensively managed protected cropping systems but commercialization may be difficult.

Research is still needed to develop reliable methods of production, formulation, and application. The challenge is to provide a sufficient duration of protection. Such treatments will need to be part of a package of control measures.

Agroforestry: Water Use Efficiency

James R. Brandle,
Laurie Hodges,
and Xinhua Zhou

Introduction

Agroforestry is the intentional integration of trees and shrubs into agricultural systems. Windbreaks, riparian forest buffers, alley-cropping, silvopastoral grazing systems, and forest farming are the primary agroforestry practices found in temperate regions of North America.[1] Placing trees and shrubs on the landscape changes the surface energy balance, influences the surrounding microclimate, and has the potential to alter water use and productivity of adjacent crops.[2,3]

In agricultural systems, water is often the major factor limiting growth. When water availability is limited as a result of limited supply or high cost, its efficient use becomes critical to successful production systems. For example, proper irrigation at the appropriate stage of crop development minimizes pumping costs and increases yield; reducing soil tillage conserves soil water and may enhance yield, and reducing surface runoff or trapping snow improves soil water storage for future crop use. These water conservation efforts contribute to the efficient use of available water and are determined primarily by management practices. In contrast, Tanner and Sinclair[4] distinguish between the efficient use of water and water use efficiency (WUE). WUE is primarily a function of physiological responses of plants to environmental conditions. This review focuses on WUE defined as the amount of biomass (or grain) produced per unit of land area for each unit of water consumed.[4]

Soil water may be consumed by evaporation from the soil surface or by the transport of water through the plant and subsequent evaporation from the leaf surface. The rate of water consumption is determined by the microclimate of the crop. Because agroforestry practices alter the microclimate of adjacent fields, they affect WUE of plants growing in those fields.

Discussion

Windbreaks, riparian forest buffers or alley-cropping systems are the practices most likely to be integrated into crop production systems. In all three practices, trees and shrubs tend to be arranged in narrow barriers adjacent to the crop field. Microclimate responses downwind of any of these types of barriers are similar and the following discussion applies to all three types of barriers. As wind approaches these barriers, it is diverted up and over the barrier creating two zones of protection, a larger zone to the lee of the barrier (the side away from the wind) and a smaller zone on the windward side of the barrier. In these zones, wind speed is reduced and turbulence and eddy structure in the vicinity of the barrier are altered. As a result of these changes, the transfer coefficients for heat and mass between the crop and the atmosphere are altered; the gradients of temperature, humidity, and carbon dioxide concentration above the soil and canopy are changed;[5] and the plant processes of transpiration and photosynthesis are altered.[6]

McNaughton[5] defined two regions within the leeward zone of protection: the *quiet zone,* extending from the top of the barrier down to a point in the field located approximately 8*H* leeward (*H* is the height of the barrier) and a *wake zone,* lying beyond the quiet zone and extending from approximately 8*H* to a distance of 20*H* to 25*H* from the barrier. Within the quiet zone where turbulence is reduced, we expect conditions to be such that the canopy is "uncoupled" from the atmospheric conditions above the sheltered zone, while in the wake zone where turbulence is increased, we expect the canopy to become more strongly "coupled" to the atmosphere above. In both locations we would expect the rates of photosynthesis and transpiration to be altered and WUE to change.

The magnitude of change in wind speed, as well as the extent of microclimate modifications within the quiet and wake zones, are largely determined by the structure of the windbreak or barrier and the underlying meteorological conditions. Structure refers to the amounts of solid material and open space and their arrangement within the barrier. Dense barriers, for example, multiple rows of conifers, generally result in greater wind speed reduction but more turbulence. More porous barriers, for example, single rows of deciduous species, result in less wind speed reduction but also less turbulence. The downwind extent of the protected area is generally greater for more porous barriers. As a result, narrow, less dense barriers (40%–60% density) are typically used to protect crop fields.

The overall influence of wind protection on plant water relations is complex and linked to temperature, humidity, wind speed, and other meteorological conditions found in the protected zone, the amount of available soil water, crop size, and stage of development.[2,3,7] Until recently, the major effect of wind protection and its influence on crop growth and yield were assumed to be due primarily to soil water conservation and reduced water stress of sheltered plants.[8,9] There is little question that the evaporation rate from bare soil is reduced in the protected zone.[3] However, the effect of reduced wind speed on transpiration, evaporation from the plant canopy, and overall plant water status is less clear.[2,3,7]

According to Grace,[9] transpiration rates may increase, decrease, or remain unaffected by wind protection depending on wind speed, atmospheric resistance, and saturation vapor pressure deficit. Cleugh[3] suggests that as stomatal resistance increases, evaporation from the canopy may actually be increased with a reduction in wind speed. When stomatal resistance is high and water is limited, stomatal resistance controls the rate of evaporation from the leaf surface, not the amount of turbulence. Under these conditions a decrease in wind speed and turbulent mixing may increase the potential for evaporation from the leaf surface.[3]

Evaporation from the leaf surface consists of two phases, an energy driven phase and a diffusion driven phase. Movement of water through the plant and out the stomata is driven by the water potential gradient within the plant. This gradient is influenced by the plant's energy balance. On the lee side of the buffer, reduced wind speed and turbulent mixing lead to increases in leaf temperature and transpiration to meet the increased energy load on the plant. If adequate water is available, it is moved through the plant to the leaf surface and the potential for evaporation from the leaf surface is increased. If water is limited, the stomata partially or completely close, transpiration is reduced, and evaporation from the leaf surface declines.

In contrast, movement of water vapor across the leaf boundary layer is controlled by the vapor pressure gradient and the thickness of the leaf boundary layer. As windspeed decreases, the thickness of this boundary layer increases, the vapor pressure gradient decreases, and the rate of evaporation from the leaf surface decreases. The relative magnitude of the two processes determines whether or not transpiration and subsequent evaporation from the canopy are increased, decreased, or remain unchanged.[7,9,10]

While these theoretical considerations are important in understanding the process, several studies[11–13] have demonstrated a good correlation between wind protection, conservation of soil water, and enhanced crop yield. Even so, the effect of wind protection on WUE is neither constant throughout the growing period[7] nor is it consistent over varying meteorological conditions.

Agroforestry practices impact the water relations of the crop by affecting the loss of water through damaged leaves. On soils subject to wind erosion, windbreaks or other agroforestry buffers provide significant reductions in the amount of wind blown soil and subsequent abrasion of plant parts and cuticular damage.[9,14] Loss of cuticular integrity or direct tearing of the leaves[15] reduces the ability of the plant to control water loss.

Agroforestry buffers have a direct effect on the distribution of precipitation, both rain and snow. In the case of snow, a porous barrier will result in a more uniform distribution of snow across the field, providing additional soil water for the crop.[16] In the case of rain, the barrier has minimal influence on the distribution of precipitation across the field; however, in the area immediately adjacent to the barrier a rain shadow may occur on the leeward side. On the windward side, the barrier may lead to slightly higher levels of measured precipitation at or near the base of the trees due to increased stem flow or dripping from the canopy.

Trees and shrubs used in agroforestry practices also consume a portion of the available water. In the area immediately adjacent to the barrier, competition for water between the crop and the barrier has a negative impact on yield. These same areas are also subject to some degree of shading depending on the orientation of the barrier. These changes in radiation load influence the energy balance and thus the growth and development of the crop and the utilization of water.[2]

Summary

In summary, agroforestry practices such as windbreaks, riparian forest buffers and alley-cropping systems generally improve both the efficient use of water by the agricultural system and the WUE of the individual crop. In the case of efficient water use, the evidence is clear. In the case of crop WUE, the evidence leaves some unanswered questions. How do we account for the varied crop yield responses reported in the literature? In many cases yields are increased but no clear relationship to crop water budget is shown. In other cases crop yield response is minimal. Under what meteorological conditions are the effects of agroforestry practices most valuable to water balance questions? Final crop yield is a integration of the environmental conditions over the entire growing season. Many different combinations of environmental conditions may result in similar plant responses. How do we address the numerous combinations of plant stress and plant growth to determine “a response” to wind protection? To answer many of these questions it will be necessary to intensify the numerical modeling methods developed by Wilson[17] and Wang and Takle.[18] With a better model to describe the turbulence fields and the transport of water, heat, and carbon dioxide as influenced by agroforestry practices, it should be possible to assess the numerous combinations of environmental factors influencing crop growth in these systems.

Bacterial Pest Control

David N. Ferro

Introduction

Although many genera of bacteria are found to be associated with insects—such as *Clostridium, Strategus, Pseudomonas, Proteus, Diplococcus, Serratia, Bacillus,* and *Enterobacter*—only *Bacillus* and *Serratia* represent agents that cause suppression of insect populations, i.e., that perform as biological control agents. Bacteria are the most widely used microbial agents for controlling insect pests. Some species of *Bacillus* and *Serratia* kill by replicating within the host, while strains of *Bacillus thuringiensis* produce protein toxins that kill soon after being ingested. Bacteria that replicate within their hosts and that persist in the environment by maintaining an infection cycle are biological control agents in the traditional sense. However, products of *B. thuringiensis* that produce toxins that kill insect pests and are applied the way an insecticide would be applied are often not considered to be biological control agents. Bacteria in the genera *Photorhabdus* and *Xe-norhabdus* are symbiotic with nematodes in the families Heterorhabditidae and Steinernematidiae, respectively. The nematodes serve as vectors that mechanically penetrate into the insect hemocoel and deposit the bacteria. The bacteria then replicate and kill the host quickly by causing septicemia. The only commercially available bacterial products are from strains of *B. popillae*, *B. thuringiensis*, and *Serratia entomophila*.

Paenibacillus (Formerly Bacillus) Popilliae (Dutky)

Milky disease was first observed in Japanese beetle larvae (grubs) in New Jersey in 1933. *P. popilliae* is an obligate pathogen of larvae in the family Scarabaeidae, as it is only found associated with its host or in the soil surrounding its host. *P. popilliae* and *Paenibacillus lentimorbus* (Dutky) both cause milky disease of scarab beetles; however, most discussions of milky disease refer to strains of *P. popilliae*. *P. popilliae* produces a crystal or parasporal body, which allows it to survive for many years in the soil in the absence of its host. Although there are dozens of strains of *P. popilliae* that infect scarab hosts, only *P. popilliae* has been used commercially as a biological control agent of the Japanese beetle, *Popillia japonica* (Newman), a major pest of turf.

The term "milky disease" describes the advanced stages of infection in scarab larvae where the host is turned a milky white by the build-up of *Bacillus* spores in the hemolymph. The infection process begins with the scarab larvae ingesting spores while feeding on roots and organic matter in the soil. The spores then undergo germination and outgrowth in the cells of the lumen of the alimentary canal. The vegetative rods penetrate the epithelial cells of the midgut, and then move into the hemolymph where they multiply and sporulate. Death often occurs a month or more after ingestion. It is unclear what the role of the proteinaceous parasporal body is in the infection process.

Culture and Control

Many attempts have been made to rear *P. popillae* on an artificial diet. Even though spores and vegetative rods from field-collected larvae can be plated on agar media, the inability of the milky disease bacteria to grow and sporulate on standard microbiological media has made it extremely costly to produce for commercial purposes. Products, to date, are made from milky larvae, primarily from naturally infected larvae collected from the field.

The spores are formulated on talc and contain 10^8 spores/g of powder. The powder is applied at about 20 kg/ha using a fertilizer spreader or by punching holes in the soil and adding bacteria. Infection can occur in all three larval stages. For optimal replication to occur, soil temperatures need to exceed 20°C. Large overwintered larvae usually pupate before soil temperatures are high enough in late spring. For this reason, applications are targeted against small larvae late in the summer when the small larvae are actively feeding near the soil surface. Control seems to be greatest when larval densities exceed 300/m^2; however, economic losses in turf occur at densities above 100/m^2. Unless a more virulent strain is found or a more cost-effective way to produce spores is developed, the use of this bacterium is likely to be restricted to lawns and playing fields that can tolerate higher densities of larvae.

Serratia Entomophila (Grimont et al.)

Amber disease of the New Zealand grass grub *Costelytra zealandica* (White) is a chronic infection of the larval gut caused by *S. entomophila*. This disease was first observed in New Zealand in 1981. Following ingestion of bacterial cells while feeding on grass roots, the bacteria adhere to the foregut and multiply in the region of the cardiac valve; the larvae cease feeding after 2–5 days and become amber colored due to clearance of the gut. Death does not occur until 1–3 mo after ingestion. As the disease progresses, the larvae become shrunken due to a general degradation of the fat cells. Invasion of the hemocoel does not occur until late stages of the disease, when general septicemia is accompanied by death of the insect.

Culture and Control

S. entomophila is produced in large fermentors as nonsporeforming bacteria to be applied as a live microbial pesticide. Recently, the Industrial Processing Division of DSIR, New Zealand produced 4×10^{10} bacteria/mL, and field trials have shown that $>4 \times 10^{13}$/ha are needed for control. The problem with using live bacteria (vs. spores) is the difficulty of maintaining viability on the shelf and in the field prior to ingestion. Currently, refrigerated product can be kept for only 3 mo.

Grass grub larvae live in the soil as pests of low-value grasslands. Because *S. entomophila* is applied as live bacteria rather than as spores, it is more vulnerable to UV light and desiccation. For this reason, it is important to place the formulated material 2–5 cm below the soil surface using a subsurface applicator, such as a modified seed drill. This approach allows for 90% survival of the bacteria. Bacteria applied in this way quickly start an epizootic, which then spreads through the grass grub population.

Bacillus Thuringiensis (Berliner)

B. thuringiensis is a spore-forming bacterium that produces a parasporal crystal (protein delta-endotoxin). After the susceptible insect larva ingests the endotoxin, in the absence or presence of the spore, the crystal is solubilized and activated by alkaline (pH 10.5) gut proteases. The toxic subunits bind to receptor sites on the midgut epithelium within minutes of ingestion. This is quickly followed by lysis of these cells, causing a cessation of feeding within 10–15 min of ingestion. Although the spores pass into the hemocoel through pores in the epithelium of the midgut, it is the starvation in conjunction with infection that kills the insect. The toxins from these bacteria are formulated in much the same way as a synthetic toxin, and do not cause an epizootic.

There are several subspecies (= strains) of *B. thuringiensis* based on the serotype of flagellar antigens, and these subspecies produce different endotoxins, or at least different amounts of endotoxins that are relatively host specific. For example, *B.t. israelensis* is effective against Nematocera (Diptera) larvae such as mosquito larvae, *B.t. kurstaki* against Lepidoptera, *B.t. aizawai* against Lepidoptera, and *B.t. tenebrionis* against Chrysomelidae (Coleoptera). Notation for the gene that encodes for the toxin is in lowercase; for example, Cry3A gene regulates the production of the Cry3A toxin. Table 1 includes a list of some of the subspecies and toxins they produce. Because these bacteria are so host-specific, they can be quickly incorporated into a pest management program in which biological control agents are an integral component.

Culture and Control

B. thuringiensis can be produced in large quantities using commercial fermentors. Formulations can be applied to foliage or other larval substrates in the same manner as most insecticides. However, several operative factors affect the effectiveness of these bacterial agents.

B.t.s are most effective against early instars (Table 2). Their effectiveness is very dependent upon ambient temperatures; the protein endotoxin is not very persistent; thorough coverage of foliage is necessary; and they are host-specific. This host specificity allows for control of the target pest without killing other insect biological control agents; however, in many cropping systems, there is a complex of insect pests

TABLE 2 Stage-Specific Larval Mortality for the Colorado Potato Beetle Fed Foliage Treated with *B. thuringiensis san diego* (= *tenebrionis*)

	LC50	Larval	95% CI	
Larval stage	(mg/l)	weight (mg)	Lower	Upper
Early 1st instar	2.03	1.0	1.46	2.60
Late 1st instar	3.92	2.3	2.02	6.27
Early 2nd instar	4.35	4.0	3.30	5.56
Late 2nd instar	14.45	7.8	10.75	19.50
Early 3rd instar	14.86	15.6	9.95	20.48

and often these need to be controlled at the same time, which may require using the *B.t.* product with a synthetic insecticide, if natural controls fail. Novel ways have been developed to deliver the toxin for ingestion by the pest.

One of the genes that control the production of the toxin has been inserted into *Pseudomonas fluorescens.* After the fermentation has been completed, the broth is chemically treated and heated to kill the bacteria. During this process, the protein toxin becomes encapsulated by the bacterial cell wall. The encapsulation process appears to protect the toxin from degradation in the field, making it more persistent. Several genes have also been inserted into plants that express the toxin in its tissues. In the case of potatoes, the transgenic plants are highly resistant to the Colorado potato beetle, which has considerably reduced the insecticide load on potatoes.

Potential Biological Control AGENTS

Bacillus sphaericus (Neide) has been shown to be toxic only to larvae of culicid Diptera mosquitoes. This bacterium can be easily produced via fermentation. Insecticidal activity is due to crystalline toxins associated with the cell wall. The toxin is released by digestion after the host insect has consumed the bacteria. *B. alvei* and *B. brevis* are infectious for larvae of several mosquito species. There is no evidence that these species are significant biocontrol agents. The success of these bacteria in the field is likely to be dependent on selection of strains that are more virulent and that can persist in a range of aquatic environments.

Bioaccumulation

Tomaz Langenbach

Molecular Properties for Bioaccumulation

Bioaccumulation occurs only with molecules with low degradability and correlates with their grade of lipophilicity.[1] Organic substances with main bonds of aliphatic and aromatic C—C, C—H, and C—Cl (or other halogens) are predominantly nonpolar molecules (Lipophilic) with low water solubility and high stability. They are less susceptible to chemical reactions of hydrolysis, oxidation, and enzymatic attack.[2] On the other hand, bonds with different functional groups with O, P, N, and other elements turn molecules more polar, soluble, and degraded more easily. Bioaccumulation can occur with molecules between 100 and 600 units of molecular weight with the maximum of 350.[3] Probably this is related to membrane permeability capacity.

A common feature of bioaccumulation is the molecular stability of lipophilic organic substances and the nondegradability of heavy metals. The severity of heavy metals is due to many factors.

1. Metals with Hg, Cd, Zn, Cu, and Pb are the most toxic and most studied types followed by metals containing Ni, Al, As, Cr, and other elements.[4] Bioaccumulation can also occur also with essential metals such as Fe, Zn, Cu, Mo, Na, and Ca.
2. Speciation is the anions or other components that constitute the heavy metal molecules. This is important in defining solubility that, for example, is high for sulfate and low for sulphide.[5] Heavy metals bound to organic molecules such as methyl, ethyl or other aliphatic or aryl groups increase penetration capacity through membranes and consequently, have a poisoning effect.
3. The sensivity to the toxic effects of heavy metals and other xenobionts is dependent on the biological material being a microorganism, plant, animal, or type of tissue.

Bioaccumulation and the Environment

The pollution sources can be released by discharge of substances with uneven distribution in air, water, and soil. The movement of these substances up to bioaccumulation can occur by different routes mainly mediated by the food chain. This process can involve water, suspended particles, sediments, food, soil, and air particles (Figure 1). An important part of these substances can be concentrated in nonliving components. From these sources, persistent organic pollutants (POP) or heavy metals can be released to biota.[6] The final distribution presented by the mass balance in the environment with a group of

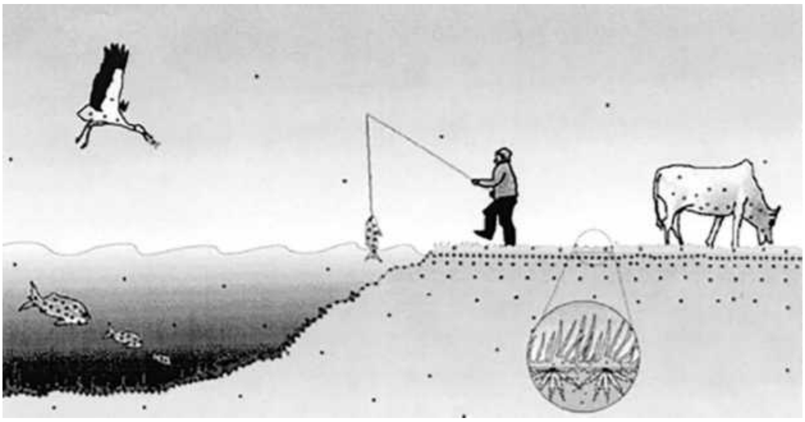

FIGURE 1 Bioaccumulation in the environment. The black points represent the pollutant molecules.

organochlorines and polyaromatics, shows that most are found in soil or sediment, whereas for highly volatile substances, most remain in the atmosphere. Less than 0.7% of the total remains in vegetation and no more than 2×10^{-3}% can be found in the aquatic biota.[7] The relationship between biota and environment shows that concentrations of bioaccumulated heavy metals in organisms are always higher than in water, but are usually lower than in sediments.[4]

Water Environment

After pollution reaches water bodies, different processes can occur to incorporate it into nonliving components as sediments and biota represented by microorganisms, plants, crustaceans, fishes, etc. The route of pollutant uptake in the biota if from waterborne, adsorption, filtration, or by food chain is an important factor in bioaccumulation.[8] Along the food chain the step-wise increase of concentration from lower to higher trophic levels, called biomagnification, can reach the bioconcentration factor (BCF) up to 100,000. In this process terrestrial animals as well as birds can be heavily contaminated by eating polluted fish.

In the global marine environment the apparent final fate of persistent organic pollutants (POP) is in the flora, fauna, and sediment of the abyss.[9] The main transport of POP follows the downstream movement of the organic flow in the water and in the long term these chemicals are incorporated in the sediment that function as final sink. It was observed that the bioaccumulation in the deep water fishes are up to 10 times higher than in surface water fishes.[9]

In the flora and fauna some heavy metals can bioaccumulate up to threshold values and others maintain a correlation with the concentration in the environment.[4] In aquatic plants, fish, and other metazoarians the distribution of the substances are quite distinct between tissues.[10] Lipophilic substances are preferentially found in adipose tissues with high lipid content.

In the Soil

Soil is polluted in large areas by pesticides application or by discharge as final disposal in landfills of industrial products. These lipophilic substances move in soil rather slowly by leaching, runoff, and volatilization. The main factor that influences bioaccumulation process in the soil is the biodisponibility. This property is conditioned by the adsorption/desorption capacity of the different soils and by the chemical nature of the pollutant. This process is driven by the stronger or weaker binding forces involved, which influence the amount that is bioavailable for plant uptake of these lipophilic pollutants.

The main flow of POP generally occurs toward organic matter from soil particles and not to biota, a process called preferential partition. A negative correlation was observed between the adsorbtion coefficient related to soil organic carbon (*K*oc) and the bioaccumulation factor by plants. This means that in organic rich soils, bioaccumulation in plants is rather small.[2] A similar situation occurs with microorganisms in which previous bioaccumulated organochorines can move out from the cell to the soil.[11] The preferential partition toward soil can be the reason why a lack of toxicity on soil microorganisms by pesticide applications was frequently observed, even in high concentrations of pesticides. Little information about bioaccumulation in soil could be observed, but nevertheless cotransport of some organochlorine accumulated in microorganisms in sand aquifers with low organic content was reported.[12]

Soil invertebrates such as earthworms, beetles, slugs, and others can bioaccumulate lipophilic pesticides. The bioaccumulation process could be seen as a soil to soil–water equilibrium followed by a soil–water to worm equilibrium.[2] Consumers of this biota in animals of higher trophic levels such as birds can biomagnificate these chemicals. Plants can adsorb and bioaccumulate products from the soil with incorporation of residues mainly in the root. The translocation from root to foliage depends on plant species and on the chemical properties of the pollutant. Several evidences show that lipophilic compounds are sorbed onto the outer surface of roots of several plants, and in this case translocation is very low.

Bioaccumulation in plants can also occur with heavy metals. As safety rules, domestic waste and sludge from wastewater treatment stations with heavy metal contamination can be applied on soil for agriculture up to limited amounts to avoid pollution with hazardous toxicological effects. Contaminated grass, grain, and fruits can be accumulated by biomagnification when consumed by mammals, insects, and birds. Terrestrial animals have a plant mediated relationship with soil contamination.

In the Air

The main sources of atmospheric pollution are pesticide spraying with the reverse process of evaporation from soil to air, poliaromatics produced by burning of fuels, and plastic incineration. The rate of entry to the atmosphere and the distance of movement are principally dependent on the vapor pressure of the pollutants and metereological conditions. In some cases movement occurs on a global scale. The dynamic nature of the atmosphere can dilute pollutants in the air to exceptionally low concentrations and in these cases no significant bioaccumultion occurs.[13] Nevertheless urban and industrial areas, as well as the margins of roads with intense traffic, can have high concentrations of pollutants. Plants exposed to xenobiotics in the form of vapor, particles, aerosol or larger droplets, can undergo a passive process of foliage adsorption with an uptake mainly in the wax cuticle.[2] Bioaccumulation in plants can result in damage and can also affect higher trophic levels that consume these vegetables.

Direct contact of animals with these chemicals can enter by the respiratory organs, in mammals, or the outer body surface, mainly in insects.

Bioaccumulation Mechanism in Biota

In terrestrial animals, pollutants can enter by dermal contact, respiration, and food consumption. Atmospheric pollutants move to the lungs, where an equilibrium is difficult to be established, while generally atmosphere dilutes pollutant concentrations, unless there is an exposure to constant pollution sources. Chemicals move from lungs to circulatory fluid (plasma) and can be metabolized with further excretion. Another route is the storage mainly in rich lipid bodies such as brain and eggs in bird's.[2] If the entrance is by food consumption, the gastrointestinal tract can eliminate[10] these substances or degrade than to more polar compounds with further excretion, or can promote adsorption by plasma following the same route described earlier.

The uptake of heavy metals in microorganisms can occur by bioadsorbtion in capsular polysaccharides and cell-wall polymers, or cross these layers and cell membranes by an active enzymatic process involving phosphatases, reaching to the cell interior.[14] Some authors define bioaccumulation as only the process in which molecules reach cell interior. Many cells from animals, plants, fungi, yeast, and bacteria have metal-binding proteins with low molecular weight called metallothioneins. These proteins bind mainly to Cd and Zn and constitute a protection mechanisms to the toxic effects of these substances. Some other cell protective mechanisms exist such as enhancement of efflux from cell to the outside. Metals bind on different macromolecules and change enzymatic activities with inhibition or stimulation effects.

Lipophilic hydrocarbons in microorganisms cross polysaccharides from capsule and cell wall polymers with adsorption mainly by the lipids of the membranes.[15] Compounds that are inserted in cell lipids are more difficult to be degraded by chemical or enzymatic processes getting higher persistence.[16] The probable mechanism of action seems to be nonspecific, this means not related to a specific target.

Applications and Future Perspectives

From the scientific point of view a better understanding of the integration between the different environment compartments and biota including modeling systems is an important approach that needs more development. Another possibility is to use bioaccumulation for environmental monitoring, based on the accumulation capacity of many pollutants in specific plants or animals, allowing chemical measurements that otherwise in water or air are below the analytic detection capacity.[17] This method has the possibility to integrate all pollutant exposure of plants or animals in a specific environment and can be in the future an important parameter for ecotoxicological evaluations.

After the disaster of the mercury pollution in the Minamata Bay in Japan in which more than 630 people died and many became physically and mentally disabled, the magnitude of poisoning effects due to bioaccumulation was recognized for the first time.[18] This was the beginning of a scientific research that produced a large amount of information. With this knowledge it became clear that bioaccumulation is a natural process that cannot be stopped by man but can be avoided with a more efficient control of pollutant release. To overcome the economic, social, and political difficulties for better pollution control together with the development of more ecological technologies are our challenge for today and for the future.

Biodegradation

Sven Erik Jørgensen

Introduction: Overview of the Properties of Toxic Chemical Compounds of Particular Importance for Environmental Management

Slightly more than 100,000 chemicals are produced in such an amount that they threaten or may threaten the environment. They cover a wide range of applications: household chemicals, detergents, cosmetics, medicines, dye stuffs, pesticides, intermediate chemicals, auxiliary chemicals in other industries, additives to a wide range of products, chemicals for water treatment, and so on. They are (almost) indispensable in modern society and cover many more or less essential needs in the industrialized world, which has increased the production of chemicals about 40-fold during the last five decades. A minor or major proportion of these chemicals are inevitably reaching the environment through their production, during their transportation from the industries to the end user, or by their application. In addition, the production or use of chemicals may cause more or less unforeseen waste or by-products, for instance, chloro-compounds from the use of chlorine for disinfection. As we would like to have the benefits of using the chemicals but cannot accept the harm they may cause, this conflict raises several urgent questions, which we already have discussed in other entries.

We cannot answer these crucial questions without knowing the properties of the chemicals. Organization for Economic Cooperation and Development (OECD) has made a review of the properties that we should know for all chemicals. We need to know the boiling point and melting point to know in which form (solid, liquid, or gas) the chemical will be found in the environment. We must know the dispersion of the chemicals in the five spheres: the hydrosphere, the atmosphere, the lithosphere, the biosphere, and the technosphere (the part of the earth that is controlled and under the influence of human technology). This will require knowledge about their solubility in water; the water/lipid partition coefficient; Henry's constant (the constant in Henry's Law, which indicates the distribution of the chemical between air and water); the vapor pressure; the rate of degradation by hydrolysis, photolysis, chemical oxidation, and microbiological processes; and the adsorption equilibrium between water and soil—all as functions of the temperature. We need to discover the interactions between living organisms and the chemicals, which implies that we should know the biological concentration factor (BCF), the magnification through the food chain, the uptake rate and the excretion rate by the organisms, and where in the organisms the chemicals will be concentrated, not only for one organism but for a wide range of organisms. We must also know the effects on a wide range of different organisms. It means that we should be able to find the Lethal Concentration causing 50% mortality oif the test animals (LC50) and Lethal Dose causing 50% mortality of the test animals (LD50) values; the Maximum Allowable Concentration (MAC) and Non-effect Concentration (NEC) values (for the abbreviations and the definitions used, see Appendix 5); the relationship between the various possible sublethal effects and concentrations; the influence of the chemical on fecundity; and the carcinogenic and teratogenic properties. We should also know the effect on the ecosystem level. How do the chemicals affect populations and their development and interactions, i.e., the entire network of the ecosystem? A reduction of one population may for instance influence the entire ecosystem because all populations are bound together in an ecological network.

Table 1 gives an overview of the most relevant physical-chemical properties of organic compounds and their interpretation with respect to the behavior of the environment. It is clear from the table that a high water solubility is not desirable as it implies that the chemical compound is very mobile. On the other hand, a low water solubility means a high solubility in fat tissue and, therefore, a high bioaccumulation and a high biomagnification. The biodegradability may, however, frequently be considered an even more important property than water solubility or K_{ow}. If a compound is biodegraded fast, it will be decomposed before it harms the environment. It means that a fastbiodegradation will, so to speak, neutralize the (harmful) effect of a high water solubility and a high solubility in fat tissue. On the other hand, if a compound is biodegraded slowly, it will stay in the environment for a very long time, which implies that a high mobility and a high risk of bioaccumulation and biomagnifications will be harmful. Therefore, it is almost possible to conclude that a compound with high biodegradability will clearly be much less harmful than a compound with a low biodegradability. Biodegradability is therefore a very crucial property for the estimation of a chemical compound's environmental effects.

The list of properties needed to give an adequate answer to the six questions mentioned above could easily be made longer (see, for instance, the list recommended by OECD). To provide all the properties corresponding to the list given here is already a huge task. More than 10 basic properties should be known for all 100,000 chemicals and organisms, which would require 1,000,000 pieces of information. In addition, we need to know at least 10 properties to describe the interactions between 100,000 chemicals and organisms. Let us say, modestly, that we use 10,000 organisms to represent the approximately 10 million species on earth. This gives a total of $1{,}000{,}000 + 100{,}000{*}10{,}000{*}10 =$ in the order of 10^{10} properties to be quantified! Today, we have determined less than 1% of these properties by measurements,

TABLE 1 Overview of the Most Relevant Environmental Properties of Organic Compounds and Their Interpretation

Property	Interpretation
Water solubility	High water solubility corresponds to high mobility.
K_{ow}	High K_{ow} means that the compound is lipophilic. It implies that it has a high tendency to bioaccumulate and be sorbed to soil sludge and sediment. BCF and Koc are correlated with K_{ow}.
Biodegradability	This is a measure of how fast the compound is decomposed to simpler molecules. A high biodegradation rate implies that the compound will not accumulate in the environment, while a lowbiodegradation rate may create environmental problems related to the increasing concentration in the environment and the possibilities of a synergistic effect with other compounds.
Volatilization, vapor	A high rate of volatilization (high vapor pressure) implies that the pressure compound will cause an air pollution problem.
Henry's constant, H	H determines the distribution between the atmosphere and the hydrosphere.
pK	If the compound is an acid or a base, pH determines whether the acid or the corresponding base is present. As the two forms have different properties, pH becomes important for the properties of the compounds.

Note: K_{ow} = Ratio solubility in octanol (represent fat tissue) divided by the solubility in water; Koc = express the adsorption ability to soil consisting of 100% organic carbon, can also with good approximation be considered as the concentration in soil with 1100% orgniac carbon divided with the concentration in water at equilibrium; H = Henry's constant in Henry's Law; pK = – log (equilibrium constant for the dissociation process of acids: $HA = A^- + H^+$).

and with the present rate of generating new data, we can be certain that during the 21st century, we shall not be able to reach 10% even with an accelerated rate of ecotoxicological measurements.

Environmental risk assessments require, among other inputs, information about the properties of the chemicals and their interactions with living organisms. It is maybe not necessary to know the properties with the very high accuracy that can be provided by measurements in a laboratory, but it would be beneficial to know the properties with sufficient accuracy to make it possible to utilize the models for management and risk assessment. Therefore, estimation methods have been developed as an urgently needed alternative to measurements. They are to a great extent based on the structure of the chemical compounds, the so-called QSAR and SAR methods (Quantitative Structure-Activity Relationship, it means estimation methods of chemical properties based on the chemical structure), but it may also be possible to use allometric principles to transfer rates of interaction processes and concentration factors between a chemical and one or a few organisms to other organisms.[1]

It may be interesting in this context to discuss the obvious question: why is it sufficient to estimate a property of a chemical in an ecotoxicological context with 20%, or sometimes 50% or higher, uncertainty? Ecotoxicological assessment usually gives an uncertainty of the same order of magnitude, which means that the indicated uncertainty may be sufficient from, for instance, the viewpoint of ecological modeling or ecological indicators, but can results with such an uncertainty be used at all? The answer in most (many) cases is “yes,” because we want in most cases to assure that we are (very) far from a harmful or very harmful level. We use a safety factor of 100–1000 in many cases. When we are concerned with very harmful effects, such as, for instance, complete collapse of an ecosystem or a health risk for a large human population, we will inevitably select a safety factor that is very high. In addition, our lack of knowledge about synergistic effects and the presence of many compounds in the environment at the same time force us to apply a very high safety factor. In such a context, we will usually go for a concentration in the environment that is magnitudes lower than that corresponding to a slightly harmful effect or considerably lower than the NEC. It is analogous to civil engineers constructing bridges. They make very sophisticated calculations (develop models) that account for wind, snow, temperature changes, and so on, and afterward, they multiply the results by a safety factor of 2–3 to ensure that the bridge will not collapse. They use safety factors because the consequences of a bridge collapse are unacceptable.

The collapse of an ecosystem or a health risk to a large human population is also completely unacceptable. Thus, we should use safety factors in ecotoxicological modeling to account for the uncertainty. Due to the complexity of the system, the simultaneous presence of many compounds, and our present knowledge, or rather, lack of knowledge, we should, as indicated above, use 10–100 or sometimes even 1000 as safety factor. If we use safety factors that are too high, the risk is only that the environment will be less contaminated at maybe a higher cost. Besides, there are no alternatives to the use of safety factors. We can, step by step, increase our ecotoxicological knowledge, but it will take decades before it may be reflected in considerably lower safety factors. A measuring program of all processes and components is impossible due to the high complexity of the ecosystems. This does not, of course, imply that we should not use the information of measured properties available today. Measured data will almost always be more accurate than the estimated data. Furthermore, the use of measured data within the network of estimation methods will improve the accuracy of estimation methods. Several handbooks on ecotoxicological parameters are, fortunately, available. References to the most important are given below. Estimation methods for the physical-chemical properties of chemical compounds were already applied 40–60 years ago, as they were urgently needed in chemical engineering. They are, to a great extent, based on contributions to a focal property by molecular groups and the molecular weight: the boiling point, the melting point, and the vapor pressure as a function of the temperature. In addition, a number of auxiliary properties result from these estimation methods, such as the critical data and the molecular volume. These properties may not have a direct application as ecotoxicological parameters in environmental risk assessment but are used as intermediate parameters, which may be used as a basis for estimation of other parameters.

The water solubility, the octanol/water partition coefficient, K_{ow}, and Henry's constant are crucial parameters in our network of estimation methods, because many other parameters are well correlated with these three parameters. The three properties can fortunately be found for a number of compounds or be estimated with reasonably high accuracy by use of knowledge of the chemical structure, i.e., the number of various elements, rings, and functional groups. In addition, there is a good relationship between water solubility and K_{ow}.[2] Particularly in the last decade, many good estimation methods for these three core properties have been developed.

During the last couple of decades, several correlation equations have been developed based upon a relationship between the water solubility, $K_{ow,}$ or Henry's constant on the one hand and physical, chemical, biological, and ecotoxicological parameters for chemical compounds on the other. The most important of these parameters are the following: the soil/water adsorption isotherms; the rate of the chemical degradation processes (hydrolysis, photolysis, and chemical oxidation); the BCF; the ecological magnification factor (EMF); the uptake rate; the excretion rate; and a number of ecotoxicological parameters. The ratio of concentrations both in the sorbed phase and in water at equilibrium Ka and BCF may often be estimated with a relatively good accuracy from expressions like Ka or BCF = $a \log K_{ow} + b$. Numerous expressions with different a and b values have been published.[3–5]

Biodegradation

It was concluded in the previous section that biodegradation is probably the most important property for the estimation of a chemical compound's environmental effect. This section is therefore devoted to the presentation of this important property.

Biodegradation rates may be expressed in several ways. Microbiological biodegradation may, with good approximation, be described as a Monod equation:[5]

$$\mathrm{d}c/\mathrm{d}t = -\mathrm{d}B/Y\mathrm{d}t = -\mu\mathrm{max}^{*} Bc/Y(\mathrm{Km}+c) \tag{1}$$

where c is the concentration of the compound considered, Y is the yield of biomass B per unit of c, B is the biomass concentration, μmax is the maximum specific growth rate, and Km is the half saturation constant. If $c \ll \mathrm{Km}$, the expression is reduced to a first-order reaction scheme:

$$\mathrm{d}c/\mathrm{d}t = -K'Bc \tag{2}$$

where $K' = \mu\mathrm{max}/(Y\,\mathrm{Km})$. B is in nature determined by the environmental conditions. In aquatic ecosystems, B is for instance highly dependent on the presence of suspended matter. B may therefore under certain conditions[5] be considered a constant, which reduces the rate expression to

$$\mathrm{d}c/\mathrm{d}t = -kc \tag{3}$$

An indication of k in the unit 1/hr, 1/24hr, 1/week, 1/mo, or 1/yr can therefore be used to describe the rate of biodegradation. If the biological half-life time is denoted t, we get the following relation:

$$\ln 2 = 0.7 = k\ t \tag{4}$$

This implies that the biological half-life time also can be used to indicate the biodegradation rate.

The biodegradation in waste treatment plants is often of particular interest, in which case the % of the Theoretical Oxygen Demand (ThOD) or the theoretical biological oxygen demand (BOD) may be used as a suitable reference. Most often, however, the 5-day BOD as percentage of the theoretical BOD is used. It may also be indicated as the BOD5fraction. For instance, a BOD5fraction of 0.7 will mean that BOD5 corresponds to 70% of the theoretical BOD. It is, however, also possible to find an indication of percentage removal in an activated sludge plant. The biodegradation is, however, in some cases very dependent on the concentration of microorganisms as expressed in the above-shown equations. Therefore *K′* indicated in the unit mg/(g dry wt 24 hr) will in many cases be more informative and correct.

In the microbiological decomposition of xenobiotic compounds, an acclimatization period from a few days to 1–2 mo should be foreseen before the optimum biodegradation rate can be achieved. We distinguish between primary and ultimate biodegradation. Primary biodegradation is any biologically induced transformation that changes the molecular integrity. Ultimate biodegradation is the biologically mediated conversion of organic compounds to inorganic compounds and products associated with complete and normal metabolic decomposition.

To conclude, the biodegradation rate is expressed by application of a wide range of units:

1. As a first-order rate constant (1/24 hr).
2. As half-life time (days or hours).
3. mg per g sludge per 24 hr[mg/(g 24 hr)].
4. mg per g bacteria per 24 hr[mg/(g 24 hr)].
5. mL of substrate per bacterial cell per 24 hr[mL/(24 hr cells)].
6. mg COD per g biomass per 24 hr[mg/(g 24 hr)].
7. mL of substrate per gram of volatile solids inclusive microorganisms [mL/(g 24 hr)].
8. BODx/BOD∞, i.e., the biological oxygen demand in x days compared with complete degradation (-), named the BODxcoefficient.
9. BODx/COD, i.e., the biological oxygen demand in x days compared with complete degradation, expressed by means of COD (-).

Estimation of Biodegradation

The biodegradation rate in water or soil is difficult to estimate because the number of microorganisms varies several orders of magnitudes from one type of aquatic ecosystem to the next and from one type of soil to the next. Artificial intelligence has been used as a promising tool to estimate this important parameter. However, a (very) rough, first estimation can be made on the basis of the molecular structure and the biodegradability. The following rules can be used to set up these estimations:

1. Polymer compounds are generally less biodegradable than monomer compounds; 1 point for a molecular weight >500 and ≤1000, 2 points for a molecular weight >1000.
2. Aliphatic compounds are more biodegradable than aromatic compounds; 1 point for each aromatic ring.
3. Substitutions, especially with halogens and nitro groups, will decrease the biodegradability; 0.5 point for each substitution, although 1 point if it is a halogen or a nitro group.
4. The introduction of a double or triple bond will generally mean an increase in the biodegradability (double bonds in aromatic rings are of course not included in this rule); -1 point for each double or triple bond.
5. Oxygen and nitrogen bridges [– O – and – N – (or=)] in a molecule will decrease the biodegradability; 1 point for each oxygen or nitrogen bridge.
6. Branches (secondary or tertiary compounds) are generally less biodegradable than the corresponding primary compounds; 0.5 point for each branch.

Find the number of points and use the following classification:

≤1.5 points: the compound is readily biodegraded. More than 90% will be biodegraded in a biological treatment plant.

2.0–3.0 points: the compound is biodegradable. Probably about 10–90% will be removed in a biological treatment plant. BOD5 is 0.1–0.9 of the theoretical oxygen demand.

3.5–4.5 points: the compound is slowly biodegradable. Less than 10% will be removed in a biological treatment plant. BOD10 ≤ 0.1 of the theoretical oxygen demand.

5.0–5.5 points: the compound is very slowly biodegradable. It will hardly be removed in a biological treatment plant, and a 90% biodegradation in water or soil will take ≥6 mo.

≥6.0 points: the compound is refractory. The half-life time in soil or water is counted in years. The structure of dichlorodiphenyltrichloroethane (DDT) corresponds, for instance, to about 7 points, and the biological half-life of DDT in soil is about 14 years.

Several useful methods for estimation of biological properties are based upon the similarity of chemical structures. The idea is that if we know the properties of one compound, it may be used to find the properties of similar compounds. If for instance we know the properties of phenol, which is named the parent compound, it may be used to give more accurate estimation of the properties of monochloro-phenol, dichloro-phenol, trichloro-phenol, and so on and for the corresponding cresol compounds. Estimation approaches based on chemical similarity give generally more accurate estimation but of course are also more cumbersome to apply, as they cannot be used generally in the sense that each estimation has a different starting point, namely, the compound, named the parent compound, with known properties.

Allometric estimation methods presume[6] that there is a relationship between the value of a biological parameter and the size of a considered organism.

The various estimation methods, including estimation methods applicable for biodegradation, may be classified into two groups:

1. General estimation methods based on an equation of general validity for all types of compounds, although some of the constants may be dependent on the type of chemical compound, or they may be calculated by adding contributions (increments) based on chemical groups and bonds.
2. Estimation methods valid for a specific type of chemical compound, for instance, aromatic amines, phenols, aliphatic hydrocarbons, and so on. The property of at least one key compound is known. Based upon the structural differences between the key compound and all other compounds of the considered type(for instance, two chlorine atoms have substituted hydrogen in phenol to get 2,3-dichloro-phenol) and the correlation between the structural differences and the differences in the considered property, the properties for all compounds of the considered type can be found. These methods are based on chemical similarity.

Methods of class 2 are generally more accurate than methods of class 1, but they are more cumbersome to use as it is necessary for each type of chemical to find for each property the right correlation. Furthermore, the requested properties should be known for at least one key component, which sometimes may be difficult when a series of properties are needed. If estimation of the properties for a series of compounds belonging to the same chemical class is required, it is tempting to use a suitable collection of class 2 methods.

Methods of class 1 form a network that facilitates possibilities of linking the estimation methods together in a computer software system, for instance,WINTOX. [1] An updated version named Estimation of Ecotoxicological Properties (EEP) is now available. EEP can estimate the biodegradability, in contrast to WINTOX. The software is easy to use and can rapidly provide estimations. Each relationship between two properties is based on the average result obtained from a number of different equations found in the literature. There is, however, a price for using such "easy-to-go" software. The accuracy of the estimations is not as good as with more sophisticated methods based upon similarity in chemical structure, but in many, particularly modeling, contexts, the results found by WINTOX and EEP can offer sufficient accuracy. In addition, it is always useful to come up with a first intermediate guess. It could, for instance, be used to estimate whether a chemical compound would be decomposed by biological treatment.

The software also makes it possible to start the estimations from the properties of the chemical compound already known. The accuracy of the estimation from use of the software can be improved considerably by having knowledge about a few key parameters, for instance, the boiling point and

Henry's constant. WINTOX and EEP are based on average values of results obtained by simultaneous use of several estimation methods for most of the parameters. It implies increased accuracy of the estimation, mainly because it gives a reasonable accuracy for a wider range of compounds. If several methods are used in parallel, a simple average of the parallel results has been used in some cases, while a weighted average is used in other cases where it has been found beneficial for the overall accuracy of the program. When parallel estimation methods are giving the highest accuracy for different classes of compounds, use of weighting factors seems to offer a clear advantage. It is generally recommended to apply as many estimation methods as possible for a given case study to increase the overall accuracy. If the estimation by WINTOX and EEP can be supported by other recommended estimation methods, it is strongly recommended to do so.

Biological Control of Vertebrates

Peter Kerr and
Tanja Strive

Introduction

Biological control is the deliberate use of one organism to control another, normally a pest species, by reducing its population size, rate of increase or geographic spread and so diminishing its environmental and economic impacts. In classical biological control, usually applied to insect and plant pest species, predators, disease agents or parasites are used to diminish the impact of the pest sometimes with considerable success. Biological control of vertebrate pests has a much more limited history and very few success stories. The advantage of biological control is that while it may be expensive to search for and evaluate biological control agents, a successful biological control provides ongoing control at little cost. Against this must be balanced the risk of unforseen ecological consequences due to the introduced agent or control of the pest and the likely diminution of the impact of the control over time. These principles, successes and limitations are illustrated by examining the natural history of biological control of vertebrate pest species together with a discussion of more recent attempts to use biotechnology to develop novel biological controls.

Vertebrate Pests

Vertebrate pest species may be invasive, feral, deliberately or accidentally introduced, or native to the area; the definition of what constitutes a pest species will vary from location to location, across time, social groups and perspectives. Pest species range from jawless fish to mammals and exist on local and continental scales. Even iconic species such as Australian koalas (*Phascolarctos cinereus*) or African elephants (*Loxodonta africana*) can have local pest status and require some form of management. Similarly, options for control of vertebrate pests will inevitably be influenced by a wide range of social, ecological and economic pressures. A particular consideration, not always addressed, is that unlike plants or insect pests, vertebrate pests are capable of feeling pain and distress, so welfare must be taken into account when control measures are proposed.

Conventional control measures for vertebrate pests can basically be summarized as exclusion by some form of barrier or deterrent (physical, chemical, habitat destruction, guardian dogs, predators) or removal, which could include capture and relocation for iconic species but will more commonly be lethal, including hunting, (commercial, recreational, directed culling), trapping and poisoning. Fertility control, using surgical, hormonal, chemical or immunological means, has been applied, at least experimentally, for some species (Pickard and Holt 2007). The inability to deliver long-acting targeted reproductive controls cheaply and on large scales currently limits the application of fertility control to localized regions or high-value iconic species.

The common problem with all conventional measures is that unless the pest can be permanently eliminated, ongoing control is necessary with the recurrent costs competing with other social and political priorities. These shifting priorities frequently result in poorly sustained control.

Biological Control

Predators as Biological Control Agents for Vertebrate Pests

Biological control of vertebrate pests using introduced predators has a long if not particularly glorious history. The classic example is the use of cats (*Felis catus*) to control rodents around human settlements, which extends back into prehistory (Driscoll et al. 2007). If pest populations are low enough then predators can prevent an increase in population size (Pech et al. 1992). However, introduction of exotic predators frequently leads to unintended consequences. For example, cats have been deliberately introduced onto many islands to control rodents or European rabbits (*Oryctolagus cuniculus*) often with unforseen and devastating consequences for bird and reptile populations (Courchamp et al. 2003, Nogales et al. 2004).

Mongooses (*Herpestes auropunctatus*) were introduced into the West Indies and subsequently Hawaiian Islands to control rodents and became major pests endangering ground-dwelling birds and many other species while in Hawaii, the rats moved into the trees and threatened arboreal birds (Courchamp et al 2003).

Similarly, in an attempt to control introduced European rabbits, weasels (*Mustela nivalis*), ferrets (*Mustela furo*), stoats (*Mustela erminea*) and cats were widely released in New Zealand during the later part of the 19th century and ferret release continued into the 1920s (Gibb and Williams 1994). Ferrets, cats and stoats became well established with serious and ongoing impacts on native birds and reptiles. In addition, ferrets have provided a reservoir host for bovine tuberculosis with trade and public health consequences. It appears unlikely that these predators had a significant effect on rabbit populations at the time of release, but following intensive rabbit control measures from the 1950s onwards and the release of rabbit hemorrhagic disease virus (RHDV) in 1997, predators may be important for maintaining populations at low levels (Gibb and Williams 1994, Reddiex et al. 2002, Henning et al. 2008).

In a further example, foxes (*Dusicyon griseus*) were introduced into Tierra del Fuego in 1951 in an attempt to control an estimated 30 million European rabbits, the endemic fox species *Dusicyon culpaeus* having been driven almost to extinction. It is improbable that the 24 introduced foxes and their progeny had any impact on this rabbit population. However, the introduction of myxomatosis in 1954 dramatically reduced rabbit numbers, and it has been suggested that the introduced foxes together with the preexisting *D. culpaeus* may have helped to prevent buildup of the rabbit population, although rabbits formed less than 2% of the diet of *D. griseus* (Jaksic and Yanez 1983).

There are, however, two small-scale success stories with predators. Gray wolves (*Canis lupus*) reintroduced to Yellowstone National Park in the United States have provided a high-order predator to control elk (*Cervus elaphus*) populations. Elk browsing had prevented regeneration of aspen (*Populus tremuloides*) and other trees since the 1920s when wolves were eliminated, leading to erosion and environmental degradation (Ripple and Beschta 2007). The presence of wolves has reduced grazing pressure on lowland aspen as the elk have changed their behavior or had their numbers reduced. However, this introduction could be seen more as a restoration of the previous ecology of the system rather than as biological control.

In a more direct example of biological control, European red foxes (*Vulpes vulpes*) were deliberately introduced onto two small islands in the Aleutians and appear to have eliminated populations of previously introduced arctic foxes (*Alopex lagopus*) although whether this was by competition for limited resources, direct predation or both is not clear (Bailey 1992). To prevent breeding, only male red foxes were released on one island and on the second, five vasectomised males and five females were released.

Reintroduction of high-order predators, such as dingoes (*Canis familiaris*) in Australia and leopards (*Panthera pardus*) in South Africa, has been proposed as a means of control for multiple vertebrate pest species. This could be potentially coupled with deployment of guardian dogs to protect livestock (Minnie et al. 2015, Newsome et al. 2016, Allen et al. 2019). Introduction of predator fish has also been investigated to control European carp (*Cyprinus carpio*) in Australia and the United States (Poole and Bajer 2019).

Biological Control of Vertebrate Pests Using Parasites

Parasites in the broadest sense are essentially another form of predator, albeit often nonlethal. Parasites are traditionally divided into microparasites (bacteria, viruses, protozoa, fungi) and macroparasites (helminths, arthropods). The earliest documented experiment with a microparasite for biological control is the use of chicken cholera bacteria (*Pasteurella multocida*) by Louis Pasteur in 1887 to exterminate European rabbits on an 8 Ha walled estate in France (Pasteur 1888). However, there are only three examples of vertebrate biocontrol by a microparasite on any large scale: myxomatosis in European rabbits, rabbit hemorrhagic disease in European rabbits and feline panleukopenia in cats.

There is some evidence that macroparasites may regulate vertebrate populations in the wild (Hudson et al. 1998, Tompkins and Begon 1999, Albon et al. 2002, Redpath et al. 2006). However, the interactions of parasites including macroparasites with other biotic and abiotic factors are complex (Tompkins et al. 2011). The only successful example of biological control with macroparasites is the release of two species of flea, *Spilopsyllus cuniculi* and *Xenopsylla cunicularis*, in Australia, which, by enhancing the transmission of the virus causing myxomatosis, act as indirect biological controls for European rabbits (see Chapter 13 Myxoma virus and Rabbit hemorrhagic disease virus as biological controls for rabbits).

Other attempts to use macroparasites as biological controls for vertebrates have been less successful. In one example, field, laboratory and modeling studies on the nematode *Capillaria hepatica* suggested it could act as a biological control to prevent irruptions of house mice (*Mus musculus*) in the cereal growing areas of south-eastern Australia (Singleton and McCallum 1990). However, intensive field releases of *C. hepatica* failed to show any impact on wild mouse populations (Singleton et al. 1995, Singleton and Chambers 1996).

Lungworms (*Rhabdias* spp.) have been proposed as possible biological controls for two invasive amphibians, cane toads (*Bufo marinus*) in Australia and coquis (*Eleutherodactylus coqui*) in Hawaii (Kelehear et al. 2009, Marr et al. 2010). However, preliminary studies with coquis were unpromising, and it is difficult to see how lungworms could effectively be introduced into the invading cane toad population on a landscape scale in the Australian outback.

The Natural History of Successful Biological Controls

Biological Control of Rabbits

The European rabbit originated in the Iberian Peninsula but has been spread deliberately or accidentally into the wild throughout much of Europe, Britain, North Africa, parts of Chile and Argentina, New Zealand, over 800 islands and, perhaps most famously, Australia (Flux 1994). All domestic breeds of rabbits are derived from these European rabbits. Wild rabbits from Britain were introduced into Australia in 1859 and within 50 years had spread across most of the nontropical parts of the continent constituting the most dramatic and rapid biological invasion ever documented for a mammalian pest (Flux 1994).

Rabbits are highly adaptive generalist herbivores that substantially modify their habitat (Thompson 1994, Myers et al. 1994). Their burrows and warrens enable survival under many different climatic extremes and high reproductive rates mean that rabbit populations can rapidly expand when rainfall triggers food availability (Myers et al. 1994). In dry areas of Australia, even quite low densities of rabbits (less than 1 per hectare) can prevent regeneration of shrubs and trees leading to local species extinctions, soil erosion, weed invasion and loss of other vertebrate species which are unable to survive in the modified habitat (Williams et al. 1995, Bird et al. 2012, Cooke 2012). In Australia, rabbits are a food source for two recently introduced predators, the European red fox and the feral cat (Woinarski et al. 2015). By supporting populations of foxes and cats, rabbits contribute to the endangerment and extinction of small marsupials by these predators (Dickman 1996, Kearney et al. 2018). In addition to the major ecological damage caused by rabbits, there is also a significant cost due to lost agricultural production from grazing pressure, weed invasion, soil erosion and crop destruction (Myers et al. 1994, Williams et al. 1995) as well as the economical and ecological costs of conventional controls such as habitat destruction and widespread poisoning (Williams et al. 1995, Cooke 2012).

Biological control of rabbits was successfully undertaken with myxoma virus (MYXV), the causative agent of myxomatosis, following its release in 1950. While initially highly successful, subsequent rabbit-virus coevolution led to a diminution of the effect of myxomatosis and a rebound of rabbit numbers, particularly in the low rainfall rangelands. In 1995, the escape of RHDV from a study site, introduced a second biological control for rabbits, which again substantially reduced rabbit numbers. These viruses and their impacts are described in detail in Chapter 13 Myxoma virus and Rabbit hemorrhagic disease virus as biological controls for rabbits.

Biological Control of Cats

The domestic cat (*F. catus*) adapts quickly to a feral lifestyle and has become a serious problem following its deliberate or accidental introduction onto islands (Courchamp et al. 2003, Nogales et al. 2004). Feral cats have also been associated with species loss or endangerment in Australia and New Zealand (Dickman 1996, Fitzgerald and Gibb 2001, Woinarski et al. 2015, Murphy et al. 2019).

Marion Island, the larger of the Prince Edward Islands, is a South African possession in the southern Indian Ocean (46°54′S; 37°45′E). This sub-Antarctic island, about 1900 km south east of Cape Town, has an area of 290 km^2 and hosts major breeding populations of penguins and seabirds (Bester et al. 2002). Five domestic cats were deliberately released in 1949 to control introduced house mice around a meteorological station (van Aarde and Skinner 1981, Bester et al. 2002).

In 1975, the cat population was estimated at 2139 ± 290 (van Aarde and Skinner 1981, van Aarde 1984). These cats would have needed to consume over 450,000 burrowing petrels a year just to satisfy their minimum energy requirements (van Aarde and Skinner 1981). At least one species of petrel was believed to have been driven to local extinction by 1965 (Bester et al. 2002). The isolation, rugged landscape and the climate of Marion Island meant that conventional control of the cat population would be difficult and so biological control was an attractive option (Bester et al. 2002). Feline panleukopenia virus (FePV) was chosen as a biological control after a limited serological survey indicated that it was not present in the cat population (van Aarde 1984).

Feline Panleukopenia Virus

FePV (family *Parvoviridae*; sub-family *Parvovirinae*; genus *Protoparvovirus*; species *Carnivore protoparvovirus 1*) is a small (25 nm diameter) icosahedrally symmetrical, non-enveloped virus with a single-stranded DNA genome of 5200 nucleotides (Murphy et al. 1999, Stuetzer and Hartmann 2014). The virus is a natural pathogen of cats; it infects most if not all Felidae; closely related viruses infect dogs, mink and other carnivores (Steinel et al. 2001). Because it needs components of the host DNA polymerase to replicate its genome, FePV only replicates in the nucleus of actively dividing cells. This means it has a tropism for lymphoid tissue, bone marrow and the dividing epithelial cells in the intestinal crypts. Destruction of these cells leads to the clinical signs of gastroenteritis and panleukopenia (massive loss of white blood cells and platelets) seen in cats infected with FePV, (in neonates and fetal kittens the virus infects cells of the developing brain and heart rather than the gut) (Truyen et al. 2009).

Infected cats shed virus in feces, urine, saliva and vomit. Estimates of the duration of shedding range from 7 days to several months (Murphy et al. 1999, Steinel et al. 2001). Very high titers of virus (10^9 ID_{50} per g of feces) may be excreted and the virus can persist in the environment in an infectious state for many months. There are thus two modes of transmission: direct from an infected to a susceptible cat and indirect from the environment (Berthier et al. 2000).

Infection is mostly via the oropharynx with virus initially replicating in the pharyngeal lymphoid tissue, followed by a viremia that distributes virus to all tissues of the infected animal. Case fatality rates have been estimated at 20% in adult cats and 80% in kittens (Berthier et al. 2000). Cats that recover from infection are likely to be immune for life with immunity primarily due to neutralizing antibody. Kittens born to immune queens are protected for some weeks after birth by maternal antibody, delivered in the colostrum (Truyen et al. 2009). Kittens infected while still partially protected by maternal antibody may have an enhanced survival rate.

Feline Panleukopenia Virus on Marion Island

In March 1977, FePV was inoculated into 96 previously trapped cats which were released back into a population estimated at 3400 (Howell 1984, van Aarde 1984). This was at the end of the breeding season when kitten numbers and sub-adult numbers were likely to be high. The virus had a case fatality rate of approximately 50% in a small number of cat passages; both cat-passaged and cell culture-passaged virus were released (Howell 1984).

Following the release, cat sightings dropped from 102 to 18.9 per sampling period, suggesting that the virus had established and was having a significant impact on the cat population. In 1978, 45 of 57 cats sampled had antibodies to FePV (Van Rensburg et al. 1987), confirming that the virus had established and spread in the population. Subsequent serological testing indicated that it was persisting in the cat population (Van Rensburg et al. 1987).

Population density was estimated to have decreased by 65% 3 years after the release from 3400 to 600 (van Aarde 1984). As would be expected, the disease had its main impact on the young and sub-adult populations causing a marked shift in age distribution, with recovered and immune cats forming a long-lived breeding population and epizootics of the disease occurring in susceptible kittens each breeding season as protection from maternal antibodies waned. By 1982, it was considered that the rate of population decrease had slowed or stabilized.

Sea bird breeding had improved in areas where cats had been eliminated, but there was still sufficient predation to impede re-establishment of some species (Bester et al. 2002). Therefore, it was decided to proceed with the complete eradication of cats from Marion Island using conventional means. Cats were finally eliminated in 1991 following intensive hunting, trapping and poisoning campaigns (Bester et al. 2002). Ironically, cats were introduced to Marion Island as a form of biological control for the house mouse. Subsequent to the eradication of cats, the house mouse is now regarded as a threatening species (van Aarde et al. 1996).

Prospects for Biological Control of Cats

Because it does not have a prolonged carrier state, FePV is unlikely to be introduced onto islands by small founder populations. However, the success of FePV on Marion Island has not seen more use of this virus in cat control. The only documented example being on Jarvis Island in the Pacific (Rauzon 1985). On this 414 Ha atoll, 31 cats were inoculated with FePV and released into a population estimated to be <200 cats. No attempt was made to determine whether the virus was already present in the population. At least 10 of 19 marked cats survived the infection, and there was no good evidence that the virus established. Cats were subsequently eradicated from Jarvis Island using conventional means (Rauzon 1985).

Modeling studies (Courchamp and Sugihara 1999) suggest that two feline retroviruses which cause persistent infections, *feline leukaemia virus* and *feline immunodeficiency virus*, could be effective biological controls on island populations with feline leukemia virus capable of eradicating cats under some conditions. FePV was regarded as unsuitable, despite the apparent success on Marion Island, because of its short transmission time. However, this is at least partially compensated by the prolonged infectivity of FePV in the environment (Berthier et al. 2000).

Potential Biological Control Agents

Koi (Carp) Herpesvirus as a Potential Biological Control for the European Carp

The introduced European carp (*C. carpio*) has become the dominant fish species in inland waterways of south-eastern Australia. Their high fecundity, ecological adaptability and omnivorous diet have made carp a highly visible pest species, with impacts due to increased water turbidity, decreased vegetation and possibly increased frequency of algal blooms due to higher nutrient levels in waterways (Koehn 2004, McColl et al. 2007). European carp are also considered a pest species in North America and New Zealand but in other parts of the world are highly valued (Saunders et al. 2010).

Cyprinid herpesvirus 3 (CyHV-3; order: *Herpesvirale*; family: *Alloherpesviridae*; genus: *Cyprinivirus*) is a widely distributed emerging pathogen of European carp that is absent from Australia. The virus has been associated with massive die-offs of koi and common carp with estimates of mortality ranging from 70–100%. It appears to be species-specific for common and koi carp although it has been suggested that goldfish (*Carassius auratus*) may be asymptomatically infected (El-Matbouli and Soliman 2011). High virulence, species specificity, and apparently ready transmission in water, together with absence from Australia suggested that this virus may have potential as a biological control agent (McColl et al. 2007). CyHV-3 was imported into the high-security Australian Animal Health laboratory for evaluation (McColl et al. 2007, Saunders et al. 2010, McColl et al. 2016). Larval carp appear highly susceptible with mortality rates of 96–100% following infection. Adults had a lower mortality rate (Saunders et al. 2010). Plans have been developed for a virus release in 2019–2020; however, there are still questions being raised about the strategy (Kopf et al. 2017, Lighten and van Oosterhout 2017, Marshall et al. 2018), and it is likely that any release will be delayed. It is considered necessary that biological control would be combined with conventional control measures and possibly future biotechnological controls (Thresher et al. 2014, McColl et al. 2018).

Future Biocontrols and Biotechnology for Control of Vertebrate Pests

Biotechnology has the potential to engineer existing parasites to enhance virulence, modify antigenicity or to deliver other antigens or regulatory molecules such as interfering RNA. Any such modification for vertebrate pest control is likely to be controversial particularly when a vertebrate pest in one country, such as the rabbit in Australia, is a valued keystone species in its natural range and because of the risk of altering the host range of the parasite. More recently, genetic biocontrols such as gene drives, based around DNA editing CRISPR/Cas9-type and similar systems, which would directly modify pest species have been investigated as potential controls for vertebrate pest species.

Virally Vectored Immunocontraception

Biological controls that inhibit reproduction or development are an attractive target for pest control. Virally vectored immunocontraception (VVIC) aimed to use a genetically engineered transmissible agent to deliver an immunocontraceptive antigen to a pest species. Infection with the recombinant organism would stimulate an immune response to the immunocontraceptive antigen which would block fertility. Potential antigens include components of sperm, the zona pellucida surrounding the egg or peptide hormones such as gonadotrophin-releasing hormone. Direct injection of such antigens is already used in some wildlife population control programs (Naz and Saver 2016). However, direct injection is not feasible for control of widespread invasive species such as rabbits, mice and foxes.

In Australia, extensive studies were undertaken to develop VVIC for three key invasive species: house mice, European rabbits and European red foxes. However, none of the technologies developed were sufficiently effective for field use (Hardy et al. 2006). While mice could be rendered sterile by inoculation with recombinant murine cytomegalovirus, the virus did not transmit effectively from mouse to mouse (Redwood et al. 2007). In rabbits, >90% of females could be rendered infertile following inoculation with recombinant MYXV, but in around 50% of cases, infertility was short-lived (Mackenzie et al. 2006, van Leeuwen and Kerr 2007). Field experiments using surgical sterilization of female rabbits indicated that levels of immunocontraception efficacy >80% would be required to have an impact on the population and reduce ecological damage (Twigg et al. 2000, Williams et al. 2007). Despite considerable effort, no effective product was developed for foxes (Reubel et al. 2005, Strive et al. 2006, Strive et al. 2007). All the recombinant viruses tested expressed zona pellucida proteins as antigens. The use of possibly more effective antigens such as gonadotropin-releasing hormone was not explored.

Prospects for Virally Vectored Immunocontraception

Although potentially a means of biological control, immunocontraception vectored by a recombinant organism has efficacy and safety hurdles to overcome before it could be a reality. These include: (1) an immunocontraceptive antigen must stimulate a long-lasting immune response that cross-reacts with a self-antigen to cause sustained infertility at least in females. (2) The recombinant organism must be able to establish in a population, transmit and be maintained in the population in competition with field strains of the organism or be able to be regularly reintroduced, possibly in a bait. As demonstrated with murine cytomegalovirus, recombinant viruses may not transmit effectively. (3) The immune response should not need boosting. (4) The vector organism and preferably the antigen should be species-specific. (5) The risk of the organism jumping species by mutation or recombination should be minimal.

These scientific and technical conditions have not yet been satisfied in any species. Beyond the technical issues, there are national and international social, environmental and political issues that would need to be addressed before vector-delivered fertility control could be a reality.

Biological Controls for Cane Toads

The cane toad (*Rhinella marinus*) is native to South America and was introduced to Australia in 1935 to control beetles in sugarcane crops (Shine 2010). While the toads failed as beetle-biocontrol agents, they proved to be excellent invaders and have spread from their original release in coastal northern Queensland south to NSW and across the tropical north of Australia as far as Western Australia and are continuing to expand towards the Indian Ocean (Shine 2010).

All life stages of the cane toad are toxic to predators due to compounds collectively referred to as bufadienolides. As a result, cane toad invasions have led to declines in populations of native predator species, such as snakes, freshwater crocodiles, goannas and quolls at the invasion front although the long-term impact is more difficult to quantify (Shine 2010).

Between 1990 and 1993, an extensive search for natural pathogens was undertaken in the toad's native range in Venezuela. A number of virus isolates from cane toads and a frog were made, all belonging to the family *Iridoviridae*, genus *Ranavirus* and considered to represent a single species. While these viruses killed cane toad tadpoles, they were also lethal to at least one Australian native frog species and considered unsuitable as biocontrol agents (Shanmuganathan et al. 2010). More recently, metagenomic studies have identified a novel rhinovirus and an endogenous retrovirus in cane toads from Australia (Russo et al. 2018).

In a biotechnological strategy, it was proposed to use a recombinant virus to deliver cane toad adult-specific proteins into tadpoles. This approach was based on the hypothesis that expression of adult-specific proteins in tadpoles would create an immune response, since tadpoles are not immunologically tolerant to adult proteins. By selecting an antigen that was critical for metamorphosis, it was proposed that maturation would be inhibited. Although proof of concept had been shown many years earlier in tadpoles of the American bullfrog immunized with adult hemoglobin (Maniatis et al. 1969), this was unsuccessful in cane toads and the work has been discontinued (Shanmuganathan et al. 2010).

To date, no biocontrol is available to effectively reduce cane toad populations or halt their spread across the Australian continent.

Genetic Biocontrol of Invasive Species

The use of genetic biocontrols such as gene drives to spread an allele through a population is receiving considerable attention (Esvelt et al. 2014). The basic concept is to use a genetic construct that copies itself into homologous chromosomes, thus creating super-Mendelian inheritance whereby more than 50% of the offspring inherit the drive element. An element that disabled a key gene involved in reproduction or caused sex bias, for example, by turning all individuals into phenotypic males, could be introduced into the population causing population crashes. The advent of CRISPR/Cas9 and other bacterial nuclease/guide systems as gene editing tools has turned this from a largely theoretical approach to a potentially practical means of controlling populations. Genetic biocontrol of pest populations would have the advantages of being self-disseminating and strictly species-specific (since only transmitted by sexual reproduction). In addition, genetic biocontrol should be much more humane than conventional lethal controls or pathogens.

Proof of concept has been demonstrated in mosquito populations under containment conditions (Kyrou et al. 2018). In vertebrates, there have been proposals to use gene drives to control invasive rodent species on islands and for invasive fish (Thresher et al. 2014, Leitschuh et al. 2018). Modeling studies have examined the opportunities and constraints, particularly the selection of resistant alleles, of gene drives for rodent control (Prowse et al. 2017). A germline-expressed gene drive has been demonstrated in laboratory mice; however, super-Mendelian inheritance occurred only in female mice (Grunwald et al. 2019). Although currently in its infancy, it is likely that this technology will rapidly improve. In the meantime, there will be considerable debate on the risks associated with driving a sterilizing gene into a population and whether these can be satisfactorily managed (Esvelt et al. 2014, National Academy of Sciences 2016).

Conclusions

A number of conclusions can be drawn from the history of biological control of vertebrate pests that should inform the search for and use of biological control agents.

1. It is challenging to find effective biological controls for vertebrates and those that have been most successful, myxomatosis and rabbit hemorrhagic disease, were emerging diseases with extreme case fatality rates not pre-existing diseases of the European rabbit in its natural range.
2. Searching for biological control agents in the original home range of the vertebrate pest, as has been so successful for plant and insect pests, may be unsuccessful for vertebrate pests because it could well be that predation or resource limitation was more important in population control than parasitism particularly by a single organism (Tompkins et al. 2011). This was exemplified by the search for cane toad pathogens in Venezuela. FePV is a natural pathogen of cats but has been successfully used on only one island and may not be species-specific.
3. Laboratory trials may be poor predictors of success in the field.
4. As the early experience with myxomatosis in Australia indicates, it may be difficult to establish a novel pathogen in a population, particularly if the epidemiology of the pathogen is not well understood.
5. The initial impact of a biological control is unlikely to be sustained.

   At the very least, the pathogen may undergo local extinction when host populations fall to low numbers. For rapidly reproducing invasive pest species, this can allow local recovery of populations. Unlike insects and plants, vertebrates surviving infection develop adaptive immunity that can protect from subsequent reinfection. This has two impacts: it provides an immune pool of breeding animals, and passive antibody transfer may protect their offspring for some weeks after birth and hence alter the impact and timing of epizootics. At some level, there will likely be selection for enhanced resistance to the pathogen and, depending on the life history of the pathogen, there may be selection for more attenuated strains of the pathogen.
6. Biological controls should not be seen as “silver bullets” that remove the need for ongoing integrated pest management strategies. However, successful biological controls such as myxomatosis and rabbit hemorrhagic disease (RHD) can significantly suppress populations on continental scales.
7. The introduction of novel high-order predators to control populations has generally not been successful due to the low species specificity of the predator and the need to reduce pest numbers to very low levels before predators can keep them in check.
8. Biotechnological approaches to vertebrate biocontrol have so far been unsuccessful. These have a lot of hurdles to overcome, not least scientific and technical, but also regulatory and social. However, given the difficulty in finding natural biocontrol agents, biotechnology should not be ignored and gene biocontrol technologies offer potentially powerful new means of controlling populations if efficacy and safety can be achieved.

Biological Controls

Heikki Hokkanen

Introduction

Biological control of pests has been actively practiced for the control of pests, weeds, and plant diseases for more than 100 years, and it has had some 150 spectacular successes,[1] which in economic terms have been just as impressive as in ecological terms: the calculated return for investment is 32:1, while for other control methods the ratio is around 2.5:1.[2,3] However, the obtained successes are only the tip of the iceberg of all the work carried out in the field. To date, more than 6000 introductions of alien natural enemies have been carried out, worldwide.[4] It is estimated that only about 35% of all introduced biocontrol agents have become ecologically established in the target ecosystem, and only 60% of these have provided any economic or biocontrol success.[3,5] Of all the individual biocontrol projects, only 16% have resulted in complete control of the target pest.[6] A major ecological and economic challenge is to improve the ratio of successes in biological control, while retaining the excellent safety record of this approach to pest control.

General Principles

While it has been shown that biological control can be effective in any climate, ecosystem, and crop, the factors determining success or failure remain largely unknown, and often are economic rather than ecological in nature.[1] Very few general principles to improve the efficacy and predictability of biological control have emerged; these include better ecological background knowledge, genetic improvement (in particular, genetic engineering) of biocontrol agents, and the utilization of new ecological associations in selecting the biocontrol agents.[7] The genetic engineering of biocontrol agents, especially insects, is still in its infancy and cannot be expected to improve the success ratios in the foreseeable future. In contrast, the new association principle has—usually unknowingly—been used for a long time, and is increasingly employed to find more effective natural enemies for current biological control programs.

New Associations

The standard biological control principle is to reestablish the ecological balance between an exotic pest and its natural enemies occurring in their country of origin (the "old association approach").[2,3] It has been argued, however, that this is an inefficient way of practicing biological control, because due to an evolved long-term equilibrium between the pest and the natural enemy, the control agent only seldom is very efficient.[6] To find more effective enemies one should search among agents that do not share an evolutionary history with the target pest (the "new association" approach). Such natural enemies can be found, for example, for the target pest in areas where the pest has been introduced only recently, or among enemies attacking related species in other geographical areas.[6]

Evidence for Improved Efficacy

Analysis of past biocontrol successes and failures have indicated that when employing the new association principle it is possible to increase the success ratio by at least 75%.[6] More detailed studies showed that some natural enemy groups may be particularly attractive as new association agents (Table 1). Such analyses are, however, often confounded by the fact that new association agents seldom have been considered as the primary choice in biological control, and consequently, usually five to seven old association agents are introduced before a new association agent is tried. In addition, on average much greater numbers (two-to fourfold) of old association agents are normally introduced (Table 1), which further increases the probability of biocontrol success, and biases the analyses against new association agents. Therefore, the estimate for improving the success ratio appears to be conservative.

Several spectacular, well-documented biocontrol successes that have employed new association control agents are known, and these include the complete control of serious pests such as the sugarcane borer *Diatraea saccharalis* in the Caribbean, coconut spike moth *Levuana iridescens* in Fiji, southern green stink bug *Nezara viridula* in Hawaii, the moth *Oxydia trychiata* in Colombia, and several scale insect species in California, Greece, and Australia.[7] Further, more detailed examples will be given below on new research with good prospects of success utilizing this approach.

TABLE 1 Comparisons of Biological Control Introductions with Old and New Association Control Agents Utilizing Tachinidae, Braconidae and Eulopidae

	Proportion (%) of Successes of All Cases (Introductions)		Total Number of Cases		Bias in the Release Numbers[a]
	Old	New	Old	New	
Tachinidae	10.9	17.1	92	41	3.8-fold
Braconidae	17.2	14.4	169	97	1.6-fold
Eulopidae	28.6	35.7	56	28	1.7-fold
Overall	17.4	18.7	317	166	

Source: Hokkanen, H. M. T., unpublished data.

[a] Indicates how many more individuals on average of old association agents were released in the introduction projects, compared with new association agents. In the case of Tachinidae and Braconidae the mean number of released new association agents was below 5000 individuals, which is considered to be the necessary number to ensure a fair chance for the natural enemies to establish themselves.

Recent Cases Employing New Associations

Eurasian Watermilfoil

The Eurasian watermilfoil (*Myriophyllum spicatum*) was introduced into North America several decades, possibly 100 years, ago. It grows rapidly, forms a dense canopy on the water surface, and often interferes with recreation, inhibits water flow, and impedes navigation. Herbicides and mechanical harvesting have been used to control infestations, costing \$150–\$2000 per acres annually in Minnesota.[8]

Sometimes naturally occurring declines of the watermilfoil have been observed. The main causal agent proved to be a native beetle *Euhrychiopsis lecontei*, the milfoil weevil, which subsequently has shown control potential in controlled field experiments. The weevil is a specialist herbivore of watermilfoils, but prefers the Eurasian to its native host, the northern watermilfoil (*M. sibiricum*). Research is in progress to use the milfoil weevil effectively as a biocontrol agent against the Eurasian watermilfoil in North America.[8]

Lantana

Lantana camara is a serious weed of Mexican or Caribbean origin, affecting cropping lands and forest areas in 47 countries. Lantana was the focus of the first weed biocontrol effort in history (1902), and there is an enormous literature on Lantana biocontrol. Several complexes of herbivores have been credited for exerting some degree of biocontrol of the weed (e.g., in Hawaii), many employing new association agents jointly with old association agents. Latest research gives data on the good efficacy and release in Australia of the moth *Ectaga garcia* originating from South America, where it feeds on the related weed *Lantana montevidensis*.[9]

Triffid (Siam) Weed

The triffid weed (*Chromolaena odorata*) is a perennial shrub native of tropical America. In recent decades it has become a serious pest of humid tropics around the world.[10] It spreads rapidly in lands used for forestry, pasture, and plantation crops and can reach a height of three meters in open situations and up to eight meters in forests. For more than two decades the triffid weed has been the subject of intensive research as a target for biological control. However, so far all attempts at biocontrol of *C. odorata* have failed. Recently the new association biological control agent, arctiid moth *Pareuchaetes aurata aurata* collected from *C. jujuensis* in South America, was considered as more promising than the related moth *P. pseudoinsulata*, an old association control agent previously thought of as one of the best biocontrol candidates.[10]

Southern Green Stink Bug

The biological control of the southern green stink bug (the green vegetable bug) (*Nezara viridula*) in Australia, New Zealand, and Hawaii has been heralded as a landmark example of classical biological control.[11] An egg parasitoid—old association agent—*Trissolcus basalis* and a tachinid fly—new association agent—*Trichopoda pennipes* have jointly provided these successes. Control by the fly has been considered as relatively more important, and indeed, in Australia where the fly has failed to establish, the control is poor and the bug remains a serious pest. Currently in Australia another new association tachinid fly, *Trichopoda giacomellii,* is being released after research showed it has excellent potential for control.[12]

Citrus Leafminer

Citrus agroecosystems have numerous potentially damaging pests often maintained under substantial to complete biological control by both old and new association agents. The citrus leafminer *Phyllocnistis citrella*, native to Asia, has spread rapidly throughout the citrus growing areas of the world in recent years.[13] It arrived in Florida in 1993 and in less than one year invaded and colonized the entire state. An old association parasitic wasp *Ageniaspis citricola* was introduced in 1994, and after establishment it has held the pest under control with significant help from native parasitoids such as *Pnigalio minio* (new association agent).[13] In some other areas native parasitoids similarly have shown significant control effect on the citrus leafminer (e.g., in Italy). This example illustrates well the fact that invading species often do not become pests, because effective local natural enemies keep them in check.

Tarnished Plant Bug

An ongoing study in the United States has identified as the most important parasitoid of the native pest *Lygus lineolaris*, the tarnished plant bug, the exotic species *Peristenus digoneutis*, originally introduced for the control of related introduced mirid plant bugs.[14] This example serves well to point out the importance of native pests, which in most if not all areas form the majority of all pest species. As old association biological control agents seldom can be utilized for the control of native pests, their biocontrol by introduced natural enemies has attracted relatively little attention and, indeed, only three decades ago was considered an impossible task. Several recent examples, usually utilizing new association control agents, show that biological control can work against native pests just as well as against exotic ones.

Future Prospects

Compared with chemical control, the success rates of biological control are outstanding. While only about one out of 15,000 tested chemicals ends up as a chemical pesticide meeting the requirements of efficacy and safety, approximately one out of seven introductions of natural enemies has been successful using old associations.[15] Using new association control agents this rate could still be increased to about one out of four, while the array of potential natural enemies is also substantially larger providing a wider choice. In addition, the potential uses for natural enemy introductions are broadened to include the control of native pests.

A major concern with respect to all biological control introductions is the question of nontarget safety. Biological control has an excellent record of safety[3,16] and it covers the new association agents as well: there have been some 1500–2000 introductions already (out of 6000) that have involved new association agents.[7] Those extremely few cases where a negative nontarget effect has been suspected as a result of biological control, all involve old association agents; therefore it is clear that new associations can safely be used to help obtain biological control successes at an increasing rate.

37

Biological Factors Impeding Recovery of Predatory Fish Populations

Catalina Chaparro Pedraza

Introduction

Historically, global fisheries have relied significantly on large predatory fish species (Myers and Worm 2003). The previous seemingly inexhaustible fish abundance contributed to the public's perception that fish stocks such as tuna, billfish, cod, salmon, and pike are almost extinction-proof. However, this perception proved to be wrong. Currently, 33% of global fish populations are exploited at biologically unsustainable levels (FAO 2018). In the second half of the 20th century, the fraction of large predatory fishes in global catches, that have increased by fivefold, have declined (Worm et al. 2009). By the turn of the millennia, large predatory fish biomasses were estimated to be only about one tenth of pre-industrial abundance (Myers and Worm 2003).

There has been much public concern over declining fish stocks on a global scale, spurring multiple United Nations resolutions on the conservation and management of fish stocks (UN 2019). Most management measurements have focused on reducing exploitation rates, which generally result in an improvement for fully exploited and overexploited stocks (Worm et al. 2009). However, reductions in fishing pressure, although necessary, are not always sufficient for recovery of depleted populations, which are estimated to be 13% of global exploited fish populations (Garcia et al. 2018). Indeed, a long-term dataset from more than 230 fish populations shows that most collapsed populations exhibit little or no recovery 15 years after collapse (Hutchings and Reynolds 2004). Only 12% of collapsed marine populations had fully recovered in this period, all of them clupeids (Hutchings and Reynolds 2004), which typically have a low trophic level in marine food webs. In contrast, even when fishing mortality has been reduced, collapsed fish populations of species in higher trophic levels exhibit little or no recovery as much as 15 years later (Hutchings and Reynolds 2004). An emblematic example is the Canadian cod collapse, which despite a prolonged moratorium in effect, exhibits no recovery after two decades (Maroto and Moran 2014; Pedersen et al. 2017).

Factors impeding recovery of depleted fish populations can be numerous including biological, environmental and socioeconomic factors (Garcia et al. 2018). Some biological factors preventing a successful recovery of depleted fish stocks are altered ecological interactions and intrinsic characteristics of the populations, i.e., life history traits. Environmental factors include loss of habitat, in particular, coastal and coral reef degradation, as well as natural oscillations in climatic and productivity variables that condition the recruitment into the depleted stock (Friedland et al. 2009). Several socioeconomic factors have been identified to cause the failure of recovery of depleted fish stocks, for instance, the inability to find alternative livelihoods for fishermen after the depletion preventing fishing mortality to be reduced, social organization and cohesion that may facilitate compliance or illegal behavior (Wakeford et al. 2009). In this chapter, I will focus on the biological factors that impair recovery of depleted predatory fish populations in more detail.

There is general consensus that life history traits affect the vulnerability and capacity to recover of fish populations. In particular, traits associated with maximum population growth include fecundity, body growth rate, age and size at maturity (Hutchings and Reynolds 2004). Although low fecundity is characteristic of fish species with low population growth rate (Musick 1999), high fecundity does not ensure recovery (Hutchings and Reynolds 2004; Dulvy et al. 2003; Hutchings and Kuperinen 2014). In fact, highly fecund species, such as Atlantic cod (DFO 2003), exhibit lack of recovery following a decrease in fishing pressure. Rapid body growth rate is associated with high potential to recover (Hutchings and Reynolds 2004). Age and size at maturity are negatively associated with maximum population growth and, thus, with recovery potential (Roff 2002; Denney et al. 2002; Dulvy and Reynolds 2002; Dulvy et al. 2003).

Biological Characteristics of Predatory Populations

Although some life history traits are specific of species or even populations, most predatory fish species are characterized by a significant increase in body size through ontogeny that can span four orders of magnitude (Werner and Gilliam 1984). This increase in body size results in changes in ecological interactions throughout an individual's life. In fact, the majority of predatory fishes do not have a predatory diet as small juveniles because its body size at birth is often similar to that of their prey (de Roos and Persson 2013). Therefore, individuals of predatory fish species prey on smaller fish species only when they reach a large body size, while small individuals necessarily feed upon other type of food that might be the same of their future prey. As a result, individuals of a predator and prey species may be engaged in a competitive or a predatory interaction depending on the life stage of the predator individual interacting. Furthermore, throughout life history, predatory interactions can be reversed, for instance, while individuals of the predator species in the adult stage feed upon large juveniles or adults of the prey species, the latter may prey upon small juveniles of the predator species (Gårdmark et al. 2015).

Depensation

As a consequence of the life history specifics, large predatory fish species described above may exhibit a reduced population growth capacity at low densities (i.e., below a threshold), a phenomenon known as depensation or Allee effect (Figure 1) (de Roos and Persson 2002).

Strong depensation effects are caused by the existence of alternative stable states. In this view, a high and a low population density constitute alternative states stabilized by internal feedbacks, and therefore, a population depleted to its low density by overexploitation cannot return to its high-density state when the exploitation rate decreases to the point at which the population has collapsed. Instead, the exploitation rate should be reduced to lower levels for the population to recover (Figure 2). The lag between the exploitation rate at which collapse and recovery occurs is known as hysteresis.

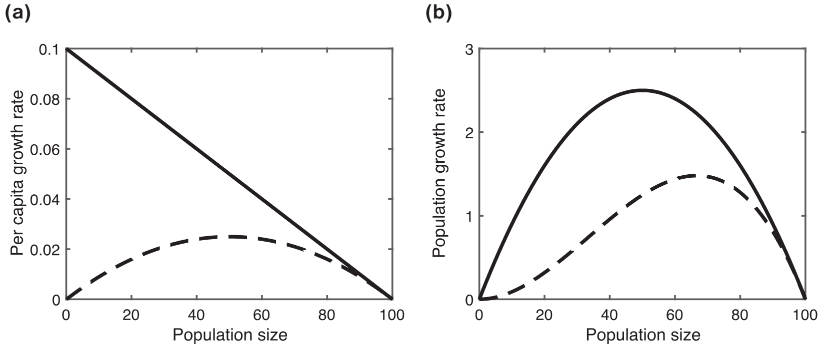

FIGURE 1 Depensation or Allee effects occur when population growth rate is reduced at small population size. (a) The per capita growth rate decreases linearly with population size when there are no Allee effects (solid line), while it is reduced at low and at high population size when there are Allee effects (dashed line). (b) As a consequence, in the absence of Allee effects (solid line), the population grows at its maximal rate at intermediate population size, while in the presence of Allee effects (dashed line), the population grows at its maximal rate when the population is large. Both populations have a carrying capacity of 100.

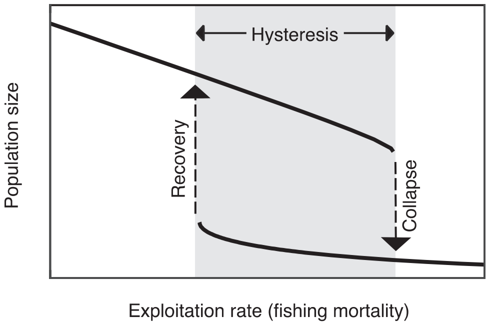

FIGURE 2 Alternative stable population states cause depensation. A population that is unexploited or exploited at low rate has a large size. As exploitation rate gradually increases, the population size gradually decreases until the exploitation rate is near the value at which the population collapses. Owing to hysteresis caused by alternative stable states, after the collapse, it is not enough for the population to recover to reduce the exploitation rate to the value where the collapse occurred. A further reduction in exploitation rate is required for the population to recover.

Several mechanisms have been hypothesized to cause depensation in fish populations that can be classified into three categories: reproduction difficulties, impaired social relations and altered ecological interactions, which are addressed in turn below.

Reproduction difficulties may emerge from: (1) sex ratio abnormalities, for instance, when fishing removes faster one sex than the other (Garcia et al. 2018); (2) insufficient spawner densities for effective egg fertilization and successful mating encounters and (3) removal of larger individuals because of their increased value and fishing tactics (i.e., minimum mesh and fish landing size (Hutchings and Reynolds 2004)). It is important to bear in mind that fecundity increases exponentially with female fish size (McIntyre and Hutchings 2003). Hence, larger fish can contribute disproportionately to population birth rate through greater weight-specific fertility and larval quality (Sogard 1997; Venturelli et al. 2012; Trippel 2004). As a consequence, populations composed of small individuals will have reduced reproductive potential (Scott et al. 2011) (migratory fish populations may be an exception when facing high costs of breeding migration (Chaparro-Pedraza and de Roos 2019)).

Depensation may be caused by impaired social relations at low population densities. For instance, by altering social behaviors such as schooling or migration, fishing may affect the reproductive process or survival of the remaining population as well as transmission of knowledge about suitable feeding and breeding areas and migration pathways from old-year classes to young ones (Petitgas et al. 2010).

Ecological interactions can cause depensation through various mechanisms. One proposed mechanism arises from the interaction between a size-selective predator and preys with density-dependent growth (de Roos and Persson 2002). Another mechanism emerges from competition between a predator and its prey in early life stages. As mentioned above, adult predatory fish individuals feed on prey fish, whereas small predatory juveniles and prey fish may compete for the same food resources (de Roos and Persson 2013). At high population density, adult predatory individuals, by controlling the prey population at low or intermediate densities through predation, reduce competition pressure on the predatory juveniles (Gårdmark et al. 2015). A release of the top-down control results in high density of prey population that controls the predatory population recruitment through competition. Alternatively, a third mechanism emerges when adult prey individuals feed upon early life stages of the predatory fish population, the recruitment in the latter is controlled by predation of abundant adult prey individuals when the predatory population is at low density.

Although theoretical work indicates that depensation through these mechanisms is likely (de Roos and Persson 2002; Maroto and Moran 2014), it has been difficult to demonstrate empirically (Garcia et al. 2018). However, recent empirical studies have revealed evidence supporting these depensatory mechanisms.

Depensation in Wild Predatory Fish

The northwest population of Atlantic cod (*Gadus morhua*) is an emblematic case of collapse and little recovery in fisheries. This collapse, due to overfishing, had devastating socioeconomic impacts. After dramatic declines of the population during the 1980s and 1990s, Canada instituted a moratorium on fishing in 1992 that left 40,000 workers unemployed, thousands left fishery to work in other trades or professions, in many cases, displaced to other parts of the country (Garcia et al. 2018). Despite this long moratorium, cod population have shown only slight increases (Pedersen et al. 2017). An analysis of the population dynamics of depleted fish stocks concluded that the lack of recovery in the Canadian cod is consistent with a depensatory phenomenon at low population densities (Maroto and Moran 2014). Likewise, the depensatory phenomenon was confirmed by a population model, which concluded that the lack of recovery of the cod population was mainly caused by predation by gray seals driving an Allee effect (Neuenhoff et al. 2018).

At the beginning of 1990s, the cod population in the Baltic Sea also collapsed as a result of overfishing concurrent with poor environmental conditions (Gårdmark et al. 2015). Following this collapse, the population did not recover during the late 1990s and early 2000s. The lack of recovery has been postulated to result from increased competition between cod larvae and sprat (*Sprattus sprattus*), a main prey of adult cod (Möllmann et al. 2009). As a consequence of the collapse of the cod population, the sprat population increased due to release from predation pressure. This caused stronger competition pressure on cod larvae for zooplankton prey. A shift in the regulation of zooplankton dynamics, from a control by limiting resources (bottom up) before the collapse of the cod population to a control by predation of sprat population (top down) after the collapse, supports this hypothesis (Casini et al. 2008). Gårdmark et al. (2015) demonstrate that the lack of top-down regulation in the sprat population after the cod collapse caused a change in the distribution of size classes in this population. As a consequence of this change, the food available for the cod in larval and adult stages was diminished and, therefore, the viability of this population reduced.

In the mid-1990s, pike (*Esox lucius*) population, a large top predator, declined substantially in the Baltic Sea (Bergström et al. 2015; Eriksson et al. 2011; Ljunggren et al. 2010; Nilsson et al. 2004). Pike is a major predator on adult threespine stickleback fish (*Gasterosteus aculeatus*) (Donadi et al. 2017).

Therefore, the decline of pike has favored the stickleback population by predator release, causing the stickleback population to grow exponentially about a decade after the collapse of the pike population (Bergström et al. 2015; Bergström et al. 2016; Donadi et al. 2017; Sieben et al. 2011). Following the collapse of the pike population in the Baltic Sea, various conservation measurements have been adopted with the aim of enabling the recovery of the pike population, including partial closure of the pike fishery and habitat restoration (Engstedt et al. 2017; Nilsson et al. 2014). In spite of this, the recovery of the pike population has been very slow, if at all (Bergström et al. 2016). A recent experimental study suggests that the cause of the impaired capacity of the pike population to recover is a depensatory effect. This study demonstrates that adult stickleback predation on pike larvae heavily reduces the recruitment of the pike population, suggesting this as the mechanism causing depensation and impeding recovery of the pike population (Nilsson et al. 2019).

The possibility of depensatory effects in severely depleted fish predatory populations may be high. However, the evidence remains scarce beyond few examples, perhaps because few populations have been depleted to densities where the population growth rate is heavily reduced (the depensatory effect or Allee effect is conspicuous) (Garcia et al. 2018). In fact, pike population in the Baltic Sea and the Canadian Cod population were depleted below 10% (Nilsson et al. 2019) and 1% (Myers and Worm 2005), respectively, of their original abundance. The collapse of these populations is, in fact, beyond the precautionary biomass limit usually imposed by fisheries that is 20%; at this limit, populations are considered heavily depleted (Garcia et al. 2018).

Evolutionary Responses to Exploitation

Most fisheries target specific age or size classes within a population. Typically, larger and older, individuals are more likely to be caught. There is compelling evidence supporting claims that large fish were caught more frequently in the early years of industrial fisheries (Allendorf and Hard 2009). For instance, cod individuals weighting more than 30 kg were frequently caught in New England waters before 1900 and even a gigantic individual of nearly 100 kg was taken off Massachusetts in 1895 (Jordan and Evermann 1902). Such selective mortality imposed on the targeted phenotypes brings about evolutionary change if the characteristics that make these phenotypes more vulnerable are heritable. Accordingly, rapid changes in phenotypic traits of fish populations have been documented as a result of fishing mortality (Haugen and Vøllestad 2001; Law 2001; Conover et al. 2007; Allendorf and Hard 2009).

Besides the immediate negative impact in the population birth rate due to loss of high fecundity potential, increased mortality of large individuals results in selection against fast body growth rate (Biro and Post 2008; Swain et al. 2007); as opposed to natural selection that usually favors this trait in unexploited populations. As a consequence of this evolutionary change in response to selective pressures induced by fishing, depleted populations are composed mainly of phenotypes with slow body growth rate, a trait associated with low potential to recover (Hutchings and Reynolds 2004). In addition to changes in growth rate, fishing pressure can alter size and age at maturity (Heino and Dieckmann 2008; Heino 1998). These and other evolutionary responses tend to improve resilience of the exploited populations to fishing mortality as slow-growth and long-lived species accelerate their turnover (Pauly 1995). However, simultaneously, these evolutionary responses may reduce trait variation and, thus, resilience of these populations to the environmental oscillations to which they were adapted through natural selection.

Since mortality caused by fishing is usually considerably higher than natural mortality, selection pressures are higher in the former. As a consequence, evolutionary changes induced by fishing pressure may emerge in few decades; however, once fishing pressure is released, it may take centuries to be reversed (Enberg et al. 2009). There is growing concern that undermined genetic variation caused by fisheries-induced evolutionary change might increase the range of hysteresis between collapse and recovery trajectories and thus enhance the effect of depensation through the mechanisms mentioned in the previous section. Therefore, evolutionary processes that may improve resilience of exploited populations, may lessen the capacity to recover once depleted.

Population Size, Environmental and Demographic Stochasticity

In addition to the negative effects on genetic variation, reduced population size makes depleted populations more vulnerable to extinction as a consequence of demographic and environmental stochasticity. Small populations are largely governed by the misfortunes of each individual. Hence, the persistence of small populations is largely dependent on realizations of random events that determine individual survival and reproduction. These random events are the result of unpredictable factors that influence the survival and fecundity of some (demographic stochasticity) or all (environmental stochasticity) individuals in a population (Lande 1993).

Along with the decline of a population, its geographical range tends to contract as individuals remain in the most favorable habitats (Swain and Wade 2010). Such geographical range contraction can further exacerbate the risk of extinction in small populations as a consequence of stochastic events. Northern cod provides an example of how such range contractions increase the risk of exposing collapsed populations to environmentally stochastic events. In April 2003, about 1500 tones of mature cod were frozen to death in a very small area of Trinity Bay along the northeast coast of Newfoundland (Hoag 2003; Hutchings and Reynolds 2004). An unpredictable oceanographic event that trapped cod in supercooled water provides the most likely explanation for this cull mass (Hutchings and Reynolds 2004). Relative to the small geographical area where the event took place, it had a disproportionally large negative effect on the population recovery because the spawning population of northern cod in 2003 was estimated to be only 14,000 tones (DFO 2003). Hence, this environmentally stochastic event in a very small geographical area probably resulted in the death of more than 10% of the breeding population.

Rebuilding Predatory Fish Populations after Depletion

Most plans for rebuilding fisheries focused on populations that have been driven below acceptable levels of productivity. These plans advocate measures that are adequate to avoid depletion, and it is often assumed that if the population has been driven to depletion, the same measures, more effectively applied, are also those that will enable the rebuilding of the population (Garcia et al. 2018). However, this assumption may be misleading. When a population has been depleted to very low level, a set of additional measures are required in order to avoid extinction and, if possible, increase the chances of recovery (Garcia et al. 2018).

Measures to reduce fishing mortality are necessary for the rebuilding of a depleted population. Rebuilding plans relying on a substantial reduction at the onset rather than on incremental minor reductions over time are more successful (Murawski 2017). However, socioeconomic and governance factors can prevent fishing mortality to be substantially reduced in the onset. For instance, the inability to find alternative livelihoods for fishermen following the depletion causes exploitation to continue, and the lack of social control facilitates illegal catch (Wakeford et al. 2009). Therefore, a successful rebuilding plan should ensure environmental and social sustainability pursuing the rebuilding of the natural resource and the people's livelihoods in concert (FAO 1995).

In addition to reductions in fishing mortality, protection of critical habitats and enhancement of stock resilience are common measures in rebuilding plans for populations that have been only lightly overfished. These measures are certainly necessary also for rebuilding populations that have been deeply overfished. However, if depensation effects govern the dynamics of the depleted population, the recovery may be slower than expected (Murawski 2017), which increases socioeconomic costs associated to the rebuilding process. Hence, implementing additional measures aim at destabilizing the present poor (small population size) stable state may speed up the rebuilding process and, thus, increase its chances of success.

Depensatory, evolutionary and stochastic effects have hampered the recovery of predatory fish populations in spite of efforts to reduce the fishing pressure and restore the habitat of these species. This indicates that, perhaps, a small population size (i.e., low density) is a stable state for these populations, and thus, additional actions that destabilize this state may be required. For instance, Persson et al. (2007)

demonstrated experimentally in a freshwater lake that the interaction between a size-selective predator and preys with density-dependent growth that has been proposed as one of the mechanisms causing depensation in predatory fish populations (de Roos and Persson 2002) can be destabilized by culling of the prey population. In this experiment, the removal of prey individuals proved to be an effective measure to trigger the recovery of the predator population.

Similarly, counterintuitive measures to reverse the negative evolutionary effects caused by size-selective fishing mortality may improve the capacity to recover of the predatory population. As mentioned before, natural selection is usually weaker than selection imposed by fishing mortality, therefore increasing the strength of selection in the same direction than natural selection may speed up the process to reverse the evolutionary effects of selection induced by fishing. For instance, while increased mortality of large size classes due to fishing results in selection against fast growing phenotypes, increased mortality of small size classes will favor these phenotypes. Indeed, experimental evidence shows that juvenile growth rates increases with high mortality of small size classes as a consequence of genetic change in somatic growth rate (Conover and Munch 2002). Furthermore, this study found that populations in which small individuals are harvested have higher yield in the long term than populations in which large individuals are harvested. Therefore, selection in favor of fast growing phenotypes through removal of small individuals in a depleted population may rapidly raise the frequency of fast growing phenotypes, increasing the potential to recover.

In this chapter, I have presented biological factors that affect the recovery of predatory fish populations. It is important to bear in mind that fisheries are social-ecological systems in which the natural and human components tightly interact and coevolve (Berkes et al. 2000). The biological factors described in this chapter interact with economic, social and governance factors in a complex manner. Therefore, the measures targeting biological factors that condition the rebuilding of predatory fish populations must account for the interactions of these with socioeconomic factors.

Bioremediation

Ragini Gothalwal

Introduction

After the industrial revolution, a significant number of industries were set up, which released organic compounds in the environment. These chemical compounds (pesticides, fertilizers, plastic, dyes, and heavy metals) are present in the form of metal, non-metal, metalloid, inorganic compounds, and organic compounds. Organic compounds are divided into aliphatic, alicyclic, aromatic, polyaromatic, and mixed types. These compounds have a tendency to transform into another compound and reach the ecosystem. Owing to the inadequacy and increased cost of physical and chemical methods available, the need for ecofriendly and cheaper methods has been strongly realized. Bioremediation has the potential to lower the cost of remediation by orders of magnitude over alternative technologies, and governmental agencies and the public as taxpayers are interested in cost-effective cleanup technologies.

Biodegradation and bioremediation are matching processes, to the extent that they are both based on the conversion or metabolism of pollutants by microorganisms. The difference between these two is that biodegradation is a natural process whereas bioremediation is a technology. Bioremediation requires an efficient bacterial strain that can degrade the largest pollutant to a minimum level. Microbial diversity offers an immense field of environmental friendly options for mineralization of contaminants or their transformations into less harmful or non-hazardous compounds. Molecular biology methods are now being employed to study bioremediation. Conjugative gene transfer occurs, through plasmid-borne catabolic genes, between bacteria in oil and the competitive, indigenous bacterial population. Therefore, it is important to understand the role of catabolic genes, by molecular cloning and characterization, in the degradation of a particular organic compound, so that it can be applied for bioremediation. This review emphasizes the distribution and extent of environmental contaminants from the ecosystem. It also accentuates the current status of research in the area of biodegradation and bioremediation and presents the new approaches available for microbial and phyto tracking in the environment.

Principle of Bioremediation

The understanding of the bioremediation process is derived from the combination of biochemical and microbiological processes,[1,2] summarized as follows:

1. The relationship of comparative biochemistry applies equally to the axenic culture of microorganisms and those in field soil.
2. Microbial growth requirements are the same whether in laboratory culture or in the field.
3. Limitations resulting from ecological interactions include the need to accommodate the presence of other microbes as well as adaptation to the physical and chemical properties of the microsite wherein the microbes live.
4. A microbe amended in a soil ecosystem not only should pass the requisite genetic information and be capable of expressing that capability *in situ,* but it must also have the capacity to become a part of the overall soil microbial community.[1] Such microbes are referred to as competent rhizospheric bacteria with intrinsic bioremediation potential.

Targets of bioremediation must be based not only in terms of structure but also in terms of the matrix containing the target. Thus, the applicability of bioremediation can be considered for each of the environmental status of matter: 1) solid (soil, sediment, sludge); 2) liquid (ground water, industrial wastewater); 3) gas (industrial air emission); and 4) subsurface environment (saturated and vadose zones). The general approaches to bioremediation (Figure 1) are as follows:

1. Bioaugmentation;
2. Biostimulation (environmental modification, through the nutrient application process);
3. Phytoremediation (addition of microbes).

The biological community for bioremediation generally consists of the natural soil microflora. However, higher plants can also be manipulated to enhance toxicant removal (phytoremediation), especially for remediation of metal-contaminated soils.[3,4]

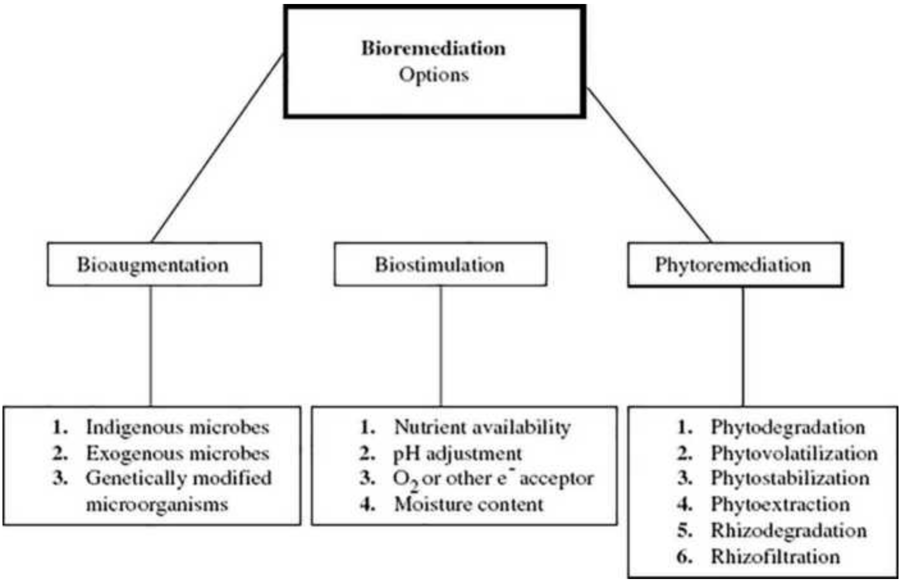

FIGURE 1 Bioremediation approaches for environmental cleanup.

Microbial Degradation of Organic Pollutants

The soil microbial diversity is regarded as a major factor responsible for many biochemical transformations, including degradation of diverse organic compounds.[5–7] The chemical structures of organic pollutants exert profound influence on the metabolic abilities of microbes. Thus, harvesting the microbiological activities for biodegradation of recalcitrant hazardous chemicals and its implementation forms the basis for the increased use of biotreatment systems (Table 1). Predominantly, noxious chemicals, such as polychlorinated biphenyls (PCBs), trichloroethylene (TCE), polycyclic aromatic hydrocarbons (PAHs), and pesticide residue in soils and water are the targets. Removal of unwanted residues, as well as pesticide efficacy, is ultimately dependent on the presence, number, and enzymatic capability

TABLE 1 Examples of Bacteria, Actinomycetes, Fungi, and Cyanobacteria Engaged in Pesticide Degradation

Organisms	Organic Compounds or Pesticides
Bacteria and actinomycetes	
Alcaligenes denitrificans	Fluoranthene (PAH)
Alcaligenes faecalis	Arylacetonitriles
Archromobacter	Carbofuran
Arthrobacter	EPTC, glyphosate, pentachlorophenol (PCP)
Bacillus sphaericus	Urea herbicides
Brevibacterium oxydans IH35A	Cyclohexylamine
Burkholderia sp. P514	1,2,4,5-TeCB
Clostridium	Quinoline, glyphosate
Comamonas testosteroni	Arylacetonitriles
Corynebacterium nitrophilous	Acetonitrile, carboxylic acid, ketones
Dehalococcoides ethenogenes 195	Trichloroethylene (TCE)
Desulfitobacterium dehalogenans	Hydroxylated PCBs
Desulfovibrio sp.	Nitroaromatic compound
Flavobacterium	PCP
Geobacter sp.	Aromatic compound
Klebsiella pneumoniae	3 and 4 Hydroxybenzoate
Methylococcus capsulatus (Bath)	Trichloroethylene
Methylosinus trichosporium OB 3b	1,1,1-Trichloroethane (TCA)
Moraxella	Quinoline, glyphosate
Nitrosomonas europaea	TCA
Nocardia	Quinoline, glyphosate
Pseudomonas aeruginosa	Nitriles, biphenyl, parathion
Pseudomonas sp.	Quinoline, glyphosate
Pseudomonas stutzeri	Parathion
Pseudomonas cepacia	2,4,5-T
Pseudomonas paucimobilis	PCP
Pseudomonas putida 6786	Propane
Pseudomonas striata	Propham, chloropham
Rhodococcus chlorophenolicus	PCP
Rhodococcus corallinus	*S*-triazines
Rhodococcus rhodochrous	Propane
Rhodococcus sp.	Propane, TCA
Rhodococcus UM1	Pyrene

TABLE 1 (*Continued*) Examples of Bacteria, Actinomycetes, Fungi, and Cyanobacteria Engaged in Pesticide Degradation

Organisms	Organic Compounds or Pesticides
	Fungi
Aspergillus flavus	DDT
Aspergillus parasiticus	DDT
Aspergillus niger	2,4-D
Candida tropicalis	Phenol
Chrysosporium lignorum	3,4-Dichloroaniline
Fusarium solani	Acylamilide
Fusarium oxysporum	DDT
Hendersonula toruloidea	2,4-D
Hydrogenomonas + *Fusarium* sp.	DDM, nitrile
Mucor alternans	DDT
Penicillium	Acylamilide
Penicillium megasporum	2,4-D
Phallinus weirii	DDT
Phanerochaete chrysosporium	PAH, 2,4,6-trinitrotoluene, PCP, DDT, 2,4,5-T, lindane
Pleurotus ostreatus	DDT
Polyporus versicolor	DDT
Pullularia	Acylamilide
Rhodotorula	Benzaldehyde
Stereum hirsutum	Phenanthrene
Trametes versicolor	Dieldrin
Trichoderma sp.	Nitrile
Trichoderma viride	DDT
Trichosporon cutaneum	Phenol
Yeast	Paraquat
	Ectomycorrhizal fungi
Tylospora fibrillosa	Mefluidide
Thelephora terrestris	
Suillus variegatus	
Suillus granulatus	
Suillus luteus	
Hymenoscyphus ericae	
Paxillus involutus	
	Cyanobacteria
Cylindrospermum sp.	BHC
Aulosira fertilissima	lindane
Plectonema boryanum	diazinon, endrin
Nostoc muscorum	Carbofuran
Wollea bhardlvajae	hexachlorocyclohexane (HCH)
Nostoc musorum	HCH
Mastigocladus laminosus	Tolkan
Tolypothrix tenuis	fluchloralin
Anabaena doliolum,	Butachlor

of soil microbes. Mineralization of these compounds takes place only when environmental condition, water activity, presence of O_2, temperature, and pH are suitable for the growth and survival of the organism (Table 2). Degradation fails when the target compound is either very concentrated or much diluted. Successful biological cleanup of soil and water contaminants takes place in the presence of aerobic microorganisms. A dichlorinating anaerobic microbial population can also be helpful in cleanup processes. Genes for complete mineralization of some of the haloaromatic compounds are also reported and effectively utilized for recruitment of microbes and environmental applications. Degradation of naphthalene is more difficult than that of bionuclear compounds such as biphenyl, dibenzofuran, and dibenzo-*p*-dioxin, and of mononuclear aromatic compounds such as aniline, benzene, salicylate, phenoxyacetate, and toluene. Peripheral or funneling, central degradative and oxoadipate pathway sequences are necessary for the complete degradation of the compounds.[8] Pentachlorophenol (PCP) and PCB are major recalcitrant compounds. The major problems of PCP degradation are the formation of toxic end products during the metabolism and substitutions of chlorine.

Organochlorine pesticides (DDT, endosulfan, hexachlorobenzene, and hexachlorocyclohexane) are degraded by microbes by means of reductive dechlorination, dehydrochlorination, oxidation, and isomerization of the parent molecule. The principal reactions involved in the breakdown of phosphotriesters (organophosphate insecticides) are hydrolysis, oxidation, alkylation, and dealkylation.[11] Microbial degradation through hydrolysis of p-O-alkyl and p-O-aryl bonds is considered to be the most significant step in the degradation of parathions, methyl parathion, and p-nitrophenol. Reductive dechlorination of organochlorine is an important microbial reaction. A classic example of this is the conversion of DDT to DDD; this reaction occurs in several species of bacteria such as *Pseudomonas, Bacillus, Arthrobacter, Clostridium;* in soil actinomycetes; in yeasts; and in fungi such as *Trichoderma viridae, Mucor alterans,* white rot fungi, *Pleurotus australis, Phellinus weirii,* and *Polyporus versicolor* (Table 3). The formation of DDE from DDT through dehydrochlorination is commonly observed in algae, diatoms, and phytoplankton (*Cylindrotrea dentorium, Cyclotella nana, Isochryeii gabana, Nitzschia* spp.). Microbial isomerization reactions involve the conversion of γ-BHC to α-BHC, diedrin to photodieldrin, and D-keto andrin to endrin by *Pseudomonas putida*.[12]

Lindane is very persistent in the environment and resistant to microbial degradation.[13] It is degraded aerobically as well as anaerobically. *Pseudomonas paucimobilis* UT26 is a unique microbe

TABLE 2 Major Factors Affecting Bioremediation

Microbial
- Growth until critical biomass is reached
- Mutation and horizontal gene transfer
- Enrichment of the capable microbial populations
- Production of toxic metabolites

Environmental
- Depletion of preferential substrates
- Lack of nutrients
- Inhibitory environmental conditions

Substrate
- Too low concentration of contaminants
- Chemical structure of contaminants
- Toxicity of contaminants
- Solubility of contaminants

Biological aerobic vs. anaerobic process
- Oxidation/reduction potential
- Availability of electron acceptors
- Microbial population present in the site

Growth substrate vs. co-metabolism
- Type of contaminants
- Concentration
- Alternate carbon source present
- Microbial interaction (competition, succession, and predation)

Physico-chemical bioavailability of pollutants
- Equilibrium sorption
- Irreversible sorption
- Incorporation into humic matter

Mass transfer limitations
- Oxygen diffusion and solubility
- Diffusion of nutrients
- Solubility/miscibility in/with water

TABLE 3 Mechanisms of Radionuclide Bioremediation

S.N.	Mechanism	Microorganisms	Remediated Radio
1.	Biosorption	*Rhizopus arrhizus, S. cerevisae, Penicillium americium, Aspergillus, Aeromonas hydrophila, Candida utilis*	Uptake
2.	Engineering biosorption	Eukaryotic metallothien, *E. coli* Lan B	
3.	Bioaccumulation	*Citrobacter* sp.	UO_2^{2+}
		Rhodococcus erythropali CS98	Cesium
		Rhodococcus sp. strain CS 402	Cesium
		Micrococcus luteus	Neptunium
		Radioresistant bacteria	
		Deinococcus radiodurans	U (Vi), Tc (Vii)
		D. geothermalis	Radioactive waste

that utilizes hexachlorocyclohexane (HCH) as its sole source of carbon and energy under aerobic conditions.[14] Five structural genes (*lin A, lin B, lin C, lin D*, and *lin E*) and one regulatory gene (*lin R*) are involved in degradation of α-HCH in UT 26. *lin A*, *lin B*, *lin C*, and *lin D* codes for dehydrochlorinase, halidohydralone, dehydrogenase, and reductive dehalogenase, respectively, and *lin E* encodes ring cleavage oxygenase. Microbial degradation of γ-HCH has also been reported in *Anabaena* sp. PCC 7120 and *Nostoc ellipsosorum*.[16] The enzyme responsible for catalyzing the hydrolysis step in parathion is organophosphate hydrolase (OPH), which is encoded by the *opd* gene. This gene has been isolated from several bacteria. A naturally occurring variant of OPH enzyme, designated as opdA, capable of degrading a broad range of organophosphates was isolated from an *Agrobacterium radiobacter* strain.[17] The slow growth and low culture yields of native OPH-producing strains make them uneconomical for practical use. Therefore, efforts have been made by several researches to improve the applicability of OPH for pesticide bioremediation. A consortium comprising two bacteria that were genetically engineered (*E. coli* and *P. putida* KT 2440) efficiently worked together to break down parathion and prevent accumulation of p-nitrophenol [PNP].[18]

Catechol is a terminal metabolite formed during the degradation pathways of various compounds, and a variety of potential degraders of catechol have been reported by Kim et al.[19] Biodegradation of phenol and toluene by *Pseudomonas* sp., *Bacillus* sp., and *Staphylococcus* sp. was studied by Prasanna et al.[20] These strains were isolated from pharmaceutical industrial effluents. Mixed cultures showed more efficient degradation than pure strains within 5–7 hr at lower concentrations. Polycyclic aromatic hydrocarbon-degrading bacteria and ligninolytic and non-ligninolytic fungi are ubiquitously distributed in the natural environment such as soils and woody materials. The principal mechanism for aerobic bacterial metabolism of PAH is the initial oxidation of the benzene ring by the action of dioxygenase enzyme to form *cis*-dihydrodiol intermediates, which can then be further metabolized via catechols to CO_2 and H_2O.[21] Many bacterial, fungal, and algal strains have been shown to degrade a wide variety of PAHs (Table 1). There are limited reports on degradation of high molecular weight PAHs with more than four benzene rings. In general, high molecular weight PAHs are degraded slowly by indigenous or augmented microorganisms, as the persistence of PAHs increases with their molecular size.

The recalcitrant nature of chloroaromatic haloalkanes is due to the low electron density at the aromatic ring which makes the enzyme oxygenase unable to attack this compound. Many soil microorganisms (*Pseudomonas* and *Alcaligenes)* which synthesize the halogenase can utilize Halogenated alkonic acids [HAA].[22] Anaerobic methane-oxidizing bacteria can degrade TCE in pure *Pseudomonas* culture through a co-metabolic process.[23] The PCP-degrading *Pseudomonas* sp. strain IST 103 has been isolated, which was found to be capable of utilizing PCP as a carbon source. The enzyme PCP-4 monooxygenase was found to be responsible for the dechlorination of PCP.[24] The gene for the degradation may be plasmid encoded or present on the chromo-some.[25,26] Attempts have been made to enhance PCB biodegradation by modifying oxygenase.[27] One of the most efficient methods of biodegradation consists of sequential anaerobic and aerobic treatments for highly chlorinated compounds. Biochemical and genetic engineering approaches for dehalogenase and oxygenase could lead to “super bugs” that could be used for the bioremediation of chlorinated compounds.[28] Modified degradative genes could be introduced into the original strain and/or major indigenous strains isolated from contaminated sites, and it is hoped that these super bugs could have application in bioremediation in the near future, confirming their usefulness and safety. Raji et al.[29] have isolated a bacterial culture able to grow on benzoate and useful for remediation of PCB-contaminated sites. *Arthrobacter* sp. IFL YN 10 demonstrated mineralization of C^{14} ringlabeled atrazine. This isolates can be used to develop a consortium for bioremediation of pesticides.[30]

To improve the biodegradation efficiency and implementation, integrating various components such a microbial strain in consortium, solid O_2 source, and appropriate role of nutrients with controlled release pattern into a granule formulation with an oleophilic matrix, may provide an ideal approach to improve remediation of crude oil pollutants.[31] Abed et al.[32] reported that salinity and temperature are important environmental parameters that influence the degradation process of petroleum compounds. The inhibitory effect of salinity was shown to be more pronounced for aromatic than for aliphatic compounds.[33] Higher temperatures also reduce the viscosity of crude oil, which increases its diffusion through sediments, a process that render oil components accessible to bacteria. The possibility of the involvement of catabolic plasmid in the degradation of anthracene by *Pseudomonas* sp. isolated from an oil filling station was investigated by Kumar et al.[34] Many γ and β proteobacterial groups (*Halophaga, Geo-thrix*, *Acidobacterium*) and green non-sulfur bacteria with a strong potential to degrade hydrocarbons were present in benthic cyanobacterial mats.[35] The aliphatic fraction of petroleum hydrocarbon[36] is degraded by *Arthrobacter, Alcaligenes, Flavobacterium,* and *Bacillus*. Kniemeyer et al.[37] came across a green *Methanospirillium* that is able to degrade aromatic hydrocarbons. Singh and Lin[38] isolated 10 indigenous microorganisms from oil-containing soil; five isolates achieved 86.94% diesel degradation in 2 weeks. The results strongly indicate that the environmental condition of the contaminated site plays a crucial role in the degradation. Cohen[39] reported the development of cyanobacterial mats in oil-contaminated courts. Cyanobacterial polysaccharides play a major role in the emulsification of oil, actually breaking the oil into small droplets, which are subsequently attacked by the heterotrophs. Bioremediations of high fat and oil wastewater by selected lipase-producing bacteria such as *Bacillus subtilis*, *B. lichenformis*, *B. amyloliquifaciens, Serratia marcescens, P. aeruginosa,* and *Staphylococcus aureus* were carried out in wastewater from palm oil mill, dairy, slaughterhouse, soap industry, and domestic wastewater. After 12 days of bioremediation, the least biological oxygen demand and lipid content was observed in consortia, and the lipid degradation capacity of *P. aeruginosa* was higher than that of other bacteria.[40] Verma et al.[41] proved the biotechnological importance and advantage of using *P. aeruginosa* SL72 and *Acinetobacter* sp. SL-3 individually or as a consortium for waste treatment, resulting in substantial removal of the crude oil within a week, using a low-cost, efficient, and environment-friendly technique.

Spent wash is dark brown due to the recalcitrant melanoidin pigment. *Pseudomonas* sp. was selected for degradation of the pigment by Chavan et al.[42] Chuphal and Thakur[43] have characterized an alkalophilic bacterial consortium (*Micrococcus luteus*, *Deinococcus radiothilus*, *Micrococcus diversue, P. syringae P. myricure)* for *ex situ* bioremediation of color and adsorbable organic halogens in pulp and paper mill effluent. Nanda et al.[44] employed *Nostoc* sp. for bioremediation of tannery effluents; the main economic advantage of this system is the lack of a serious sludge disposal problem, consequently resulting in a much cheaper operating cost. No microorganism has been found to degrade polythene without an additive such as starch. The discovery of new enzymes and the cloning of genes for synthetic polymer-degrading enzyme from *Pseudomonas* sp. were reviewed by Premraj and Doble.[45]

Chemotaxis has been postulated to play an important role in enhancing biodegradation as it increases the bioavailability of pollutants to bacteria. Some toxic organic compounds are chemoattractants for different bacterial species, which can lead to improved biodegradation of these compounds. A *Ralstonia* sp. was chemotactic toward different Nitro aeromatic compounds (NACs), i.e., p-nitrophenol (PNP), p-nitrobenzoate (PNB), and o-nitrobenzene (ONB).[46]

Mycoremediation

The key to mycoremediation is determining the right fungal species to target specific pollutants. Certain strains have been reported to successfully degrade the nerve gases VX and sarin. Battelle in a plot of soil contaminated with diesel oil was inoculated with mycelia of oyster mushrooms; within weeks, more than 95% of PAH had been reduced to non-toxic components. Mycofiltration is a similar process using fungal mycelia to filter toxic waste and microorganisms from waste in soil. Breakdown (70%–100%) of anthracene oil found in PAH was reported in 27 days in an N_2-limited culture of *Phaenerochaete chrysosporium*. Pentachlorophenol is an important constituent of paper mill effluents, and *Phaenochaste chrysorperiucm* immobilized on rotating biological contactor disk efficiently degrades 2,4-dichlorophenol, 2,4,6-trichlorophenol (TCP), polychlorinated quiacole, and several chlorinated vanillins.[47]

Bioremediation of Inorganic Contaminants

Microbes encounter metals such as Cr, Mn, Fe, Co, Ni, Cu, Zn, Ni, Ag, Cd, Pb, and Au, and metalloids such as As, Se, and Sb, having a diverse nature, in the environment. Microbes can detoxify metals by valence transformation, extracellular chemical precipitation, or volatilization. Such microbes combat high concentrations of heavy metals by the following processes:

1. Inactivation of metals;
2. Alteration of the site of inhibition;
3. Enhancement in impermeability of metals; and
4. Other by-pass mechanisms.[48]

Bacterial biomass can also bioaccumulate heavy metals both in live and dead states through intracellular accumulation and extracellular absorption, respectively, giving an effective alternative for small-scale remediation purposes.[49] Bacteria can remediate heavy metals by a variety of mechanisms, including bioaccumulation, biosorption, and bioremediation (Figure 2). Bioaccumulation is the retention and concentration of a substance by an organism through the cell membrane into the cytoplasm, where the metal is separated and immobilized. However, in biosorption, the negatively charged metal ions are separated through adsorption to the negative ionic groups on the cell surface (carboxyl residue, phosphate residue, SH groups, or hydroxyl group) such as capsule or slim layers. The charged functional groups[50] serve as nucleation sites for the deposition of various metalbearing precipitatesi[51] *Bacillus* SJ-101 exhibits a much higher capacity of intracellular Ni accumulation, which is attributed to the anionic nature of its cell surface. In bioremediation, biologically catalyzed redox reactions lead to immobilization of metals. Microorganisms are known to reduce a wide variety of multivalent metals that pose environmental problems.[52,53] The reduced species are highly insoluble and precipitate out from solution.

Bioremediation is one such promising option that harnesses the impressive capabilities of microbes associated with roots to degrade organic pollutants and transform toxic metals. Since it is a plant-based *in situ* phytorestoration technique, it is proven to be economicaly efficient and easy to implement under field conditions.[54] All plant growth-promoting rhizobacterial strains (*Azotobacter chroococcum, Bacillus megatorium, B. mucilaginosus, B. subtilis* SJ-101, *Pseudomonas* sp., *P. fluorescens, Rhizobium leguminosarum, Kluyvera ascorbata* SUD165)[55] can be used for bioremediation of metals. Rhizobacteria associated with hyperaccumulators (*B. subtilis*, *B. pumilus*, *P. pseudoalcaligens*, *and Brevibacterium halotolerans*) are also widely used in bio and rhizoremediation of multimetal-contaminated sites.[56] The rhizobacteria are used or manipulated with three main objectives for bioremediation of metal-contaminated soils: 1) hyperaccumulation of metals in plants; 2) reduction of the uptake of metals; and 3) *in situ* stabilization of

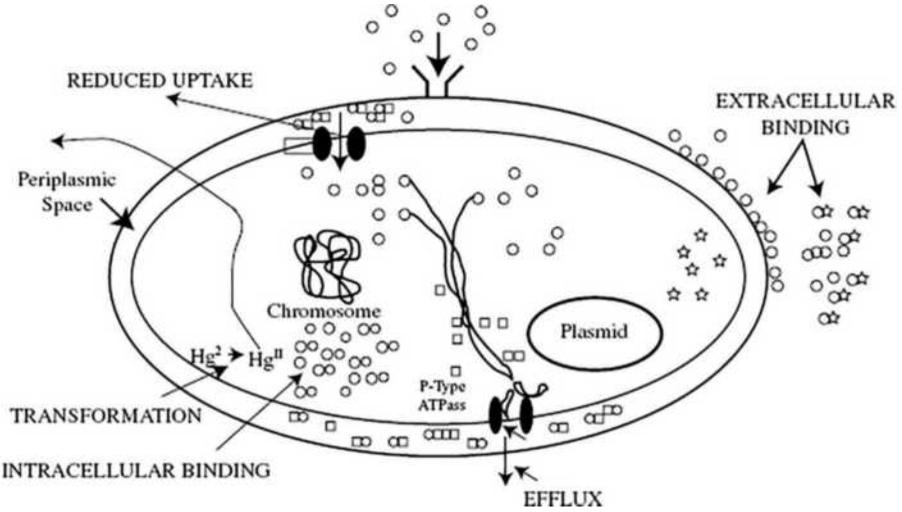

FIGURE 2 Different metal resistance mechanisms in bacteria.
Source: Singh and Srivastava.[66]

the metals as organocomplexes (Figure 2). The chemical conditions of the rhizosphere differ from bulk soil as a consequence of various processes induced by plant roots as well as by rhizobacteria,[57] such as secretion of organic acids followed by reduction in pH and production of siderophores, phytochelains, amino acid, and ACC deaminase. *Pseudomonas maltophilia* was shown to reduce the mobile and toxic Cr (VI) to non-toxic and immobile Cr (III) and also minimize the environmental mobility of other toxic ions (Hg, Pb, Cd).[58] Al Ayely et al[59] studied the effect of increasing levels of As and P on fern injected with mycorrhiza. The greater diversity of plant species may be responsible in part for the greater bacterial diversity in the bulk soils.

Redox Reaction Leading to Immobilization

The direct enzymatic reduction of soluble uranium (Vi), Cr (Vi), and Tc (Vii) to insoluble species is well documented.[60,61] A number of Cr (Vi)-reducing microbial strains, including *Oscillatoria* sp., *Arthrobacter* sp., *Agrobacter* sp., *Pseudomonas ambigua*, *Chlamydomonas* sp., *Chlorella vulgaris, Zoogloea ramigera, P. aeruginosa*,[62] and anaerobic sulfate-reducing bacteria have been isolated from chromate contaminated soil water and sediment.[63]

Redox Reaction Leading to Solubilization

Solubilization of adsorbed and co-precipitated metals may occur by direct or indirect microbial processes. The solubilization of toxic heavy metals and radionuclide from coprecipitates requires at least partial solubilization of oxide minerals.[64] Presumably, the organic acids formed by the metabolic activity of microbes lowers the pH of the system so that it interferes with the electrostatic forces that hold heavy metals and radionuclides on the surface of iron or Mn oxide minerals. Extracellular polymeric substances serve as biosorbing agents by accumulating nutrients from the surrounding environment, and also play a crucial role in biosorption of heavy metals. Being polyanionic in nature, exopolysaccharide forms complexes with metal cations, resulting in metal immobilization with the exopolymeric matrix.[65] Biofilm formation is a strategy that microorganisms might use to survive a toxic flux in these inorganic compounds; biofilm populations are protected from toxic metals by the combined action of chemical, physical, and physiological phenomena, which are in some instances linked to phenotypic variations among the constituent biofilm cells. Harrison et al.[67] have prepared a multifunctional model by which a biofilm population can withstand metal toxicity by the process of cellular diversification.

An effective ecofriendly approach for the removal of Mn from e-waste by the fungus *Helminthosporium solani* was shown by Savitha et al.[68] through the process of nonmetabolism-dependent biosorption under different environmental conditions of metal concentration, pH, and dry biomass concentration. “Metallothionein” has become a generic term applied to low molecular weight proteins or polypeptides that bind metal ions in metal thiolate clusters, and whose synthesis increases in response to elevated concentrations of certain metals.[69] The maximum cobalt removal efficacy (1 μg of ^{60}Co/g, dry wt) of bacterial mass (*B. megaterium, P. putida, Flavobacteriuam devorans, Salmonella typhimurium, Streptomyces gresius, Rhizopus* sp., *Rhodococcus* sp., *E. coli*) could be achieved within 6 hr[70] compared with the 8–500 ng/g attained after 24–48 hr. The gum kondagogu, a natural carbohydrate polymer, was investigated[71] for its adsorptive removal of the toxic metal ions Cd^{2+}, Cu^{2+}, Fe^{2+}, Pb^{2+}, Ni^{2+}, Zn^{2+}, and Hg^{2+} present in industrial effluents. Kondogogu has a potential to be used as an effective, non-toxic, economical, and efficient biosorbent cleanup matrix for the removal of toxic ions with re-adsorption capacity at 90% level even after three cycles of desorption. *Klebsiella oxytoca* was able to biodegrade cyanide to a non-toxic end product (ammonia) using cyanide as the sole N2 source, which might preceed using ammonia as an assimilatory substrate.[72]

Microorganisms interact with radionuclides via several mechanisms (Table 3), some of which are used as the basis of potential bioremediation strategies. Based on the different types of effluents generated, a single technology cannot be suitable to address the problems. Cyanobacteria have the capacity to utilize nitrogenous compounds as well as phosphates; in addition, they pick up metal ions such as Cr, Co, Cu, and Zn very effectively. It has been observed that immobilized cyanobacteria have greater potential than their free cells. Various natural polymers such as alginate agar and carrageenan, and synthetic polymers such polyacrylamide and polyurethane have already been tried.[73] Novel methods of immobilization, including coimmobilizations of various species, are required for the symbiotic interaction among themselves, which will result in synergistic enhancement or removal capabilities. A gene cluster composed of nine open reading frames involved in Ni^{2+}, Co^{2+}, and Zn^{2+} sensing and tolerance in *Synechocystis* sp. PCC 6803 has been identified by Mario Garcia et al.[74] The biosorption of Hg^{2+} by *Spirulina platensis* and *Aphanothece flocculosa* was studied under a batch stirred reaction system,[75] and more than 90% from *A. flocculosa* and 100% mercury recovery from *S. platen-sis* can be achieved for 4 and 1 cycle, respectively. Protein and total non-protein thiols were measured as stressresponsive metabolites in response to Ni in *Anabaena doliolum*.[76] As *A. doliolum* is a high-biomass-producing strain, it can be conveniently separated from the solution by filtration and can be used at pilot-scale removal of Ni from wastewater.

Phytoremediation: A Beneficial Alternative

Phytoremediation is a promising green technology for accelerated decontamination of soil and water. It is a natural process in which plants are used to remove pollutants (pesticides, solvents, explosives, crude oil, PAHs) from soil and water. Plants can degrade or transform both the organic and metal (landfill leachates and radionuclide) contaminants by acting as filters or traps. Plants and associated microbes can degrade the pollutants or at least limit their spread in the environment. There are several ways in which plants can be used for the phytoremediation of organic contaminants viz. phytoextraction, phytodegradation, rhizodegradation, and phytovolatization (Figure 3). They can be compared to solar driven pumps for extraction and concentration of elements from the environment.[4] The plants can also be used for "phytomining." Rugh et al.[77] inserted an altered mercuric ion reductive gene (*mer A*)

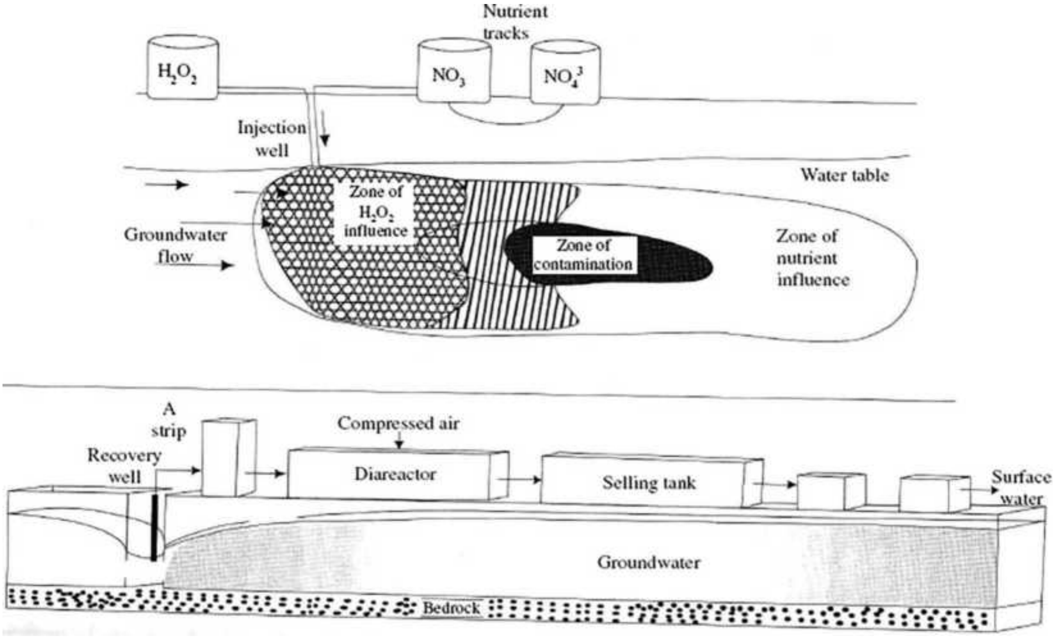

FIGURE 3 ***In situ*** bioremediation processes of bioaugmentation and biostimulation.
Source: Thakur.[81]

into *Arabidopsis thaliana,* creating a transgenic plant that volatilizes mercury to the atmosphere. Phytoremediation depends on a variety of factors, including physical conditions, chemical properties of the contaminant, and relative tolerance of the plant to the contaminant. Morphological characteristics of plant uptake are controlled by soil factors such as clay content, organic matter, soil moisture, and pH. The plant root can alter the pH in the rhizosphere by secreting organic acids, thus effecting the bioavailability of certain compounds, i.e., ionic pollutants whose solubility and desorption from soil colloids are pH dependent. Certain plants also produce biosurfactants that may increase the solubility of more lipophilic compounds.

Rugh[78] reported laboratory model plants such as *Thale cress* and tobacco to enhance phytoremediation of organomercurials, TCE, and nitroaromatic explosives that have been engineered with a non-plant transgene. Hyperaccumulator plants are also grown along with non-hyperaccumulators to enhance the heavy metal uptake by intermingling the roots and induce the colonization of efficient rhizobacteria. Recombinant *Mesorhizobium huakii*, by incorporating the phytochelatinase gene from *Arabidopsis thaliana* into *M. huakii* subsp. *rengei* 133, increased Cd accumulation by 1.5-fold in *Astragalus sinicus.*[79] The phytoremediation potential of water hyacinth (*Eichhornia crassipes*) in the treatment of tannery effluents was evaluated by Athaullah et al.[80] who found a promising risk reduction, cost-effective technology for water sanitation and conservation.

Bioremediation Technology

Bioremediation technology using microorganisms was invented by George M. Robinson in 1960. Bioremediation technologies can be generally classified as *in situ* or (microbial ecological approach) or *ex situ* (microbial approach) (Figure 3); some examples of these technologies include bioventing, land farming, bioreactor, composting, bioaugmentation, rhizofiltration, biostimulation, and solid phase bioremediation. In the development of the technology, the following points should be considered:

1. Heterogeneity of the contaminant
2. Concentration of the contaminant and its effect on the biodegradative microbe
3. Persistence and toxicity of the contaminant
4. Behaviour of the contaminant in soil
5. Conditions favorable for the biodegradative microbe or microbial population

Bioremediation is one of the most promising technologies for treating military sites, industrial wastes, municipal/urban wastes, mining waste, chemical spills and hazardous wastes, etc. *In situ* bioremediation can be implemented in many treatment modes, including aerobic, anoxic, anaerobic, and co-metabolic. The aerobic mode has proved to be most effective in reducing contaminant levels of aliphatic and aromatic compounds. Biofiltration is best suited for airstream containing volatile organic compounds.

Pollution remediation of tannery effluents is very complex. A multiprong treatment is thus required for a combination of nanotechnology and microbial technology, with a prior proceeding such as cycloning, flotation, microflotation, or electroflotation.

Bioremediation can be done on site, is often cheap, with minimal site disruption, eliminates waste permanently, eliminates long-term liability, has greater public acceptance, and can be coupled with other physical or chemical methods.[15] Table 2 shows the major factors affecting bioremediation. Another technique employed for bioremediation involves bioaugmentation, i.e., pumping genetically engineered microorganisms or microorganisms with enhanced degradation ability into the subsurface. Timely bioremediation of petroleum-contaminated soils is possible with innovative engineering and environmental manipulation to enhance microbial activity beyond the natural effective season.[82]

The first field slurry process used to remediate the nitroaromatic herbicide dinoterb used SABRE (sequential anaerobic bioremediation process), which was renamed as the FAST (fermentative anaerobic soil treatment) process.[83] Hence, the optimized remediation strategies exploring microbial diversity are being executed *in situ* successfully.

The aim is to translate research findings from the laboratory into viable technologies for remediation in the field. In the injection method, bacteria and nutrients are injected directly into the contaminated aquifer, or nutrient or enzymes are often referred fertilizer, that stimulate the activity of the bacteria are added. Bioreactors using immobilized cells have several advantages over conventional effluent-treatment technologies. Degradation of 4-chlorophenol by anaerobes attached to granular activated carbon in a biofilm reactor was evaluated during both open and closed modes of operation. Continuous flow fluidized bed reactor and bench scale continuous flow activated sludge reactor were used to study the removal of TCP, TeCP and PCP[84] which are used as sole source of carbon and energy. The ability of *Arthrobacter* cells to degrade PCP was evaluated for immobilized, non-immobilized, and co-immobilized cells. Fixed film bioreactor has been used with mixed bacterial communities for the treatment of pulp and paper mill effluent. The effluent after treatment showed a removal of color (80%), Chemical oxygen demand (71%), and chlorinated organic compound (68%).[85] The fungal slurry was successfully applied for compost preparation and biomediation of the Cr-contaminated tannery soil. The treated effluent was used for seed germination of crops without any phytotropic influence.[86]

Biocolloid formation methods have been adapted for bioremediation of metals by bacteria and fungi without the need *ex situ* treatment. Electrokinetically enhanced *in situ* soil decontamination and dispersing by chemical reaction together with microbes. Chlorophenol-contaminated saw mill soil used composting without bioaugmentation in a cheap and feasible method.[89] The use of biphenyl as an *in situ* co-substrate is expensive and environmentally problematic,[90] thus there was a need to investigate the ability of alternative cosubstrates to support the co-metabolic degradation to PCBs.

Biocapsules have been tested for various applications and can be produced for site-specific applications (Bioremediation Applied Bioscience http://www.bioprocess.com). *In situ* groundwater biodegradation in the United States has been carried out through various processes by numerous companies, as shown in Table 4. The removal effectiveness can reach 100% (Figure 4).

TABLE 4 In Situ Ground Water Biodegradation Examples of Process and Companies

S.N.	Name of Company	Technology Used	Types of Environmental Pollutant Remediated
1.	Bio-genesis Technology	Custom-blended microbial culture (GT-1000 series)	Oil, BTEX, diesel fuel
2.	Biopim	Biological sand filter	BTEX, TPH, phenol monochlorobenzene, metals
3.	ENSR Consulting and Engineering Technology (remediation beneath building foundation)	Steam injection, soil vapor extraction, ground water extraction, and air stripping	TCA, TCE, DWAPLS
4.	Petro Clean Bioremediation System	Indigenous microorganisms	Gasoline, diesel fuel, aviation fuel, solvents, PNAs, VOCs, and other organic compounds
5.	Kemron Environmental Services	Engineered, site-specific, groundwater recirculation system	Petroleum products solvents, halogenated volatiles and semivolatiles, BTEX, polynuclear aromatics, and organic acids
6.	Remediation Technologies Inc.	Treating groundwater in saturated zone injection, recovery well, monitoring wells	Dissolved contaminants
7.	SBP Technologies	Encapsulated cell inserted into a well	PAH (high mol. wt.), chlorinated aromatics (PCP), and pesticides

Molecular Probes in Bioremediation

The traditional method of bacterial enumeration is often insufficient for monitoring the specific microbe's biochemical reaction in mixed microbial communities. It has became apparent that a significant number of microbes in these systems are viable but non-culturable. The catabolic enzymes, genes, and proteins expressed in the microbes can be exploited for the detection of the fate and effect of microbes in the bioremediation process.[91] Antibody- and fatty acid-based probes, nucleic acid sequences, and DNA probes can be used to detect genes in the bacterial genome or on plasmid, or to detect mRNA or tRNA. Other relevant techniques employed are PCR, repetitive sequence-based PCR, 16S rDNA, random amplified polymorphic DNA, and fluorescence *in situ* hybridization.[81] In a previous study, a specific synthetic PCR-amplifiable DNA fragment was introduced into a *Pseudomonas* chromosome to allow genetically engineered microbes to be identified easily.

The development of a new field of metabolic engineering involves the improvement of cellular activities by manipulation of enzymatic, transport, and regulatory function of the cell by using recombinant DNA technology. Advances in the field of genetic engineering, sequencing of the whole genome of several organisms, and developments in bioinformatics have speed up the process of gene cloning and transformation. Furthermore, many powerful analytical techniques have been developed for metabolic pathway analysis and analysis of cellular functions, such as gas chromatography (GC), gas chromatography-mass spectrometry (GC-MS), nuclear magnetic resonance, 2D gel electrophoresis, matrix-assisted laser desorption/ionization time of flight (MALDI-TOF), liquid chromatography-mass spectrometry (LC-MS), and DNA chips. Metabolic engineering is, therefore, an effort to improve the ability of microorganisms. Bioremediation require the integration of huge amount of data from different sources. Pazos et al.[92] developed "Meta Router," a system for maintaining heterogeneous information related to bioremediation in a framework that allows its query, administration, and mining. The system can be accessed and administered through a web interface for studying and representing the global properties of the bioremediation network. Bioinformatics require the study of microbial genomics, proteomics, systems biology, computational biology, phylogenetic trees, and data mining, and the application of major bioinformatics tools for determining the structure and biodegradation pathway of xenobiotic compounds. Bioinformatics has taken on a new glittering by entering the field of bioremediation.[93] The limitations of bioremediation has paved the way for the development of Genetically engineered microorganisms (GEMs), or designer biocatalysts harboring artificially designed catabolic pathways.[94] Database such as the University of Minnesota Biocatalysts/Biodegradation database provide a scope for *in silico* designing of biocatalysts for in vivo construction followed by *in situ* application. In the era of functional genomics, it is easy to construct GEMs by reshuffling the gene(s), promoter, etc., to enhance their performance in situ.

Conclusion

The popularity of bioremediation is further enhanced because it is perceived as being more "green" than other remediation technologies. As a result, bioremediation companies have a viable future regardless of the long-term effectiveness of the process. Special emphasis is required on the exploitation of biotechnological innovations to improve presently available biocatalysts, and for the evaluation of future effects of microorganisms and their proper application in the optimization of *in situ* bioremediation. The use of enzymes for degradation of pesticides can be developed as a technology for bioremediation. A super strain can be created to achieve the required result in a short time frame. One important characteristic of this technology is that it is carried out in a non-sterile open environment, which contains a host of microbes. Therefore, a strategy should be tailored in such a manner that due consideration be given to the various environmental constraints (type and amount of pollutant, climatic condition, hydrogeodynamics) that affect a particular location. Feasibility studies are essential and can have an enormous impact on the cost of full-scale remediation. Rhizoremediation can contribute to the restoration of polluted sites. Phytoremediation will require an integration of activities by plant scientists, microbiologists, chemists, and engineers, so that these systems that can be used to prevent and remediate pollution can become a reality. Environmental friendly processed need to be developed to clean up the environment without creating harmful waste products. For the development of economically usable technologies, scientists and technologists would have to offer creative solutions for either introducing new capabilities or enhancing current efficiencies.

Introduction: Biological Waste (Biowaste)

Solid waste composition has varied since ancient times depending on the activity that originates it. One of the most important fractions is municipal solid waste (MSW), which represents a heterogeneous collection of wastes produced in urban areas, the nature of which varies from region to region.

Biowastes (biodegradable wastes) arise from living or once-living sources from several human, agricultural, horticultural, and industrial sources, in three groups—waste of directly animal origin (manures), plant materials (grass clippings and vegetable peelings), and processed material (food industry and slaughterhouse wastes and paper and paperboard wastes)—and include any waste that is capable of undergoing anaerobic or aerobic decomposition. Different terminologies have been applied to this kind of waste, such as *putrescible, green, food, yard, biosolids, garden,* or simply *organic wastes,* but chemically speaking, biowaste is characterized by high carbon content in the form of cellulose, hemicelluloses, and lignin, or even proteins and fat, that can be biologically degraded into carbon dioxide, methane, and water.[1]

Disposal Problems Associated with Biowaste

Disposal of biowaste either through uncontrolled landfill or if abandoned, presents some health and pollution issues that should be addressed. In fact, as biowaste is biologically degradable, it is a free food source for every kind of microorganism, including pathogens that could endanger an entire population.

Leachate

As water percolates through biowaste, it leaches out inorganic and organic compounds, with the risk of soil and groundwater contamination. Also, some persistent pathogens that can be found in long-term deposits of biowaste could endanger population. Landfill leachate is an organicrich liquor that is an excellent food source for heterotrophic microorganisms, but being so concentrated, its treatment is hardly achieved. Also, the existence of heavy metal contamination is toxic to microorganisms that could otherwise be successful in performing the leachate treatment.

Methane

The second pollution issue from disposal of biowaste is that methane (CH_4) is produced under anaerobic conditions that naturally occur in landfills. The problems with methane are that it is a greenhouse gas, with more than 20 times the damaging effect of carbon dioxide (CO_2), and that it remains in the atmosphere for approximately 9–15 years.

Regulatory Issues of Waste Management

Europe is committed to recycling as one of the main objectives of the waste management policy. Through recycling, materials contained in solid waste are reintroduced in the production cycle, leading to raw materials and energy savings and reducing the cost of landfill disposal.[2] Current European Directive on solid waste management[3] demands that countries adopt appropriate waste treatment methods, aiming to reduce the amount of waste sent to its final destination—landfill. Taking this into consideration, waste valorization through reusing and/or recycling, or by using other processes (energetic, organic), is also intended. The organic fraction of solid waste can be valorized by composting or anaerobic digestion and, according to the established in the Council Directive on the landfill of waste,[4] should be diverted from the flux of wastes to landfill. Taking the year 1995 as baseline, member states should reduce landfilling of biodegradable MSW to 75% by 2010, to 50% by 2013, and to 35% by 2020.

The organic matter (OM) in solid waste (currently constitutes about 40% of the MSW in Portugal, 25% in the United States,[5] almost 50% in Abu Dhabi City,[6] 50% in France,[7] and almost 77% in Brazil[8]) can be recycled to useful products (compost, methane gas, etc.,) through biological treatment processes. MSW valorization is mainly achieved by recycling constituents such as glass, metals, plastics, paper and cardboard, and OM, which is only possible when these residues are mostly collected selectively, although construction of mechanical biological treatment (MBT) facilities, comprising screening and other physical separation units, can contribute to the achievement of the established targets.

Composting is seen as a valuable recycling process for the organic fraction of MSW (OFMSW) and, thus, is of particular importance given the already existing systems and the potential to grow. Nevertheless, in the European Union (EU), it was not yet possible to come to an agreement on biological treatment of biowaste, in spite of the long work that has been done and that resulted in the publication of a Working Document on Biological Treatment of Biowaste in 2001.[9] This is not only due to the enormous differences in the degree of development of waste management of the various member states but also, in part, due to the existing lobbies.

Biological Aerobic Waste Treatment: Composting

Composting is the biological process used most often for the controlled aerobic conversion of OFMSW and any kind of solid and semisolid organic waste to a humus-like material, known as compost. Overall, the composting process can be represented by the reaction in Figure 1.

This exothermic process is realized in the presence of oxygen by a biological consortia of microorganisms and takes place in two distinct phases: a first phase, in which predominantly thermophilic biochemical degrading reactions occur (temperature rises as a result of the heat produced biologically), and a second phase, in which the humification/stabilization processes occur.[10,11] (Hogan and collaborators[12] suggested that the temperature rise results from the low thermal conductivity of waste.) Compost resulting from this process is a stable product, free of pathogens and plant seeds that can be applied, with benefits to the soil. This definition is intended to distinguish the composting process from the ordinary decomposition that occurs in nature.[13] Moreover, Bertoldi[14] clarified that the stabilization phase corresponds to a humification process that can be prevented under conditions of oxygen scarcity and substrate inadequacy.

Depending on the feedstock nature, the nitrogen, phosphorus, and potassium content of the compost may be insufficient for its classification as an organic fertilizer, allowing instead for its usage as a soil improver. This means that compost properties allow for soil pH amendment, acting as a source of OM that can enhance the water retention and cation exchange capacity of the soil and improve soil aeration.[15]

These are the reasons why composting is currently known as a process of recycling the OM in the solid waste and why using compost in soil represents the reintroduction of OM in soils, reducing erosion and thus desertification that is increased due to intensive land use.

Composting can be successfully applied to garden waste, separated MSW, mixed MSW, co-composting with sludge from urban and industrial wastewater treatment plants (WWTPs), and agricultural and livestock residues.

Composting Backgrounds

Organic soil correction with agricultural and livestock waste dates back to the utilization of soil for crop production, having been the principal means of restoring the nutrient balance in soil.[16] Composting is known, for a long time, by farmers as a method that allows obtaining an organic fertilizer from domestic waste. There are records of composting in piles in China for more than 2000 years, and there are even biblical references on the practice of soil correction. About 1000 years ago, Abu Zacharia described these procedures that have been practiced 3000 years earlier in the manuscript of *El Doctor Excellente Abu Zacharia Iahia de Sevilla,* translated from Arabic into Spanish by the order of King Carlos V, and published in 1802 as *El Libro de Agricultura.* In this book, Abu Zacharia insisted that animal manure should not be applied too fresh or directly to the soil, but only after mixing with 5 to 10 times its weight of vegetable and animal bedding waste.[17]

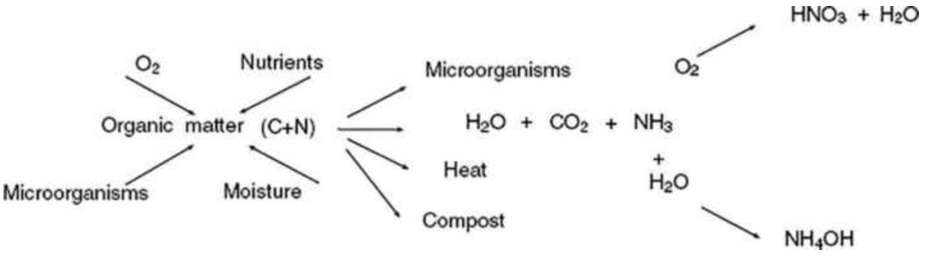

FIGURE 1 Schematics representation of the composting process.

In the growing cities in Europe, during the 18th and 19th centuries, farmers exchanged their products by MSW, using them as soil improver. Until the mid-20th century, MSWs were almost completely recycled through agriculture and did not pose an accumulation problem.[17] Composting of organic wastes and residues was envisaged as more of an art than a science until about the 1930s. By then, several developments of mechanical or intensive systems were achieved in Europe (Itano process in 1928, Beccari in 1931, and VAM in 1932). The Europeans continued to develop and install composting systems in Europe, South America, and Asia, and it was only in 1974 that the U.S. Department of Agriculture at Beltsville, Maryland, developed the "static pile" method that was currently used until the 1990s in the United States.[18]

By the end of 1960, composting was considered an attractive process for stabilization of the OFMSW with the final product being sold profitably as soil improver.[19] However, by the end of the same decade, composting was no longer that interesting for MSW management, not only due to the lower quality of solid waste but also due to the lack of market for compost. Recent stress on usage of less environmental impacting methods has redirected interest into the composting process, particularly concerning the recycling of MSW and urban and industrial WWTPs.

Despite the fact that implementing this process to agricultural wastes is ancient, scientific support was only established in the early 20th century, mainly due to the work done by an English agronomist (Sir A. Howard, 1924–1931) in Indore, India. This agronomist established the fundamental principles for the maintenance of a microbial population in optimal conditions of activity: the need to mix vegetable and animal wastes, the need for neutralization of the fermenting biomass, and the need for provision of adequate amounts of air and water. Thus, materials were stacked in piles (windrows) that have a dimension of 9×4.2 m and a height of 60 cm, which allows for maintaining adequate levels of heat and humidity.[20] Construction of these windrows was made by successive layers of waste (manure, soil, and straw) and moistening them conveniently. Windrows were revolved 16, 30, and 60 days after the start of the procedure that needed 90 days before completion and incorporation of the product in soil could be done.

Although windrow composting was the most common practice, during 1950–1960, there was a huge amount of publicity for projects involving composting in reactors.[21,22] However, these projects had almost universally poor results and had an abrupt end due to bad performance and high economic costs. Bad performance was generally the result of an inadequate project or operation and not of the process or technology itself. In the 1950s, there were already more than 20 patented composting systems.[23] In this period, mechanical separation for removal of any non-compostable from the waste stream was initiated.[14]

Co-composting of MSW and biosolids (composting simultaneously MSW and sludge) has attracted increasing attention.[24] MSWs are used as bulking agent and the biosolids act as readily available nitrogen and humidity source. This technique was investigated and applied fully and systematically in the 1950s,[25,26] but moisture content (96%) of the digested solids was a limiting factor as biosolids dehydration was not frequent by then.[27]

In the EU, production of agricultural and food wastes exceeds 1 billion tons/yr, which is 3 times larger than the production of sludge and 6 times higher than the production of MSW.[28] Intensive livestock farming incrementation worsened the problem through production of large amounts of animal waste, often in specific locations. Despite this, the relatively reduced application of composting in the management of this waste should be noticed, especially when compared with the application of this process in the management of MSW.[29] This is probably due to the fact that the agricultural wastes are often applied directly to soil, without any previous treatment, and that composting is generally considered a process for pollution control rather than a beneficial and efficient process for nutrient recycling.

Taking into account the requirements of EU legislation regarding waste management and environmental protection, and because there is nowadays a greater awareness of the importance of controlling the loss of nutrients in the waste treatment processes, recently, there has been a greater research effort to develop strategies that can control gaseous emissions, stabilize OM, and ensure nutrient retention and the absence of toxic products or pathogens in the compost. There are currently several groups of European researchers working on specific issues of composting of livestock and agricultural waste (such as kinetics of composting of MSW, effect of the composition of agricultural waste on compost quality and composting kinetics, effect of contaminants on composting process and on compost quality, etc.), aiming to produce good quality compost.[24,29–34] It is expected and highly desirable an increase in the world-wide application of composting for the treatment of these wastes and the use of its compost for agricultural purposes.

Composting has been successfully applied, including for the waste treatment of animal slaughter and carcasses.[35] Mesquita[36] enumerated some composting projects, where different raw materials were successfully used, and Williams[37] identified several large-scale separate composting schemes implemented in Europe.

Advantages and Drawbacks of Composting

If correctly used, the composting process for MSW treatment presents several advantages. When it is a part of a MSW integrated management system, these advantages are even more important; thus, valorization of the OFMSW by the integrated management can be achieved, and consequently, the final product quality can be improved.

A relevant issue is that besides being a process of effective organic waste treatment, composting is also an excellent recycling process, retaining in the final product (compost) macro- and micronutrients that may return to the soil and supplement other energy cycles in nature.[38]

The main advantages of the composting process are as follows:

- Economy and natural resource preservation and reuse of OM and of macronutrients (N, P, K, Ca, and Mg) and micronutrients (Fe, Mn, Cu, Zn, etc.,) owing to composting being a recycling process.
- Environmental benefits as a result of elimination of air, soil, and water pollution due to proper disposal of organic wastes or their appropriate confinement in controlled landfills. Also, there are additional benefits from using organic compost (instead of artificial fertilizers and soil improvers): in the recovery of degraded, contaminated sites and salty soil, in reforestation, in soil erosion control, etc.
- Public health benefits, due to the elimination of pathogens. In developing countries, this issue contributes to child mortality control.
- As an offshoot of health benefits, e.g., prevention and elimination of diseases, economic benefits arise, contributing to the reduction of costs of treatment and increased productivity. Another benefit is the elimination of costs for land remediation of uncontrolled dump sites.
- Social benefits arise from the fact that in addition to eliminating the practice of using organic waste as food for animals, composting promotes employment either in the treatment units (selective collection, sorting, processing) or in compost utilization and application.

The main disadvantages arising from composting are as follows:

- Being a labor-intensive process, composting gives rise to operational costs (compensated with positive social impact).
- Producing compost from selective organic collection entails high costs.
- The possibility of compost contamination (if the adopted process is not technologically appropriate and poorly conducted).

Methods of Composting

Composting is a simple technology that requires a fairly low intervention and has modest initial, operational, and support costs. It can be very attractive to authorities charged with biowaste management but with reduced budgets.

There are many factors that can influence the decision on the specific details of composting methods that should be adopted, but composting of OM in MSW or similar materials will most naturally be based in one of two options, either source-separated biowaste or biowaste recovered from MBT plants. Either of these options will ultimately be put in practice in home composting systems or in centralized composting facilities.

While home composting takes advantage of many distributed and local production units, centralized or large-scale facilities comprise two large groups of systems, both open and closed.[39] Among open systems of composting, three types can be distinguished: windrow (or revolved piles), the static aerated piles, and vermicomposting.[30] Closed systems of composting include reactors (either horizontal or vertical) of different sizes and shapes equipped with different feeding and aeration systems, aimed at accelerating the startup of the oxidation process, especially in cold climate countries, thus allowing for a more efficient control of odor emissions and minimizing the land area requirements.[37]

The choice of a specific type of system relies essentially on socioeconomic factors, on the amount of biowaste to compost, and on its final destination. Open systems are generally more suitable for developing countries[40,41] and for agro/livestock facilities[42] due to their easier operation and lower mechanization, building, maintenance, and operational costs.

Processing of agricultural and livestock waste using any of these technologies not only presents substantial benefits from the health, economic, and environmental points of view but also allows for a safe and potentially useful final product that can be used as a soil conditioner, valorized as a fertilizer, or for the floriculture and horticulture industries. Its use for agricultural purposes is important, both in countries where soil is extremely poor in OM (such as those of southern Europe) and in countries where extensive use of inorganic soil fertilizers has endangered its structure.[40]

The most common technologies, particularly for composting the OFMSW and similar biowaste, are presented below.

Home Composting

Home composting is one of the most interesting ways of managing biowaste. In fact, while people compost at home, they are guaranteeing the removal of OM from MSW flux, thus facilitating the achievement of the goals established in the EU Landfill and EU Waste Management Directives, as well as contributing to the reduction of waste management costs by reducing the total amount of waste that needs treatment. Also, by using home-produced compost, households do not need to use other fertilizers or soil conditioners; hence, they also have lower garden maintenance costs. Home composting demands the direct involvement of households, leading to higher separation rates of other recyclables as well.

One of the biggest issues in home composting is the choice of the compost bin. Although there are several configurations available in the market (Figure 2), some of them are far more efficient than others

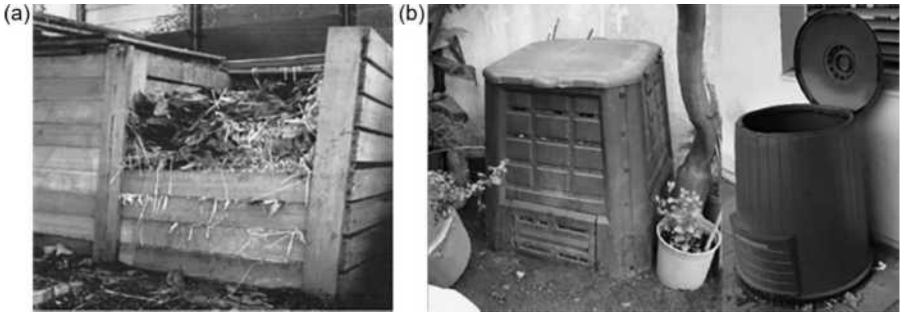

FIGURE 2 Home composters: (a) Wood, homemade, with two composting chambers, 1 m^3 each. (b) Commercial plastic, with openings for air circulation (0.4 m^3), offered by the Terra-à-Terra project.

and their cost is not always according to quality. In some cities, there are special programs that try to address this problem, reducing costs to the consumer. In Porto, Portugal, Lipor has been developing a project—Terra-à-Terra—that aims to promote organic waste reduction at the households of Lipor's municipalities. Householders with a garden or that work in companies with a garden in the project area can receive a free compost bin after attending a free composting training session. Through this project that started in 2007, more than 4500 composters have been delivered in 3 years, and it is estimated that there is a potential biowaste reduction of about 3000 tons/yr that will prevent the emission of 528 tons of CO_2 per year if this waste is treated at the energy recovery plant.[43]

Centralized Composting

Seasonal variation in the composition of the MSW requires a flexible and competent management of the composting system.[1,44] For this reason, careful choice of the system and a thorough control of the facilities are of primary importance.

Windrows

This technology is based on the Indore composting method. Rows of parallel piles of material with a height of 1.5–2 m and a width of 3–4 m are constructed until they reach 100 m or more. The shape of the piles is such that sufficient heat is generated to maintain temperatures while allowing for oxygen diffusion into the center of the pile, through natural convection. Batteries of piles must be constructed on an impermeable surface (e.g., cement) so as to facilitate the collection of leachate that eventually will form and so that piles can be easily turned. Windrows must be turned periodically (initially at the end of 5 days and then every 2 or 3 days), as shown in Figure 3. The convex shape of the windrows allows rainwater to drip along the surface and not infiltrate the pile of material. This system has some drawbacks such as being prone to anaerobiosis due to layer compaction, reduction of free space for aeration, and production of leachate that fills the remaining voids between particles, which further contributes to reducing aeration.

Aerated Static Piles

Piles are similar to those in windrow composting. However, the material is not mechanically aerated. Temperature control is achieved by natural air convection or forced aeration, either by introduction of compressed air or by vacuum induction (Figure 4).

The material for composting remains stacked during a very long period, which might result to collapsing and thus pore clogging. To prevent this, it is a common practice to mix biowaste with some bulking material (such as wood chips or sawdust) that should be more stable and have a higher particle size, thus providing a structure that will help prevent the material in the pile from collapsing. Aerated piles should be covered with a layer of compost or wood chips that confer some insulation, act as a biofilter, and reduce odor release.[42]

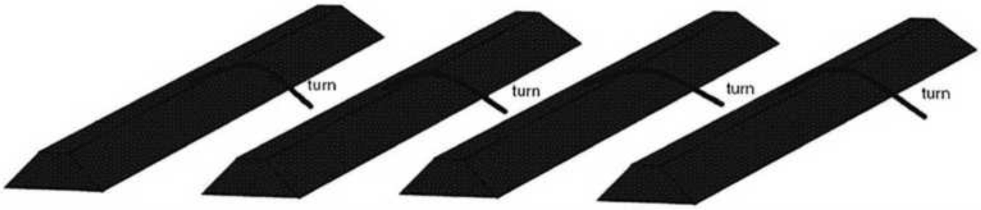

FIGURE 3 Schema of windrow composting and how to turn composting piles; the upper material will stay in the bottom after turning.

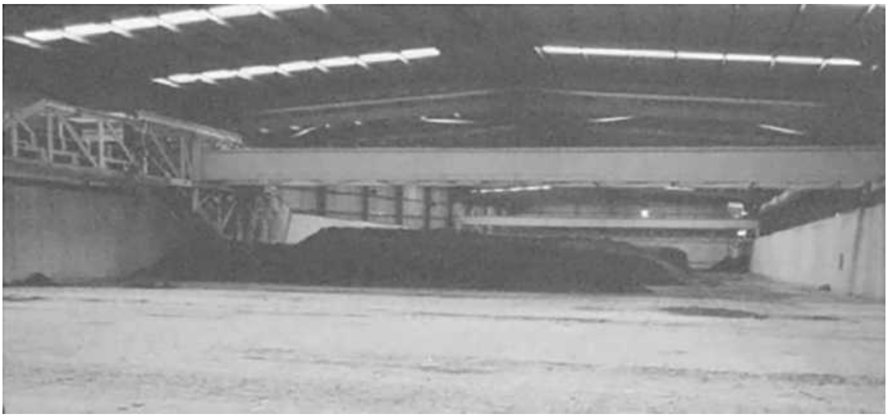

FIGURE 5 Indoor aerated static pile system with aeration through vacuum induction.

These composting technologies were traditionally implemented in open courtyards. Currently, and in regions where environmental conditions are particularly unsuited to this type of processing, these technologies are implemented in covered spaces or indoors (Figure 5), in which case, it is possible to perform air treatment in biofilters, achieving a dramatic reduction in odorous emissions.

In-vessel

Due to being enclosed, in-vessel systems allow for tighter control of temperature, moisture, aeration, and biowaste mixing. In-vessel systems include different configurations such as tunnels, rotating drums, reactor tanks, silos or towers, agitated bays and beds, enclosed halls, or even containers.[37] Although the operating systems are essentially the same as for windrows or aerated piles, these reactors are much more efficient, thus needing much less area.[1]

Silos or Towers

This technology is based on the use of silos or other types of structures with a height exceeding 4 m. These reactors are fed at the top, via a distribution mechanism, and the material progresses towards the bottom by way of gravity, usually after 14 days of composting. After this period, a curing time of ca. 2 months is needed to stabilize the compost.[42] Process control is commonly performed by air injection at the base of the reactor, moving upwards countercurrent to the biowaste (Figure 6).[47] Due to the great height of the reactor, it is necessary to use large airflow per unit surface area of distribution, which

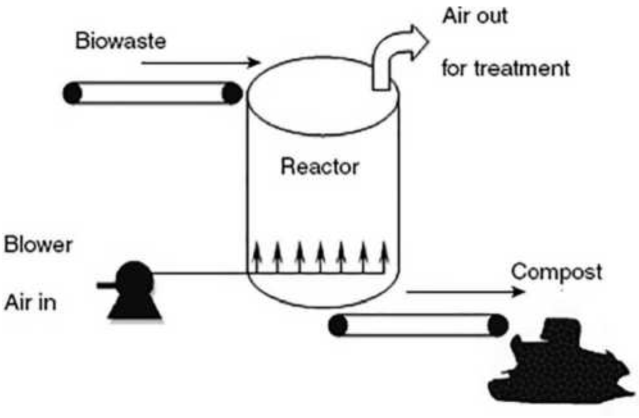

FIGURE 6 Schematic drawing of vertical reactors system for composting.

makes it difficult to control the process.[48] It is not easy to keep the temperature and oxygen at optimal levels, due to material compaction and to inexistence of mixing in the silo.[42] To minimize these problems, material should be thoroughly mixed prior to feeding the silo and air distribution and collecting systems must be improved, by changing the direction of airflow from vertical to horizontal between alternating sets of inlet and exhaust pipes.[44]

This type of reactor has been successfully used for composting of sludge from WWTPs (where the addition of bulking materials for porosity enhancement and a uniform feed facilitates process control) but is rarely used for processing heterogeneous materials, such as the OFMSW.[44]

Horizontal Reactors (Tunnels and Agitated Beds)

These reactors allow controlling the occurrence of high temperature, moisture, and oxygen gradients, which are frequent in vertical reactors, because air needs to travel lower distances through the material. There are a variety of configurations, comprising static or agitated reactors, with aeration by air injection or vacuum induction. Agitated systems usually take advantage of the revolving process to displace the material along the reactor continuously, while the static systems usually need loading and unloading mechanisms. Handling equipment can also grind the material, exposing new areas for decomposition, but excessive grinding can also reduce porosity. Typically, aeration systems are installed at the base of the reactor and can use temperature and/or oxygen concentration as control variables. The agitated systems with less than 2 to 3 m thick beds have been successfully used in heterogeneous MSW treatment (Figure 7, left).

FIGURE 7 Horizontal composting systems: (left) tunnel composting system composed of horizontal parallel beds; (right) turning machine for a tunnel composting system.

Tunnels are formed in long parallel channels (Figure 7, left), made of concrete walls with a movable porous floor, like a grid to allow for greater airflow (usually forced aeration) under the compost, and covered by a roof. Biosolids are revolved by a turning machine (Figure 7, right) running on tracks along the concrete walls between channels. The turner movement along the bed displaces the compost until it is ejected at the end of the bed.[49] The duration of the composting process is determined by the length of the bed and the turning frequency, ranging from 6 to 20 days, after which the compost must be further processed in windrows or aerated static piles for 1 to 2 months. Agitated bed systems operation ranges from 2 to 4 weeks; also, an extended curing period is needed to stabilize compost.[18]

Rotary Drums

In these reactors, biomaterial stays for only a few hours or days. Their effect is essentially homogenization and grinding of materials, only allowing start of composting by temperature control. As the reactors (diameter, 2 to 4 m; length, up to 45 m) have a slight inclination and have a rotating movement (0.5 to 2 rpm), the flow of material is continuous, countercurrent to the air supply; thus, the material leaving the reactor is cooled by fresh air and the material entering the drum makes contact with warm air, which favors bacterial growth (Figure 8).[42] These reactors are particularly interesting in processing the OFMSW for composting[46] as they allow for a faster startup of the process while reducing the malodorous emissions to the atmosphere. The DANO drum is a commercial rotating cylinder that has retention times of about 3 days with eventual interest in modern MBT plants. Most of the biological process has to be realized after leaving the reactor.

All of the systems described above can be used for composting different types of materials. Obviously, capital and operational costs of reactor processes are significantly higher than those of a windrow or aerated static pile process; thus, the residence time in the reactors is rarely enough to obtain mature compost. For this reason, a reactor is used in the early stages of composting to allow an easier control of the process, which facilitates odor emission reduction. After this processing, the material that comes out of the reactor must be stabilized in windrows or aerated static piles.[44] As the OFMSW treatment is difficult due to high cellulosic carbon content and sometimes low moisture and low porous structure, it may take as long as 6 months for compost maturation and stabilization, unlike compost from WWTPs that usually only takes 2–3 mo to be stabilized.

Vermicomposting

Vermicomposting is an alternative technology to conventional composting in which selected species of earthworms (*Lumbricus terrestris* and *Dendrobaena veneta*) and red worms (*Eisenia foetida,* Figure 9) eat organic material, absorb the nutrients they need, and excrete the rest, producing a humus-like material, known as vermicompost.[1,50] Vermicomposting should be applied preferentially to residues of fruit and vegetables, tea leaves, tea bags, coffee grounds, paper, and shredded green garden waste and has large application in agricultural wastes, including manure wastes.[51] Vermicompost produced from

FIGURE 8 Composting rotary drum: (left) side view and (right) view from the waste admission side.

FIGURE 9 *Eisenia foetida* in a home/commercial vermicomposter.

OFMSW is a "nutritive biofertilizer" 4–5 times more powerful than conventional composts and even better than chemical fertilizers for better crop growth and safer food production.[52]

Vermicompost systems can range from inexpensive wood or plastic boxes to sophisticated modular units (Figure 9) that are self-contained and fully automated to keep controlled environmental conditions while processing waste into earthworm castings. Open systems range from windrows or beds of variable scales to open field operations. Usually, windrows are built no more than 30 cm deep for easy aeration of the beds.[51] Vermicompost has the advantage of being a material that growers can produce "on-farm" and use as a biofertilizer, using own feedstock and implementing either a midscale vermicomposting unit technology or a modular unit.[1]

Worm beds can be as long as 50 m; feedstock can be the resulting product of a MBT plant, whereas OFMSW is processed in a rotary drum. Worms should be kept at temperatures of 10–35°C. Moisture is fundamental to worms; they breathe oxygen through their moist skin.[51] Resulting worm casts can be used as a biofertilizer as they contain 5 times more N, 7 times more P, 1.5 times more Ca, 11 times more K, and 3 times more exchangeable Mg than the soil. These casts are also rich in humic acids (which condition the soil), have a perfect pH balance, and have plant growth factors similar to those found in seaweed.[51]

Under the optimum temperature (20–30°C) and moisture (60%–70%) conditions for worm breeding, about 5 kg of worms (ca. 10,000) can process 1 ton of waste into vermicompost in 30 days.[53]

Worms can be easily recovered for further processing because they do not like light (a few hours of direct exposure to sunlight can cause paralysis or death), dryness, or even some specific odors (onions), migrating naturally for places where fresh wastes have been added. Worms can also be harvested by using a trommel screen.[54]

Vermicompost produced from organic wastes, such as food and yard wastes, have enormous economic potential for increasing crop yields, suppressing attacks from pests, and controlling the spread of diseases.[55–57]

Evaluation of a Composting System

Among the various criteria used for assessing the system efficiency, the most important for MSW composting are product quality, rejected ratio, and recycling rate. Compost quality can be evaluated by its appearance and by functional characteristics and the nature of the contaminants, characteristics that are critical for its commercialization. Rejected ratio and recycling rate affect the quality of the product, as they affect the contaminant's concentration and the amount of final waste that must be disposed off in landfill.

Compost quality should constitute the main objective of the composting facility. Some of the aspects of quality, such as the degree of maturation and size of particles, can be corrected at the end of the process by increasing the curing time and by using physical processes for particle size reduction. However, other issues may be far more difficult to remedy, as when there is chemical contamination.

A composting factor should be not only thoroughly thought about when conceiving the biowaste management system but also observed during the initial phases of processing. Chemical contamination can be caused by heavy metals or other chemicals, often from domestic hazardous waste. Contamination can also be of physical type; that is, the product may be contaminated with inert materials (glass, plastics and metals, brick and concrete, etc.,) that arise from domestic or commercial waste either voluntarily or by mistake. Removal of physical contaminants may not be very difficult from a technological point of view but represents a high fraction of the economic costs of a composting facility, which cannot be completely eliminated because even source-separated waste can be contaminated. However, the use of a source-separated raw material is of primary importance for high-quality assurance of the compost.

Phases of Composting

Throughout the composting process, the microbial population will vary and different types of microorganisms will play distinct roles during the various stages of the process.[38] Thus, in the first step, there will be predominantly mesophilic bacteria that hydrolyze the easily fermentable organic material. The reactions are exothermic, leading to heat release and temperature rise. Thermophilic microorganisms (bacteria, fungi, and actinomycetes) begin to develop on a large scale—from 40°C.[58] The thermophilic microorganisms multiply, and as soon as the temperature reaches 55–60°C, the attack on complex molecules (carbohydrates, proteins, etc.,) starts, which will result in their transformation into simpler products (simple sugars, amino acids, etc.,) that are used by other microorganisms (Figure 10). If there is no external control, the temperature of the composting material can reach 80°C, which represents the limit for the thermophilic population, resulting in microbiological activity inhibition and survival only of spores of bacteria. As degradation is reduced, and temperature lowers, mesophilic bacteria, actinomycetes, and fungi (mostly those that were in the outer areas of the pile) gain further activity, attacking the most resistant compounds (such as lignin and cellulose, the less readily biodegradable components of biowaste).[1] Complex enzymatic reactions are responsible for humus production, mainly by lignin and protein combination. At this stage, protozoa and some higher organisms (worms, nematodes, and millipedes) can be found in compost.

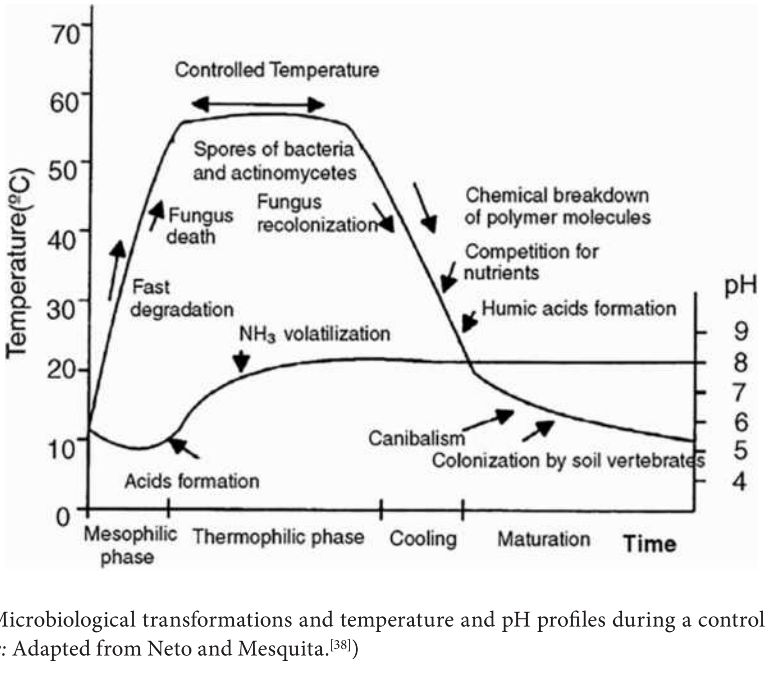

FIGURE 10 Microbiological transformations and temperature and pH profiles during a controlled composting process. (*Source:* Adapted from Neto and Mesquita.[38])

Process Parameters in Composting

Preparation of a composting process is not a simple task, especially for achieving optimal results. For this reason, in commercial applications, mechanization is a key factor, allowing for efficiently controlling the most important project factors (temperature, pH, moisture, C/N ratio, aeration rate, particle size, and mixing/turning).[58]

As any biological process, composting is conditioned by factors that affect the activity of the microorganisms involved in the process.

Temperature

Temperature is the process parameter that best describes the biological equilibrium and shows the efficiency of the process. Aerobic composting systems operate under mesophilic (20–40°C) and thermophilic (40–60°C) conditions that change along the process as a result of the respiration and metabolic activities of the organisms involved in the composting process.[1]

Temperature control of the composting material under static pile or in-vessel processes can be achieved through temperature monitoring and control of the air flow rate. In these processes, temperature can be controlled in the thermophilic range, around 60°C, which allows for the development of a more complex microbiological consortia, responsible for increasing the rate of decomposition of the OM (higher process efficiency), better compost sanitation or pathogen elimination, and elimination of weed seeds, insect larvae, and parasite eggs, among other advantages of the process.[38]

In windrow composting systems, temperature can only be controlled indirectly, by changing the turning frequency of the composting material. After turning, temperature lowers 5–10°C, rising again after only a few hours, as a result of the increase in oxygen availability. On the other hand, if temperature rises above 70°C, most of the microorganisms will die or enter the dormant phase, slowing the composting process and resulting to lower-quality compost. Also, high temperature can lead to humidity and nitrogen loss (through ammonia volatilization at a pH of 7.5).

In a system adequately controlled, temperature in the composting pile will rise up to 40–60°C from the second to the fourth day and will lower down to 35–38°C after 10 to 15 days because easily biodegradable organic material has already been converted. The increase in temperature also depends on factors such as nutrient availability, moisture content, particle size, aeration, turning of the pile, and the thermal insulation of the system (either exposed systems or confined systems).

Typical temperature profiles in non-controlled composting systems (with and without turning) are shown in Figure 11.

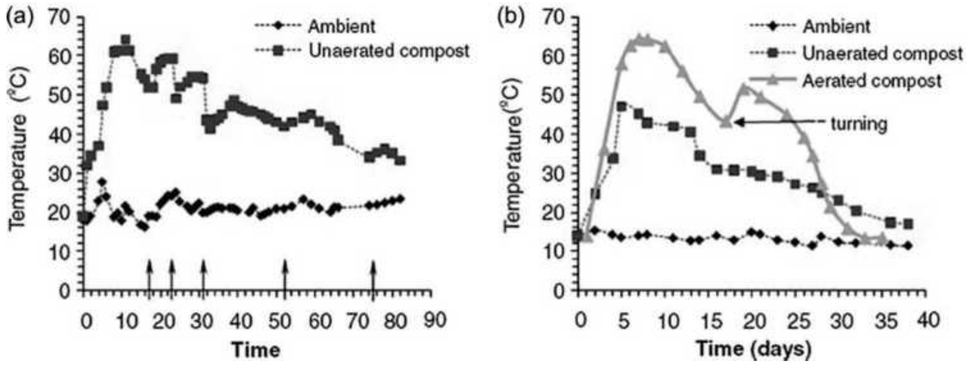

FIGURE 11 Typical temperature history observed in (a) windrow composting systems with turning[59] and (b) static piles with and without forced aeration.[59]

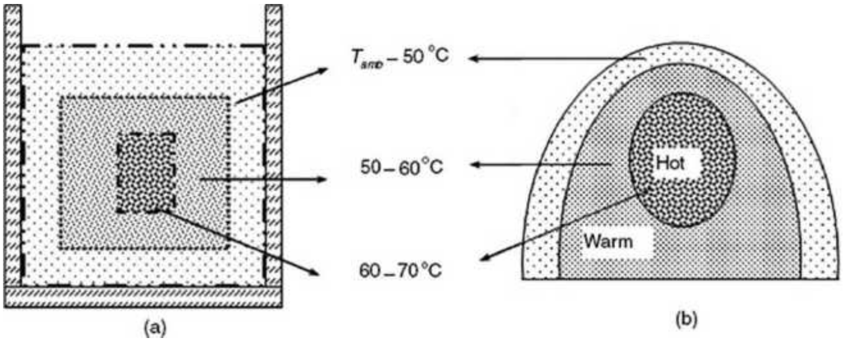

FIGURE 12 Temperature profile in a composting pile: (a) in-vessel/tunnel; (b) windrow.

It should also be noted that temperature is usually not uniform along the composting pile, the inner material having a higher temperature than the outer layers, as shown in Figure 12.

Moisture

Decomposition of the OM mainly depends on moisture content to enable microbiological activity. Microorganisms have, in their structure, about 90% water that is needed not only for new cell production but also and specially for the dissolution of the nutrients needed for cellular metabolism.

Moisture content can be adjusted either through mixing different materials or through water addition to an optimum between 40% and 70%. Below 30% humidity, composting rate dramatically decreases, but more than 70% moisture content may lead to pore filling with water, thus preventing oxygen from reaching the OM and inducing anaerobic conditions. This is why the most recommended value is 60%.[1,42]

Also turning of the composting material can help control moisture content. If the organic material has 55%–60% humidity and the composting period is 15 days, the first turning should be done on the third day and then every other day.[58]

Aeration

Aeration is very important in composting and holds two main functions: the first, and most important one, is to supply aerobic microorganisms with the oxygen they need for their respiration and metabolic activity, and the second function is to control temperature and, consequently, the rate of oxidation of the OM as well as odor emission.

Theoretically, the optimal rate of aeration would be the one that would allow for biological oxygen demand (BOD) supply during all the different composting steps. Nevertheless, parameters such as the nature of the composting material, particle size, aeration technology, moisture content, and porosity of the material in the pile may prevent full satisfaction of this requirement.[23] On the other hand, excessive aeration may cause excessive loss of humidity and heat leading to the misidentification of the end of the composting process.

In static pile systems, initial oxygen concentration in the pores is similar to that in the surrounding air (ca. 17%), because this is the air that was trapped in these spaces when the pile was built, whereas CO_2 concentration is significantly lower (ca. 0.5%–5%). As aerobic degradation occurs, oxygen concentration will decrease and CO_2 concentration will increase. Anaerobic conditions will develop at O_2 concentration lower than 5%, which can be prevented through introduction of air, vacuum induction, or turning of the material in the composting pile (which will also allow for a more efficient distribution of nutrients and microorganisms).

In systems with forced aeration, air flowrate and total air needed in the process are fundamental project parameters that help maintain the level of available O_2 very close to the required level throughout the whole process. The total amount of oxygen required and the total amount of CO_2 produced in the process can be estimated through the mass balance in Equation 1, where the composition of the OM for degradation and of the compost can be represented as $C_aH_bO_cN_d$ and $C_wH_xO_yN_z$, respectively.[58]

$$C_aH_bO_cN_d + 0.5(ny + 2s + e - c)O_2 \rightarrow$$

$$nC_wH_xO_yN_z + sCO_2 + rH_2O + (d - nz)NH_3 \tag{1}$$

with $r = 0.5\,[b - nx - 3\,(d - nz)]$ and $s = a - nw$.

If ammonia produced in the process is converted into nitrate (nitrification), some more oxygen will be needed, as estimated using Equation 2.

$$NH_3 + 2O_2 \rightarrow HNO_3 + H_2O \tag{2}$$

Particle Size

It could be expected that the lower the particle size of the organic material, the higher would be the rate of biochemical reactions, due to the increase in surface area exposed to microorganisms and to oxygen, which translates to the composting period being reduced. However, if particle size is too small, porosity will be reduced along with oxygen and CO_2 diffusion, which is fundamental during the thermophilic phase of the process, when oxygen consumption is higher.

An optimum particle size of 25–50 mm has been accepted for most of the materials, but this can vary between 13 and 75 mm depending on the nature of the composting material. A shredding operation may be needed prior to composting, which will entail an increased operational and financial cost.

Porosity of the composting material can be enhanced through introduction of bulking material that will allow for easier aeration while keeping structural characteristics that are essential for the construction of composting piles. Also, the height of the composting piles is based on particle size, in order to avoid excessive compaction during composting.

Feedstock Composition

The biomaterials used in composting have such a diversified composition that can usually supply all the elements that are fundamental for microbial metabolism (carbon, nitrogen, phosphorus, potassium, calcium, iron, copper, etc.).

Of these, the most important is undoubtedly the C/N ratio; an optimal ratio of 30/1 is recommended. Carbon is the source of energy and an essential factor for multiplication of cell material, and nitrogen is present (and available) in such an amount that it can be used for protein, amino acid, and nucleic acid formation.

Mixing of wastes with different compositions is usual since hardly ever a substrate has all the characteristics required for efficient and effective composting, leading to a compost with the recommended values of carbon/nitrogen ratio (C/N), moisture content, particle size, density, etc. Usually, these mixtures are prepared using carbon-rich vegetable waste and separate solid material (newsprint paper, manure, slurry or sludge, yard wastes) characterized by containing high levels of nitrogen, in order to obtain a C/N ratio of about 25/1 to 30/1[30] (Table 1). If the C/N ratio is lower than 30/1, there will be a loss of nitrogen as ammonia, causing malodorous emissions, but if C/N is higher than 80/1, nitrogen concentration will be so low that it will become a limiting factor. It must also be taken into consideration that in the OM, not all carbon will be in the readily available form, i.e., biodegradable, in contrast to nitrogen

TABLE 1 Nitrogen Content and C/N Ratio of Common Materials Used in Composting (Dry Basis)

Material	N (%, dry weight)	C/N Ratio[a]
	Food processing wastes	
Fruit wastes	1.52	34.8
Mixed slaughterhouse wastes	7.0–10.0	2.0
Potato tops	1.5	25.0
Coffee grounds		20.0
Vegetable wastes	2.5–4.0	11–13
	Manure	
Cow manure	1.7	18.0
Horse manure	2.3	25.0
Pig manure	3.75	20.0
Poultry manure	6.3	15.0
Sheep manure	3.75	22.0
	Sludge	
Digested activated sludge	1.88	15.7
Raw activated sludge	5.6	6.3
Wood and straw		
Lumber mill wastes	0.13	170.0
Oat straw	1.05	48.0
Sawdust	0.10	200.0–500.0
Wheat straw	0.3	128.0
Wood (pine)	0.07	723.0
	Paper	
Mixed paper	0.25	173
Newsprint	0.05	983
Brown paper	0.01	4490
Trade magazines	0.07	470
Junk mail	0.17	223
	Yard wastes	
Grass clippings	2.15	20.1
Leaves (fleshly fallen)	0.5–1.0	40.0–80.0
Tree trimmings	3.1	16
	Biomass	
Water hyacinth	1.96	20.0
Bermuda grass	1.96	24

[a] C/N ratio based on total dry weight.

that is readily available. Thus, lignocellulosic material that is rich in carbon is very hardly biodegradable, so when it is present, the most adequate value for the C/N ratio would be 35/1 to 40/1.[60]

During the composting period, C/N ratio slowly decreases because when OM is degraded, about 65% of the carbon is released as CO_2 and the remainder is used with nitrogen in cell, which is released only when there is cellular death. The final compost should have a C/N ratio of 15/1.

pH Control

Although authors agree that pH affects biological processes, composting studies using MSW and wastewater sludge where the initial pH of the composting material was varied have shown that a self-regulation of pH occurs;[10] thus, pH is not a critical factor in the composting process. Most of the times, there is no need for pH correction, although in few particular situations, lime can be added for pH correction.

Most of the bacteria involved in the process operate better in the pH range of 6 to 7.5, but fungi prefer a pH of 7.5 to 9. In the composting process, there is a pH variation across time. Thus, in the first phase of the process, simple organic acids are produced, lowering pH to 5 or even less. After only 3 days, pH starts rising up to 8–8.5, as organic acids are being further transformed. In the cooling phase, the pH of the compost will be slightly reduced until 7–8 (Figure 13). Ideally, pH must be less than 8.5 so that nitrogen loss (as ammonia) is minimized.[58]

Odor Control

Odor problems arise from development of anaerobic conditions that allow for formation of organic acids, or ammonia release, most of which are extremely malodorous. Nevertheless, material in the pile can act as a biofilter that retains and degrades part of these compounds.

Pathogen Control

Pathogen destruction is of primary importance in composting systems as it is affected by temperature profile and aeration process. Pathogens can be eliminated under different conditions (*Salmonella* is destroyed in 15–20 min at 60°C, but at 55°C, it will take 1 hr). As a recommendation, if biowaste is kept at 70°C for 1–2 hr, all pathogens will be eliminated. It should be noted that in the second stage of the composting process (humification), the *Penicillium* fungus that destroys pathogens, acting as an antibiotic, appears.

Most European countries recommend a temperature of 55–65°C for 4–15 days to guarantee compost sanitization.[1,58]

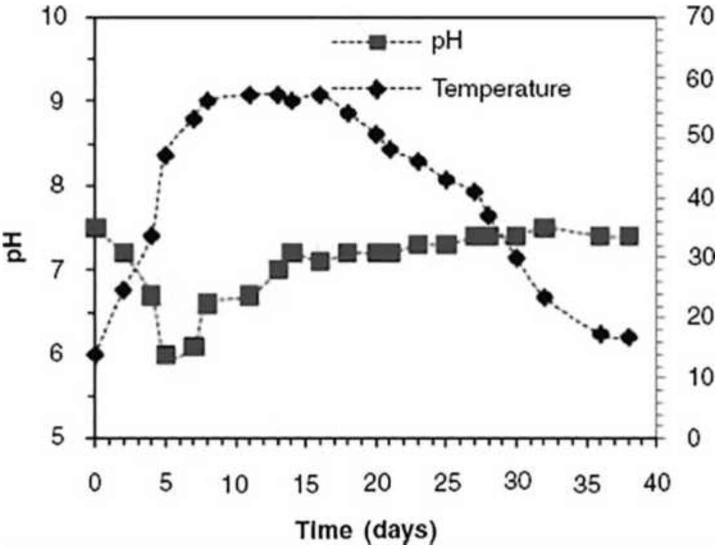

FIGURE 13 Typical temperature and pH range in windrow composting. (*Source:* Fonseca and Amorim.[59])

Evaluation of Maturation and Compost Maturity

As stated before, compost cannot be produced in record time; the length of the composting process depends on several factors, such as the feedstock material, particle size, nutrient balance, moisture content, and the composting technique. Although some authors and technologies claim to compost wastes in 7 or 20 days, this is not possible because compost produced in this time is not stabilized as total humification of the OM can only be achieved after about 110 days.[23] Thus, composting of garden or food waste materials can be successfully achieved in 3 mo under aerated, in-vessel, or even turned windrow systems but will take as long as 1 year in an unaerated static pile.

Compost maturation is fundamental in order to prevent ammonia liberation into the roots of cultures (at very low C/N ratios), biochemical reduction of soil nitrogen (when residual carbon in high C/N ratio compost is used by microorganisms), production of toxins that inhibit plant metabolism and seed germination, and microbiological activity that may lead to oxygen demand as well as other toxic effects to plants.[10]

The degree of maturation and stabilization of compost can be assessed using different methodologies: 1) final drop in temperature and self-heating capacity (the absence of temperature increase after turning and humidifying the biowaste up to 50% moisture content means that the process has ended); 2) amount of decomposable and resistant OM in the compost (lignin content higher than 30% means that compost is stable);[58] 3) chemical oxygen demand (COD) (a COD value below 350 mg O_2/g compost shows that the compost is stable); 4) oxygen uptake rate [it should be less than 40 mg of O_2 per kilogram of dry matter per hour for compost to be considered stable; a specific oxygen uptake rate (SOUR) test[61] can be performed]; 5) CO_2 production (it should be small, meaning that there is no significant microorganism activity); 6) C/N ratio (it usually decreases along the process, but it should be interpreted taking into account the initial characteristics of the OM and composting conditions. If OM has an initial C/N ratio of 35–40, the stabilized compost should have a C/N ratio of 18–20; however, if the initial C/N ratio is 10 or even lower as in manure wastes, an increase of the C/N ratio should be expected during the composting process);[17] 7) growth of the fungus *Chaetomium gracilis*;[58] and 8) the absence of ammonia in the compost and the presence of nitrates.[38]

Commercialization Issues

To be marketed, compost must have a uniform size; must be free of contaminants such as glass, plastics, and metals; and must be free from unpleasant odors. Typically, compost is a dark color product, has a wet soil smell, has a nice texture, and does not show the original raw material (Figure 14). The most common treatments before compost packaging are crushing and screening, although sometimes compost is commercialized as pellets.

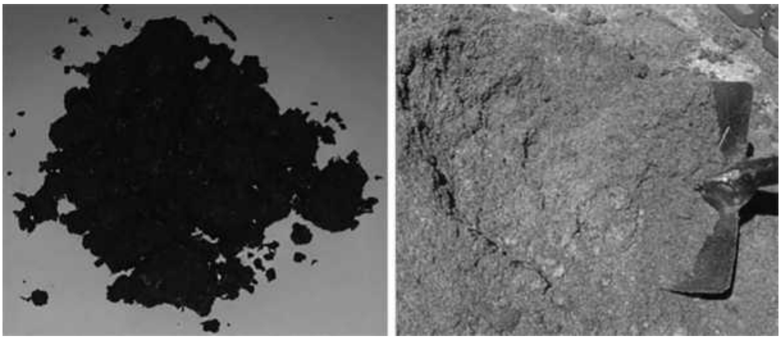

FIGURE 14 How compost looks like: (left) from OFMSW; (right) from co-composting of slaughterhouse with sawdust and agricultural waste.

Conclusion

Methods that can be used to perform composting over biowastes of different nature have been presented, from the simpler and less expensive ones, to some more sophisticated and expensive technologies. Most of the composting processes are based on reactions involving microorganisms, but worms can also be used to perform the same task of degrading OM and producing a stabilized and mature product (that is sterilized and of good quality) that can be used as a soil conditioner or fertilizer. With CO_2 and H_2O being the only by-products, composting can be considered environmentally benign and can contribute to OM recycling. The influence of the main operational parameters has been discussed, and it was shown that under appropriate conditions, almost any OM can be composted.

Insects and Mites: Biological Control

Ann E. Hajek

Introduction

Biological control is defined as the use of natural enemies to suppress a pest population, making the pests and their associated damage less abundant. Natural enemies were first used to control insect pests when farmers in ancient China and Yemen moved colonies of predaceous ants to control pests of tree crops. Today, the natural enemies used to control insect and mite pests include a diversity of predators, parasitoids, and pathogens. Specific strategies have been developed for release of natural enemies or enhancement of their persistence and activity. Biological control has been used very successfully for permanent suppression of introduced pests. Among natural enemies applied for shorter-term control in 1990, even the most widely used biological control agent, *Bacillus thuringiensis*, accounted for <1% of the insecticide market. However, biological control agents are widely used for control in environmentally sensitive areas or controlled environments and constitute important components of integrated pest management programs.

Strategies for Using Biological Control

Natural enemies can be used in a variety of very different ways. The first major uses of natural enemies for pest control were directed at control of introduced insect pests. Natural enemies from the land of origin of introduced pests were released in areas of pest introduction. This strategy, called classical biological control, now also includes introduction of exotic natural enemies to control native pests. In all cases, a high degree of host specificity is required in the natural enemies to be introduced. After the exotic natural enemy is established in the new location, its effectiveness is based on population increases in response to increasing densities of pest populations. Classical biological control can be dramatically effective, with 34% of insect natural enemies that are released becoming established and 17% completely controlling devastating pests. Classical biological control is known to be extremely cost effective with cost benefit estimates of up to 200:1, if a program is successful at establishing an effective natural enemy.

A second strategy, augmentation, involves releasing natural enemies for pest control, usually in instances where natural enemies can be effective but are not sustained in the environment at high enough densities to provide control. Inundative augmentation is used when only the natural enemies that are released in high numbers are expected to exert control. Under inoculative augmentation, control effects are more delayed and are predominantly exerted by the progeny of the released organisms. Natural enemies used for augmentation are often mass reared, so understanding requirements for mass production of high quality natural enemies that are healthy and active after shipment and release is critical for the use of this strategy.

The third major strategy, conservation, involves manipulations to enhance the persistence and activity of natural enemies already occurring in the environment. This strategy takes on a diversity of forms based on requirements of the individual natural enemies. To cause less mortality of natural enemies, use of synthetic chemical pesticides that kill natural enemies can be altered in different ways ranging from eliminating their use to selecting pesticides with less impact on natural enemies to timing pesticide applications to minimize the effect on natural enemies. Alternatively, natural enemy populations can be increased by maintaining or improving the environment to provide ideal conditions. For example, irrigating, strip-harvesting, intercropping, retaining vegetation adjacent to crops, and planting cover crops all have been shown to provide favorable habitats and food to maintain or increase populations of natural enemies. In a program to control the brown plant- hopper on rice in south and southeast Asia, the activity of a suite of native natural enemies, aided by host plant resistance and application of insecticides only when absolutely necessary, provided better control than pesticides alone.

Types of Natural Enemies

Predators

Predators are generally larger than their prey and each usually consumes several prey individuals either for growth of immatures or for subsistence and reproduction of adults. The predatory life style is very common among insects and mites but predators with the most importance for biological control belong to four insect orders (Hemiptera, Coleoptera, Diptera, and Hymenoptera) and eight mite families (Figure 1). Predators feed on a diversity of prey life stages, from eggs to adults, and display a range of host specificity, from feeding only on one prey species to generalized feeding on many prey species. One of the most famous examples of classical biological control is the introduction of the highly host-specific Vedalia beetle that was imported from Australia and released against outbreak populations of the introduced cottony cushion scale threatening the southern California citrus industry. After the 1888–1889 releases of this predator, cottony cushion scale populations decreased dramatically and, by 1890, scale populations had been decimated. The immense success of this early program was instrumental in building interest in use of natural enemies for biological control. As a second example, in more recent years, phytoseiid mites attacking tetranychid spider mites have been developed for mass release in greenhouses or on some outdoor crops. Pesticide-resistant mite strains have also been developed for use against spider mites attacking tree crops.

Parasitoids

Parasitoids develop at the expense of a single host and usually kill their hosts. Parasitoids have been used extensively for biological control because, in contrast to predators, the impressive degree of host specificity often characteristic of parasitoids leads to sensitive responses to changes in host density. Parasitoids used for biological control are predominantly in the Order Hymenoptera (Figure 2) with less common use of Diptera. The immature parasitoid is usually a featureless larva associated with the host while winged adults disperse to mate and find new hosts. To enable their close association with hosts, parasitoids have adopted amazing and diverse life cycles. Different species of parasitoids attack different life stages of hosts (egg through adult) and can develop either externally on hosts or internally within

FIGURE 1 An adult of the multicolored Asian lady beetle (Harmonia axyridis), which was introduced from Asia for control of aphids and scales (length ca. 1 cm). Both larvae and adults are predatory. (Photo by J. Ogrodnick.)

FIGURE 2 An adult of the parasitoid Muscidifurax raptor (length ca. 2 mm) parasitizing house flies. Females lay eggs in fly puparia, larvae grow while consuming the fly pupae and winged adults then emerge to mate and find more hosts. These flies can be purchased and released to augment naturally occurring populations. (Photo by S. Long.)

hosts. One to many parasitoid individuals of one or more species can develop within a host. Parasitoids have been more widely used for classical biological control than either predators or pathogens. In recent years, the tiny wasp Epidinicarsis lopezi was released by land and air in 34 countries in Africa to control the introduced cassava mealybug. Due to the activity of this wasp, cassava mealybug is no longer considered a problem, saving African farmers hundreds of millions of dollars in reduced crop losses. Some parasitoids widely used for augmentative biological control are tiny species of Trichogramma attacking eggs of Lepidoptera and Encarsia formosa, a member of the Aphelinidae that attacks whiteflies. Both of these tiny wasps are mass produced in insectaries and shipped to users for release against pest populations threatening crops.

FIGURE 3 Gypsy moth (Lymantria dispar) larvae killed by the entomopathogenic fungus Paecilomyces farinosus (each larva ca. 3 cm in length). When infecting, this fungus penetrates externally through the larval cuticle, then increases within the host and, after host death, grows out through the integument to produce spores that will infect healthy hosts. (Photo by T. Ebaugh.)

Pathogens

Microorganisms that are parasitic, referred to as pathogens, are masters at exploiting insect and mite hosts (Figure 3). Pathogens important for biological control include a diversity of viruses, bacteria, fungi, protozoa, and nematodes. This range of types of pathogens exhibits a comparable medley of diverse interactions with their hosts. Of primary importance, viruses, bacteria, and most protozoa must be ingested by hosts in order to infect, while fungi and some protozoa can penetrate directly through the host cuticle. The nematodes of greatest importance to biological control, Steinernema and Heterorhabditis, can enter hosts through body openings although some possess the ability to penetrate directly through the cuticle. While some pathogens have mechanisms for active dispersal to find new hosts, host finding is generally not directed and these pathogens rely principally on their production of huge numbers of progeny in order to be assured of locating healthy hosts. Associations between pathogens and hosts range from facultative to obligate but pathogens important for biological control are all specialized for infecting only insects and mites. Pathogens have been used for classical biological control relatively infrequently although some programs have provided complete control. Much of the development of pathogens has been directed toward inundative augmentation of mass- produced microbes. The bacterium *Bacillus thuringiensis* is applied more than any other biological control agent. Strains of this bacterium predominantly kill Lepidoptera, Diptera, and Coleoptera through the activity of a toxin destroying the integrity of the gut. For many years, this bacterium was applied principally as a spray but recently several crop plants have been engineered to express genes encoding the toxin.

Biological Control in Practice

There is great demand for use of biological control programs to eliminate insect and mite pests, especially in environmentally sensitive areas and areas where humans live. Use of natural enemies to control pests can be highly effective due to the diversity of types of natural enemies and approaches. However, because biological control involves management of living organisms, it can be somewhat unpredictable. Therefore, biological control programs generally are tailored to specific pest systems and to optimize control, often require knowledge of the biology and ecology of the insect or mite host. Biological control has proven to be most effective under certain conditions (Table 1), although these generalities should not prevent investigations of use of biological control for alternative situations.

TABLE 1 Characteristics of Systems and Conditions More Commonly Associated with Successful Biological Control

Highly efficient natural enemy
Less mobile pest living in an exposed location
Perennial crop, natural habitat, or controlled environment, for example, a greenhouse
Crop or environment where some pest damage is tolerated
Controls for other pests do not interfere with the activity of natural enemies

Introduced pests are not insignificant, comprising 39% of the 600 major arthropods pests in the United States. By 1990, more than 4300 introductions of exotic parasitoids and predators had been made to control insect pests, many of which were introduced. Due to its low cost and permanent effectiveness when successful, classical biological control continues as one of the first control strategies to be investigated after a new pest has been introduced.

Augmentation and conservation are now often employed as important parts of integrated pest management programs. Although since the late 1940s (the start of the DDT era), for most pests synthetic chemical pesticides have been the first control strategy considered, use of natural enemies for control is increasing, especially for specific applications and systems.

Invasion Biology

Jennifer Ruesink

Introduction

Biological invasions occur when species or distinct populations breach biogeographical barriers and extend their ranges to areas where they were not historically present.[1–3] Invasion biology concerns the causes and consequences of these new species, which are also referred to as invasive, introduced, alien, exotic, nonnative, or nonindigenous species.

Biological invasions occur in five steps: arrival, establishment, population growth, population spread, and impact (Table 1). Only a small proportion of species that arrive actually establish, and so forth; thus, each step acts as a filter for the invasion process. Successful invasion depends on characteristics of the invading species, recipient environment, and process by which the two are brought together.[4] However, no widely accepted method currently exists for identifying the characteristics that promote invasion a priori.[5]

TABLE 1 Reasons for and Responses to Five Steps of an Invasion

Step	Why?	Control
Arrival	Intentional releases, intentional imports, unintended hitchhiking (by product)	Risk assessment—choice of species, treatment, or quarantine of vectors
Establishment	Suitable abiotic conditions, available resources, propagule pressure	Reduce pathways, containment
Population growth	Intrinsic rate of reproduction, apomixis/vegetative reproduction	Early eradication
Population spread	Mobility—dispersal, home range size, transport by humans	Eradicate new populations, reduce human transport
Impact	Density (abundant resources), few enemies, per capita effect (new role), alteration of resource base	Effective screening prior to introduction; mechanical, chemical, or biological control; make environment less suitable

Why Do New Species Invade?

Species have always expanded their ranges, but the pace of invasion has accelerated recently due to increased human travel and trade.[5–7] Humans transport species in three ways: (1) on purpose, with the intention that they will grow in outdoor environments (fish and game, plantation trees, and biological control agents), (2) on purpose but with no intention that they will establish (pets, horticultural and agricultural plants, aquaculture, and sterile releases), and (3) accidentally (hitchhiking on packages, live imports, and people). The contribution of each of these main pathways varies among taxa. Of South Africa's weeds, 89% were intentionally introduced[8] but only 11% of insect invaders in North America were intentional.[9] Ducks, pheasants, pigeons, finches, and parrots have more introduced species worldwide than would be expected by chance because these bird families include many pet or game species.[10]

Which Species Invade?

Propagule Pressure

Species can invade a new area if abiotic (especially climatic) conditions are suitable and an exploitable resource exists. Those species that can invade, will invade if given sufficient opportunity.[11–13] High rates of arrival have been termed "propagule pressure" and can occur either through numerous releases or releases of many individuals. Some of the best evidence that propagule pressure affects invasion come from compilations of biocontrol introductions: the successful establishment of insect predators rose seven times when the number of introductions doubled, and releases >31,200 individuals were eight times more successful than those of <5000 individuals.[14]

Species Traits

For a given propagule pressure, some species may be more likely to invade than others. Traits promoting invasion could include the ability to increase rapidly from low density, a generalist diet, and broad climatic tolerance. Although statistical relationships between species traits and invasibility are often weak,[15] analyses of certain taxa introduced to particular environments have been successful.[16,17] For instance, invasive species of pines in South Africa tend to have small seeds, short intervals between reproductive bouts, and short times to maturity, whereas noninvasive species show the opposite traits.[18] For woody plants, those that have become invasive in North America often reproduce vegetatively, germinate easily, and have a long fruiting period.[19]

Where Do Species Invade?

In addition to species traits, characteristics of the recipient community may also influence the ease with which new species invade. Indeed, particular conditions in native environments (e.g., disturbance and species interactions) may select for species that are effective invaders of other areas, thus resulting in asymmetric patterns of invasion. For instance, European insects have invaded forests in North America but not vice versa,[20] and there has been a unidirectional appearance of tillering grasses in bunchgrass habitats worldwide.[21] Assemblages may be more resistant to invasion if they are undisturbed[22,23] or contain many natural enemies.[24,25] For many years, it was a rule of thumb that species-poor islands were invasible and species-rich tropics were not.[1] However, surveys of plant assemblages indicate that areas of naturally high species richness tend also to have numerous invaders, perhaps because soil and climate conditions are generally conducive to plant growth.[26] Although species richness per se may not influence invasion, loss of species could make systems easier to invade.

Habitat alteration (flooding, drought, fire, wind, eutrophication, and channeling) creates new conditions that are suitable for a new suite of species. These species are often introduced. For instance, western North America hosts many conspicuous invasive fishes in part because once fast-flowing rivers are now lakes separated by dams.[27] Roadsides in North America contain a high proportion of European plant species, probably because European plants have had millenia to evolve to take advantage of disturbance, whereas disturbance in North American habitats has risen recently.[28] Based on an Australian study of two invaders, both physical disturbance and nutrient addition improve the performance of invasive plants.[29]

Which Species Have Effects and Where?

Impacts of invaders relevant to pest management include the ecological and/or economic damage from pests and the effectiveness of biocontrol agents.[30] Impacts are expected to be particularly pronounced when species reach high abundances or have high per capita effects.[31,32] High abundances can occur when species escape limits to population growth (abundant resources or few enemies). High per capita effects may arise when a species plays a new role, especially by altering the resource base. For instance, many of the worst plant invaders of natural areas are nitrogen fixers (which alter nutrients) or climbing vines (which alter light).[33]

A disproportionate number of invasive species have harmful effects, more so if introduced accidentally rather than intentionally. In Japan, for instance, 8% of native insects are considered pests, but 72% of introduced insects are pests.[34] Of agricultural weeds in North America, 50–75% are nonindigenous.[6] On the other hand, only 1–6% of nonindigenous plant species in Great Britain have become weedy or widespread.[8] Some introduced species may be problematic due to an absence of natural enemies, but this escape from control does not appear to be entirely general. Based on a compilation of life tables for 124 holometabolous insects, mortality rates due to parasitoids, predators, and diseases do not differ for native and introduced species.[35]

Species introduced accidentally often have harmful effects, and, conversely, species introduced intentionally have beneficial effects less often than desired. Of 463 grasses and legumes introduced to Australia to improve pasture, only 5% have raised productivity.[36] About a third of established biocontrol insects actually reduce the target organism.[37] Although impact in the native environment is not necessarily a useful indicator of what a species will do once introduced, one indicator of potential impact is the fate of prior introductions.[19]

Pest status tends to be based on economic considerations, but introduced species also cause ecological damage. Invasive species contribute to endangerment of nearly 50% of species listed under the United States Endangered Species Act,[38,39] and they have dramatically altered the structure and function of ecosystems.[40,41] Ecological and economic effects have the same root causes—abundance and high per capita effects of invaders—but the affected habitats can be quite distinct. Only 25% of plants that cause problems in natural areas are also agricultural weeds.[33] Thus, screening procedures that keep out economic pests would fail to restrict many species that cause ecological harm.

Time Lags and Surprises

Introduced species have occasionally surprised researchers by expanding to previously intolerable places or irrupting after remaining localized and rare for many years. “Boom and bust” patterns have also been observed, in which an invader initially reaches high abundance and then declines, sometimes even going extinct. Tolerance of new conditions (e.g., temperature or host plants) may require genetic adaptation, which could result in time lags before invasion.[42] Of 184 woody species currently considered invasive near Brandenburg, Germany, 51% did not appear to be invasive until >200 years after their initial introduction.[43] However, only 7% of 627 cases involving biocontrol introductions showed time lags before population increase, whereas 28% increased and 27% went extinct immediately.[44]

Regardless of frequency, cases in which invaders have unexpected impacts have become well known, especially for biocontrol agents with nontarget effects such as feeding on endangered species (e.g., the weevil *Rhinocyllus conicus* on thistles and the moth *Cactoblastis* on *Opuntia* cacti)[45–47] or competing with natives (e.g., the ladybird beetle *Coccinella septempunctata*)[5]

Can Invasions Be Controlled?

The first steps of an invasion can be controlled by limiting entry or vigilantly eliminating newly established populations of invaders. For instance, an assessment of species associated with raw logs indicated a potential loss of billions of dollars due to forest pests if Siberian larch was not treated prior to import into the United States.[48] For many years, medflies (*Ceratitis capitata*) have epitomized the notion that "an ounce of prevention is worth a pound of cure." California spent $100 million to eradicate an incipient invasion in 1981, thereby preventing nine times that amount of crop damage. By 1996, however, medflies were apparently established and spreading. The extent of the invasion makes eradication unlikely.[49] Humans simply have to learn to live with these naturalized species.[50]

Control during the last steps of an invasion usually involves chemical, biological, or mechanical reduction of unwanted species in areas where effects are most serious. Control efforts at this stage would benefit from considerations of demography and behavior of invaders. For instance, seedling competition among annual plants is often fierce, so efforts to reduce seed production will not reduce plant numbers. Instead, control efforts should be directed at reducing seedling growth and survival.[51] Knowing how insects move among microhabitats could aid in trap placement or crafting habitats that promote desirable species and discourage undesirable ones.[52] Knowing encounter and feeding rates could aid in calculating the number of consumers necessary for effective biological control.

Species invasions are a form of ecological gambling in which the consequences of any particular introduction are uncertain, despite an emerging framework of factors contributing to high risk invasions. The influx of new species can be slowed by reducing pathways for introduction and intentionally introducing species only when beneficial effects will be large and native alternatives do not exist.[53] Distinct biotas are valuable and intriguing but increasingly difficult to maintain under pressures of globalization.

Contents

SECTION I APC: Anthropogenic Chemicals

SECTION II COV: Comparative Overviews of Important Topics for Environmental Management

SECTION III CSS: Case Studies of Environmental Management

SECTION IV DIA: Diagnostic Tools: Monitoring, Ecological Modeling, Ecological Indicators, and Ecological Services

SECTION V ELE: Focuses on the Use of Legislation or Policy to Address Environmental Problems

SECTION VI ENT: Environmental Management Using Environmental Technologies

SECTION VII NEC : Natural Elements and Chemicals Found in Nature

SECTION VIII PRO: Basic Environmental Processes

Preface

Given the current state of the world as compiled in the massive Millennium Ecosystem Assessment Report, humans have changed ecosystems more rapidly and extensively during the past 50 years than in any other time in human history. These are unprecedented changes that need certain action. As a result, it is imperative that we have a good scientific understanding of how these systems function and good strategies on how to manage them.

In a very practical way, this multi-volume *Environmental Management Handbook* provides a comprehensive reference to demonstrate the key processes and provisions for enhancing environmental management. The experience, evidence, methods, and models relevant for studying environmental management are presented here in six stand-alone thematic volumes as follows:

VOLUME 1 – Managing Global Resources and Universal Processes
VOLUME 2 – Managing Biological and Ecological Systems
VOLUME 3 – Managing Soils and Terrestrial Systems
VOLUME 4 – Managing Water Resources and Hydrological Systems
VOLUME 5 – Managing Air Quality and Energy Systems
VOLUME 6 – Managing Human and Social Systems

In this manner, this handbook introduces in the first volume the general concepts and processes used in environmental management. The next four volumes deal with each of the four spheres of nature (biosphere, geosphere, hydrosphere, and atmosphere). The last volume ties the material together in its application to human and social systems. These are very important chapters for a wide spectrum of students and professionals to understand and implement environmental management. In particular, the features include the following:

- The first handbook that demonstrates the key processes and provisions for enhancing environmental management.
- Addresses new and cutting-edge topics on ecosystem services, resilience, sustainability, food–energy–water nexus, socio-ecological systems, etc.
- Provides an excellent basic knowledge on environmental systems, explains how these systems function, and gives strategies on how to manage them.
- Written by an outstanding group of environmental experts.

Since this handbook covers such a wide range of materials from basic processes, to tools, technologies, case studies, and legislative actions, each handbook entry is further classified into the following categories:

APC: Anthropogenic chemicals: The chapters cover human-manufactured chemicals and activities
COV: Indicates that the chapters give comparative overviews of important topics for environmental management

- **CSS:** The chapters give a case study of a particular environmental management example
- **DIA:** Means that the chapters are about diagnostic tools: monitoring, ecological modeling, ecological indicators, and ecological services
- **ELE:** focuses on the use of legislation or policy to address environmental problems
- **ENT:** Addresses environmental management using environmental technologies
- **NEC:** Natural elements and chemicals: The chapters cover basic elements and chemicals found in nature
- **PRO:** The chapters cover basic environmental processes.

The third volume, with over 70 entries, hones in on soils and terrestrial systems, with chapters covering many aspects of agriculture and soil management and rehabilitation. The topic of erosion and desertification is covered by over 20 specific entries. New chapters on impacts of drought, pasture grazing, and climate impacts on soils are included.

Editors

Brian D. Fath is Professor in the Department of Biological Sciences at Towson University (Maryland, USA) and Senior Research Scholar at the International Institute for Applied Systems Analysis (Laxenburg, Austria). He has published over 180 research papers, reports, and book chapters on environmental systems modeling, specifically in the areas of network analysis, urban metabolism, and sustainability. He has co-authored the books *A New Ecology: Systems Perspective* (2020), *Foundations for Sustainability: A Coherent Framework of Life–Environment Relations* (2019), and *Flourishing within Limits to Growth: Following Nature's Way* (2015). He is also Editor-in-Chief for the journal Ecological Modelling and Co-Editor-in-Chief for *Current Research in Environmental Sustainability*. Dr. Fath was the 2016 recipient of the Prigogine Medal for outstanding work in systems ecology and twice a Fulbright Distinguished Chair (Parthenope University, Naples, Italy, in 2012 and Masaryk University, Czech Republic, in 2019). In addition, he has served as Secretary General of the International Society for Ecological Modelling, Co-Chair of the Ecosystem Dynamics Focus Research Group in the Community Surface Modeling Dynamics System, and member and past Chair of Baltimore County Commission on Environmental Quality.

Sven E. Jørgensen (1934–2016) was Professor of environmental chemistry at Copenhagen University. He received a doctorate of engineering in environmental technology and a doctorate of science in ecological modeling. He was an honorable doctor of science at Coimbra University (Portugal) and at Dar es Salaam (Tanzania). He was Editor-in-Chief of *Ecological Modelling* from the journal inception in 1975 until 2009. He was Editor-in-Chief for the *Encyclopedia of Environmental Management* (2013) and *Encyclopedia of Ecology* (2008). In 2004, Dr. Jørgensen was awarded the Stockholm Water Prize and the Prigogine Medal. He was awarded the Einstein Professorship by the Chinese Academy of Sciences in 2005. In 2007, he received the Pascal Medal and was elected a member of the European Academy of Sciences. He had published over 350 papers, and has edited or written over 70 books. Dr. Jørgensen gave popular and well-received lectures and courses in ecological modeling, ecosystem theory, and ecological engineering worldwide.

Agricultural Soils: Nitrous Oxide Emissions

John R. Freney

Introduction

Nitrous oxide is a gas that is produced naturally by many different micro-organisms in soils and waters, and as a result of human activity associated with agriculture, biomass burning, stationary combustion, automobiles, and the production of nitric and adipic acids for industrial purposes. According to the Intergovernmental Panel on Climate Change (IPCC),[1] ~23.1 million metric tons (Mt) of nitrous oxide is emitted each year, 14.1 Mt as a result of natural processes (~4.7Mt from the oceans, ~6.3 Mt from tropical soils, and ~3.1 Mt from temperate soils); and ~9 Mt as a result of human activities (5.5 Mt from agricultural soils, 0.6 Mt from cattle and feedlots, 0.8 Mt from biomass burning, and 2.1 Mt from mobile sources and industry). While there is considerable uncertainty associated with each of these estimates, it is apparent that most nitrous oxide is derived from soils.

Because of the intimate connection between the Earth and the atmosphere, much of the nitrous oxide produced enters the atmosphere and affects its chemical and physical properties. Nitrous oxide contributes to the destruction of the stratospheric ozone layer that protects the Earth from harmful ultraviolet radiation, and is one of the more potent greenhouse gases that trap part of the thermal radiation from the Earth's surface. The atmospheric concentration of nitrous oxide is ~313 parts per billion. It is increasing at the rate of ~0.7 parts per billion each year, and its lifetime is ~166 years.[2] It seems that the increased atmospheric concentration results from the increased use of synthetic fertilizer nitrogen, biologically fixed nitrogen, animal manure, crop residues, and human sewage sludge in agriculture to produce food and fiber for the rapidly increasing world population.[3]

Nitrous Oxide Emission from Agriculture

All soils are deficient in nitrogen for the growth of plants, but the deficiency can be overcome by adding fertilizer nitrogen. When the fertilizer (e.g., urea or ammonia-based compounds) is applied to soil, it is transformed by microorganisms as follows:

$$\begin{aligned}\text{Fertilizer nitrogen} \xrightarrow{1} \text{Ammonium} \xrightarrow{2} \text{Nitrite} \\ \xrightarrow{3} \text{Nitrate} \xrightarrow{4} \text{Nitrate} \\ \xrightarrow{5} \text{Nitric oxide} \xrightarrow{6} \text{Nitrous oxide} \\ \xrightarrow{7} \text{Dinitrogen}\end{aligned} \tag{1}$$

When the soil is aerobic (i.e., when oxygen is present) ammonium is oxidized to nitrite and nitrate (Steps 2 and 3). This process is called nitrification. After addition of irrigation water or rain, the soil may become anaerobic (devoid of oxygen). The nitrate is then reduced by soil organisms to nitrite and the gases nitric oxide, nitrous oxide, and dinitrogen (Steps 4–7) in a process termed denitrification.[4]

When atmospheric scientists first expressed concern that nitrous oxide emission into the atmosphere, as a result of fertilizer use, would lead to destruction of the ozone layer, it was thought that nitrous oxide was produced mainly from the microbiological reduction of nitrate in poorly aerated soils. However, research in the latter part of the 1970s showed that significant nitrous oxide was emitted from aerobic soils during nitrification of ammonium, and subsequent work has shown that nitrification is a major source of nitrous oxide.[4]

Nitrous Oxide from Denitrification

Certain micro-organisms in the absence of oxygen have the capacity to reduce nitrate (or other nitrogen oxides). Most denitrifying bacteria are heterotrophs—that is, they require a source of organic matter for energy—but denitrifying organisms that obtain their energy from light or inorganic compounds also occur in soils. The capacity to denitrify has been reported in more than 20 genera of bacteria, and almost all are aerobic organisms that can only grow anaerobically in the presence of nitrogen oxides. The dominant denitrifying organisms in soil are *Pseudomonas* and *Alcaligenes.* In addition to the free-living denitrifiers, Rhizobia living symbiotically in root nodules of legumes are able to denitrify nitrate and produce nitrous oxide.[4]

The general requirements for biological denitrification include the presence of micro-organisms with denitrifying capacity, nitrate (or other nitrogen oxides) and available organic matter, the absence of oxygen, and a suitable pH and temperature environment. In aerobic soils, denitrification can occur in anaerobic microsites in soil aggregates or in areas of high carbon content, where active microbial activity rapidly consumes all of the available oxygen.[4]

Nitrous Oxide from Nitrification

The process of nitrification is normally defined as the biological oxidation of ammonium to nitrate with nitrite as an intermediate.[4] The first step in the reaction, the oxidation of ammonium to nitrite, is carried out mainly by the microorganism *Nitrosomonas.* The second step, oxidation of nitrite to nitrate, is carried out by *Nitrobacter.* It has been shown in a number of publications that *Nitrosomonas europaea* produces nitrous oxide during the oxidation of ammonium.[4]

The possibility that significant nitrous oxide can be produced in soils by nitrifying organisms was indicated by studies that showed that soils incubated under aerobic conditions with ammonium produced more nitrous oxide than soils amended with nitrate.[4] In addition, treatment of aerobic soils with nitrapyrin, which inhibits nitrification of ammonium but has little effect on denitrification, markedly reduced the emission of nitrous oxide.[4] Production of nitrous oxide by nitrification in soils is increased by increasing temperature, pH, water content, available carbon, and the addition of ammonium-based fertilizers, plant residues, and animal manure.

Flooded Soils

In the past few years, increased attention has been given to nitrous oxide emission from paddy soils. The concern is that the introduction of management practices to reduce methane emissions from flooded soils may result in increased emissions of nitrous oxide.

Flooded soils are characterized by an oxygenated water column overlying an oxidized layer at the soil-water interface, an aerobic zone around each root, and anaerobic conditions in the remainder of the soil. This differentiation of the flooded soil into oxidized and reduced zones has a marked effect on the transformation of nitrogen.[5] The resulting reactions are as follows:

1. Ammonium in the reduced zone diffuses to the oxidized zone;
2. Ammonium is oxidized to nitrate by nitrifying organisms;
3. The nitrate formed diffuses to the anaerobic zone;
4. Denitrification occurs with the production of nitrous oxide and dinitrogen;
5. The gaseous products diffuse through the soil and water layers to the atmosphere.[6]

It is apparent that the rate of diffusion of ammonium to an oxidized layer and the rate of nitrification in the oxidized layer are factors controlling the production of nitrous oxide in flooded soils. The rate of diffusion of nitrous oxide through the soil and water layers will control its rate of emission to the atmosphere, or its further reduction to dinitrogen.[5]

A number of mechanisms have been identified for the transfer of nitrous oxide from the soil to the atmosphere.[3] Nitrous oxide may diffuse from the zone of production through the saturated soil and water layer to the atmosphere. It may also enter the roots of the rice plant and move by diffusion through the plant to the atmosphere in the same way as methane. Bhadrachalam et al.[6] studied the importance of the two pathways in intermittently flooded rice in the field in India and found that nitrogen gas fluxes were ~30% greater when transfer through the plants was included.

In the tropics, rice is usually transplanted and fertilized some time after flooding. Because of the anaerobic conditions that develop before fertilization and the slow rate of diffusion of nitrous oxide in flooded soils, most of the nitrous oxide is reduced to dinitrogen and very little escapes to the atmosphere. Nitrous oxide emission from intermittently flooded rice was relatively large compared with that from permanently flooded rice, reflecting the different oxidation states of intermittently and continuously flooded soils.[6] Studies of nitrous oxide emission from rice fields from the time the soils were drained for harvest, through to flooding the soil in preparation for planting the next crop, showed that nitrous oxide was emitted continuously while the soil was not flooded. Overall, the rate of emission of nitrous oxide from flooded soils was less than that from upland soils after application of nitrogen fertilizer.[3]

Biomass Burning

During combustion the nitrogen in the fuel can be converted into gaseous forms such as ammonia, nitric oxide, nitrous oxide, dinitrogen, and hydrogen cyanide. It is estimated that biomass burning contributes between 0.3 and 1.6 Mt nitrous oxide per year globally to the atmosphere.[3] Most of the biomass burning (~90%) takes place in the tropics as a result of forest clearing, savanna and sugar cane fires, and burning of agricultural wastes and firewood.[7]

Biomass burning is not only an instantaneous source of nitrous oxide, but it results in a longer-term enhancement of the production of this gas. Measurements of nitrous oxide emissions from soils, before and after burning showed that significantly more nitrous oxide was exhaled after the burn through alteration of the chemical, biological, and physical processes in soil.[7]

Fertilizer Consumption and Nitrous Oxide Production

Nitrous oxide emissions from agricultural soils are generally greater and more variable than those from uncultivated land. Application of fertilizer nitrogen, animal manure, and sewage sludge usually results in enhanced emissions of nitrous oxide.[7] Generally, there is a large emission of nitrous oxide immediately after the application of fertilizer. After about 6 weeks, the emission rate falls and fluctuates around a low value. Mosier[8] concluded that interactions between the physical, chemical, and biological variables are complex, that nitrous oxide fluxes are variable in time and space, and that soil management, cropping systems, and variable rainfall appear to have a greater effect on nitrous oxide emission than the type of nitrogen fertilizer. Consequently, Mosier et al.[9] recommend the use of one factor only for calculating the emission of nitrous oxide from different fertilizer types:

$$N_2O \text{ emitted} = 125\% \text{ of N applied } (\text{kg/ha}) \tag{2}$$

This equation is based on data from long-term experiments with a variety of mineral and organic fertilizers, and encompasses 90% of the direct contributions of nitrogen fertilizers to nitrous oxide emissions.

Mosier et al.[3] developed a methodology to estimate agricultural emissions of nitrous oxide, taking into account all of the nitrogen inputs into crop production. They included direct emissions from agricultural soils as a result of synthetic fertilizer addition, animal wastes, increased biological nitrogen fixation, cultivation of mineral and organic soils through enhanced organic matter mineralization, and mineralization of crop residues returned to the field. Indirect nitrous oxide emissions resulting from deposition of ammonia and oxides of nitrogen, leaching of nitrate, and introduction of nitrogen into sewage systems were also included. They concluded that in 1989, 9.9 Mt of nitrous oxide was emitted into the atmosphere directly or indirectly, as a result of agriculture (Table 1).

TABLE 1 Calculated Emission of Nitrous Oxide from Agricultural Activities

	Mt Nitrous Oxide per Year
Direct soil emissions	
Synthetic fertilizer	1.4 (0.28–2.5)
Animal waste	0.9 (0.19–1.7)
Biological nitrogen fixation	0.16 (0.03–0.3)
Crop residue	0.6 (0.11–1.1)
Cultivation of Histosols	0.16 (0.03–0.3)
Total	3.3 (0.6–5.9)
Animal production	
Waste management systems	3.3 (0.9–4.9)
Indirect emissions	
Atmospheric deposition	0.47 (0.09–0.9)
Nitrogen leaching and runoff	2.5 (0.2–12.1)
Human sewage	0.3 (0.06–4.1)
Total	3.3 (0.35–17.1)
Total	9.9 (1.9–27.9)

Source: Modified from Mosier et al.[3]

Management Practices to Decrease Nitrous Oxide Emission

The low efficiency of fertilizer nitrogen in agricultural systems is primarily caused by the large losses of mineral nitrogen from those systems by gaseous loss: nitrous oxide emission is directly linked to the loss processes. It is axiomatic that any strategy that increases the efficiency of nitrogen fertilizer use will reduce emissions of nitrous oxide, and this has been directly demonstrated for a number of strategies.[3]

The IPCC[1] reported that some combination of the following management practices, if adopted worldwide, would improve the efficiency of the use of synthetic fertilizer and manure nitrogen, and significantly reduce nitrous oxide emission into the atmosphere:

1. Match nitrogen supply with crop demand.
2. Tighten nitrogen flow cycles by returning animal wastes to the field and conserving residues instead of burning them.
3. Use controlled-release fertilizers, incorporate fertilizer to reduce volatilization, use urease and nitrification inhibitors, and match fertilizer type to precipitation.
4. Optimize tillage, irrigation, and drainage.

The potential decrease in nitrous oxide emissions from synthetic fertilizer, as a result of the mitigation techniques, could amount to 20%.[1]

Agriculture: Energy Use and Conservation

Guangnan Chen
and Tek Narayan
Maraseni

Introduction

Farming is often an energy-intensive operation. With the rising energy costs and increasing concern over greenhouse gas (GHG) emissions, effective energy use and conservation are becoming increasingly important.[1,2] In many parts of the world, energy inputs represent a major and rapidly growing cost input for growers, with on-farm fuel requirement in cereal cropping systems often exceeding 100 L/ha for tillage, seeding, fertilizing, spraying, and harvesting.[3–5] In the United States, it has been found that the operations of food systems, including agricultural production, food processing, packaging, and distribution, accounted for approximately 19% of America's national fossil fuel energy use.[6]

Methods of Energy Audit

Energy audits and assessments are a first step and crucial part of the energy and environmental management process. Energy audits refer to the systematic examination of an entity, such as a firm, organization, facility, or site, to determine whether, and to what extent, it has used energy efficiently.[7] They may also assess opportunities of potential energy savings through fuel switching, tariff negotiation, and demand-side management.

Energy audits may be broadly classified into the following three levels:[7,8]

- Energy audit level 1, or preliminary audit. The main purpose of this level of energy audits is to overview the total energy consumption of a farm. This is the simplest and cheapest form of energy audits. It usually involves collating all the energy use data from the farm, including the total fuel usage from diesel, petrol, and other fuels and the total electricity energy consumed, in order to derive basic energy performance indices such as GJ/ha and GJ/t.

- Energy audit level 2, or standard/general audit. Level 2 energy audits generally involve breaking down the total energy usage into each individual major processes. A level 2 audit is usually process-based and involves some specific measurements for the key processes. It may also involve considerable farmers' interviews to identify the major energy usage.
- Energy audit level 3, or detailed specific operation investigation. This is the highest and the most expensive level of energy audits. It may involve investigating ways to improve the efficiency of a specific operation so that the investment return can be accurately predicted. This will usually involve the uses of a range of different sensors to measure the performance of a variety of machines. Data loggers may be used to record the data for a considerable period of time.

Underpinning the energy audit assessment process is the identification and development of a set of toolkits (software, hardware, and other supporting information and resources) that can be applied to different farm production systems. A number of farm energy calculators[4,7–9] have already been developed to evaluate the energy uses from agricultural systems. Various hardware and technologies such as electricity power meters, fuel flow meters, data logging, and monitoring equipment may also be used for undertaking field measurements.[9–11] By itemizing farm energy usage from each operation, farmers will be able to identify where energy is mostly consumed and therefore explore ways to reduce energy use.

Brown and Elliot[12] found that although the currently available data of agricultural energy use may be sufficient for general policy development, the quality of existing energy end-use data is often unsatisfactory. They suggested that further research be conducted to achieve a clear and consistent definition of farm types and energy end uses. Energy uses of individual operations will also need to be more accurately measured.

Effect of Farming Systems on Energy Use

Considerable research has been conducted on energy use and conservation both in agriculture[13–16] and in other industries.[17] In the cropping sector, it has been identified that a number of practice changes and technology developments may be adopted to reduce fuel/energy use or energy use intensity. Examples of these may include more effective machinery operation, conservation farming practices, improved irrigation methods and water use efficiency measures, precision agriculture, and, where appropriate, the use of renewable energy and planting of alternative crops.

Machinery Operation

Farm machinery is integral to many aspects of modern farming systems. Without it, we may not be able to effectively implement the farming systems. It was estimated that since the Second World War, more than 25% of the increase in grain productivity may be attributed to machinery innovations. When the ownership cost and timeline loss are taken into consideration, it is estimated that machinery may consist of up to 40%–50% of total farm input costs.[18]

Farm machinery often consumes a large amount of energy and therefore produces considerable emissions, especially carbon dioxide. Figure 1 shows the average percentage contribution of the direct energy input for different farming processes in European tillage-based systems. Chen et al.[19] and Smith[20] showed that by changing gear selection and engine speed, up to 30% of energy can often be saved for the same tractor power output. Careful selection of energy-efficient farming equipment and proper matching of tractor and implement are also important.[21] At the systems level, it is possible that much larger improvements can be achieved by changing the cropping practices and systems. Table 1 shows the estimated average fuel use for different tillage operations,[22] where a ratio of up to 3:1 or 4:1 from the highest to the lowest energy use can be found.

Conservation Agriculture

Conservation agriculture is the generally accepted label for farming systems developed with the specific objective of improving productivity and sustainability, by reducing input waste and resource degradation. Conservation tillage involves reduced tillage, in which a crop is planted in the residue from a previous crop with either minimal (minimum tillage) or zero (zero tillage) soil disturbance. The weed control function may be achieved by using a combination of herbicides and agronomic measures (cover crops, rotation, seed bank depletion) and soil damage minimized by better management (soil health, traffic intensity, controlled traffic).

Based on 2 years experiments in Croatia, Kosutic et al.[23] demonstrated that compared with the conventional "intensive" tillage, up to 82.6% of energy could be saved by the adoption of no-till conservation farming system, and without the significant yield reduction. Gulden and Entz[24] found that this was 36% in Canada. Bailey et al.[25] showed that in terms of total energy used, when compared with conventional farming systems on a per-hectare basis, the integrated arable systems had the potential to reduce overall energy consumption by about 8% in the United Kingdom. However, in terms of energy use per kilogram of output, their results were less conclusive. A comparative study of conventional tillage and conservation farming was also carried out by Smith[26] to compare the impact of these practices on soil characteristics, crop performance, and economic outcomes.

While many no-till seeders have been marketed in recent years, there is still no one universally applicable machine that guarantees success under all conditions. In fact, better seed and fertilizer placement and good depth control and stubble handling have been identified by farmers as the highest priority needs in the design of planting equipment, particularly on "unprepared" soil with heavy stubble in direct drilling/conservation farming.[27] Difficulties of no-till seeding are therefore the major stumbling block to the adoption of full conservation agriculture. Despite these issues, effective machine/system combinations for no-till seeding have been evolved for many cropping environments, particularly in the subtropical grain production, where conventional tillage-based systems were causing major erosion damage and loss of organic matter. Where soil degradation problems are less obvious, for instance, in the long-established plough-based systems of Europe, adoption of conservation agriculture has been much slower,[28] and the same is true in most horticultural and intensive cropping areas, worldwide. This situation is expected to change slowly as cropping inputs, particularly fuel, fertilizer, and water resources, become more expensive, improving the attractiveness of system change.

Controlled traffic is a farming system in which the wheel tracks of all operations are confined to fixed paths so that re-compaction of soil by traffic (traction or transport) does not occur outside the selected paths. It has been shown that in addition to benefits of improved productivity and soil and water conservation, this method could also provide up to 50% reduction in power and fuel requirements of field operations.[29,30] Tullberg[31] demonstrated the effects of system change from the conventional tillage-based to no-till and to controlled traffic no-till in Australian grain production, clearly illustrating the significance of the reduction of energy and GHG emissions. It was shown that the total GHG emissions per ton of grain production can be reduced from 314 to 306 and to 175 kg, respectively. One survey indicated that in 2003, some form of controlled traffic was in use over 1 million ha in Australia.[32] To achieve further widespread adaptation, it is identified that the lack of compatibility between different machinery would have to be overcome.[31]

Irrigation Methods

Irrigation can be broadly defined as the practice of applying additional water (beyond what is available from rainfall) to soil to enable or enhance plant growth and yield. The water source could be groundwater pumped to the surface or surface water diverted from one location to another. On a global scale, it was estimated that 17% of irrigated cropland produces 40% of the total production.[33]

Farm irrigation systems may be broadly classified as surface irrigation, pressured sprinkler systems, trickle, and subsurface systems. In Australia, surface irrigation systems, such as border check and furrow irrigation, are the most widely used irrigation systems, covering some 70% of the total irrigated area.[34] This is then followed by the pressurized spray irrigation methods (22%) and trickle and subsurface systems (8%).

Irrigation is however often a very energy-intensive operation. It was estimated that 23% of the on-farm energy use for crop production in the United States was for on-farm pumping.[35] Figure 2 shows the estimated total lifecycle energy consumption for different irrigation methods.[34] It can be seen that

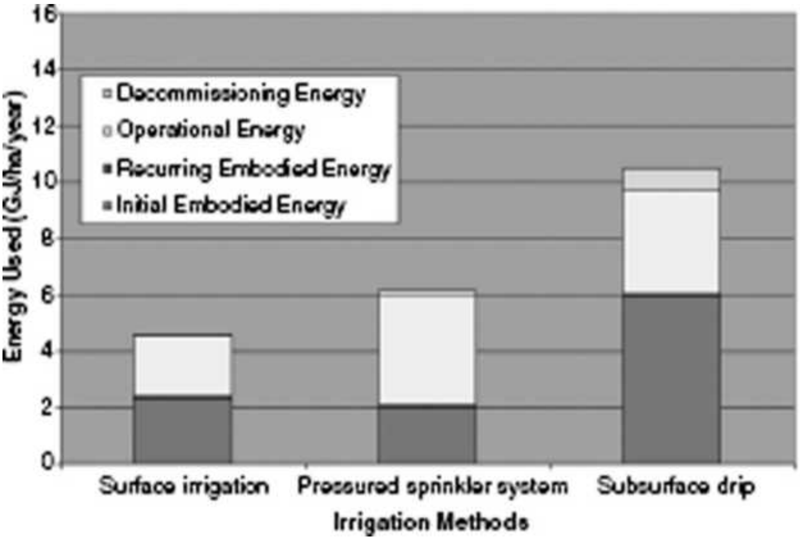

FIGURE 2 Life-cycle energy consumption for different irrigation systems.

the pressurized irrigation system can use significantly more energy over its life cycle than a gravity-fed system, with a ratio of about 1.5 or 2. The increased wateruse efficiency of pressured irrigation systems will therefore need to be balanced against the higher cost of the energy needed.[36] At the current market condition, 1 GJ of energy would typically cost around \$10–\$40. The corresponding GHG emissions range from 0 (using renewable energy) to around 78 kg CO_2/GJ (using diesel fuel).

Brown and Elliot[12] found that the largest on-farm energy savings might be available in motorized systems, especially in irrigation pumping. Barron[37] also identified that poor system design contributed significantly to low pumping efficiency. Pathak and Bining[38] showed that for irrigation, fuel saving of more than 50% was feasible through improvement in the irrigation equipment and improved water management practices. Chen et al.[19] demonstrated that with suitable operation adjustments, up to 55% of pumping energy can be saved. It has also been reported in the United States that energy efficiency audits on irrigation systems have, on average, identified savings of at least 10% of the energy bill—and in many instances up to 40%.[38] Very often, the irrigators who owned these inefficient systems were unaware of any problems.[39]

Overall Systems Comparison

Table 2 summarizes some of the published energy use data for different crops in different countries.[8,39–44] It can be seen that significant variation in energy input costs occurs between different crops and between different growers due to the adopted production system and a grower's performance within that system. Depending on the farming systems adopted, the direct on-farm energy input may range from 2.5 GJ/ha for wheat production in Europe to 53.4 GJ/ha for greenhouse tomato production in Turkey. This is a ratio of approximately 20.

It is noted that on-farm energy uses of crop production is only a proportion of total energy usage. The others include the post-farm processing, transport, distribution, and energy used to produce agricultural inputs such as fertilizers and pesticides.[44–46] Table 3 shows the estimated embodied energy content for manufacturing various chemical fertilizers and herbicides. It can be seen that with the current manufacturing technology, the production of 1 kg of nitrogen fertilizer would typically require the energy input equivalent to 1.5–2 kg of fuel, while 1 kg of pesticides would require the energy input equivalent to up to 5 kg of fuel.[44] It is therefore important to reduce not only the on-farm energy uses but also the embodied energy and post-harvest energy uses. This is especially important, as the embodied energy of farm chemicals may account for up to 50%–70% of the total energy input in agricultural production. In particular, the cost of nitrogen fertilizer is mostly a reflection of energy costs, so maximizing the

efficiency of fertilizers or using legumes to produce nitrogen can help reduce energy costs on farms. It was demonstrated that energy input in the integrated forage-grain rotation was approximately 40% lower than that in the grain-based rotation.[47]

Yaldiz et al.[48] reported that fertilizers and irrigation energy dominated the total energy consumption in Turkish cotton production. Yilmaz et al.[41] showed that the energy intensity in agricultural production was closely related with production techniques. They estimated that cotton production in Turkey consumed a total of 49.73 GJ/ha energy, consisting of 21.14 GJ/ha (42.5%) direct energy input and 28.59 GJ/ha (57.5%) indirect energy input. Modern rice production in the United States also requires a total energy input of 64.89 GJ/ha for a yield of 5.8 tons/ha or 11.19 GJ energy input per ton of grain produced.[43]

To save energy and cost, the precision-agriculture technologies such as controlled traffic farming, high spatial and temporal precision in input placement, sensor-controlled spraying, and variable-rate fertilizer applications may offer significant benefits. Pimentel et al.[3] also showed that by appropriate technology changes in food production, processing, packaging, transportation, and consumption, fossil energy use in the U.S. food system could be reduced by about 50%. Using corn production as a model crop, it was estimated that total energy in corn production could be reduced by more than 50% by combining the following changes: 1) using smaller machinery and less fuel; 2) replacing commercial nitrogen applications with legume cover crops and livestock manure; and 3) reducing soil erosion through alternative tillage and conservation techniques. Hoeppner et al.[47] and Ziesemer[49] also showed that energy input in the organic management system was approximately 50% lower than that in the conventional management system.

Development and Applications of New Technology

With the advance of biotechnology, new crop varieties with higher yield and improved performance such as reduced herbicide and pesticide usage are being continuously introduced.[50] This will reduce not only the amount of herbicide and pesticide used but also the fuel usage associated with the crop spraying operations. For example, it was reported that with the adoption of genetically modified cotton, pesticide use has been reduced by up to 70%–90% in the Australian cotton industry.[51] To address the public's concern, the introduction of biotechnology to food crops may require a more careful approach.

Where the opportunities are appropriate, renewable energy such as solar, wind, and biofuel may also be integrated into the farming operations to save energy costs and reduce GHG emissions.[52–55] Examples of direct applications include solar crop drying, solar space and water heating, and using biomass for heating purpose. Other applications include generation of off-grid electricity for electric fences, lighting, irrigation, livestock water supply, wastewater treatment, pond aeration, communication, and remote equipment operation. Table 4 shows the estimated costs for various electricity generation technologies. Overall, renewable energy at present may not be viable to serve in large scale as a primary energy source, and in many cases, additional government support and financial incentives would still be required to compete with more polluting fossil fuels. However, because of the increasing concern over the GHG emissions and declining reserves of fossil fuel, use of renewable energy is on the rapid rise globally.[56] Various user-friendly design and cost estimation tools have also been developed to promote specific applications.[57]

TABLE 4 Estimated Costs of Various Electricity Generation Methods

Energy Type	Cost (¢/kWh)
Hydropower	4–10
Coal-fired power	2–4
Gas-fired power	5
Wind energy	5–8
Solar PV electricity	15–25

Conclusion

Energy use efficiency and conservation are of significant interest to the agricultural industry. Within highly mechanized agricultural productions systems, operational energy inputs (i.e., diesel, petrol, gas, and electricity) often represent a major cost to the growers. In the United States, it has been found that the operations of food systems, including agricultural production, food processing, packaging, and distribution, accounted for approximately 19% of America's national fossil fuel energy use. A total of up to 64.89 GJ/ha of energy is spent in the rice production in the United States.

It has been shown that significant variation in energy input costs can occur between growers due to the adopted production system and a grower's performance within that system. In the cropping sector, it has been identified that a number of practice changes and technology developments may be adopted to reduce fuel/energy use in agriculture. These may include more effective machinery operation, conservation farming practices, improved irrigation methods and water use efficiency measures, precision agriculture, and, where appropriate, the use of renewable energy and planting of alternative crops or crop rotation. It has been demonstrated that by changing the farming systems (e.g., changing to conservation tillage system, controlled traffic, or organic management system) and undertaking the same operation more efficiently (e.g., more precise targeting and use of fertilizers and irrigation), up to 50% of overall energy use may be realistically saved. It has also been found that from the highest to the lowest energy use, the estimated average fuel use for different tillage operations may be up to a ratio of 3:1 or 4:1. In many cases, the largest on-farm energy savings might be available in motorized systems, especially in irrigation pumping. The energy efficiency audits on irrigation systems in the United States have, on average, identified savings of at least 10% of the energy bill—and in many instances up to 40%. Because the embodied energy of various chemicals and machinery may make up 50%–70% of the total energy input and GHG emissions in agricultural production, the applications of variable-rate fertilizer technology and replacement of commercial nitrogen applications with legume cover crops and livestock manure would bring significant benefits.

With the development and applications of new technology and the increasing cost of fuel, fertilizer, and water resources, it is expected that various energy-saving measures will be increasingly adopted by the farmers. In particular, with the increasing concern over the GHG emissions and the depleting of fossil fuel, renewable energy such as solar, wind, and biofuel may be integrated into the different farming operations, including solar crop drying and heating, off-grid electricity supply for fences, lighting, irrigation, livestock water supply, wastewater treatment, pond aeration, communication, and remote equipment operation. With the adoption of genetically modified cotton, pesticide use has been reduced by up to 70%-90% in the Australian cotton industry.

Agriculture: Organic

Kathleen Delate

Introduction

The USDA National Organic Standards Board (NOSB) defines organic agriculture as "an ecological production management system that promotes and enhances biodiversity, biological cycles, and soil biological activity.[1] It is based on minimal use of off-farm inputs and on management practices that restore, maintain, or enhance ecological harmony. The primary goal of organic agriculture is to optimize the health and productivity of interdependent communities of soil life, plants, animals and people."[1] The term "organic" is defined by law. The labels "natural," "eco-friendly," and similar statements do not guarantee complete adherence to organic practices as defined by law.

History

In 1990, the U.S. Congress passed the Organic Food Production Act (OFPA). This law was heralded as the first U.S. law established to regulate a system of farming. The OFPA requires that anyone selling products as "organic" must follow a set of prescribed practices that include avoidance of synthetic chemicals in crop and livestock production, and in the manufacturing of processed products. "Certified organic" crops must be raised on land to which no synthetic chemical (any fertilizers, herbicides, insecticides, or fungicides) inputs were applied for three years prior to the crops' sale. Organic certification agencies became established in the United States to deal with a required "third-party certification." There are at least 20 private certification agencies and 15 state agencies certifying organic production and processing in the United States. Proposed rules implementing the federal OFPA law were promulgated in 1997, after seven years of revisions. Unfortunately, these rules did not meet private certification agencies' standards, and a record number of complaints (275,000) were issued in the public comment period. Now that the federal rules are established (released in 2001), all certifiers must utilize the federal standards as the minimum standard for the "certified organic" label in the United States. European regulation is under the auspices of the International Federation of Organic Agriculture Movements (IFOAM) with national certification agencies in each country.[2] Japan currently certifies under the Ministry of Agriculture and Forestry. Certification for the European Union and Japan is extended to several U.S. certifiers that meet international standards.

Organic agriculture is the oldest form of agriculture on earth. Farming without the use of petroleum-based chemicals (fertilizers and pesticides) was the norm for farmers in the developed world until post–World War II. The war era led to technologies that were adapted for agricultural production. Ammonium nitrate used for munitions during WWII evolved into ammonium nitrate fertilizer; organophosphate nerve gas production led to the development of powerful insecticides. These technical advances since WWII have resulted in significant economic benefits, as well as unwanted environmental and social effects. Organic farmers seek to utilize those advances that yield benefits (e.g., new varieties of crops, more efficient machinery) while discarding those methods that have led to negative impacts on society and the environment, such as pesticide pollution and insect pest resistance.[3] Instead of using synthetic fertilizers and pesticides, organic farmers utilize crop rotations, cover crops, and naturally based products to maintain or enhance soil fertility.[4,5] These farmers also rely on biological, cultural, and physical methods to limit pest expansion and increase populations of beneficial insects on their farms. By managing their ecological capital through efficient use of on-farm natural resources, organic farmers produce for diverse and specialized markets that provide premium prices.

Because genetically modified organisms (GMOs) constitute synthetic inputs and pose unknown risks, GMOs, such as herbicide-resistant seeds, plants, and product ingredients are disallowed in organic agriculture. Organic livestock, like organic crops, must be fed 100% organic food or feed in their production. Synthetic hormones and antibiotics are dis- allowed in organic livestock production. Traditional farmers throughout the world have relied on natural production methods for centuries, maintaining consistent yields within their local environment. While "green revolution" technologies have led to increased yields in many less developed countries, many farmers have seen an increase in pest problems with new varieties and high input–based systems.

Motivations for organic production include economic, food safety, and environmental concerns. All organic farmers avoid the use of synthetic chemicals in their farming systems, but philosophies differ among organic farmers regarding methods to achieve the ideal system. Organic farmers span the spectrum from those who completely eschew external inputs, create on-farm sources of compost for fertilization, and encourage the activity of beneficial insects through conservation of food and natural habitats, to those farmers who import their fertility and pest management inputs. A truly sustainable method of organic farming would seek to eliminate, as much as possible, reliance on external inputs.

Worldwide Statistics

USDA does not publish systematic reports on organic production in the United States. The most recent census in 1994 identified 1.5 million acres of organic production in the United States with 4050 farmers reporting organic acreage.[6] This figure underrepresents current production because many organic farmers opt to sell their products as organic without undergoing certification. The U.S. organic industry continues to grow at a rate of 20% annually. The industry was listed as a $4.5 billion industry in 1998, with predicted future growth to $10 billion by 2003. The organic industry is a consumer–driven market. According to industry surveys, the largest purchasers of organic products are young people and college–educated consumers. Worldwide consumption of organic products has experienced tremendous growth, often surpassing U.S. figures of 20% annual gain. Much of the increase in consumption worldwide has been fueled by consumers' demand for GMO–free products. Because GMOs are disallowed in organic production and processing, organic products are automatically segregated as GMO–free at the marketplace. European consumers have led the demand for organic products, particularly in countries such as the Netherlands and Scandinavia. Two percent of all German farmland, 4% of Italian farmland, and 10% of Austrian farmland is managed organically.[2] Prince Charles of England has developed a model organic farm and established a system of government support for transitioning organic farmers. Major supermarket chains and restaurants in Europe offer a wide variety of organic products in their aisles and on their menus. Industry experts predict that the establishment of federal rules will advance organic sales in the United States. Although the organic industry began as a niche market, steady growth has led to its place in a "segment" market since 1997. The organic dairy industry, for example, expanded by 73% from 1996 to 1997, and continues to grow today. Organic markets can be divided into indirect and direct markets. Indirect or wholesale markets include cooperatives, wholesale produce operations, brokers, and local milling operations. Many supermarket chains buy directly from farmers or from wholesalers of organic products. Because meat can now be labeled as "organic," as of 1999, the marketing of organic beef, pork, chicken, and lamb has been significantly simplified. Roadside stands, farmers' markets and community supported agriculture (CSA) farms constitute the direct marketing end of the organic industry. Most consumers relate their willingness to pay premium prices for food that has been raised without synthetic chemicals because of their concern for food safety and the environment. Supporting local family farmers also enters into their purchasing decisions.

Crop and Pest Performance in Organic Systems

The basis for all organic farming systems is the health of the soil.[4,7] In addition to maintaining adequate fertility, organic farmers strive for biologically active soil, containing microbial populations required for nutrient cycling.[8,9] Crop rotations (required for all organic operations) provide nutrients such as nitrogen in the case of legume crops (alfalfa and clover) and carbonaceous biomass upon which beneficial soil microorganisms depend for survival.[10,11] A crop rotation plan is required as protection against pest problems and soil deterioration.[12–15] Ideally, no more than four out of six years should be in agronomic crops, and the same row crop cannot be grown in consecutive years on the same land. Legumes (alfalfa, clovers, and vetches) alone, or in combination with small grains (wheat, oats, and barley), must be rotated with row crops (corn, soybeans, amaranth, vegetables, and herbs) to ensure a healthy system. A typical six–year rotation in the Midwestern United States would be corn (with a cover of winter rye)–soybeans–oats (with an underseeding of alfalfa)–alfalfa–corn–soybeans.[16,17] Horticultural crops must be rotated with a leguminous cover crop at least once every five years.

Pest management in organic farming systems is based on a healthy plant able to withstand some pest injury and on the inherent equilibrium in nature, as most insect pests have natural enemies that regulate their populations in unperturbed environments.[18,19] Because only naturally occurring materials are allowed in organic production, insect predators, parasites, and pathogens exist without intervention from highly toxic insecticides.[20] Most organic farmers rely on naturally occurring beneficial insects on their farms, but some farmers purchase and release lacewings and other natural enemies every season, for example. There are also commercial preparations of natural insect pathogens, such as *Bacillus thuringiensis* (Bt), which are used to manage pestiferous larvae, such as corn borers. Botanical insecticides, such as neem and ryania, are also allowable in organic production, but as with all insecticides, sprays should be used only as a last resort. Although these materials are naturally based, some materials may affect natural enemies. Prevention is a cornerstone of organic farming.[21] Pest–free seeds and transplants, along with physical and cultural methods, are used to prevent pest infestations. Physical methods include the use of row covers for protection against insects such as cabbage butterflies and aphids. Cultural methods include sanitation and resistant varieties. Plant varieties are used that have been bred traditionally (i.e., no manipulated gene insertion or engineering involved) for insect, disease, and nematode resistance or tolerance.

Most organic farmers rely on multiple tactics for their weed management.[22,23] Allelopathic crops, cultivation, mulching, and flame burning are all methods available for organic farmers. Allelopathic crops, such as rye and oats, produce an exudate that mitigates against small weed seed germination. Depending on the crop, cultivation offers the least labor–intensive method of organic weed management. Timely cultivation is key; without specific schedules, weeds proliferate. Propane flame burning is generally used in conjunction with cultivation, particularly during times of high field moisture. Mulching with straw or wood chips is commonly used in many organic horticultural operations.

Yields comparable to conventional crops have been shown for organic crops in three university long–term experiments in the United States (South Dakota State University,[24] Iowa State University,[16] and the University of California–Davis.[25] and in many European studies.[26] Factoring in an organic premium (ranging from 50 to 400%, depending upon crop and season), organic systems consistently out–performed conventional systems in terms of economics.[17,27,28] Pest problems were not a critical factor in these organic systems. Other studies have shown the benefits of organic practices, such as composting, in mitigating root–borne diseases.[8]

Key Issues Requiring Additional Research

Continued verification of the long–term benefits of organic versus conventional farming in terms of soil quality,[29] pest management, and nutritional benefits.[30] is needed. Key issues include the development of management practices to increase nutrient cycling for maintenance of crop yields and optimize biological control of plant pests and diseases[31] Economic analysis, including risks of the three–year transition required for organic certification, will provide useful information for growers interested in alternative systems.[26,32] Appropriate tillage systems, which protect soil quality and provide adequate soil preparation, remain as important issues for organic producers. The improvement of natural parasiticide formulations, such as diatomaceous earth, is required for optimum organic livestock production. Marketing and support needs include the availability of reliable statistics for organic operations and prices. Although many European countries support their farmers in their organic production practices through environmental subsidies,[33] the United States has made small gains in this area. Some state agencies (Minnesota Department of Agriculture) and the USDA Natural Resources Conservation Services (NRCS) through the Environmental Quality Indicators Program (EQIP) offer financial incentives to organic farmers during their transitioning years. More of these support services are needed to encourage farmers interested in the conversion to alternative production.[34]

Erosion by Water: Accelerated

David Favis-Mortlock

Introduction

Soil erosion by water occurs when rain falls onto, or runoff flows over, the surface of the earth under the influence of gravity. The kinetic energy possessed by this water may be sufficient to give it the ability to remove and redistribute the "cream of the soil," its nutrient-rich upper layers. The first section of this entry focuses on the physical processes of water erosion. There are several, and they all interact in a complex way. The results are erosional features that span a wide range of spatial and temporal scales: these are the focus of the second section.

Erosion by water is a natural phenomenon: this is "background" or "geological" erosion. However, if the soil's protective cover of vegetation is removed owing to unwise agricultural practices, overgrazing, or poorly executed construction activity, then erosion rates can increase greatly. The result is accelerated water erosion, which is a present-day problem over much of the earth's surface. Mankind's modification of natural water erosion is the focus of the third section. The impacts of accelerated water erosion may be both on-site (at the place where the erosion occurs) and off-site (downstream from this): the fourth section describes these impacts. The fifth and final section discusses future soil erosion by water. This will be affected by anthropogenic climate change: both directly, owing to changes in the amount, timing, and intensity of rainfall, and the amount and timing of snowmelt-generated runoff; and indirectly, owing to climate-driven shifts in vegetation growth and land usage.

Processes of Erosion by Water

Water erosion is driven by the energy of rainfall and flowing water. When rain falls upon unprotected soil, its kinetic energy may be sufficient to detach soil particles: this is one of the subprocesses[1] of water erosion (RD-ST in Figure 1), and is often referred to as "rainsplash erosion" or "splash erosion."

A more accurate term is "rainsplash redistribution," since although considerable quantities of soil can be moved by splash, almost all of it is merely redistributed, moved only a few millimeters or centimeters on the soil's surface. There will be a net downslope movement of splashed soil, but this is generally rather small. Rainsplash redistribution is most effective where rainfall intensities are high,[2] e.g., as a result of convective rainstorms in the world's equatorial regions. Low-intensity rainfall is often of frontal origin: where such rainfall is common (e.g., temperate northwest Europe), rainsplash is a relatively ineffective subprocess of erosion.

Some of the rain may infiltrate into (i.e., be absorbed by) the body of the soil. In dry conditions, all of the rain may infiltrate: the result is then rain with no runoff (Figure 1). Conversely, if the soil is fully saturated, none of the rainfall will infiltrate: all of it becomes either runoff (which is also known as "overland flow") or detention storage (see below). If the soil is fully saturated, this will occur irrespective of the rain's intensity (i.e., the rate at which it falls). Runoff that results from the soil being fully saturated is known as "saturation excess overland flow." It is preferentially generated from the lower parts of a catchment, since the soil in these areas is likely to become saturated first.

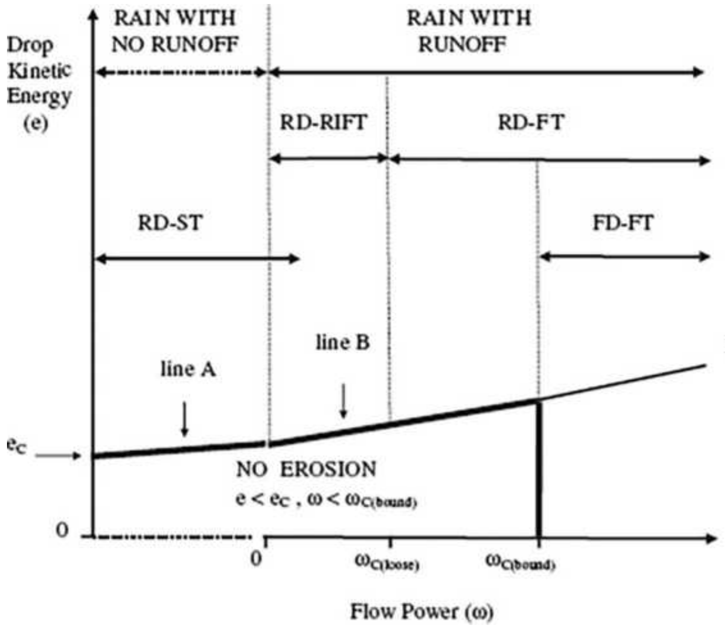

FIGURE 1 Detachment and transport processes associated with variations in raindrop and overland flow energies. The *Y* axis represents raindrop kinetic energy *e*, which is a function of rainfall intensity. The *X* axis represents overland flow power *ω*. The leftmost zero on the *X* axis (at the beginning of the dotted section) indicates the start of rainfall, and the zero to its right (at the rightmost end of the dotted section of the *X* axis) represents the beginning of overland flow. During a rainstorm, flow power generally increases with time provided sufficient rain, with a sufficiently high intensity, has fallen and produced ponding and runoff. Thus, the *X* axis is a rough surrogate for time during a rainstorm. Horizontal left-to-right line traverses of the diagram indicate the changes of detachment and transportation processes that occur during a rainstorm, for a given constant rainfall intensity. Non-horizontal left-to-right traverses incorporate some changes in rainfall intensity. e_c, critical raindrop energy to cause erosion; line A, raindrop energy before flow (this often increases slightly over time, as a soil crust develops); line B, raindrop energy when flow occurs (increases over time, as more drop energy is used in penetrating the deepening overland flow); $\omega_{\mathrm{c(loose)}}$, critical flow power for transporting loose soil material; $\omega_{\mathrm{c(bound)}}$, critical flow power for detaching soil from the surface of the soil matrix; RD-ST, raindrop detachment, splash transport; RD-RIFT, raindrop detachment, raindrop-induced flow transport; RD-FT, raindrop detachment, flow transport; FD-FT, flow detachment, flow transport.
Source: Kinnell.[1]

High-intensity rainfall (i.e., a great deal of rain arriving during a short period) can give rise to runoff of a different kind. This is "infiltration excess overland flow" (or "Hortonian overland flow"), and is the result of rain arriving too quickly to infiltrate into the soil. The pre-existing moisture content of the soil is of lesser importance in determining the occurrence of infiltration excess overland flow, compared with saturation excess overland flow. As a result, infiltration excess overland flow tends to be more spatially uniform, often being generated over a whole catchment (or at least that portion of it which is receiving rain from a single storm). However, a major factor that influences the occurrence of infiltration excess overland flow is the state of the soil's surface, in particular any crusting or capping that may have occurred. Crusting and capping can be the result of physical, chemical, or biological agencies, and is not necessarily spatially uniform.

While saturation excess overland flow and infiltration excess overland flow are distinct, they commonly interact spatially and temporally. For example, during a single rainstorm, saturation excess overland flow may be the first to occur, beginning in the topographic lows of a catchment, with the contributing area gradually increasing as a great area of soil within the catchment becomes saturated. A subsequent increase in rainfall intensity during the storm may result in infiltration excess overland flow being generated over the whole area of the catchment. A later decrease in intensity may result in a return to predominantly saturation excess overland flow, originating from only part of the catchment's surface area.

In certain circumstances, topographically lower areas within a catchment may experience subsurface return flow. This is water that has previously infiltrated in some upslope location, moved laterally downslope within the soil, and then exfiltrated to once again become (or join) hillslope runoff.

However it is generated, runoff tends to flow downhill under the action of gravity. This thin diffuse film of water has lost virtually all the kinetic energy that it possessed as falling rain; thus, it moves only slowly, has a low flow power, and is generally incapable of detaching or transporting soil particles ("no erosion" in Figure 1).

The microtopography (i.e., small-scale pattern of irregularities) of the soil's surface tends to cause this overland flow to concentrate in closed depressions, which slowly fill: this is known as "detention storage" or "ponding." Both the flowing water and the water in detention storage protect the soil from raindrop impact, so that rainsplash redistribution usually decreases over time within a storm, as the depth of surface water increases. There are, however, complex interactions between rainsplash and overland flow (Figure 1).

If the rain continues, the increasing depth of water will eventually overtop the depressions. Overland flow that is released in this way is likely to flow downhill more quickly and in greater quantities (i.e., will possess more flow power as a result of its kinetic energy). Thus, it will begin to be able to transport soil particles that have already been detached (RD-RIFT, RD-FT in Figure 1). If its velocity continues to increase, eventually the overland flow will be able to detach and transport soil particles from the soil matrix (FD-FT in Figure 1). Where it does so, the soil's surface will be lowered slightly. Lowered areas form preferential flow paths for subsequent flow, and these flow paths are in turn eroded further. Eventually, this positive feedback[3] results in small, well-defined linear concentrations of overland flow ("microrills" or "traces").

In many cases, individual microrills become ineffective over time because of sedimentation. A subset, however, grow further to become rills,[4] and a smaller subset may go on to develop into gullies. This process of "competition" between microrills and rills leads to the self-organized formation[13] of networks of erosional channels (dendritic on natural soil surfaces[5]; constrained by the direction of tillage on agricultural soils[6]), which form efficient pathways for the removal of water from hillslopes. It is in such erosional channels that water erosion also operates most effectively to detach and remove soil by its kinetic energy.[7] In most situations, erosion by concentrated flow is the main agent of erosion by water. The flow-dominated erosional channels are separated by interrill areas[8] where the dominant processes are rainsplash and diffuse overland flow; however, boundaries between rill and interrill areas are both ill defined and constantly shifting.

In some circumstances, subsurface flow may be important in determining where channel erosion will begin and develop (e.g., at the base of slopes,[9] and in areas of very deep soils such as tropical saprolites[10]). Meltwater from thawing snow operates in a broadly similar way to rain-derived overland flow,[11] detaching and transporting unfrozen soil in areas of concentrated flow; however, snowmelt erosion is less well studied and less well understood.

As erosional channels increase in size (i.e., become large rills and gullies[12]), processes such as gravitational collapse of channel walls and heads increase in importance.[13] Runoff and sediment from rills and gullies may be moved into ditches, stream and rivers, and so transported well away from the point of origin. However, sediment may also be deposited within the rill or gully, or beyond the rill or gully's confines in a depositional fan, at locations where the gradient slackens. Here, it may be stored for a variable period of time,[14] possibly being reworked by tillage activity, until a subsequent erosion event is of sufficient size to re-erode the stored sediment. It may then be redeposited further downstream, or make its way into a permanent watercourse and thence to lake or ocean.

Erosion by Water: Spatial and Temporal Scale

The complex hierarchy of subprocesses of water erosion (Figure 1) means that erosion by water operates (and is studied) over a wide range of spatial scales.[15] Rainsplash redistribution and the initiation of microrills and rills occur at a scale of millimeters (Figure 2). Rill erosion on agricultural hillslopes operates at a scale of meters to tens of meters (Figure 3), while gully erosion can occur on a scale of hundreds of meters, or even kilometers. The offsite impacts of erosion can affect very large areas, sometimes hundreds or even thousands of square kilometers (Figure 4).

At every spatial scale, however, erosion is highly patchy. Even in areas of severe erosion, rates of soil loss can vary greatly from point to point on the landscape as the vagaries of topography and land use influence erosive flows over a wide range of spatial scales.[16] Obvious erosion in one field can be found side by side with virtually untouched areas, and within an eroded field, the severity of erosion can vary markedly.

Often, erosion by water also varies across a range of temporal scales. Soil loss from water erosion occurs both incrementally, as a result of many small rainfall events, and more dramatically, as a result of large but relatively rare storms. Dramatic erosion events can produce large gullies, and create flooding and property damage that hits the news headlines. However, a significant proportion of total soil loss may be due to small but frequent erosion events, which nonetheless have a notable cumulative impact.[17]

Global Problem of Accelerated Erosion by Water

While soil erosion by water has been occurring naturally for some 450 million years (since the first land plants formed the first soil), accelerated erosion is of much more recent origin. Yet, on a human timescale, accelerated erosion is old. There is considerable archaeological evidence from many parts of the world that accelerated erosion by water is often associated with early agriculture.[18,19] The association of water erosion with unwise agricultural practices was first noted within a scientific context during the second and third decades of the 20th century by pioneers of soil conservation such as Hugh Hammond Bennett in the United States, and subsequently by workers in other parts of the globe. During the period of colonialism, the imposed adoption of European agricultural methods frequently led to accelerated erosion in developing countries, a problem that continues to the present day.[20,21] During the last few decades of the 20th century, a move toward intensive agricultural technologies that leave the soil bare during times of heavy rainfall meant that previously problem-free areas of the world, such as northwest Europe, began to experience notable increases in water erosion.[22]

Yet despite the global nature of the problem of erosion by water, even today we do not have good information regarding the global extent of erosion by water.[23,24] Data on the severity of erosion are also often limited.[25]

Impacts of Erosion by Water

These can be categorized into on-site and off-site problems.

The removal of the upper horizons of the soil by erosion results in an on-site reduction in soil quality,[26] i.e., a diminution of the soil's suitability for agriculture or other vegetation. This is because the eroded upper horizons are usually the most nutrient rich. Also, because the finest constituents of eroded soil tend to be transported furthest, eroded soils become preferentially depleted of their finer fraction over time, which often reduces their waterholding capacity.[26] Increased use of artificial fertilizers may to an extent, and for a time, compensate for erosion- induced loss of soil quality where economic circumstances are favorable. This is not usually feasible in developing countries, however.[20,21] Loss of soil quality is a long-term problem; globally, it is the most serious impact of water erosion.[27,28]

Movement of sediment and associated agricultural pollutants into watercourses is the major off-site impact resulting from erosion. This leads to silting up of dams, alteration of the water and sediment conveyance capacity of streams and rivers, disruption of the ecosystems of lakes, and contamination of drinking water.[22] Rates of erosion do not have to be high for significant quantities of agricultural pollutants to be transported off-site.[29] This is a shorter-term impact than loss of soil quality; in the more affluent areas of the world, it can be the main driver for present-day soil conservation policy initiatives.[24] Another off-site effect can occur in situations where eroded soil has a decreased capacity to absorb water: increased runoff may lead to downstream flooding and local damage to property.[30]

Future of Soil Erosion by Water

Anthropogenic modification of global climate[31] will modify the future severity and impacts of water erosion. One way of categorizing the effects of future climate change on soil erosion by water is as follows.

- Direct effects: changes in rainfall amount, timing, and intensity, and changes in the amount and timing of snowmelt-generated runoff
- Indirect effects: climate-driven changes in vegetation and land usage

Direct Effects of Future Climate Change

The most direct route by which future climate change will influence future rates and extent of water erosion is by modifying the erosive power of rainfall and runoff.[32,33] The moisture-holding capacity of the atmosphere increases as global temperature increases. This leads to more water vapor in the atmosphere, and thus a more vigorous hydrological cycle, promoting a trend toward more intense precipitation events.[34] This trend is distinct from change in future rainfall amount: it is possible for rainstorm intensities to increase even if total annual precipitation decreases. Climate models predict a continued increase in intense precipitation events during the remainder of the 21st century:[31] more intense rainfall will result in an increase in runoff due to the infiltration excess mechanism, as described earlier. The result will be an increase in erosion and problems associated with erosion.

Amounts and timing of rainfall and snowfall are also predicted to change in many locations globally, but this is less amenable to generalization. Any increased rainfall during times when tillage leaves the soil bare will certainly lead to more severe erosion problems.

Indirect Effects of Future Climate Change

Future climate change will also indirectly affect soil erosion by water by modifying the protection that plants give to the soil. Changes in temperature and rainfall will influence the rate at which existing vegetation (both natural and agricultural) will grow. The complex changes in plant biomass resulting from changes in climate have the potential both to increase erosion rates through faster residue decomposition from increased microbial activity,[35] and also to decrease erosion rates through an increase in soil surface canopy cover and ground cover.[36]

Changes in climate will provide relatively affluent farmers with opportunities to modify tillage practices and timing for crops that are currently grown. It will also provide them with opportunities to introduce new crops. Significant changes in plant biomass, and the protection which it offers to the soil, will occur as a result of such shifts in agricultural practice and land use.[35,37] For example, the introduction to northwest Europe of new crops suited to warmer conditions, such as maize and sunflowers, increases the risk of erosion since both take a significant amount of time to provide adequate crop cover in early summer.[38] Also, the thermal altitudinal limit for agriculture increases as air temperature increases.[39] This could enable farmers to replace permanent grasslands in upland areas with grass leys or cereals; however, such practices have the potential to significantly increase erosion rates, as upland areas often have high rainfall and areas of steep slopes.[38] Farmers in less affluent situations, however, will have fewer options.

Conclusion

Rainfall and runoff can give rise to soil erosion by water: this is an easily learned truism of school geography lessons. However, it is an oversimplification. A closer look shows that water erosion is much more complicated. The many interacting subprocesses of erosion mean that water erosion is still only imperfectly understood, despite almost a century of scientific research. This is unsurprising, since "There are three great frontiers in science: the very big, the very small, and the very complex."[40] Water erosion is very complex, and we still have much to learn about it. This knowledge deficit has many practical implications: for example, computer models that aim to predict rates and extent of water erosion are, after 50 years of development, still decidedly imperfect.[41]

Nonetheless, accelerated soil erosion by water, viewed from still another perspective, is very simple. It is always the result of human actions such as unwise agricultural practices, overgrazing, or poorly executed construction activity. Removal of protective vegetation at times of heavy rainfall inevitably increases the risk of water erosion. The challenge for farmers, for example, is to implement agricultural practices that do not leave the soil vulnerable, while retaining acceptable levels of productivity.

This is not at all simple, and is likely to become an even more challenging task under the influence of future anthropogenic climate change.

Erosion: Irrigation-Induced

Robert E. Sojka and
David L. Bjorneberg

Introduction

Erosion is the greatest threat to agricultural sustainability. Most irrigation is on fragile arid soils that have enormous crop yield potential when irrigated. However, the yield potential is easily lost if the thin veneer of "topsoil" is eroded.[1] Erosion prevention on irrigated land is arguably more important than on rainfed land. Yields from irrigated land are more than double than those from nonirrigated land, with nearly triple the crop value per hectare.[2] In addition, runoff and irrigation return flows (necessary in many surface irrigation schemes) deliver sediment; human, animal and plant pathogens; nutrients and pesticides to downstream fields and riparian waters. These pollutants accumulate in runoff primarily as a result of erosion.

Irrigation's Unique Erosion Characteristics

Irrigation-induced erosion and rainfall-induced erosion result from the same physical and chemical processes. However, the processes come together and interact very differently in each case.[2–4] The magnitude of the differences depends upon the type of irrigation system and on soil and water properties. Briefly, the most important differences stem from soil and water chemistry, wetting rate, water application and infiltration patterns, and, for surface irrigation, absence of water drop impact. These factors are the basis for many erosion control practices unique to irrigation.[4–7] Since 1990, advances in irrigation erosion control have resulted from improved understanding of water quality and antecedent soil condition effects on erosion and from development of polyacrylamide (PAM) use.

The key to controlling erosion is controlling runoff. Runoff is controlled in two ways. It is minimized by scheduling irrigation to meet, but not exceed, crop water and salt leaching requirements (i.e. avoid over-irrigation), and it is managed by using application rates during each scheduled irrigation that minimize runoff and erosion for that event. Systems should be designed and operated to minimize over-irrigating of some areas in order to adequately irrigate others. In furrow irrigation this is accomplished by reducing the length of furrows; managing inflow rates and advance times, and where possible, cutting back inflow rates once runoff begins; or through use of surge irrigation (surge irrigation sometimes erodes near the inlet because of higher flows during initial pulsing of water). Sprinkler systems can reduce runoff with variable rate emitters that match application rates to soil infiltration rates at specific field locations.

Erosion reduction from improved scheduling and application management is usually proportional to runoff reduction. Reducing over application also reduces pumping costs and losses of applied nutrients and agri-chemicals. In surface irrigation systems, where 20%–40% runoff is often required to achieve field application uniformity, erosion remediation can be integrated into water supply enhancement by pumping sediment-laden drain water back onto fields. This does not prevent erosion, but does replace most of the eroded soil along with the saved water for the pump-back cost.

Methods of Control

Conversion to Sprinklers

One effective way to prevent irrigation-induced erosion is conversion from surface to sprinkler irrigation. Again, the soil conservation benefit from conversion to sprinklers derives from and is proportional to the reduction of runoff. Sprinkler irrigation has higher technical, capital, energy, and infrastructure requirements than surface irrigation. Therefore, sprinklers are used only on a small fraction of global irrigated area, whereas, nearly 60% of US irrigated land uses sprinklers. Properly designed and managed sprinkler systems eliminate 100% of off-site sediment losses. However, with sprinklers, there is a tendency to extend irrigation to steeper slopes or otherwise more erosive lands. On steep land, when sprinkler systems are poorly designed or managed, erosion can occur.

Center pivots can cause erosion problems because of water running in wheel ruts, down steep slopes, or due to high application rates at outer reaches of the pivot,[8] especially when using extendable booms and high volume end-guns to reach corners. Erosion from high application areas, or where runoff concentrates, can be reduced using tillage, pitting, and mulching between rows to increase surface roughness storage and reduce runoff.[9–11]

Soil Protection and Tillage

Many approaches developed to control rainfall-induced erosion can prevent irrigation-induced erosion, particularly under sprinklers, e.g., no-till and conservation tillage, which rely on crop residue to protect the soil surface. Despite typical erosion reductions >90%, often with increased yields,[12] no-till and conservation tillage are rarely practiced by surface irrigators. Floating residue often migrates along and clogs irrigation furrows, washing out adjacent beds and furrows, while under-irrigating the blocked furrow. In basin flood irrigation, floating debris can interfere with water spreading, sometimes concentrating initial flows, eroding some areas, and burying emerging plants with sediment or debris. No-till farming with furrow irrigation is further complicated by crop rotations that require different row (and furrow) spacings each season.

Sojka et al.[13] demonstrated 60% reduction in field sediment loss from furrow-irrigated potatoes that were paratilled (subsoiled) following planting. Slight yield increases and significant tuber grade improvements raised profitability under both furrow and sprinkler irrigation with paratilling.[14] Because irrigation assures crop water availability, yield benefits from improved root development are not consistently seen with subsoiling in irrigated crops.[15] Subsoiling is commonly practiced with sprinkler irrigation to enhance infiltration and decrease runoff, thereby reducing erosion. However, farmers are cautious about subsoiling furrow-irrigated crops because of the potential for irregular water flows in subsurface cracks to interfere with irrigation uniformity. Field preparation or land forming practices that reduce water application uniformity, or increase runoff, are avoided by irrigators.

Placing mulch or growing sod in irrigated furrows reduces erosion. Sod nearly eliminated runoff sediment.[16] Straw mulching reduced sediment loss from 52% to 71%.[17–20] Drawbacks of these techniques relate to the management of sodded furrows, the added operations and equipment needed to place straw, and debris migrating along and clogging mulched furrows.

Site Modification

Various "engineering" approaches have been used to reduce field sediment losses from surface irrigation. The most common is use of settling basins. Large quiescent pools to facilitate particulate settling from runoff collected from fields up to 20 hectares are fairly typical. Settling pond size depends upon the area served, rate and volume of runoff, sediment concentrations expected, and particle size distribution. Small settling basins along the bottom of surface irrigated fields, serving a few rows per basin, are sometimes easier to manage at season's end, when trapped sediment spread back onto the field using farm equipment. Big ponds require large scale equipment for construction, cleaning, and soil redistribution. For medium-textured soils, about 60% of suspended mass entering settling ponds is retained. The nonretained soil is of the clay size range.[21] Since clay carries most of sediment's adsorbed nutrient and chemical load, failure of ponds to retain clay impedes retention of agricultural chemical pollutants, despite the high percentage of sediment mass captured. Furthermore, effectiveness declines as ponds fill with sediment, reducing water residence time. Another variation on ponds is installation of buried drains and stand pipes to regulate water level in tail ditches.[22] The stand pipes force ponding and prevent gradual concaving of field tail ends. They do not, however, prevent loss into the drain of sediment entrained in runoff from upper field reaches.

Altering canopy configuration can reduce erosion. Sojka et al.[23] halved field sediment loss using narrow or twin row plantings. Water ran between closely placed furrows, reducing irrigation duration (and runoff) and allowing root systems and canopy debris to reduce soil detachment in the furrow. Filter strip crops drilled at right angles into the final 3–6 m of furrow-irrigated row crops also remove entrained sediments from runoff,[6] but do not prevent sediment migration from field inlet to tail end. Because filter strip management is a compromise between two crops, yield from the strips is typically half that expected for either crop alone.

Water Properties

Both the physical and chemical properties of irrigation water affect erosion. Erosion is greatly reduced by reducing sprinkler droplet size or energy[24,25] or by reducing stream flow in furrows.[26] These physical changes require adjustments in application timing, furrow lengths, and irrigation durations to properly match water application constraints with crop water needs.

Water electrolyte chemistry greatly affects the erosiveness of irrigation water.[27–30] High sodium adsorption ratio (SAR) and low electrical conductivity (EC) contribute to soil aggregate detachment, disruption, and dispersion of fine primary soil particles in runoff. The effect of low EC and high SAR are synergistic. Increasing electrolyte concentration with a calcium source lowers SAR, shrinks the ionic diffuse double layer around charged soil particles, and prevents dispersion, thereby maintaining aggregate stability and resisting erosion. The conjunctive use of waters from different sources or the addition of calcium can raise EC and/or lower SAR to reduce erosion potential and improve infiltration by stabilizing surface- soil structure.

Adding large polymeric compounds to irrigation water is an effective erosion prevention technology.[31–33] These compounds, when delivered in dilute concentrations (typically 1–10 ppm) by the irrigation stream, increase aggregate stability and inter-aggregate cohesion as water infiltrates. Erosion reduction of 95% is typical for application of 1 to 2 kg /ha per treated irrigation. Adoption has been greatest for furrow irrigation erosion reduction, but interest in extending the technology to sprinklers is growing as much to improve infiltration uniformity as to reduce erosion.[34–36] The most successful class of polymers has been anionic polyacrylamide, allowing safe, easy, and effective erosion prevention for seasonal application rates of 3–5 kg/ha^{-1}, or under \$35/ha^{-1} per season.[37]

Pesticide Translocation Control: Soil Erosion

Monika Frielinghaus,
Detlef Deumlich,
and Roger Funk

Soil Erosion: A Global Problem

One-third of the world's agricultural soils are reported to be in a degraded state. Water and wind erosion contribute to approximately 84% of the observed deterioration. The worldwide soil loss from soil erosion is estimated at about 75 billion tons yr^{-1}.[1] The changes caused by soils by human-induced erosion over many years are significant and have often resulted in valuable land being abandoned.[2] Given a very slow rate of soil formation, any soil loss of more than 1 ton ha^{-1} yr^{-1} within a time span of 50–100 yr can be considered as irreversible. Soil from the Sahel zone in Africa is picked up in Florida and the Brazils Amazonas region and blown across the Atlantic Ocean each year. Regularly, when the Chinese till their land in spring, whirled-up soil is detected in Hawaii. Most soil loss can be traced to inappropriate land management practices. Viewed on a large scale, these scenarios create an agricultural dilemma of global proportions.

Pesticides are used in nearly all agricultural systems and provide essential help against diseases, pests, and weeds, thereby contributing substantially to securing global food supply. However, the pesticides' translocation due to wind and water erosion causes heavy environmental damages.[3] In many regions, sediment transport by surface runoff or wind is the most important nonpoint pollutant generated by agriculture. While pollutants may be too insoluble or soil bound to be transported in runoff water, erosion can mobilize them into runoff. Erosion sediment is also an important vehicle for the translocation of pesticides that are water insoluble or strongly bound to eroding soil. Although wind erosion has been overlooked in the past as a land degradation process, it has received more attention now as an important source of atmospheric pollution.[4] Mainly, this is attributed to the removal of fine soil particles and organic material, carrying the adsorbed pesticides.

Water and Wind Erosion and Sediment Transport

The processes of soil erosion involve detachment of material by two processes: raindrop impact and drag force traction. Material is then transported either by overland water flow or by saltation through the air.

Water Erosion

Runoff caused by heavy rainstorms (high intensity or long duration) is the most important direct driver of severe soil erosion by water (Figure 1). Mean losses of 20 to 40 tons ha^{-1} in individual storms may happen once every 2 or 3 years. More than 100 tons ha^{-1} soil loss is measured after extreme storms.[5]

The water erosion rate is a complex result of high rainfall amount or intensity, soil erodibility (instability), slope steepness and length, and the type of land use. As to the latter, the main causes are inappropriate agricultural practices, deforestation, overgrazing, forest fires, and construction activities.

The formation of a water erosion system on agricultural areas without surface protection by crops or plant residues causes rainwater and sediment transport in rills or gullies. The first phase after ponding is a concentration of water at linear paths. The rill formation may be influenced by a variety of different factors like soil crusting, wheel tracks, and reduced infiltration by soil compaction. Rills and gullies often develop in close proximity to one another. The second phase is a heightened concentration of water at morphological deep lines (thalways). The hydrological power of transport water as well as the off-site risk for sediment and pesticide transport into the lakes or rivers is increased with the thalways' catchment area (Figure 2).

Often, the interaction between runoff and sediment transport complicates the process' description.

Wind Erosion

Wind erosion occurs when three conditions coincide: high wind velocity, a susceptible surface with loose particles, which can be picked up, and insufficient surface protection by plants or plant residues (Figure 3).

Wind erosion results from wind moving across a dry soil surface and dislodging soil particles by pressure and lifting forces. The process is self-perpetuating; blowing sediment disturbs additional particles that are then lifted into the airstream.

The potential wind erosion rate is influenced by high wind velocity, soil erodibility (size/weight of particles), the degree to which the landscape is wind exposed, and the uses of land. The real wind erosion risk depends on the actual soil moisture and the real soil cover rate.

The modes of soil particle motion are closely related to particle size, density, and shape. It is important on agriculturally used soils of each textural class with organic material and absorbed pesticides (Figure 4). Particles with a smaller terminal velocity than the turbulent motions become suspended. Particles smaller than 20 μm are subjected to long-term suspension whereby they can be carried across several hundred kilometres for several days. Particles with diameters between 20 and 70 pm remain suspended for only a few hours and cannot be transported very large distances. These kinds of small particles are an important factor regarding the adsorption of pesticides.[6]

Assessment of Pesticide Translocation

Pesticide findings even during the non-spraying seasons indicate that the occurrence is not only due to direct contamination from accidental spills and incorrect handling but also to diffuse contamination originating from normal pesticide use.

Pesticide mobility may result in redistribution within the application site or movement of some amount of pesticide off-site.

Pesticide characteristics are relevant for determining the fate of transport by wind or water erosion. These properties include solubility in water, tendency to adsorb to the soil, and pesticide persistence in soil.[7]

Water solubility is measured in milligrams per liter. Pesticides with more than 30 mg L^{-1} solubility tend to move with surface runoff during an erosion event. Pesticides with solubility about less than 1 mg L^{-1} tend to remain on the soil surface and may move with soil sediment in surface runoff if soil erosion occurs.

Soil adsorption is measured by K_{oc}, which is the tendency of pesticides to be attached to soil particles. Higher values (>1000) indicate a pesticide that is strongly attached to soil and less likely to move unless sediment transport occurs. Lower values (<300–500) indicate pesticides that tend to move with surface runoff. Among other things, sorption is influenced by soil moisture, organic matter content, and texture. These parameters are also important to quantify soil erodibility. Soils high in clay or organic matter content, or both, have a higher potential to adsorb pesticides, because small particles have plenty of surface area and are chemically more active compared with sandy soil particles.

Pesticide persistence is measured in terms of the halflife, or the time in days required for a pesticide to degrade in soil to one-half of its original amount. A pesticide with a half-life >21 days may persist long enough to move with surface runoff or erosion before it degrades. For example, experiments with dieldrin and aldrin show half-life values of about 3 or 4 years. These two pesticides lost 90% of their original concentration in no less than 10 years.[8]

Field investigations to estimate the pesticide transport during an erosive rain were known by Gouy et al.[9] and Klöppel et al.[10]

In the first experiment, pesticides were applied onto the bar soil surface. The simulated rainfall with an intensity of 33 and 44 mm hr^{-1}, respectively, began 20 hr after pesticide application (Table 1).

Atrazine, simazine, and alachlor, for example, were mainly transported in surface runoff. In contrast, 90% of transported trifluralin was adsorbed on eroded particles. Lindane, for example, showed an intermediate status and the high dynamic of pesticide translocation.

TABLE 1 Total Amounts of Pesticide in Runoff Samples and Their Distribution between Sediment and Liquid Phases

Pesticide	Water Solubility (mg L–1)	Adsorption, Koc (mL g–1)	Total Amount (% of Applied)	Distribution On Sediment	Distribution In Solution
Atrazine	33	100	13	0.8	12.2
Simazine	6	130	9	0.6	8.4
Alachlor	240	170	14	0.8	13.2
Lindane	7	1100	17	6.0	11.0
Trifluralin	1	8000	14	12.6	1.4

The second rainfall simulation study on small field plots provided information about worst cases for pesticide translocation (rainfall intensity of about 70 mm hr^{-1} and 100 mm accumulated rainfall).[10] The pesticides of the first group had water solubility concentrations of 65 and 700 mg L^{-1}, e.g., isoproturon and dichlorprop-p, respectively. The second group had solubility concentrations <1 mg L^{-1}, e.g., bi-fenox. Two different soil cover conditions were tested.

The results demonstrate that the influence of soil cover characteristics on concentrations and total runoff losses of pesticides for the highly soluble group is restricted to the start of the rain event after pesticide application and the runoff rate. The sediment concentration of pesticides in the fairly soluble group was comparable to those of the first runoff event independent of the time lapse between the application and rainfall event. The fairly soluble pesticides are thus exiting the field sites only by being adsorbed to eroded sediment. The cumulative soil loss is the most reliable indicator that explains the decrease in sediment and pesticide concentrations during each rainstorm (Table 2).

It is not possible to compare these results with other data from literature, due to the great variety of parameters concerning the performance of experiments. However, the findings are consistent in that a rough estimation of pesticide concentration in runoff and total pesticide losses is possible when rainfall (duration, intensity) and soil erosion potential are known.

Pesticide transport by wind may occur through isolated pesticide displacement or in a sediment-bounded form. At present, only initial findings of the amount of translocated pesticides are available. It is assumed that the horizontal transport of particulate-bounded pesticides is more than 50% of the total loss resulting from extreme wind erosion events. The herbicide loss of about 1.5% of the total amount, which was applied and integrated into the upper humus horizon on steppe soils in Canada, was measured after 13 wind erosion events. Herbicide loss from a non-integrated application on soil surfaces was approximately 4.5%.[11]

Experiments in a wind tunnel with the pre-emergence herbicide flurochloridone showed <1% to <58% displacement dependent on soil erodibility and measuring height.[6]

Determination of pesticide content in the atmosphere is extremely important but very difficult. Additionally, pesticides enter the atmosphere via many different processes, particularly by volatilization (simulated with PEARL, PELMO), unconsidered in our context.[12]

The investigation of atrazine, alachlor, and acetochlor concentrations on soil surface and dissipation rates of wind-erodible sediment and larger fractions from two soil types was important.[13] Undisturbed and incorporated (5 cm deep) soil surface were analyzed. The surface (1 cm) of soil was removed by vacuum 1, 7, and 21 days after herbicide treatment. About 50% of the recovered material was classified as wind-erodible sediment. This erodible sediment contained about 65% (undisturbed soil surface) and 8% (incorporated soil) of the applied herbicides, respectively, after 1 day. The concentrations were similar after 7 and after 21 days. However, a 50% dissipation rate for each herbicide was found after 15 days for wind-erodible sediments compared with 30–55 days for greater fractions. These data indicate that wind-erodible size aggregates and particles could be a source of herbicide contamination, but there is currently no information about quantities.

TABLE 2 Average Pesticide Losses in Relation to Applied Pesticide Dependent on Time (Rainfall Intensity: 70 mm hr^{-1}, Accumulated Rainfall: 100 mm)

Name of Pesticide	Pesticide Transporting Medium	Time and Concentration Lapse between Pesticide Application and Rainfall Event				
		2 hr	1 day	3 days	5–7 days	14 days
Application on Bare Soil Surface Sites (Pre-Emergence Application) % of Applied Amount						
Isoproturon	Total	4.5–12.4	4.0–17.2	5.4–13.3	2.1–11.2	n.e.
	In runoff water	3.8–9.8	2.9–13.9	4.0–9.8	1.4–9.0	n.e.
	In eroded sediment	0.7–2.6	1.7–3.3	1.4–3.5	0.7–2.2	n.e.
Dichlorprop-P	Total	2.1–10.4	2.2–16.7	5.9–10.4	1.2–8.3	n.e.
	In runoff water	1.9–9.8	1.8–15.3	5.3–9.3	0.9–7.0	n.e.
	In eroded sediment	0.2–0.6	0.4–1.4	0.6–1.1	0.3–1.3	n.e.
Bifenox	Total	15.6–19.0	19.3–21.6	14.3–17.2	9.3–13.8	n.e
	In runoff water	<0.1–0.9	<0.1–0.3	<0.1–0.3	<0.1–0.2	n.e.
	In eroded sediment	14.7–19.0	19.0–21.6	14.0–17.2	9.3–13.6	n.e.
Application on Small Covered Soil Surface (Barley with 3–5 Leaves) % of Applied Amount						
Isoproturon	Total	2.8–13.3	1.8–16.4	4.1–11.2	1.5–6.0	1.6
	In runoff water	2.2–11.4	1.5–13.5	3.3–8.6	1.0–4.6	1.1
	In eroded sediment	0.4–1.9	0.3–2.9	0.8–2.6	0.5–1.4	0.5
Dichlorprop-P	Total	0.8–10.0	0.9–9.2	1.0–8.3	0.7–4.1	0.8
	In runoff water	0.7–9.4	0.8–8.4	0.8–7.5	0.6–3.7	0.7
	In eroded sediment	0.1–0.6	0.1–0.8	0.2–0.8	0.1–0.4	0.1
Bifenox	Total	11.2–15.0	7.8–15.5	7.8–15.9	3.4–9.8	5.2
	In runoff water	<0.1–0.9	<0.1–0.2	<0.1–0.4	<0.1–0.3	<0.1
	In eroded sediment	11.2–14.1	7.8–15.5	7.4–15.9	3.4–9.5	5.2

It is important to recognize that only one fraction of pesticides in use is very strongly soil bound as to be transported in the sediment phase of runoff principally today (insecticides paraquat and pyrethroid, and other non-ionic hydrophobic species). Such pollutants may be too insoluble or soil bound to be transported in runoff or wind stream, but erosion can mobilize them.

Monitoring and Modeling

Monitoring in landscapes with a high erosion risk (water and wind) is predicted upon the estimation of rain and wind erosivity, soil erodibility, and the morphological factors of the areas (slope steepness, field length, wind openness, thalways). In sites with an erosion risk, well-designed field studies are the best way to assess off-site transport paths. When these data are not available, estimation about modeling will be necessary.

Water Erosion Models

Pesticide transport models are rare. Therefore, currently, water and wind erosion models serve as a basis for risk assessment, as a means to an end (Table 3).[14]

Most of the models were developed to assess impacts of different agricultural management practices; they are not adapted to predict exact pesticide, nutrient, or sediment loading in an area. The curve number method is an event or field scale orientated model and limits the results of some other models (ANSWERS, GLEAMS, CREAMS, and SWAT). In most erosion models, runoff and sediment load are only computed for the catchment outlet. Most of the hydrological models predict total runoff better than

TABLE 3 Selected Erosion Models and Hydrological Models with Integrated Pesticide Transport

sediment load. The models over-or underestimate empirical results for small erosion events especially. Also, these models do not consider any attenuation or partitioning during transport and therefore fail to predict loads of soluble pesticides to surface waters.

WEPP and EROSION 3D models simulate the erosion and sediment transport continuously. The WEPP model is based on fundamentals of erosion theory, soil and plant science, channel flow hydraulics, and rainfall–runoff relationship.

It is possible to extend erosion and sediment transport models to a transport model for pesticides as well as sediment particles. The pesticide transport behavior that includes interaction processes in solutions is unknown for watershed scale.

Wind Erosion Models

A physical-based process model is the wind erosion prediction system (WEPS). This is a continuous, daily time-step model for simulation of weather, field conditions, and wind erosion. It has the capability of simulating spatial and temporal variability or soil surface parameters and soil loss or deposition within a field. To aid in the evaluation of offsite impacts, the soil loss is subdivided into components and reported as saltation creep, total suspension, and fine particulate matter components (PM 10). The transport capacity for insoluble pesticides bounded in kind of suspension or PM 10 is appreciable.[5]

Further models are the revised wind erosion equation (RWEQ) and WHEELS, which can be used for single event simulation, long-term risk assessment, and assessment of changing management strategies.

Soil Erosion and Pesticide Translocation Control

The best management strategy requires inventory and risk analysis.

A step-by-step analysis is the basis for an effective pesticide translocation control:

Step 1: Monitoring the pesticide content in lakes or rivers.
Step 2: Quantification and elimination of pesticide point sources.
Step 3: Definition of non-point pesticide sources.
Step 4: Evaluating the pesticide management in the catchment (water solubility, adsorption, persistence, time of application).
Step 5: Estimating the potential water erosion or wind erosion risk (erosivity of rainstorms and wind, erodibility of soil, landscape and field openness, composition, thalways).
Step 6: Estimating the actual water and wind erosion risk (soil cover by plants or plant residues, crop rotation, humus status, soil tillage practices).
Step 7: Development of an efficient concept to realize a sustainable control of soil erosion, runoff, and pesticide transport.

The most important soil-protection strategy is based on the principles of precaution that took into consideration the economic and ecological consequences of the high costs and the endangerment to life and biodiversity.

As a result, the risk of soil erosion and pesticide transport should be addressed by an appropriate selection and a carefully timed application of pesticides. Products with low water-soluble active substances and a very short persistence should be preferred for slopes with a high runoff potential, caused by a network of waterways nearby the lakes or rivers. For example, it is advisable to replace products with isoproturon or isopropylamine with products containing pendimethalin or bifenac. For purposes of crop protection, water-soluble products that infiltrate into the upper soil layer should be used on areas with a high risk of wind erosion. Pre-emergent application on bare soil surface should be avoided on areas with a high water or wind erosion risk.

The most effective system to prevent sediment transport and reduce runoff is a temporal and spatially closed vegetation or residue covering. This cover protects the soil surface from the initial soil detachment action caused by raindrop splash forces or wind power. The result is a lower volume of runoff and sediment transport. Plant roots retain soil particles and reduce the sediment load (Table 4).

The extent of soil cover material, green plant mass, or crop residues can be influenced by the farmer's management and soil tillage practices.

The farmers can estimate the risk of their tillage system independently (Table 5).

The rate of soil cover is a highly effective indicator for assessing the risk of water and wind erosion. This indicator addresses the following questions: 1) how much soil cover is necessary to reduce the threat of erosion, runoff, and pesticide translocation for a high-risk area; and 2) how much cover can be realized dependent on crop type, crop rotation, tillage, and management practices in different regions. Based on this analysis, appropriate preventive management practices can be required.

The greatest wind and water erosion risk occurs after seedbed preparation, which is characterized by the lowest degree of soil surface roughness and bare soil. Crop selection, improved crop rotations, and a change in soil tillage practices are established methods for increasing the soil cover for a reduced pesticide transport by wind and water erosion and runoff.

More basic management methods such as contour tillage or strip cropping practiced in some parts of the world are not as effective as conservation tillage in minimizing soil erosion.

Other technical solutions to reduce pesticide transport in areas with high erosion risk are engineering measures such as small ponds or farm-track construction. Alteration of field design, hedge planting to reduce wind openness, and waterways with permanent grass-covered banks or buffer strips nearby the lakes or rivers are effective arrangements to interrupt pesticide transport.

Therefore, precautionary measures against water and wind erosion as well as pesticide translocation have to be targeted (for example, prevention of pesticide pollution), site specific (for example, adequate for water and wind erosion risk), and applied for a longer period.

TABLE 4 Correlation between Cover Rate, Runoff, and Soil Loss Estimated from Long-Term Experiments with Conventional and Conservation Tillage Treatments.

Soil Cover with Green Plants	Soil Cover with Plant Residues	Runoff	Relative Soil Loss by Sediment Transport in Runoff	Relative Soil Loss Caused by Wind Erosion

Erosion and Runoff Control: Part of the Environmental Legislation

Precautionary measures play an important role in promoting sustainability and realizing the European Water Framework Directive (EU-Com, 2000, Water Framework Directive. Official Journal L 327). The Directive is a contribution to the progressive reduction of hazardous substances emission to water. Strategies against pollution of water are formulated in Articles 2 and 16: "Pollution means the direct or indirect introduction of substances or heats into the air, water or land as a result of human activity, which may be harmful to human health or the quality of aquatic ecosystems or terrestrial ecosystems directly depending on aquatic ecosystems …" The Commission identified priority hazardous substances like pesticides (Annex X). Quality standards as to the concentration of these substances in surface water, sediment, or biota exist.

There are diverse conditions and needs in the community members that require different specific solutions. The main principles of soil erosion control are formulated in the strategy entry of the EU-Com: "Strategy for soil protection 1995–2005."

A regional legislation is the German Soil Protection Act (1999).

The meaning of hazard prevention is defined in § 4: "(1) official directive for analysis of damage and erosion pattern after serious events; (2) legislative ordinance for conservation and land-use change to prevent future hazards."

The definition of precaution is paraphrased with the term "best management practice in agriculture" (§17 of the Act). The essentials of best practice in agricultural soil use are the monitoring of soil fertility and functional capacity as a natural resource. Best management practice is founded on the principle that "soil erosion shall be avoided wherever possible, by means of site-adapted use, especially use that takes slope, water and wind conditions and the soil cover into account; … the predominantly natural structural elements of field parcels that are needed for soil conservation, especially hedges, field shrubbery and trees, field boundaries and terracing, shall be preserved.…"

The German Federal Immission Control Act (2002) must also be considered in implementing the precautions necessary to protect the environment by wind-initialized pesticide transport in the form of PM 10 emission.

Similar acts and regional precautionary basis information exist in other European countries like Austria and Switzerland.

The Australian Pesticide Act (1999) aims to reduce the risks associated with the use of pesticides to human health, the environment, property, industry, and trade.

The U.S. Food, Conservation, and Energy Act of 2008 contains Title II, "Conservation" with the Conservation Reserve Program (Subtitle B) and the Environmental Quality Incentives Program (Subtitle F). The Environmental Protection Agency (EPA) regulates the sale and use of pesticides in the United States through registration and labeling of pesticide products. The EPA is directed to restrict the use of pesticides as necessary to prevent unreasonable adverse effects on people and the environment (Pesticide Registration Improvement Act of 2004, P.L.108–199).

Conclusion

Most soil loss caused by wind and water erosion can be traced to inappropriate land management practices. Pesticide findings even during the non-spraying season indicate that the occurrence is due not only to direct contamination from accidental spills and incorrect handling (point source). Non-point sources of pesticide water and air pollution are water and wind erosion. Pesticide solubility, soil adsorption of pesticides, and pesticide persistence are important parameters to estimate the translocation by runoff water and sediment movement. Rainfall simulation studies demonstrate the different kinds of translocation, dependent on the solubility: highly soluble pesticides were analyzed in runoff water and the concentration decreased after application (for example, atrazine, simazine, isoproturon, and dichlorprop); fairly soluble pesticides were analyzed, and they only adsorbed onto eroded sediment (for example, bifenox and trifluralin). The second group could be transported via water or wind erosion.

Only one fraction of pesticides in use is very strongly soil bounded and therefore too insoluble to be transported in runoff or wind stream, but erosion can mobilize them.

That means that soil erosion control includes non-point pollution by pesticide translocation. A step-by-step analysis is the basis for an effective, sustainable, and site-adapted land use and agriculture management. The risk for soil erosion and pesticide translocation should be addressed by an appropriate selection on a carefully timed application of pesticides. Products with low water-soluble active substances and a very short persistence should be preferred for slopes with water erosion risk. Water-soluble products that infiltrate into the upper soil layer should be used on areas with a high wind erosion risk. The most effective system to prevent sediment transport and runoff reduction is a temporal and spatial closed vegetation or residue covering. The farmers can evaluate their management self-contained to change the system.

Pesticides

Marek Biziuk,
Jolanta Fenik,
Monika Kosikowska, and
Maciej Tankiewicz

Introduction

A numerous and diverse group of chemical compounds with an extensive range of action,[1] pesticides are very widely used, though primarily to eliminate insect pests and weeds and to limit their negative effects in agriculture and in the household.[2–4] They enable the quantities and quality of crops and food to be controlled and help to limit the many human diseases transmitted by insect or rodent vectors. Despite their many merits, however, pesticides are some of the most toxic, environmentally stable and mobile substances in the environment, which are able to bioaccumulate. They can also participate in various physical, chemical, and biological reactions, as a result of which even more toxic substances may be produced; by accumulating in living organisms, these can lead to irreversible, deleterious changes. The non-rational application of pesticides also adversely affects the environment and humans, increasing susceptibility to diseases and poisoning.[1]

Characteristics of Pesticides

The following are the current uses of pesticides:

- To remove, control the number of, or attract various kinds of pests destroying plants and plant products
- To kill weeds
- To destroy foliage and excess numbers of flowers
- To increase the production of animal and plant biomass
- To combat human, animal, and plant pathogens
- To control the growth of plants or their parts
- To combat microorganisms causing farm produce to rot and decay
- To combat insects and other animals occurring in homes, cellars, stores, etc.
- To protect fabrics in textile mills and dry-cleaning establishments
- To prevent the growth of algae in swimming pools
- To combat fungi in paints and paper products
- To protect museum exhibits against the action of pests
- To counteract growths on boats and ships[1]

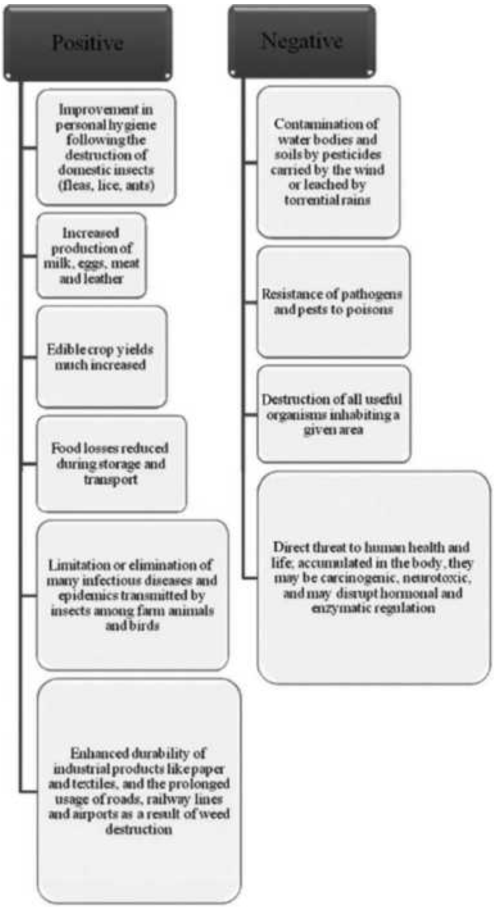

FIGURE 1 The effects of using pesticides.
Source: Biziuk et al.,[1] Moreno et al.,[5] and Hajslova and Zrostlikova.[6]

Ideally, pesticides should be applied only in accordance with their purpose, so that they do not have a negative effect on humans, flora, or fauna. In practice, however, such complete selectivity is unattainable.[1,4] The factor determining whether a particular agent can be used is its rapid biodegradability and its minimal toxicity vis-à-vis the environment.

Chemical pesticides are of enormous importance in increasing the efficiency and quality of agricultural produce. They enter the environment in various forms: powders, moistened powders, powders for preparing aqueous solutions, and concentrates for making up emulsions or sprays. The ubiquitous application of pesticides not only contaminates water, soil, and air but also causes them to accumulate in farm produce like fruit and vegetables. Figure 1 summarizes the effects of pesticide application.[1,5,6]

According to Their Chemical Structure

TABLE 1 Classification of Pesticides according to Their Chemical Structure

Class	Examples
Inorganic pesticides	Arsenic and fluoride insecticides, inorganic herbicides
Organic pesticides	Organochlorine and organophosphorus insecticides, carbamates

Source: Biziuk et al.[1]

According to Their Chemical Class

TABLE 2 Classification of Pesticides according to Their Chemical Class

Class	Examples
Organochlorine	DDT, endosulfan, methoxychlor
Organophosphorus	Malathion, dichlorvos, fonophos
Carbamates and their derivatives (urethanes)	Aldicarb, aminocarb, furathiocarb
Derivatives of phenoxycarboxylic acids	2,4-D, MCPA, dicamba
Triazines and their derivatives	Atrazine, simazine, anilazine

Source: Biziuk et al.[1]

The diversity of their chemical structure, action, and application makes any classification of pesticides difficult.[1] There are a number of criteria according to which they can be categorized: toxicity, purpose of application, chemical structure, environmental stability, and the pathways by which they penetrate target organisms. Tables 1–4 outline some of these classifications:[1]

According to Their Application

TABLE 3 Classification of Pesticides according to Their Application

Class	Subclass	Application
Zoocides—agents for combating animal pests	Insecticides	Destruction of insects
	Aphicides	Destruction of aphids
	Acaricides	Destruction of plant mites
	Attractants	For attracting pests
	Bactericides	Destruction of bacteria
	Larvicides	Destruction of larvae
	Limacides	For killing slugs

(*Continued*)

TABLE 3 (Continued) Classification of Pesticides according to Their Application

Class	Subclass	Application
	Molluscicides	For killing snails
	Nematocides	For killing nematodes
	Ovicides	Destruction of the eggs of insects and mites
	Repellents	For repelling insects
	Rodenticides	For combating rodents
Fungicides		Fungicidal and fungistatic agents
Herbicides		Weed killers
Plant growth regulators—	Deflorants	For removing excess flowers
stimulants or inhibitors of the	Defoliants	For removing excess leaves
life processes of plants	Desiccants	For drying plants
Synergetics		For potentiating the action of other substances

Source: Biziuk et al.[1]

According to Their Toxicity

TABLE 4 Classification of Pesticides according to Their Toxicity

Toxicity Class	Median Lethal Dose LD50 (mg/kg body mass) When Administered via the Digestive Tract	Stability in the Soil (Time for Degradation to Harmless Products)	Stability in the Aquatic Environment (Time for Degradation to Harmless Products), Number of Days
I—Highly toxic	≤25	More than 2 years	>30
II—Toxic	25 < LD50≤200	0.5–2 years	11–30
III—Harmful	200 < LD50 ≤2000	1–6 mo	6–10
IV—Not very harmful	>2000	Within 1 mo	<5

Circulation of Pesticides in the Environment

Nowadays, pesticides are very widely applied, not just in agriculture. Their ubiquity and ever-increasing consumption pose a greater hazard to the environment to which they are transported. Pesticides can enter the environment in their primary form or as decomposition products. When in the environment, they are subject to various transformations. They may be borne by wind or rain from their points of application to neighboring areas and crops, where they are not required or may be harmful. The quantity of pesticides circulating in a given region depends to a large extent on their intensity of application or the type of crop being grown there. Both modern pesticides and older ones are present in the environment. Figure 2 illustrates the circulation of pesticides in nature.

Pesticides in the Aquatic Environment

Pesticides are the most common contaminants in surface water and groundwater. There are also many reports of pesticides being found in drinking water, well water in farming areas, rainwater, subterranean water, and ice from the polar regions. Once in the aquatic environment, pesticides have a deleterious effect on the quality of waters used as sources of drinking water for the large majority of the Earth's

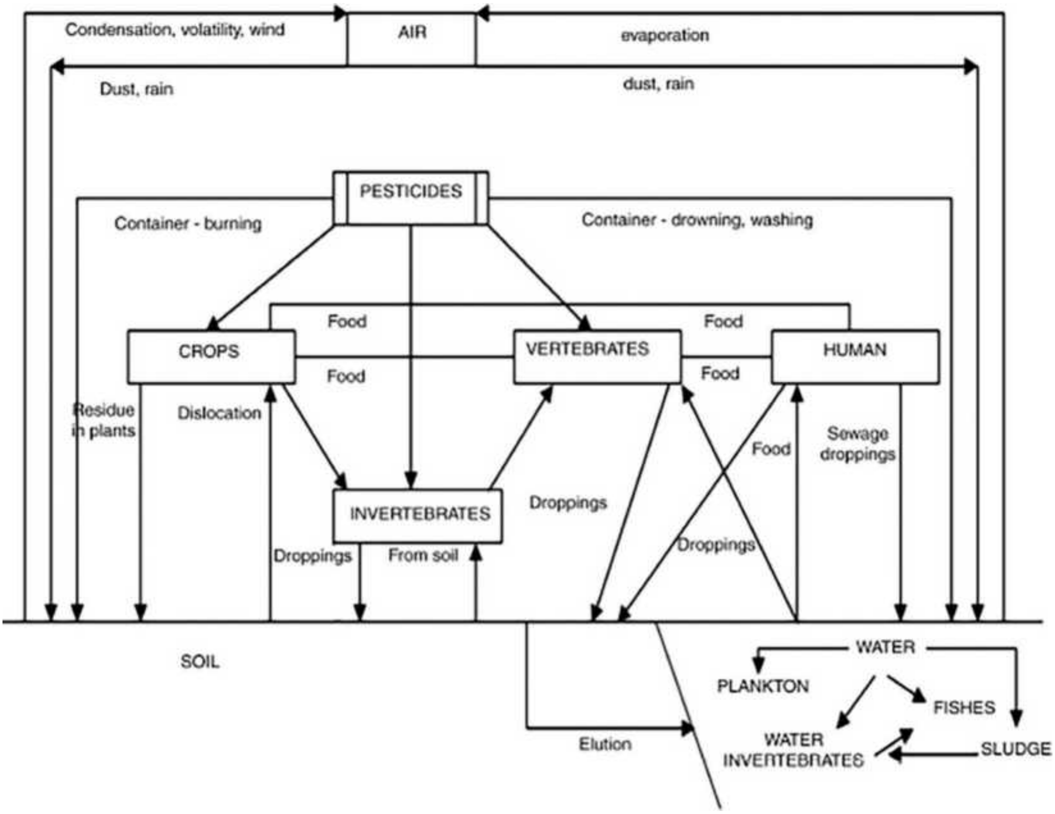

FIGURE 2 The circulation of pesticides in nature.
Source: Biziuk et al.[1]

human population. Concentrations are highest during the spring snow melt period and when pesticides are being applied to crops.[1,2] There are many sources from which pesticides get into the aquatic environment. Usually, these are area sources (e.g., precipitation, farming areas), but they may also come from point sources such as effluents of various kinds or leaking waste disposal sites. They can also be transported in the air for great distances.[1,7] When in the aquatic environment, pesticides are subject to a variety of transformations and processes:

- Physical (accumulation, deposition, dilution, diffusion)
- Chemical (hydrolysis, oxidation)
- Photochemical (photolysis, photodegradation)
- Biochemical (biodegradation, biotransformation, bioaccumulation)[3,8]

Substances of greater toxicity may be formed as a result of these processes, and when they accumulate in aquatic organisms, they can cause much irreversible damage to them.

Pesticides in the Air

The widespread application of pesticides contaminates not only waters and soils; the air is also affected. This is because pesticides rise into the air as they are being sprayed and thereafter (post-application emission).[1] An estimated 30%–50% of pesticides sprayed onto crops get into the atmosphere. By "post-application emission," we understand the evaporation of pesticides from soil or plant surfaces and due to the wind erosion of the soil. Depending on their stability, pesticides in the air may be degraded, or transported over long distances before being deposited. After their application, pesticides are present in the atmosphere in gaseous form, adsorbed onto solid particles, or dissolved in water vapor.

Pesticides in Crops

The presence of pesticides in the environment causes them to accumulate in crops like fruit and vegetables. The contamination of plant foods by pesticides is particularly dangerous because these compounds can reach every part of the plant, regardless of how they are applied. The degree of contamination of crops depends, among other things, on the dose and number of applications, the form of the pesticide preparation, the weather conditions, and the time elapsing between pesticide application and crop harvesting. Contamination is reduced by such factors as rainfall, wind, and chemical changes caused by oxygen, moisture, light, and plant enzymes. Plants with a large surface area relative to their mass retain larger amounts of pesticides.[1] Fruit and vegetables are capable of retaining larger quantities of pesticides. Pesticides can accumulate in fruit skins. The crops most exposed to the presence of pesticides are grapes, citrus fruits, and potatoes. Adsorbed pesticides can reduce the nutritious value of crops or alter their organoleptic properties. The contamination of crops with pesticides is due to their application in contradiction to good agricultural practice and the insufficient monitoring of their application. Their total elimination is, of course, often not possible, but the amounts applied can be limited to those that are harmless to human health.

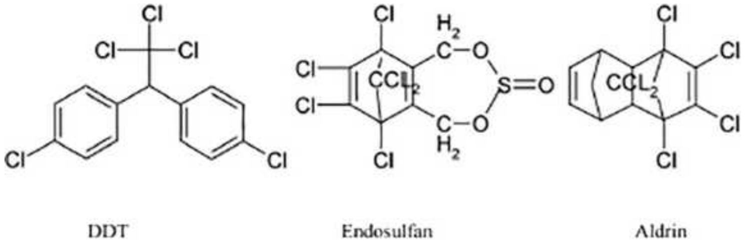
Pesticides in Soil

Pesticides are transported to soil because of deliberate human activity. It is estimated that about 50% of pesticides come from washing processes of soils' surface. Transport of pesticides to plant material depends on their stability, and the main ways of absorption are via roofs and leaves. They can be also adsorbed on the molecules of clay. In this case, they do not penetrate the soil. Stability and fate of pesticides in soil depend on chemical structure, type of plant material, type of soil and their pH/temperature, weather conditions, etc.[1]

Modern Pesticides

Organochlorine pesticides were widely used in agriculture and pest control. These pesticides are insecticides composed primarily of carbon, hydrogen, and chlorine (see Figure 3). Most of them break down slowly and can remain in the environment long after application and in organisms long after exposure.

These chemicals were introduced for the first time (DDT [dichlorodiphenyltrichloroethane]) in the 1940s, and many of their uses have been nowadays cancelled or restricted because of their environmental persistence and potential adverse effects on wildlife and human health. Many organochlorines are no longer used in most countries, but other countries continue to use them (in Africa, South America, and Asia).



DDT Endosulfan Aldrin

FIGURE 3 The chemical structure of some organochlorine pesticides.

Organochlorine pesticides can enter the environment after pesticide applications, disposal of contaminated wastes into landfills, and releases from manufacturing plants that produce these chemicals. Some organochlorines are volatile, and some can adhere to soil or particles in the air. In aquatic systems, sediments adsorb organochlorines, which can then bioaccumulate in fish and other aquatic mammals. These chemicals are fat soluble, so they are found at higher concentrations in fatty foods. Organochlorine pesticides are hydrophobic, lipophilic, and extremely stable. Organochlorines have a wide range of both acute and chronic health effects, including cancer, neurological damage, and birth defects. Many organochlorines are also suspected endocrine disruptors.[1,9,10]

The present-day trend is to move away from persistent pesticides and to apply agents with a short decomposition time and no tendency to bioaccumulate.[1] That is why organochlorine pesticides have been withdrawn.[11–14] Because of their great stability (as long as 30 years), however, they may still be present in the environment and be transported by air or water over great distances. Organochlorine pesticides have been replaced by organonitrogen and organophosphorus pesticides. They have become very popular because they are cheap and readily available, have a wide range of efficacy, are able to combat a large number of pest species, and have a shorter environmental half-life than their organochlorine predecessors.

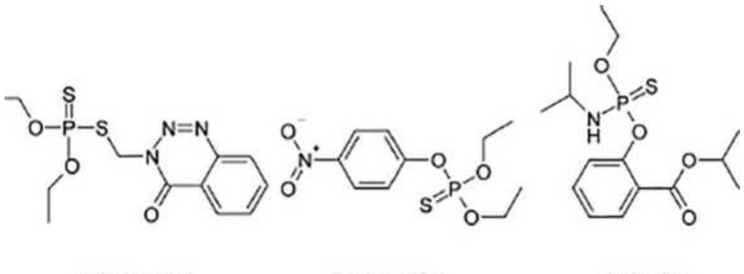
Currently used pesticides in comparison with formerly used ones are less persistent in the environment and generally are more polar. Polarity of pesticides determines their presence, transport, and stability in different compartments of the environment. Polar pesticides are more soluble and penetrate the surface water and groundwater faster. Because they are less stable in the environment, their presence can be established in less time (since the application). By contrast, non-polar pesticides are typically sparingly soluble in water, which is associated with their greater persistence in the environment, and transport mechanisms of these compounds are different. They are mostly adsorbed on solid particle and only partially dissolve in water. In addition, pesticides accumulate in sediments or suspensions and are present there even for decades.[1]

One of the principal classes of compounds used for plant protection, organophosphorus pesticides (insecticides) embrace all organic compounds containing phosphorus. Usually taking the form of esters (Figure 4) and degrading fairly easily, they are very poorly soluble in water, though better so in organic solvents and fats.

The umbrella term "organonitrogen pesticides" is a convenient way of referring to the large number of nitrogen- containing organic pesticides. In practice, however, these pesticides are known by the names of the various chemical classes. In the literature, the term "organonitrogen pesticides" usually refers to carbamates and triazines and their derivatives (see Figure 5).[15–17]

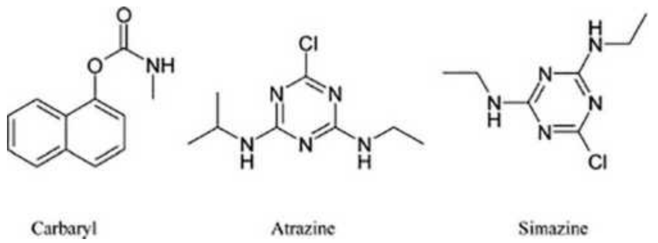
Table 5 presents the characteristics of organonitrogen pesticides.[1,18,19]

In recent years, new insecticides—neonicotinoids— have been introduced to replace pyrethroids, organophosphorus compounds, and carbamates. This was necessary as insect pests were becoming extremely resistant to the latter agents. At present, neonicotinoids are used to combat the Colorado potato beetle (Mospilan 20 SP, active substance: acetamiprid).[20]



Azinphos-ethyl Ethyl parathion Isofenphos

FIGURE 4 The chemical structure of some organophosphorus pesticides.



Carbaryl Atrazine Simazine

TABLE 5 The Characteristics of Organonitrogen Pesticides

Chemical class	Characteristics
Carbamates	Mostly carbamic acid esters; decompose rapidly in the soil; poorly soluble in water, better soluble in organic solvents and fats; used worldwide to combat insects, fungi, and weeds, and also as plant growth regulators
Triazines	Used to combat weeds and to control the growth of maize, soybean, grains, and other crops; highly toxic towards mono- and dicotyledons, and extremely stable in the soil; one of the triazines is atrazine, 90% of which is applied to maize crops

Dangers Resulting from the Application of Pesticides

Human beings come into contact with pesticides in a variety of situations.[7,21] Ubiquitous and constituting a risk to human health, these substances can enter the body through

- The skin
- The respiratory system (through the nose)
- The digestive system (accidental swallowing of the product)
- Consumption of food contaminated with pesticides

Penetration through the skin is easier because pesticides can remain on the skin for a long time, the area of contact is large, and absorption of these compounds is rapid, especially through damaged skin. The inhalation of pesticides in contaminated air is very dangerous, as harmful substances very quickly enter the lungs and blood, and thence reaching all the organs of the body. The symptoms of pesticide poisoning include headache, a feeling of cold, giddiness/dizzi- ness, and skin rash. Organochlorine pesticides are capable of accumulating in the fatty tissues of living organisms, although their quantities in particular organs depend on the degree of fatness of the latter. When poisoning reaches a critical level, the most vulnerable organ is the brain. It was stated not long ago that some pesticides stimulate the production of microsomal hepatic enzymes responsible for the metabolism of some drugs (hypnotics, antiepileptics, analgesics), which reduces their therapeutic efficacy. Further symptoms of pesticide poisoning are as follows:

- Impairment of ion transport, leading to impaired neural conductivity
- Disturbances to neurotransmitter metabolism
- Abnormal immunological reactions
- Destruction of hepatocytes, leading to cirrhosis of the liver
- Cardiac arrhythmia

Organophosphorus and organonitrogen pesticides act as receptor inhibitors. They bind to the receptors of the enzyme acetylcholinesterase, which is essential for the correct functioning of the nervous system, preventing the decomposition of acetylcholine and acting through contact or systemically.[1,22] Blockage of cholinesterase activity causes the amount of acetylcholine at the synapses to increase, leading to a state of hyperarousal and paralysis of the muscles and central nervous system. If a xenobiotic binds to a receptor, one of the more important stages in metabolism may be blocked, elicit a harmful metabolic process, or alter the rate of transmission of nervous signals.[5,7,23,24] In addition, some carbamate insecticides, (e.g., carbaryl) can, in large doses, be teratogenic and can be nitrosated to form strongly carcinogenic nitroso compounds.

Methodologies for Determining Pesticides

It is essential to monitor the levels of pesticide residues as they can easily make humans more vulnerable to different diseases. An assessment of the state of contamination by pesticides requires a knowledge of the maximum permitted levels of individual active substances. The full determination procedure consists of several stages (see Figure 6). Because of the complex composition of samples and the different concentrations of the target analytes, the sample must be adequately prepared for analysis by the use of

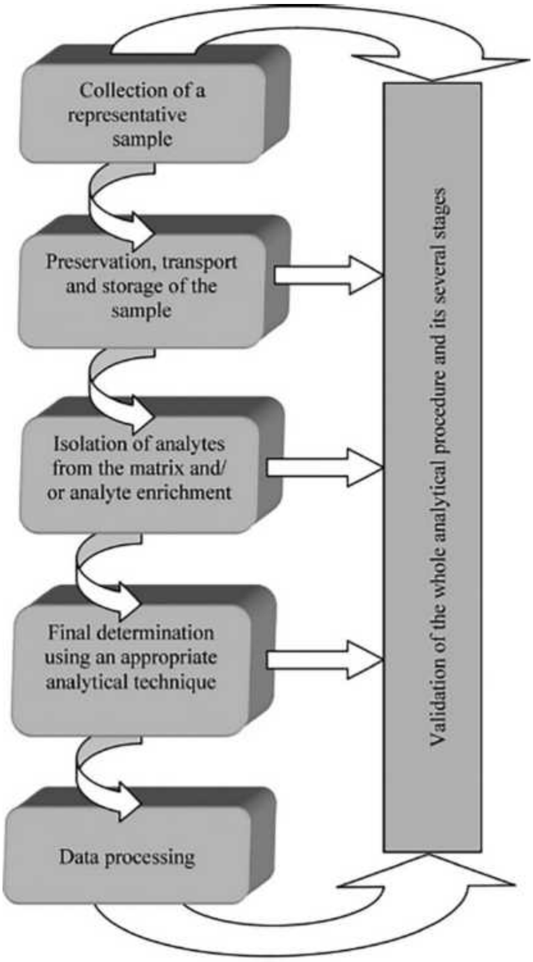

FIGURE 6 The main stages in the analytical procedure for determining modern pesticides.
Source: Biziuk et al.,[1] Beyer and Biziuk,[4] Namiesnik,[25] and Namiesnik and Górecki.[26]

techniques for efficiently extracting the target compounds and for their cleanup prior to the quantitative determination stage.

The choice of methodology for determining pesticides depends in large measure on the sample matrix and the structure and properties of the target analytes. In view of the numerous legal regulations laying down highest permissible levels of pesticides in various matrices, sensitive and selective analytical techniques are used, appropriate to the low concentrations at which the target analytes occur in them.[27] In addition, each stage in the analytical procedure, as well as this process in its entirety, should be validated.[4,26]

The analysis of environmental samples for the presence of pesticides is fraught with difficulties, because arduous and time-consuming operations and processes have to be carried out in order to prepare the samples for analysis, and these could be a source of further contamination and error.

The normally low concentrations of target analytes and the often complex matrix composition are further problems the analyst has to face. Highly efficient extraction and cleanup techniques therefore need to be applied to the target compounds prior to their quantitative determination.

Determination of Modern Pesticides in Water Samples

Collection and Preparation of Samples for Analysis

Environmental samples are diverse and complex materials to analyze because of the sampling site, type of matrix, the presence of interferents, and the concentration of target analytes. To a large extent, it depends on the appropriate preparation of the sample whether the analysis will actually provide the desired information about the sample. That is why this stage is usually a complex task, and the operations and processes involved in this stage may be a cause of analyte loss as well as a source of additional contamination. Table 6 lists the usual sample preparation processes and examples of their implementation.[1,21,25,26,28–30]

A representative sample is taken for analysis using an appropriate sampler. Which type of sampler is used depends on the type of sample, the objective of the analysis, the site and frequency of sampling, and the sample size. Mains water is usually collected in dark glass bottles; surface waters or sewage (effluent) is placed in different containers.

Techniques for Isolating and Enriching Analytes from Water Samples

Because of the low concentrations of pesticides in the various compartments of the environment, it is essential not only to isolate the organic compounds from the complex matrix but also to enrich them prior to final determination. The use of passive dosimetry at the sample collection stage, with which analytes can be isolated and preconcentrated at the same time, is worth mentioning. The free transport of mass takes place across a membrane to the sorbent as a consequence of the difference in chemical potentials of the compounds in the sorbent and the water in which the sampler has been immersed.[30,31]

TABLE 6 The Usual Sample Preparation Processes and Examples of Their Implementation

Basic Processes during the Preparation of Samples for Analysis	Examples of Implementation
Separation of suspended matter	Filtration
Chemical preservation	Reduction of the sample pH, addition of bactericides (e.g., saturated aq HgCl2, formaldehyde, sodium azide)
Physical preservation	Storage of the sample at a low temperature (2–4°C), storage in the dark, sterilization by UV irradiation

Source: Biziuk et al.,[1] Biziuk et al.,[21] Namieśnik et al.,[25] Namieśnik and Górecki[26] Namieśnik and Szefer,[28] Demkowska et al.,[29] and Łopuchin and Namieśnik.[30]

For sampling pesticides from coastal waters and rivers, one uses polyethylene dosimeters packed with iso-octane or stainless steel dosimeters filled with cyclohexane as sorbent. Three or four samplers of one type are deployed, usually for 30 days. Most passive samplers are fairly small in size, which substantially reduces the amounts of organic solvents required (the volume of the dosimeter chamber is ca. 1 mL) and makes them easy to transport and to assemble at the deployment site. With the use of passive dosimeters, there are fewer steps in the analytical procedure, which means results are more reliable and reproducible. The shortcomings of such dosimeters, however, include an insufficient sensitivity to brief fluctuations in target analyte levels and a susceptibility to environmental factors like temperature and water movement, which means that samplers have to be calibrated in order to set the rate of analyte collection.[30,31]

During extraction and/or enrichment steps, the concentration of analytes is raised in order to make their determination at all possible. Moreover, analytes are transferred from the primary matrix to a secondary one with concomitant removal of interferents. The choice of technique depends on the properties of the target analytes, their volatility, polarity, and solubility in water and organic solvents. Table 7 lists the standard techniques for extracting modern pesticide analytes.

An equally important technique is membrane extraction, which may replace classical liquid-liquid extraction (LLE) as it uses smaller quantities of solvents or even none at all.[65] As a result, a number of drawbacks are eliminated, among them, the problem of emulsion formation. Table 8 lists the membrane extraction techniques used during the determination of pesticides in water samples.[65]

TABLE 7 The Standard Techniques for Extracting Modern Pesticide Analytes

Extraction Technique	Characteristics
LLE (liquid-liquid extraction)	Based on the partition of analytes between two immiscible liquids, usually an aqueous solution and an organic solvent. The most common extraction solvents are dichloromethane[17,32–36] and mixtures of petroleum ether and dichloromethane[37] and methylene chloride and hexane·[33] Though relatively simple and cheap, this method has many shortcomings: it requires relatively large quantities of often toxic solvents, and there is a risk of an emulsion forming during agitation. To achieve the desired enrichment coefficient, the excess solvent usually has to be evaporated, and the extracts often have to be cleaned up.
DLLME (dispersive liquid–liquid microextraction)	This is one example of the miniaturization of LLE, in which a dispersing solvent, e.g., acetone or methanol (0.5–2 mL) with added extraction solvent, e.g., C2CI4, CS2 (10–50 μL), is added to the water sample (5–10 mL). This procedure yields a turbid solution, which is then centrifuged to obtain ca.5 mL of extract phase. By reducing the amounts of solvents, some of the inconveniences of LLE have been eliminated.
SPE (solid phase extraction)	This technique is based on the sorption of analytes on a sorbent—this is usually silica gel, aluminum oxide, Florisil, a porous polymer XAD-2, XAD-4, XAD-7, XAD-16, usually modified with octadecyl groups·[15,33,38–51] Desorption of adsorbed analytes is usually carried out using methanol,[15,37,40,43,46,51] ethyl acetate,[33,35,44] dichloromethane,[38,39,41,50] and mixtures of methanol and water,[45,49,51] methanol and acetonitrile,[42,47] and acetonitrile and water.[48] Research is in progress to develop selective sorbents (MISPE: *Molecularly Imprinted Solid Phase Extraction; immunosorbents*), which would be applied in the case of samples with a complex matrix composition such as sewage.
SPME (solid phase microextraction)	Simple to use and does not require solvents. Based on extraction from the liquid phase to an adsorption or absorption layer coated on an extraction fiber. It is also possible to introduce the fiber into the headspace (HS-SPME). The materials used for coating fibers include polydimethylsiloxane (PDMS),[53–58] polyacrylate (PA),[48,54–57,59,60] and also mixtures of polydimethylsiloxane and polydivinylbenzene (PDMS-DVB),[53–55,60–64] carbowax and polydivinylbenzene (CW-DVB),[53,57,64] and carbowax and molecularly imprinted resin (CW-TPR).[60] The analytes most frequently adsorbed are transferred to the GC injector where they are thermally desorbed and then determined.
SBSE (stir bar sorptive extraction)	The extractant, usually polydimethylsiloxane (PDMS), is used to coat a magnetic stir bar.[29] The adsorbed analytes are then thermally desorbed. The parameters determining the effectiveness of this type of extraction are the sample volume, the extraction time, and the stirring speed.

TABLE 8 Membrane Extraction Techniques Used during the Determination of Pesticides in Water Samples

Technique	Type of Membrane	Combination of Phases Used: Donor/Membrane/Acceptor
MASE: membrane-assisted solvent extraction; PME: polymer membrane extraction	Non-porous	Aqueous/polymer/aqueous Organic/polymer/aqueous Aqueous/polymer/organic
MMLLE: microporous membrane liquid–liquid extraction	Non-porous (microporous)	Aqueous /organic/organic Organic/organic/aqueous

Determination of Modern Pesticides in Ambient Air

Sampling Techniques

Pesticides in the air can be determined in the following types of samples:

- Atmospheric dusts
- Analytes sampled from the gaseous phase

Dynamic[66] and passive (diffusional)[67,68] sampling methods are the usual ways of collecting air for determining its pesticide content.

Dynamic sampling enables the collection of pesticides present in the gaseous phase and in suspended form by pumping air through a filter coated with a solid adsorbent. Pesticides present in suspended dust particles are retained on the filter, while those in the gaseous phase are adsorbed by the sorbent.

The standard filters are of glass with different diameters (Ø = 30 cm, 10 cm, 90 mm, and 25 mm) and of quartz filters (Ø = 102 and 150 mm).

For collecting gas samples, the sorbents (XAD-2, XAD-4, Carbopack, Carbotrap, Carboxen, Tenax TA, Chromo- sorb, silica gel) are coated onto the filters, as mentioned above, or placed in stainless steel or glass vessels containing polyurethane foam (PUF).

The conventional methods of collecting gas samples for the determination of their pesticide content involve passing a fixed volume of air through a solid sorbent, for which pumps and flowmeters are needed. The expense of the former and the need to frequently calibrate the latter mean that it is difficult to collect gas samples in a fully professional manner. Analytes retained on sorbents require not only thermal desorption but also chemical desorption with expensive and potentially toxic solvents. The sampling time depends on the method's sensitivity and the breakthrough volume of the sorbents by the target analytes (Table 9). In order to collect samples without the need to use toxic solvents and expensive pumping equipment, we need an unpowered air sampler.[69]

Universal and inexpensive passive air samplers (PASs) have been developed as an alternative to the conventional active sampling methods. Passive sampling is based on the free flow of analytes from the environment sampled to a medium on which the analytes are sorbed (Table 10).

There are several types of PASs, using the following:

- SPMD semipermeable membranes.
- PUF discs; the passive samples consist of PUF discs placed inside stainless steel containers covered with a dome-shaped lid to reduce the effect of wind speed on the rate of sampling. This arrangement is also used to protect the PUF discs from precipitation, the direct deposition of dust, and UV light.
- Resins.
- A thin layer of ethylene/vinyl acetate as the sampling medium.

TABLE 9 Comparison of Techniques for Collecting Air Samples Depending on the Sampling Time, Type of Filter, and Adsorbent

Sampling Time (hr)	Type of Filter	Adsorbent	References
5.5–9	GFF	XAD-2, s-PUF	[70]
24	GFF	XAD-2	[66–68,71,72]

PDMS	14 days	[109]
SPMD	7 days	[98,110]

Solid-phase microextraction (SPME) is another way of sampling analytes from air. A solventless method, it is very convenient for use in the field, simple to operate, and, under optimal conditions, does not require the use of pumps.

When only suspended dust is to be sampled, the samples are often fractionated according to particle diameter, a process that is possible because the different fractions have different physical and chemical properties: the fine-grained fraction (<2.5 pm) is often acidic, whereas the coarse-grained fraction (>2.5 pm) is basic. Fractionation minimizes interactions between particles of different pH. Cascade impactors (absorbers) are also used. These operate on the principle that the dust-containing air is made to flow through nozzles of ever-decreasing diameter. At each nozzle, the linear velocity of the airflow increases and the relevant dust fractions are separated at the steps of the cascade impactor. If dust concentrations in gas samples are very high, cascade cyclones are used. These direct the dust-containing gas at a tangent to a cylinder, and the particles move under centrifugal force from the stream of gas to the inside wall of the cylinder.[111]

Methods of Extracting Analytes from Sorbents and Filters

The next step, after sampling but before the final determination, involves extracting the preconcentrated analytes from the solid sorbents or filters (Table 11). This is the most crucial step in the analytical process, since the aim of extraction is to liberate the greatest possible quantities of pesticides from the sorbent. To this end, both solvent and solventless techniques are employed.

TABLE 11 Techniques Most Frequently Used for Extracting Analytes from Air Samples

Sample	Extraction Technique	References
PM2.5 dust	Accelerated solvent extraction (ASE, PFE, PLE)	[76,112]
Dust and gaseous phase	Soxhlet apparatus	[66,67,71,7, 113–119,121]
Gaseous phase	Agitation assisted (LE)	[122]
Gaseous phase	Ultrasound assisted (UE)	[123]
PM2.5 dust	Microwave assisted (MAE)	[124]
Gaseous phase	Thermal desorption	[125]

TABLE 12 Solvents Most Commonly Used for Extracting Analytes from Air Samples

Sample	Solvent	References
Suspended dust	Petroleum ether	[74,88,96]
Suspended dust	Acetone	[76,79,80,83]
Suspended dust/air	Hexane/acetone	[113]
Suspended dust	Hexane/dichloromehane	[66,67,71,72,75,114–116]
Suspended dust/air	Dichloromethane/ petrochemical ether (diethyl ether, MTBE)	[117–119,123]
Suspended dust/air	Hexane/benzene	[121]
Suspended dust	Dichloromethane	[112]
Air	Ethyl acetate	[122]

The most commonly used solvents for extracting analytes from air samples are shown in Table 12.

The next step in sample preparation is evaporation and/or change of solvent. It is standard practice to evaporate the solvent in a vacuum evaporator, a quick and simple method. Another possibility is to evaporate the solvent in a stream of gas, usually nitrogen, again simple to carry out. These methods may be applied separately or in combination.

Extract Cleanup

Extract cleanup involves fractionating the extract, which can be done in a number of ways:

- With column LC chromatography with normal phase (NP) or reversed phase (RP), including high-performance liquid chromatography (HPLC)
- With adsorption chromatography
- Passing the extract through a filter
- With gel chromatography (GPC)

In some cases, mainly when highly selective detectors like gas chromatography-tandem mass spectrometry (GC–MS/ MS) and liquid chromatography–tandem mass spectrometry (LC–MS/MS) are used, the cleanup of extracts is not necessary. Before deciding whether the cleanup step can be omitted or not, however, matrix effects must be investigated for possible interferents and their influence on the apparatus.

Determination of Modern Pesticides in Fruit and Vegetables

Sample Collection and Preparation of Samples for Analysis

It is extremely important that samples of material intended for analysis are homogeneous and representative; they should be stored frozen and in the dark.[28] The sample preparation process consists of several steps. In the case of fruit and vegetables, one of these steps involves the removal of surface contaminants by, for example, washing the sample in distilled water, after which the sample is dried (at an elevated temperature, at ambient temperature, or with the aid of a desiccant). Then, the sample has to be broken up, crumbled, minced, or ground with a pestle and mortar. It is then homogenized in special equipment. The sampling process depends on the type of biological material under investigation, and one has always to be mindful of possible losses of analytes and contamination of the sample as a result of human agencies.

Techniques for Isolating Pesticides from Fruit and Vegetable Samples

Isolation and/or enrichment involves the transfer of analytes from the primary matrix to a secondary one with the concomitant removal of interferents and the increase of analyte concentrations to levels above the limit of detection (LOD) of the analytical technique used. Since pesticide concentrations in fruit and vegetables are low, samples often require enrichment.[126,127]

The following are the usual techniques for isolating pesticides from fruit and vegetable samples:

- Liquid-liquid extraction (LLE)
- Accelerated solvent extraction (ASE)
- Supercritical fluid extraction (SFE)
- Soxhlet or Soxtec extraction
- Microwave-assisted extraction (MAE)

The merits of solvent extraction by agitation are ease of implementation and low cost; in addition, expensive and complicated apparatus can be dispensed with. Unfortunately, however, this technique requires a large quantity of toxic solvents and its selectivity leaves much to be desired. Soxhlet extraction are easy to carry out and enables the extract to be separated from the residue; on the downside, this type of extraction takes a long time with large amounts of solvent, and only single samples can be extracted. For this reason, the more efficient Soxtec apparatus was introduced; with this albeit very expensive apparatus, the extraction time is now much shorter, and several samples can be extracted simultaneously. Solvent extraction techniques are frequently assisted with microwaves or ultrasound in order to improve extraction yields. Acetone, acetonitrile, and ethyl acetate are the solvents (or their mixtures) (Table 13) most commonly used for the extraction of fruit and vegetable samples.

Extract Cleanup

The cleanup of the extract is an essential step that should always precede its analysis. It is important, because during isolation, we obtain not only the target analytes but also in- terferents, which can distort the final result of the analysis. The usual cleanup techniques used with fruit and vegetable samples are as follows (Table 14):

- Solid-phase extraction (SPE)[131]
- Solid-phase microextraction (SPME)[132]
- Matrix solid-phase dispersion extraction (MSPDE)[133]
- Stir bar solvent extraction (SBSE)[134]
- Gel chromatography (GPC)[135–137]

TABLE 13 Solvents for the Extraction of Samples of Fruit and Vegetables

Sample	Solvent
Cabbage, grapes	Ethyl acetate, methanol, acetone[128]
Oranges, apples, grapes, pears	Ethyl acetate[126]
Apples, tomatoes	Acetone[127]
Tomatoes, pears, oranges	Acetonitrile[129]
Peppers, tomatoes, Brussels sprouts, melons, apples, lemons	Ethyl acetate[130]

TABLE 14 Extract Cleanup Techniques in the Determination of Pesticides in Fruit and Vegetables

Sample	Extract Cleanup Technique
Oranges, apples, grapes, pears	mspd[126]
Apples, tomatoes	hs-spme[127]
Oranges, apples, peaches, pears, tomatoes, lettuce, potatoes, leeks	gpc[140]
Tomatoes, pears, oranges	spe[129]
Vegetables	spme[141–144]
Oranges	MSPD, SBSE[145]
Strawberries, cherries	hs-spme[146]
Oranges, tangerines, grapefruits, lemons	mspd[147]

SPE is currently the most popular extract cleanup tech- nique.[138] It involves passing the sample through a bed of sorbent on which the target analytes are adsorbed. The retained compounds are then liberated by means of a solvent and analyzed. This method is easy to carry out and readily lends itself to automation. Its shortcomings, however, are that the sorbent bed has to be conditioned before each use and that analyte yields are low. A modification of SPE, i.e., SPME,[139] involves the adsorption of analytes on a fiber coated with a suitable solid phase that can be pushed out of a microsyringe. The analyte is then thermally desorbed and transferred to the GC injector. The benefits of this method are that solvents can be eliminated and that it is impossible to overload the column because of the limited volume of adsorbent. Optimization of the method is a problem, however. Depending on where the fiber is placed in relation to the sample, SPME can be divided into direct (Direct Immersion [DI]-SPME) or headspace (HS-SPME).

GPC is just as frequently used as a cleanup technique. It enables micromolecular pesticides to be separated from macromolecular substances present in the matrix. While the considerable longevity of the columns is an advantage, the poorer resolution in comparison with adsorption techniques, especially when gradient elution techniques are used, is a disadvantage.

Approaches are being sought to develop pesticide determination techniques that are quick, simple, cheap, effective, and safe. QuEChERS (quick, easy, cheap, effective, rugged, and safe)[148–157] is one such method. It is based on a number of stages (see Figure 7).

The consumption of sample and toxic solvents with the QuEChERS method is minimal. By applying QuEChERS to the determination of pesticides in fruit and vegetables, matrix effects are eliminated and high recoveries of target analytes are possible. The method can be modified depending on the type of sample and the target analytes. To improve the extraction of polar organophosphorus pesticides, the method is modified by the addition of acetic acid. When samples of citrus fruit are under investigation, protective wax coatings can be removed by freezing the samples for at least 1 hr. For the analysis of citrus fruits, blackcurrants, and raspberries, it is recommended to add aq NaOH to reach pH = 5 and to improve the analysis.

Determination of Recently Applicable Modern Pesticides in Soil Samples[158–161]

Sample Collection and Preparation of Samples for Analysis

In order to determine the chemical composition of soil samples, it is necessary to preserve their natural structure. They are cut by manual scoop or a similar tool from the central, typical part of the material. In the next step, the material is introduced to a special cylinder of known volume. After this operation, the drying of the sample is desirable.

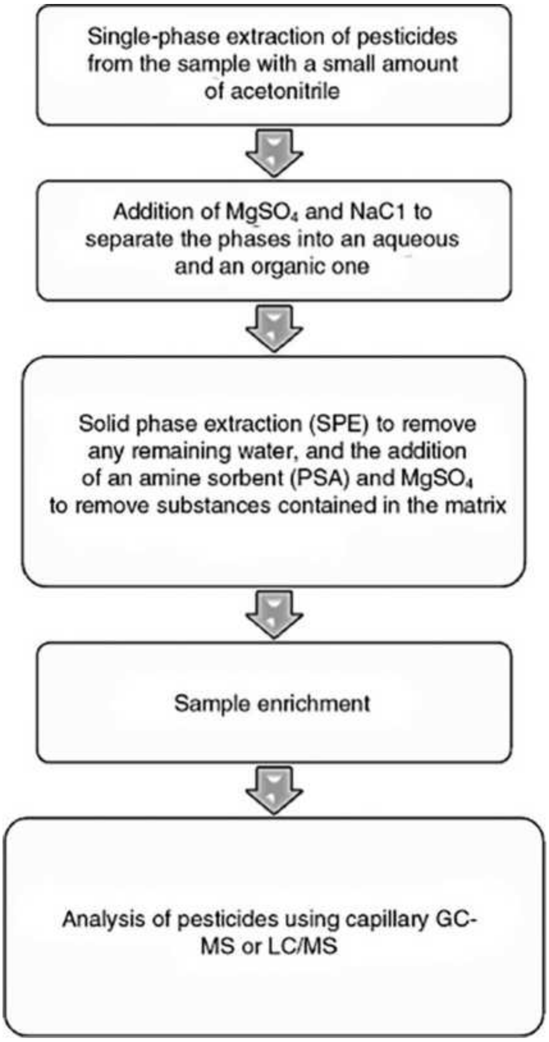

FIGURE 7 Stages in the determination of pesticides using the QuEChERS method.

The drying step consists of two stages:

- Preliminary drying (also drying with circulation air masses) in temperature from 40°C to 100°C/105°C and drying in reduced temperature (lyophilization)
- Final drying, drying by chemical binding water, and drying using water adsorption

Techniques of Isolation and/or Enrichment Analytes from Soil Samples

For extracting the analytes from soil samples, the ultrasound-assisted liquid extraction (shaking)[162] or conventional Soxhlet extraction[163,164] can be used. In these cases, a mixture of non-polar and polar solvents is used. In addition, the extraction of analytes from soil samples can be investigated:

- Using supercritical fluid in-process—critical conditions are obtained by using highly compressed gases (the most compressed being CO2) in the critical temperature range.[165,166]

- Using microwave process—microwave energy is absorbed by molecule compounds.
- As an ASE—the process runs at elevated temperature and pressure, providing appropriate solvent condition (liquid state of solvent).

Evaporation of the solvent is the next step, which provides the enrichment of the extract. Among the known methods for enriching the extract, the following are the most popular:

- Evaporation of the solvent in vacuum evaporator (vacuum distillation)
- Evaporation of the solvent in Kudern-Danish apparatus
- Evaporation of the solvent in a gas stream (nitrogen or air)

An important step in the preparation of the soil samples is removal of interfering substances. For elimination of sulfur, it is possible to use various chemical reactions, for example, reactions with sodium sulfate (IV), and aluminum oxides, or reactions with heavy metals. Aside from the use of chemical reactions, the methods of electrophoresis, chromatography, and saponification are also notable in the removal of interfering substances. To remove fats from soil samples, LLE,[167] adsorption chromatography, saponification, decomposition reaction using sulfuric acid at low temperature, precipitation, GPC,[168] and semipreparative HPLC can be applied.

Purification of the Extract

The purification process of extracts, which contain pesticides, includes fractionation of the extract. It can be carried out by different methods. Among the available methods are adsorption chromatography, GPC, and column chromatography.[169]

Derivatization of Pesticides

By converting pesticide compounds into their derivatives, selectivity, analyte enrichment, target analyte resolution in the column, and selectivity of detection are all improved. Derivatization also enables a larger number of compounds to be determined in the sample. The inference is that the isolation of target analytes from the matrix and their enrichment are not always effective without changing the chemical structure of the analytes or the matrix.[1] Pesticides to be determined by GC are usually derivatized with pentafluorobenzyl bromide (PFBB).[67,72,75]

Final Determination

The last stage in the analytical procedure is the identification of compounds and their quantitative determination using an appropriate analytical technique. The usual techniques involved include the following:

- Capillary GC. Pesticides to be determined by GC should be volatile and thermally stable. During capillary GC, the injector can be operated in split mode (when the stream of carrier gas is divided) or splitless mode (when the carrier gas stream is not divided); either mode can be used for determining pesticides in environmental samples. The on-column injector, with which samples can be injected directly into the chromatographic column, is also used for the GC determination of pesticides.
- HPLC, usually in reversed-phase mode, is used for determining pesticides that cannot be determined by GC, for example, thermally unstable polar compounds like herbicides, carbamates, triazines, and also compounds that require derivatization.

Gas chromatography can be used to determine the residues of all pesticide classes. The choice of chromatographic column is extremely important as regards the separation of analytes and their qualitative and quantitative determination. The column should be highly efficient and be resistant to changes in separation parameters. The solid (stationary) phase should be thermally stable and be highly selective with respect to the constituents of the mixture being analyzed. The following detectors are used (Table 15):[157,170–172]

- ECD (electron capture detector)—highly sensitive in relation to compounds containing electronegative atoms
- FPD (flame photometric detector)—applied in the determination of organophosphorus compounds
- NPD (nitrogen phosphorus detector)—used for the simultaneous determination of organonitrogen and or- ganophosphorus pesticides
- TSD (thermionic specific detector)—used to determine compounds containing nitrogen or phosphorus
- MS (mass spectrometry) or MS/MS (tandem mass spectrometry)
- UV–DAD (ultraviolet–diode array detector)—used in LC

Once a target analyte has been detected quantitatively, for example, by GC-NPD, the result must be confirmed by another independent method. The conditions of the process can be altered, say, by changing the temperature program or by using a different chromatographic column. It is crucial to obtain confirmation by another method as identification based solely on retention times is insufficient. MS/MS improves sensitivity and selectivity of analytical methods. In this technique, ions that were separated in the first analyzer are again fragmented and the derivative ions were analyzed in the second one. The chromatogram background is reduced, as a result of which the signal value is enhanced with respect to noise and the LOD of the target analytes is lowered.[174–176] Better chromatographic peak resolution and a

TABLE 15 Characteristics of Detectors Used for the Determination of Pesticide Analytes

Type of Detector	Merits	Drawbacks
Mass spectrometer (MS and tandem MS)	• Both quantitative and qualitative information obtainable • Highly sensitive • Used with both GC and LC • Applicable to trace determinations, in complex matrices • Can be universal or selective, as the need arises • Has a wide range of application used in multimethods for determining pesticides of different classes • Better sensitivity and greater specificity sometimes obtainable with GC coupled to tandem MS (MS/MS) • Can operate in single ion monitoring (SIM) mode, which provides for greater sensitivity than the SCAN mode • A highly specific detector; in the case of pesticides, used to determine organochlorine compounds	• Expensive
Electron capture detector (ECD)	• A detector suitable for selected classes of compounds	• Applicable only to compounds containing electronegative atoms
Thermoionic detector (NPD)	• Has a wide range of application	• Useful only for compounds containing nitrogen and phosphorus
Flame ionization detector (FID)	• Suitable for almost all organic compounds • Highly sensitive and with a wide range of linearity • Highly sensitive and with a wide range of linearity	• The sample is destroyed

Source: http://www.pg.gda.pl.[173]

smaller influence of the matrix on the final result can also be achieved using two-dimensional (2D) gas chromatography (GC×GC). This uses two columns: the partially separated constituents from the first column are further separated in the second one by a different mechanism.

Fast GC is equally frequently used to shorten the time of analysis and to obtain better peak resolution. Compared to classical GC, it requires shorter capillary columns with a smaller diameter and solid-phase films ca. 0.1 μm in thickness, as well as a faster flow rate and higher pressure of the carrier gas. These parameters yield determination results of a better precision.[174,177,178]

The trend at present is to develop analytical methods enabling a broad spectrum of analytes to be determined in a single analytical run (MRMs—multiresidue methods). However, the problem here is that the compounds to be determined simultaneously, often present at low concentrations, have different physicochemical properties depending on their chemical structure. Such a methodology, apart from being able to determine a large number of compounds in one run, should:

- Ensure maximum removal of interferents from extracts
- Give large recoveries of target compounds, high sensitivity, and good precision
- Be environmentally friendly, i.e., require the smallest possible quantities of samples and chemical reagents, especially organic solvents
- Be cheap, quick, and easy to carry out

Research continues for the improvement of existing analytical methods and the development of new ones capable of supplying reliable results for a wide range of analytes.

Summary

The increasingly widespread application of pesticides— substances with different physical and chemical proper- ties—means that ever-larger amounts of these compounds are getting into the environment. As a result of the various processes they are subjected to, they may be converted to even more toxic compounds. They are currently regarded as some of the most dangerous environmental contaminants because of their stability, mobility, and long-term effects on living organisms. Moreover, they are usually present in the environment at very low concentrations in complex matrices, which makes their analysis difficult. Their determination is therefore prolonged by the need to perform time-consuming and often arduous processes in order to prepare samples for analysis, which themselves may be sources of further contamination and error. That is why for the analysis of pesticides in the environment, procedures that enable a large number of compounds to be detected simultaneously are required. It is often the case at present that target pesticide analytes have to be isolated from the matrix and enrichment before their final determination can be undertaken. To counteract the adverse effects of pesticides on human health, the continuous monitoring of their presence in the environment is fundamental. European Union recommendations are in place for analyzing the quality of water, air, and food in this respect. Existing techniques are being improved and new ones are being developed so that different classes of pesticides can be reliably determined in a quick, simple, cheap, and environmentally friendly manner.

Salt-Affected Soils: Sustainable Agriculture

Pichu Rengasamy

Introduction

Worldwide, more than 800 million hectares of land are estimated to be salt-affected.[1] This is based on the traditional outlook on saline soils as being dominated by sodium salts. However, this area can be larger if lands affected by the input of several other types of salts, including contaminants, are taken into account. The demand for agricultural production from salt-affected soils will increase in the future as the expected world population increases to 9 billion by the year 2050. Global agriculture is now in a state of crisis, both from the economic and ecological considerations. Salinity in agricultural soils enhances the possibility of economic downturn in the farming sector and environmental degradation.

Agricultural soils accumulate soluble salts in the root zone by various processes, including weathering of minerals, salt added through rain and agronomic practices such as fertilizer and pesticide application, saline groundwater intrusion, irrigation with saline water sourced from bore, recycled waters or wastewaters, dumping of industrial and municipal wastes into soils, and other soil processes leading to reduced leaching of salts from the root zone. Depending on the concentration and nature of salts, the growth and productivity of different crops are variously affected. Soluble ions affect the soil structure and porosity, restricting air and water movement within soil layers, and also the water-storing capacity. Salt movement through leaching will alter the quality of groundwater, and that by drainage will influence the environment in the disposal region. Thus, environmentally sustainable agriculture depends on managing many soil processes to maintain appropriate soil conditions for plant growth and avoiding contamination of the surrounding natural resources. Attention by the global community to soil health care and enhancement to achieve water conservation and efficient use in conjunction with the adoption of climate-resilient technologies has become a necessity.

Soluble Salts and Salinity Impact

Even though several types of organic and inorganic compounds are present in the soil, the concentration and type of ions in soil water derived from soluble compounds cause “salt stress” on plants, affecting crop productivity in addition to influencing soil properties (Figure 1). While the salt input into soils can vary considerably according to various resources, the contribution by irrigation water can be estimated by the salinity of irrigation water and the application rate (Table 1).

The predominant constituent cations of total soluble salts commonly found in salt-affected soils are sodium, potassium, calcium, and magnesium; the anions are chloride, sulfate, bicarbonate, and carbonate. However, the presence of ionic species of plant nutrient elements like N and P, and other microelements such as Fe, Al, B, Cd, Zn, Cu, Mn, Co, Cr, Mo, As, Pb, Hg, Se, and Sr, although in small amounts (hence called microelements), can either interfere with the plant nutrition or induce toxicity in plants. The solubility of all these compounds and the nature of ionic species depend on the pH of the soil water, and also pE (–log [electron]) when a soil is waterlogged. Crop growth responds to ionic concentrations in soil water in two phases: a continuous osmotic phase that inhibits the water uptake by plants due to osmotic pressure of soil water lowering its potential energy (water always moving from a higher to lower potential energy levels); and a slower-acting ionic phase when the accumulation of a given ion in the plant over a period leads to ion toxicity or ion imbalance.[2] However, the interactions between root zone environments and plant responses to increased osmotic pressure (due to total dissolved salts) or specific ion concentrations in the field soil are complicated by many soil processes such as soil water dynamics, soil structural stability, nutrient and water movement, and changes in soil air composition.[3]

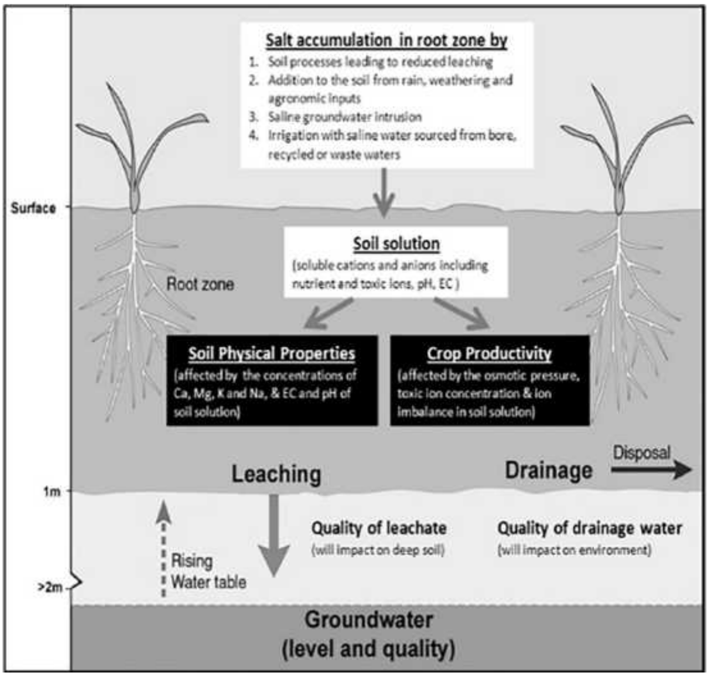

FIGURE 1 Schematic diagram of salt accumulation, soil solution affecting soil structure and crop productivity, leaching, and drainage—all influencing sustainable management of salt-affected soils.

TABLE 1 Example of Amount of Salt Applied per Hectare Based on Irrigation Water Salinity (dSm–1) and Application Rate (MLha–1)

	Irrigation Application Rate			
Irrigation Water Salinity EC (dSm–1)	2 MLha–1	4 MLha–1	8 MLha–1	16 MLha–1
	Salt input into soil (tha^{-1})			
0.5	0.64	1.28	2.56	5.12
1.0	1.28	2.56	5.12	10.24
3.0	3.84	7.68	15.36	30.72

Soil Structural Stability in Salt-Affected Soils

The integrity of soil aggregates when in contact with water, either during rainfall or irrigation, is an important feature of soil structural stability. Unstable soil structure leads to collapse of aggregates into fine particles. This results in agricultural soils becoming less porous, affecting water and air movement within root zone and with reduced water storage capacity. During high rainfall events, these soils can be waterlogged and soil particles can be easily eroded by overflowing water.

Soil microaggregates (<≈250 μm) are formed by the linking of clay, silt, and sand particles by various inorganic ions and organic compounds. The stability of microaggregates depend on the nature of interaction between water molecules and soil particles, particularly clay. Clay-to- clay bonding is mediated by cations such as sodium, potassium, magnesium, and calcium, which are adsorbed on soil clays from soil solution and known as exchangeable cations. Clay particles are negatively charged and cations are positively charged. Hence, they attract each other and form different types of bonding linking the clay particles. However, the nature of this bonding can be ionic or covalent or a combination of both. Water molecules, being polar, can interact with ionic bonds while they do not interact with covalent bonds.

Organic compounds are all made up of covalent bonds and hence they do not react with water. When organic matter is high in soils, water interaction is minimal because clays are either bound by clay-organic bonds, which are mostly covalent, or soil aggregates are enveloped by organic materials formed by covalent bonding. Hence, the soil aggregate structure is highly stable. Further, microaggregates are linked to form larger macroaggregates influenced by organic materials, including living species such as plant roots and fungal hyphae.[4] The phenomenon of "slaking" occurs when macroaggregates on wetting break into microaggregates, depending on the nature of the linkage.

Clay–sodium bonding is highly ionic, and the clays bound by sodium are easily separated by water. Clay particles with high exchangeable sodium easily separate when in contact with water. This phenomenon is known as clay swelling when water content is low and clay dispersion when water content is high, both leading to soil structural deterioration.

Soil structural deterioration increases with an increase in exchangeable sodium percent (ESP), which is defined as

$$\mathrm{ESP} = (\text{exchangeable Na} / \text{cation exchange capacity}) \times 100$$

In Australia, soil with an ESP of 6 is considered "sodic," and when ESP is >15, it is considered as "highly sodic." In the United States and other parts of the world, an ESP >15 is the criterion for a sodic soil. The value of ESP depends on the ratio of sodium to divalent ions in soil solutions or soil extracts. This ratio is known as sodium adsorption ratio (SAR), which is defined as follows:

$$\mathrm{SAR} = \mathrm{Na} / (\mathrm{Ca} + \mathrm{Mg})^{0.5},$$

where the concentrations of cations are expressed as mmolL^{-1}.

Generally, the SAR of soil saturation extract is approximately equal to the ESP of the soil. As the measurement of SAR is simpler than that of ESP, SAR is conveniently used as index of soil sodicity and the degree of structural deterioration. Clay dispersion from soils, measured in the laboratory, is highly related to SAR in soil solutions.[5]

Generally, sodium is considered to cause clay dispersion in soils. However, potassium, being a monovalent cation, can also induce similar effects. Our studies have shown that clay–cation bonding has different degrees of ionicity, depending on the cation. The degree of ionicity is in the following order: Na>K ≫ Mg>Ca. While both Na and K promote clay dispersion, they are not equal in their effects. Similarly, both Ca and Mg promote clay flocculation (aggregation of clay particles), but they have different flocculating powers.[6] Salt-affected soils are found to have different combinations of these cations, and to consider only sodium as dispersive cation can lead to erroneous conclusions. Therefore, we[7] have derived a new formula, "cation ratio of soil structural stability (CROSS)," analogous to SAR but which selectively incorporates the individual dispersive effects of Na and K, and the individual flocculating effects of Mg and Ca. This ratio was derived from the flocculating power of these cations detailed in Rengasamy and Olsson.[6]

$$\mathrm{CROSS} = (\mathrm{Na} + 0.56\ \mathrm{K}) / (\mathrm{Ca} + 0.6\ \mathrm{Mg})^{0.5}$$

The effects of cations on clay dispersion from salt- affected soils (indicative of soil structural degradation), characterized by either SAR or CROSS, are evident only when the ionic strength of the soil solution is below a "threshold level."[5]Above this level, the soil clays are flocculated by dissolved salts without any impact on soil physical behavior. Thus, Figure 2 schematically describes the relation between the indices (SAR or CROSS) of soil structural degradation and the ionic strength of the soil solution (measured as electrical conductivity, EC, of the soil solution) in salt-affected soils. As these indices increase clay dispersion is favored, while as EC increases flocculation (aggregation of clay particles) is promoted. However, above a certain level of EC, plant growth is affected by salinity stress. The relationship featured in Figure 2 is highly dependent on soil pH, which affects the net charge on clay particles.[8]

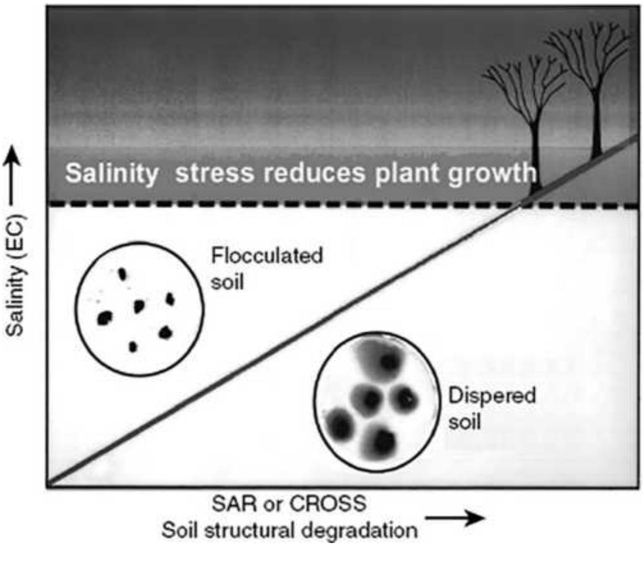

FIGURE 2 Schematic diagram relating SAR or CROSS with EC of soil solutions to indicate soil structural degradation in salt- affected soils.

Categories of Salt-Affected Soils

As sodium salts dominate in naturally occurring salt- affected soils, the soils are generally "saline–sodic," which become "sodic" when soluble salts are leached. Similarly, a sodic soil becomes saline–sodic when salts accumulate in soil layers because of restricted drainage imposed by a degraded soil structure. When sodium salts are not dominant, the soils are referred to as "saline" soils. Generally, saline, sodic, and saline–sodic soils have a spectrum of disorders and the soil solutions have a range of values of cations concentrations and electrical conductivity. Sodic soils are considered[9] to have pH >8.5 because of the predominance of carbonate ions in arid soils. However, sodic soils with neutral and acidic pH with the predominance of anions Cland SO_4^{2-} have been reported to be widely present, particularly in Australia.[10] Soil pH also controls the presence of a variety of ionic species, in addition to influencing soil structure. For example, chlorides and sulfates dominate in neutral and acidic soils, whereas in alkaline soils bicarbonate and carbonate ions are prevalent. Microelements such as Fe, Al, Zn, Mn, Mo, Cr, B, Cu, As, Cd, and Se occur in soil solutions as differently charged ionic species ranging from cationic to anionic forms dictated by equilibrium pH.[11]

Thus, the SAR, EC, and pH of soil solutions are determined by the ionic composition and hence, the impact on crop growth and yield, and as well as on soil structure. Table 2 gives different categories of salt-affected soils on the basis of SAR_e and EC_e of soil saturation paste extracts (subscript e denoting saturation paste extract) and pH measured in 1:5 soil-water suspensions. Measurements of ions in extracts from saturated soil paste are common in many parts of the world. If measurements are made in soil solutions from different soil-to-water ratios, the values will be different and appropriate conversion factors have to be used to derive SAR_e and EC_e.[3] Table 2 also gives the possible mechanisms through which plant growth is affected in each category. Measurements of all ions in soil solution are necessary to identify toxicity, deficiency, or ion imbalance of various nutrients and microelements in relation to crop productivity.

Toxic Elements in Salt-Affected Soils

The accumulation of toxic elements including heavy metal ions in the form of soluble salts in agricultural soils, in recent years, is caused by the long-term application of wastewater, industrial effluents, mining wastes, sewage sludge (or biosolids), and compost. As a result of global industry outputs, atmospheric deposition (such as acid rains) is another cause of toxic ion dynamics in productive soils. Landfill leachates also pollute nearby farming lands. Although the amounts of these elements are usually much smaller than the major elements (considered to be useful in crop production), their availability for plant uptake or being leached into groundwater is an important environmental issue. Plant uptake of toxic ions, in addition to causing decline in crop production, can affect human health by entering into the food chain. More details on the distribution and properties of heavy metals (or trace elements) in soils can be found in many publications.

Soil Water Dynamics and Salinity Stress

Salt concentration in agricultural soils is transient and varies with depth and changes throughout the growing season in response to rainfall and irrigation, surface evaporation, water use by vegetation, and the hydraulic conductivity (hence the leaching fraction) of soil layers.[12] As the soil dries because of evapotranspiration, the salt concentration increases, as does the osmotic pressure of soil water. Concomitant changes in matric and osmotic potentials (Table 3) determine plant water uptake in the field. The influence of soil texture and type of clay on plant-available water compounds the effects of matric plus osmotic potentials. As the total water potential decreases below –900 kPa, plant water uptake is greatly reduced, and at –1500 kPa plant wilts completely.[3] The two plant responses to salinity, viz. osmotic stress and ion-specific stress, can occur sequentially, giving rise to a two-phase growth response.[2] Our experiments[13]

TABLE 2 Categories of Salt-Affected Soils Based on EC_e (dSm^{-1}), SAR_e, and $pH_{1:5}$ of Soil Solutions, and Possible Mechanisms of Impact on Plants

No.	Category of Saline Soil	Criteria	Possible Mechanisms of Impact on Plants
1	Acidic–saline soil	ECe >4; SARe <6; pH <6	Osmotic effect; microelement (Fe, Al, Mn, etc.), toxicity; SO42– toxicity in very low pH
2	Neutral saline soil	ECe >4; SARe <6; pH 6–8	Osmotic effect; toxicity of dominant anion or cation other than Na+
3	Alkaline–saline soil	ECe >4; SARe <6; pH 8–9	Osmotic effect; HCO3– and CO32– toxicity
4	Highly alkaline-saline soil	ECe >4; SARe <6; pH >9	Osmotic effect; HCO3– and CO32– toxicity; microelement (Fe, Al, Mn, etc.) toxicity
5	Acidic–saline–sodic soil	ECe >4; SARe >6; pH <6	Osmotic effect; Na+ and microelement (Fe, Al, Mn, etc.), toxicity
6	Neutral saline–sodic soil	ECe >4; SARe >6; pH 6–8	Osmotic effect; Na+ toxicity; toxicity of dominant anion (Cl– or SO42–)
7	Alkaline–saline–sodic soil	ECe >4; SARe >6; pH 8–9	Osmotic effect; Na+ toxicity; HCO3– and CO32– toxicity
8	Highly alkaline–saline–sodic soil	ECe >4; SARe >6; pH >9	Osmotic effect; Na+ toxicity; HCO3– and CO32– toxicity; microelement (Fe, Al, Mn, etc.), toxicity
9	Acidic–sodic soil	ECe <4; SARe >6; pH <6	Indirect effect due to soil structural problems; seasonal waterlogging can induce microelement (Fe, Al, Mn, etc.), toxicity
10	Neutral sodic soil	ECe <4; SARe >6; pH 6–8	Indirect effect due to soil structural problems; seasonal waterlogging; Na+ toxicity at high SARe
11	Alkaline–sodic soil	ECe <4; SARe >6; pH 8–9	Indirect effect due to soil structural problems; seasonal waterlogging; Na+ toxicity at high SARe; HCO3– and CO32– toxicity
12	Highly alkaline–sodic soil	ECe <4; SARe >6; pH >9	Indirect effect due to soil structural problems; seasonal waterlogging; Na+ toxicity at high SARe; HCO3– and CO32– toxicity; microelement (Fe, Al, Mn, etc.), toxicity
13	Non-salt-affected soil	ECe <4; SARe <6; pH 6–8	Can have problems due to factors other than salts

Note: Toxicity, deficiency, or ion imbalance due to various ions will depend on the ionic composition of soil solution.
Source: Data from Rengasamy.[3]

using soils in pot experiments and also field observations have shown that when the osmotic pressure of soil water is >900 kPa (EC of soil water >25 dSm^{-1}), the osmotic effect is predominant and specific ion (such as Na or Cl) effect may be significant at lower levels of salinity (Figure 3). In moderately saline soils when soil fertility level is low and nutrient deficiency is an issue, application of fertilizer at an appropriate level alleviates the salinity stress on plants.[14] Similarly, adding a small amount of calcium has been reported to enhance the salt tolerance of plants at moderate levels of NaCl salinity.[15]

Different levels of salinity in the field during the crop growing season induced by the changing soil water content (Table 3) will affect crops differently, either by a predominant osmotic effect or an ion-specific effect. In dryland cropping, a high concentration of salt combined with a low rainfall in the start of the season severely affects the germination of seeds. Similarly, dry spells, enhancing salt concentration, during critical physiological periods of crop growth such as flowering and grain filling, can result in the significant reduction in yield.[3] Apart from vertical and temporal variations, spatial variation in salinity across a field can also be large in both dryland and irrigated cropping regions. These factors have to be considered in choosing appropriate crop species relevant to different sections in the field and seasonal weather pattern in farming systems.

TABLE 3 Changes in Matric, Osmotic, and Total Water Potentials of an Alfisol (Loam) and a Vertisol (Clay) with Changes in Soil Water Content

	Water Content	EC	Soil Water Potential (kPa)		
Soil Water Status	(g g–1)	(dS m–1)	Matric	Osmotic	Total
Alfisol (loamy soil)					
1:5 Soil water	5.00	0.64	+0.1	–23.0	–22.9
Saturation paste	0.35	9.14	–0.1	–329.1	–329.2
Field capacity (FC)	0.20	16.00	–10.0	–576.0	–586.0
Drier than FC	0.14	22.86	–680.0	–823.0	–1503.0
Permanent wilting point	0.05	64.00	–1500.0	–2304.0	–3804.0
Vertisol (clayey soil)					
1:5 Soil–water	5.00	0.64	+0.1	–23.0	–22.9
Saturation paste	0.80	4.00	–0.1	–150.0	–150.1
Field capacity (FC)	0.40	8.00	–10.0	–288.0	–298.0
Drier than FC	0.16	20.00	–780.0	–720.0	–1500.0
Permanent wilting point	0.08	40.00	–1500.0	–1440.0	–2940.0

Hypoxia and Salinity Effects

During high rainfall seasons, soils with restricted drainage become waterlogged and air-filled soil pores are eliminated with severely reduced oxygen availability (hypoxia). Sodic soils with limited porosity become saturated with water in wet conditions, and hypoxia is common in these soils. Hypoxia may lead to many problems that plants may experience such as shortage of ATP in anoxic root cells, reduced carbohydrate production, production of reactive oxygen species, toxic reduction products and raised CO_2 and organic acids, and shoot wilting from decreased hydraulic conductivity.[16] Hypoxia can worsen the growth of plants exposed to salinity.[17] Because of increased solubilities due to changes in pH and pE associated with hypoxia,[11] toxicity of Mn, Fe, Al, B, and reduction products such as H_2S and methane is common in waterlogged salt-affected soils.

Management of Salt-Affected Soils in Relation to Agricultural Production and Environmental Protection

The solution to improving agricultural production in salt-affected soils without degrading the environments is to link the plant improvement to tolerate salinity and other associated abiotic stress with appropriate soil management and cropping practices. As mentioned earlier, there are different categories of salt-affected soils, each one requiring a specific strategy depending on how root zone processes and plant interactions are affected by soil solution composition. Broadly, there are three ways with some possible actions to resolve the problems in salt-affected soils, based on the schematic presentation in Figure 1: 1) prevention of salt accumulation; 2) removal of accumulated salts; and 3) adaptation to saline environment.

Prevention of Salt Accumulation

Natural processes responsible for salt input, such as mineral weathering and deposits from rain and wind, are difficult to prevent or control. However, salt input through irrigation can be reduced by managing irrigation water quantity and quality. Adding salts and toxic elements by adding composts, industrial effluents, mining wastes, sewage sludge, biosolids, and wastewater can be prevented by environmental regulations and guidelines for safe application of these materials. Salt input through groundwater intrusion in soils with shallow water tables can be minimized by growing deep-rooted perennial plants with high transpiration rates to use groundwater and reduce recharge, thus controlling groundwater levels. However, this strategy will concentrate more salt in the root zone in soils where the water table is deep.[12]

Removal of Accumulated Salts

Accumulated salts in the root zone layers can be removed by leaching. In dryland cropping regions, good infiltration of rainfall and water movement through the soil profile by improving soil structure can effectively reduce salt load. In irrigation agriculture, the quantity and quality of irrigation water should be evaluated for providing leaching fraction to maintain salt balance. In both cases, care should be taken to avoid leachates from the soil contaminating the deeper soils or the surroundings in the drainage disposal region (Figure 1). Contamination due to As and Se from the drainage water has been reported in different parts of the world.

Adaptation to Saline Environment

Agricultural production in the saline environments can be enhanced by using plants that tolerate salt in the root zone. High genetic variations exist among plant species and crop cultivars that are thriving under different saline environments (or categories of salt-affected soils, Table 2). This can be exploited to develop better-adapted salt-land plants. Selection, breeding, and genetic modification to improve crop performance should focus on the many soil processes and soil solution compositions discussed above to find the new cultivars that are effective in the field so that farmers can adopt them.[18] Plant improvement must also be linked to appropriate soil management and agronomic practices, taking into account of temporal, vertical, and spatial variations in salinity in the field dictated by soil water dynamics.

Conclusions

The constituent cations and anions in solutions of salt- affected soils affect both soil properties and crop productivity. The interactions between root zone environments and plant response to increased osmotic pressure or specific ion concentrations are also influenced by soil processes such as soil water dynamics, soil structural stability, and soil pH and pE. Soil structural stability affects plant performance and also the environment by way of soil erosion. There are 12 categories of salt-affected soils based on the SAR_e, EC_e, and pH of soil extracts. The mechanisms by which plant growth is affected are specific to each category. Elements toxic to plant growth can occur naturally in these soils and also owing to use of wastewater and waste materials such as biosolids, sewage sludge, and compost. The solubilities of these elements are influenced by several factors, but mainly by soil pH and pE. Management of salt- affected soils in relation to agricultural production and environmental protection can be achieved by three ways, viz. prevention of salt accumulation, removal of accumulated salts, and adapting to saline environment by growing appropriate salt tolerant crops. While minimizing salt load in the root zone, care should be taken to avoid leachates from the soil contaminating the deeper soils or the surroundings in the drainage disposal region.

Sodic Soils: Irrigation Farming

David Burrow

Properties of Sodic Soils Affecting Irrigation Farming

Hydraulic Properties

The movement of water into the soil following rainfall or surface irrigation, its redistribution within subsurface layers, and drainage below the rootzone are important for productive irrigation farming. Water entry into the soil, measured by the infiltration rate (IR), and through soil layers, measured by the hydraulic conductivity (HC), both decrease with increasing exchangeable Na and decreasing soil salinity. For strongly sodic soils, heavy rainfall or low-salinity irrigation may lead to surface waterlogging on flat land or run off on sloping ground.[1] Similarly, freshwater irrigation of sodic soils with low HC may lead to shallow depths of wetting, uneven wetting, and low plant available water capacity.[2] These hydraulic traits, together with lower air-filled porosity and excessive penetration resistance in dry soils, can restrict plant growth.[3]

The low IR of a strongly sodic soil during irrigation is usually attributed to the formation of a surface seal or crust, which in turn derives from the physiochemical dispersion of clay-sized particles from unstable surface aggregates. These dispersed clay particles migrate with water flow and eventually block conducting pores.

Early studies showed that soil HC varies up to two orders of magnitude, depending on the salt concentration of a percolating solution and soil-exchangeable sodium percentage.[4] Reductions in HC were explained by swelling and dispersion of clay particles but these factors are modulated by clay mineralogy, sesquioxide and $CaCO_3$ content, soil texture, organic matter content, pH, soil weathering, and other exchangeable cations.

The effects of soil sodicity on IR and HC, resulting from saline–sodic irrigation are exacerbated in climatic zones with a marked rainfall season because of the leaching of salts from surface soil horizons. Rainfall, with negligible salinity (EC <0.1 dS/m) infiltrates and reduces soil EC below a threshold electrolyte concentration (TEC) in these layers, resulting in clay swelling or dispersion. In the field, these processes are not necessarily detrimental to HC as they may be accommodated by pore geometry and slow wetting rates, or circumvented by preferential flow through large cracks. However, the maintenance of soil EC above TEC is an essential first step toward managing sodic soils under irrigation.

Nutrient Status

In sodic soils, high Na/Ca and Mg/Ca ratios reduce the amount of Ca available for plant uptake and can induce Ca deficiencies in crops. Data, obtained principally from greenhouse and laboratory studies, indicate that cereal species are sensitive to Ca deficiencies and particularly during seedling growth stages.[5]

Poor productivity on sodic soils has also been attributed to lowered availability and plant uptake of nitrogen or micronutrients. Nitrogen availability in these soils is restricted under anaerobic conditions,[6] while micronutrient availability is controlled by adsorption and precipitation reactions.[7]

The relative solubility of boron (B) and high Na/Ca ratios in some sodic soils also means that B and Na toxicity may contribute to crop production losses. However, the relative importance of nutrient availability and specific ion toxicity on crop production losses for sodic soils is difficult to judge, because of the compounding influence of poor soil physical properties on crop growth and yield.

Soil Management

Specific tillage operations and cropping systems have been designed to overcome some of the poor physical properties of sodic soils.[1,8] Field grading and raised-bed cropping systems are used in landscapes of low gradient to encourage runoff and limit surface waterlogging. Deep ripping is used to break up massive subsoil structures and for the incorporation of gypsum into subsurface horizons. Shallow tillage, at moisture contents close to the lower plastic limit, is used to generate seedbeds of fine tilth, rather than massive clods. Following crop establishment, zero tillage is typically advocated in order to minimize mechanical destruction of surface aggregates and subsequent dispersion of clays during irrigation.

Tillage practices, which aim to stabilize surface soil aggregates of an appropriate size distribution, are aided by the use of cover crops, mulch applications, and gypsum applications.[1] Soil cover crops, such as *Lolium rigidum,* tend to stabilize topsoil aggregates by means of entwining root systems and the incorporation of root mucilages within the rootzone. Mulches are used for the creation of a more favorable soil microclimate, which encourages turnover in microbial populations, microbial detritus, and the generation of stabilizing, organic glues. Careful applications of gypsum or other calcium products at the soil surface aim to reduce soil sodicity or maintain soil EC above TEC.

Irrigation Management

Water Quality

Water quality guidelines for crop production based on salinity (EC_{iw}) and sodicity (SAR_{iw}) have been developed for infiltration, crop salinity tolerance, and specific ion toxicity.[8] In contrast, water quality guidelines for soil permeability (HC) and potential dispersion of clay tend to be based on soil chemical properties.

According to infiltration guidelines, calculated on paired EC_{iw} and SAR_{iw} ranges, the quality of irrigation waters used throughout the world (Table 1) should rarely limit their application to land.[8] However, when the EC of infiltrating water falls below 0.2 dS/m, e.g., as occurs after rainfall, severe infiltration problems are predicted. Crop salinity tolerance guidelines predict severe Na toxicity for sensitive crops, based on $SAR_{iw}>9$, and severe salinity effects on crop productivity, based on $EC_{iw}>3$ dS/m. However, these predictions when applied to data in Table 1 only concern irrigation of crops with drainage waters, because of their typically high SAR_{iw} and EC_{iw}.

[a] Range values are shown in italics.
Source: Ayers and Westcot.[8]

The use of an adjusted SAR_{iw} (adj $R_{Na\ iw}$) in Table 1, accounts for the effects of high bicarbonate concentrations in some irrigation waters. Bicarbonate tends to precipitate Ca, and to a lesser extent Mg, as a carbonate solid, with the net result of an increase in SAR_{iw}. Transformations of Ca (and Mg) between soluble, exchangeable, and precipitated forms are modulated by pH and the partial pressure of CO_2, hence these two factors indirectly affect SAR_{iw}.

Irrigation Practices

Specific irrigation practices complement tillage and chemical additions to improve the production potential of sodic soils. These practices include increased frequency of irrigation, preplanting irrigation, and adoption of alternative irrigation systems. Uniform applications of polyacrylamide or finely powdered gypsum to topsoils, for the purpose of stabilizing fragile aggregates, are also best achieved through an initial irrigation.

Increasing the frequency of short-duration irrigations on soils with high initial IR (e.g., cracking clays) and low final IR (due to sodicity), maximizes the periods of high IR to wet the rootzone, and decreases the risk of waterlogging. Preplanting irrigation wets the entire rooting depth and if timed correctly allows restoration of soil aeration before crop planting. This technique is especially effective on sodic soils of very low IR. A change from surface irrigation systems (e.g., flood or furrow) to sprinklers or drippers, can alleviate waterlogging on low IR soils by matching water delivery rates to the IR. The slow wetting of topsoils, under these alternative irrigation systems, also decreases aggregate slaking and clay dispersion.

Drainage of Sodic Soils

Drainage is essential for the continued practice of irrigation farming on sodic soils. Surface drainage prevents waterlogging and the development of anaerobic conditions in the topsoil, while adequate subsurface drainage allows leaching of toxic or plant-dehydrating salts from the profile.

For some irrigated regions, the presence of a shallow watertable restricts drainage through a diminished hydraulic gradient. These watertables are frequently saline–sodic and contribute to sodification of soils via capillary transmission of Na-salts. Hence, the removal in these regions of subsurface water through drains (open or piped) and pumped bores is essential for sodium management. Because installation of open or piped drains is expensive, the use of cheaper mole drains within subsurface layers has been proposed. However, in unstable sodic soils, mole drains soon collapse and therefore are not generally used.[9]

Periodic leaching of soil profiles is required for removal of salt or toxic ions. Analytical equations have been developed to predict the leaching requirement for soil sodicity under saline–sodic irrigation.[10]

However, these equations do not fully account for Na-induced changes in IR or HC, which impinge on leaching capability.

Practically, intermittent irrigation is more efficient in salt removal than continuous ponding by promoting diffusion of salts into more favorable leaching pathways. Efficient leaching of sodic soils also requires irrigation with water of low SAR_{iw} and $EC_{iw} > TEC$, together with provision of sub-surface drainage for removal of salts.

Conclusions

A range of farm management practices on irrigated, sodic soils have been briefly described. Adequate control of water quality with respect to SAR_{iw} and EC_{iw}, and provision of drainage to remove excess sodic salts from the rootzone are pivotal in controlling soil sodicity. Concurrent management of surface soils with ameliorants (e.g., gypsum, organic polymers, mulches), cover crops, and appropriate irrigation methods enhances farm operations on these sodic soils at relatively low cost. Adequate modification of drainage and sodicity in subsoils is more costly and therefore less frequently attempted, particularly for cereal and forage crops. Consequently, the control of soil sodicity in irrigated farming still remains focused on irrigation water quality, irrigation systems and scheduling, provision of surface runoff, and application of soil ameliorants to the soil surface. The continual emergence of irrigation and soil chemistry simulation software for computers should enhance further scientific research and refine farm management of soil sodicity.

Agricultural Soils: Carbon and Nitrogen Biological Cycling

Alan J. Franzluebbers

Introduction

Carbon (C) and nitrogen (N) are two of the most important elements that affect soil productivity and environmental quality.[1] Carbon is found throughout nature in a wide variety of forms and particularly in soil as 1) complex organic compounds (e.g., carbohydrates—$C_xH_{2x}O_x$, lignin, etc.,) derived from living organisms; 2) carbonate minerals such as calcite ($CaCO_3$) and dolomite [$CaMg(CO_3)_2$]; and 3) carbon dioxide (CO_2) and methane (CH_4) as decomposition end products. Nitrogen is an essential element of plants, animals, and microorganisms—a part of chlorophyll, enzymes, amino acids, and proteins, which are necessary for growth and development of organisms. In typical unpolluted soil, quantity of N in organic matter and fixed as ammonium (NH_4^+) in clay minerals far exceeds quantities in plant-available forms of soluble nitrate (NO_3^-) and NH_4^+. Among several soils in North America, total N in 1 m depth of soil was 16.0 ± 6.9 Mg N ha^{-1} with 13% ± 15% fixed as NH_4^+ in clay minerals and <1% as soluble NO_3^-.[2]

Agriculture, i.e., the growing of plants and animals for human and livestock consumption, is a widespread land usage throughout the world. Globally, agriculture occupies approximately 38% of the total land area with 1.5 billion ha in cropland and 3.4 billion ha in perennial grassland.[3] Addition of N, phosphorus (P), potassium (K), and other nutrients to soil is often needed to satisfy the demands by high-production crops and forages. A portion of these nutrients is naturally supplied through plant residue and soil organic matter decomposition, but amendment with inorganic or organic fertilizers is often needed to achieve high production. Unfortunately, there are many pathways for nutrients to escape from the agricultural landscape into nearby streams, lakes, groundwater, and the atmosphere. Preventing these losses is one of the goals of sustainable, ecologically based approaches to agricultural production.

Carbon and Nitrogen Cycles

Both C and N are biologically fixed from inorganic atmospheric forms to organically bound plant and microbial forms. Photosynthesis converts inorganic CO_2 from the atmosphere into organic carbohydrates in plants, algae, and cyanobacteria. Biological N fixation is a unique transformation carried out by a number of bacteria, which convert N_2 gas into ammonia (NH_3) for biological utilization. N-fixing bacteria are most prevalent in symbiotic relationships with plants, such as *Rhizobium* that forms nodules on the roots of clovers where the nitrogenase enzyme catalyzes the reaction. Fertilizer manufacturing converts N_2 gas into NH_3 in a similar manner without an enzyme, but rather large quantities of energy necessary to create the pressure required for the transformation.

Under certain conditions, both inorganic C and N can be chemically fixed in the subsoil. Carbon dioxide forms carbonic acid in water, which can precipitate with the basic cations, Ca^{2+}, Mg^{2+}, and Na^{+}, to form pedogenic carbonates. Inorganic C is most abundant in soils of the semiarid and arid regions. Ammonium can be fixed as nonexchangeable components of the lattice structure of 2:1-type clay minerals, which are especially prevalent in the subsoil of many younger soils.

Carbon and N occur in various forms and undergo transformations from one form to another, primarily through biochemical manipulations involving enzymes.[4,5] Enzymes are proteins, functioning to catalyze very specific reactions either 1) intracellularly within plants, microorganisms, or soil animals; or 2) extracellularly in soil solution or attached to soil colloids. Some major enzyme categories and their reactions with C and N substrates in soil are 1) hydrolases, such as amylase and cellulase, which hydrolyze various carbohydrate and macromolecular compounds; 2) oxyreductases, which catalyze various electron transfer reactions; 3) proteinases, which convert proteins to amino acids; 4) lignocellulases, which catalyze the ecologically resistant step of lignin breakdown; and 5) lyases, which form double bonds through reactions other than hydrolysis or oxidation. Two key enzymes involved in the fixation of C and N into organic forms are 1) ribulose bisphosphate carboxylase (rubisco), which is the photosynthetic enzyme catalyzing the transformation of CO_2 from the atmosphere into carbohydrates; and 2) nitrogenase, which catalyzes the biological N fixation reaction in symbiotic bacteria associated with leguminous plant roots:

$$N_2 + 6\ H + \text{energy} \rightarrow 2\ NH_3$$

Forms and fluxes of an element are commonly illustrated in a cycle following the principles of conservation of mass (i.e., elements are transferred from one molecule to another) (Figure 1). Carbon and N cycles have global dimensions with terrestrial, aquatic, and atmospheric components of major significance.[6,7] The sun initiates a chain of energy reactions, which drive elemental cycles. The elemental cycles of C and N interact closely with the water cycle, as water is a fundamental internal component of life and a major transport mechanism of nutrients.

In natural systems without significant import of N from fertilizers, the cycling of N is largely dependent upon the cycling of C. Since growth of plants is often limited in N supply due to the strong competition for N by soil microorganisms, which have a steady supply of C-rich substrates at the surface of undisturbed soil, N losses from natural systems are typically low.[8] The need for additional N in agricultural systems can be historically derived from two major pathways: (1) high protein harvest of grain, forage, and animal products that requires supplemental N to replace the already limited N supply in natural systems (and eventual lack of recycling waste and manure by-products from harvested food products back to the land); and (2) loss of soil-surface residue cover and soil organic matter with intensive tillage that initially stimulates N release to crops, but that eventually exhausts the soil resource in its ability to supply N to crops. Loss of C-rich surface residue and soil organic matter essentially removes the C stimulus needed to conserve N in soil, thereby resulting in major losses of N from agricultural systems with time and creating a system that relies heavily on external N inputs to supply crops with not only the N removed from harvested crops but also the N lost via leaching, runoff, volatilization, and

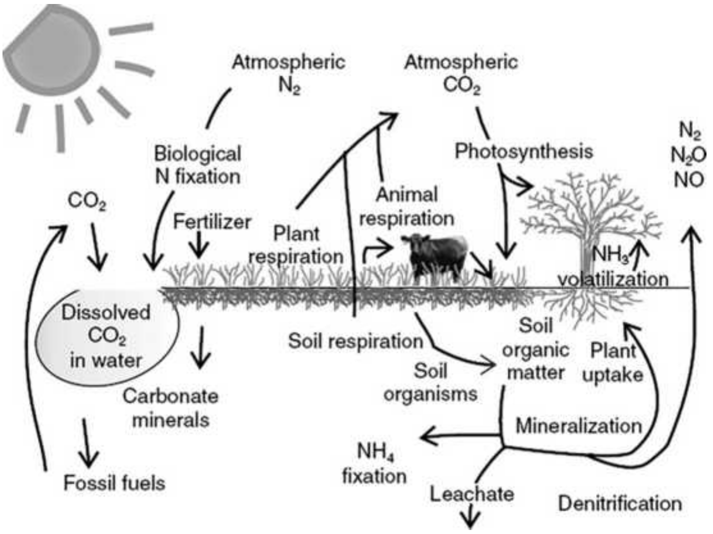

FIGURE 1 Generalized diagram of the C and N cycles in soil.

denitrification. Estimated global production of N and P fertilizers was 100 and 41 Tg (10^{12} g), respectively, in 2007,[3] which compared to about 10 Tg of production for each nutrient in 1960.[9]

Autotrophic fixation of atmospheric CO_2 by plants captures the energy of the sun within organic compounds via the process of photosynthesis (Figure 1):

$$6\ CO_2 + 6H_2O + \text{energy} \rightarrow C_6H_{12}O_6 + 6\ O_2$$

Inorganic N is taken up by plant roots and synthesized into amino acids and proteins during plant development. Plants are eventually consumed by animals or microorganisms, transferring portions of this stored energy through biochemical processes into various cellular components. Once in soil, the C cycle is dominated by the heterotrophic process of decomposition, i.e., the breakdown of complex organic compounds into simple organic constituents. Mineralization is the complete decomposition of organic compounds into mineral constituents:

$$C_6H_{12}O_6 + 6O_2 \rightarrow 6\ CO_2 + 6H_2O + \text{energy}$$

$$R - NH_2 + H_2O \rightarrow R - OH + NH_3$$

Immobilization of N occurs simultaneously with N mineralization when soil organisms require additional inorganic N to meet the high demand for new body tissue while decomposing C-rich substrates low in available N. Net N mineralization occurs when gross N mineralization exceeds that of N immobilization.

Environmental Influences on Soil Microbial Activity

Organisms predominantly responsible for decomposition of organic matter and associated mineralization of C and N are soil microorganisms, composed of bacteria, actinomy-cetes, fungi, and protozoa.[10,11] Soil fauna are larger soil organisms, such as beetles and earthworms (macrofauna, >2 mm width × >10 mm length), collembolan and mites (mesofauna, 0.1–2 mm width × 0.2–10 mm length), and protozoa and nematodes (microfauna, <0.1 mm width × <0.2 mm length), that also indirectly affect C and N cycling by 1) comminuting plant residues and exposing a greater surface area to soil microorganisms; 2) transporting plant and animal residues to new locations in the soil to facilitate decomposition, interaction with soil nutrients, or isolation from environmental conditions; 3) inoculating partially digested organic substrates with specific bacteria and enzymes; and 4) altering physical characteristics of soil by creating burrows, fecal pellets, and distribution of soil particles that influence water, air, nutrient, and energy retention and transport. With suitable environmental conditions, soil microorganisms grow rapidly in response to the availability of organic substrates rich in C and N.

Soil Temperature

Temperature controls both plant and soil microbial activity, although not at the same level (Figure 2). Plant and soil microbial activity are limited by low temperature resulting in low photosynthetic potential, as well as low decomposition potential. For many plants, net photosynthetic activity is optimized between 20 and 30°C, because at higher temperatures, plant respiration consumes energy for maintenance. In many temperate soils, microbial activity is maximized between 30 and 35°C and decreases at higher temperatures. An intermediate temperature is often ideal for maximizing C retention in soil, because optimum plant activity competes well against soil microbial activity.

Soil Water Content

Diversity of soil microorganisms is greatest under aerobic conditions, where maximum energy is obtained. However, there are a number of soil bacteria that thrive under anaerobic conditions, in which alcohols, acetic acid, lactic acid, and CH_4 become C end products via fermentation and nitrate is

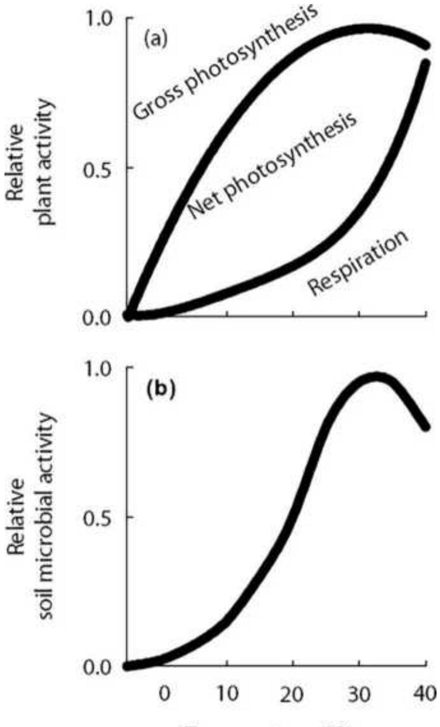

FIGURE 2 Typical responses of plant and soil microbial activities to temperature.

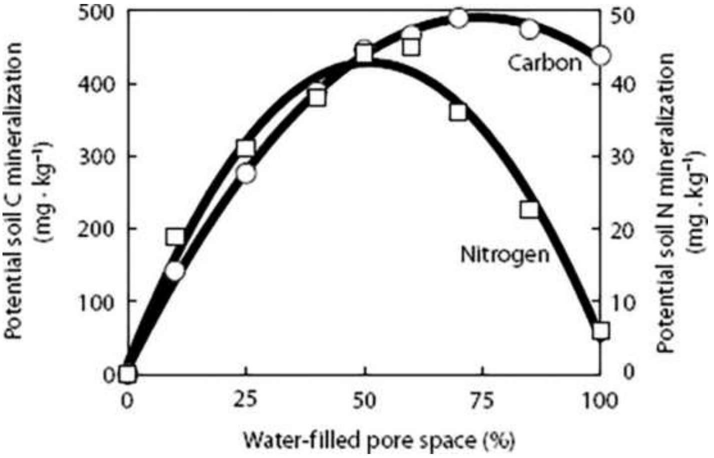

FIGURE 3 Responses of potential soil C and N mineralization to water-filled pore space in Typic Kanhapludults in Georgia, USA [air-filled pore space would be 100 − (water-filled pore space)].
Source: Franzluebbers.[12]

converted to N gases (e.g., N_2, N_2O, NO) via the process of denitrification. Soil C and net N mineralization are maximized at an optimum balance between soil moisture and oxygen availability (Figure 3). Significant denitrification occurs at water-filled pore space >70%, resulting in low availability of inorganic N to plants.

Soil Texture

Soil texture can influence both the quantity of C and N accumulation in soil and their potential mineralization. Potential C mineralization is often greater in coarse-textured soils than in fine-textured soils, due to both increased microbial predation by soil fauna and greater accessibility of organic substrates in coarse-textured soils. Organic C and N can also be protected from decomposition when bound within soil aggregates. Water-stable aggregates are a coherent assemblage of primary soil particles (i.e., sand, silt, clay) cemented through natural forces and substances derived from root exudates and soil microbial activity.

Spatial Distribution of Organic Substrates

Distribution of organic substrates in soil has a major impact on potential C and N mineralization. Potential C mineralization is often several-fold greater in the rhizosphere (i.e., 0–5 mm zone surrounding roots) than in bulk soil. However, because of the high demand for N by plant roots and the stimulated soil microflora, net N mineralization is often initially lower in the rhizosphere because of immobilization of N. Keeping soil active with roots whenever conditions are conducive for plant growth will 1) keep inorganic N at low levels (as well as keep soil covered with protective plant cover to guard against soil erosion); 2) stimulate soil biological activity; and 3) create a richly diverse soil microbial community, all of which prevent nutrients from being lost from the soil.

Surface soil often contains greater quantities of organic matter than at lower depths due to surface deposition of plant residues, as well as greatest plant root activity. Surface soil usually undergoes the most extreme drying/wetting cycles and has the greatest exchange of gases, both of which contribute to enhanced soil microbial biomass and activity. Tillage of soil with traditional agriculture redistributes organic substrates uniformly within the plow layer, often resulting in immediately stimulated soil microbial activity from disruption of organic substrates protected within stable soil aggregates.

Minimum soil disturbance with conservation tillage practices can reduce oxidation of soil organic matter and preserve more C within soil, which can have implications for potentially mitigating the greenhouse effect.[13]

Stratification of soil organic matter with depth is common in natural ecosystems and in conservation agricultural systems (Figure 4). Conservation agricultural systems are defined as those that 1) minimize soil disturbance with tillage; 2) maximize soil-surface cover with continuous plant and/or residue cover; and 3) stimulate biological activity through diverse crop rotations and integrated nutrient and pest management.

Depth stratification of soil organic matter with time occurs when soils remain undisturbed from tillage (e.g., with conservation tillage and pastures) and sufficient organic materials are supplied to the soil surface (e.g., with cover crops, sod rotations, and diversified cropping systems). Depth stratification with time can be viewed as an improvement in soil quality, because several key soil functions are enhanced, including water infiltration, conservation and cycling of nutrients, and sequestration of C from the atmosphere.[15] Depth stratification of soil organic C generally reduces water runoff volume and soil loss from agricultural fields. Grasslands often reduce water runoff volume and soil loss even further than with conservation-tilled cropland due to even greater accumulation of surface soil organic matter. Total runoff loss of nutrients is often lower with conservation tillage than with conventional tillage, because of a reduction in sediment-borne nutrients (Figure 5). Soluble (or dissolved) N and P in water runoff can be a threat to water quality with excessive nutrient applications from fertilizers and manures (even under conservation management), and therefore, further research is being conducted to identify ways of reducing nutrient loss.[31]

Stratification ratio of soil organic C has been proposed as an index of soil quality, because soil-surface enrichment of organic matter is important for improving water-stable aggregation, water infiltration and storage, nutrient cycling, and soil microbial biomass, activity, and diversity.[32] In a land-use survey in the southeastern United States, stratification ratio of soil organic C was related to the total stock of soil organic C in the surface 20 cm depth (Figure 6). This relationship indicates that the majority of C stored with conservation management in these Ultisols and Alfisols of the region occurred within the surface 5 cm.

Organic Substrate Quality

Quality of organic substrates has a major influence on the rate of decomposition and the transformations that occur in soil. Plant residues do not vary greatly in total C concentration on a dry-weight basis (e.g., 37–47 mg g^{-1}), but do vary enormously in the type of C compounds, which determine its quality or conversely its resistance to degradation. The diversity of organic compounds attacked by soil microorganisms is extensive (e.g., organic acids, polysaccharides, lignins, aromatic and aliphatic hydrocarbons, sugars, alcohols, amino acids, purines, pyrimidines, proteins, lipids, and nucleic acids). Almost all naturally occurring organic compounds, and even most synthetic organic compounds, are susceptible to decomposition given the appropriate environment, microbial community, and time.[34,35] Generally, the primary components of plants can be categorized according to relative rate of decomposition: rapid (sugars, starches, fats, and proteins), intermediate (cellulose and hemicellulose), and slow (lignin and lignocellulose). Young plants are of high quality and low resistance to decomposition, whereas with aging, lignin and polyphenolic concentrations increase, resulting in greater resistance to decomposition. Low N concentration of organic amendments usually results in temporary net N immobilization into microbial biomass, which grows rapidly in response to the availability of organic C. Soil microbial biomass typically maintains a C-to-N ratio of 10 ± 5. Following a proliferation of microbial biomass

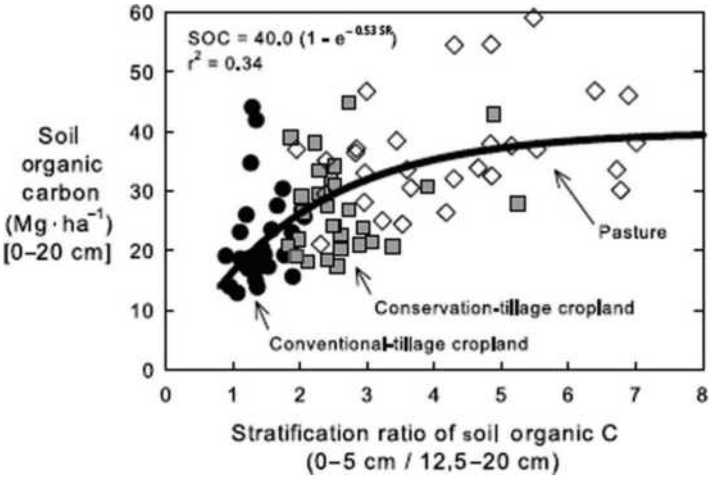

FIGURE 6 Relationship of soil organic C storage at a depth of 0–20 cm to the stratification ratio of soil organic C among conventional-tillage, conservation-tillage, and pasture land uses on different soils throughout the southeastern USA.
Source: Causarano et al.[33]

that depletes the source of readily decomposable organic C, N in excess of microbial demands becomes mineralized and available for plant uptake (Figure 7). In general, plant residues with C-to-N ratio >40 will result in longer periods of net N immobilization.

Soil Organic Matter

Soil organic matter is composed of a large diversity of organic compounds that can be characterized in many ways. A useful separation of soil organic matter for modeling is based on turnover times, whereby at least three pools can be defined: 1) active (composed of microbial biomass and light fraction material with a turnover time of <1 year); 2) passive (composed of macroorganic matter and protected organic matter with a turnover time of 3–10 years); and 3) slow (stable humus fraction with a turnover time of >100 years). Fractions of soil organic matter have also been methodologically characterized and can be tied to above-mentioned kinetic pools.[36] Active fractions have been characterized using soil microbial biomass techniques (chloroform fumigation-incubation, chloroform extraction, substrate-induced respiration, microwave irradiation, phospholipids, and flush of CO_2) and determination of labile substrates (mineralizable C and N during incubation, hot-water extractable C and N, dilute permanganate oxidizable C, carbohydrates, light-fraction C and N, amino sugars). Passive fractions have been estimated using particulate organic matter, glycoproteins, and humic materials. Slow fractions of soil organic matter have been characterized with various resistant components, such as charcoal, lignins, aliphatic macromolecules, humin, nonhydrolyzable organic matter, and silt-and clay-associated organic matter.

Losses of Nitrogen from Soil

Nitrogen cycling in soil is different from that of C because of the more numerous transformations that can occur upon mineralization to an inorganic form.[2] Mineralization of N from organic matter results in NH_4^+released into soil solution. In the presence of nitrifying bacteria, NH_4^+ is converted to NH_3^-, a process called nitrification. The fate of NH_3^- in soil depends upon environmental conditions. Active

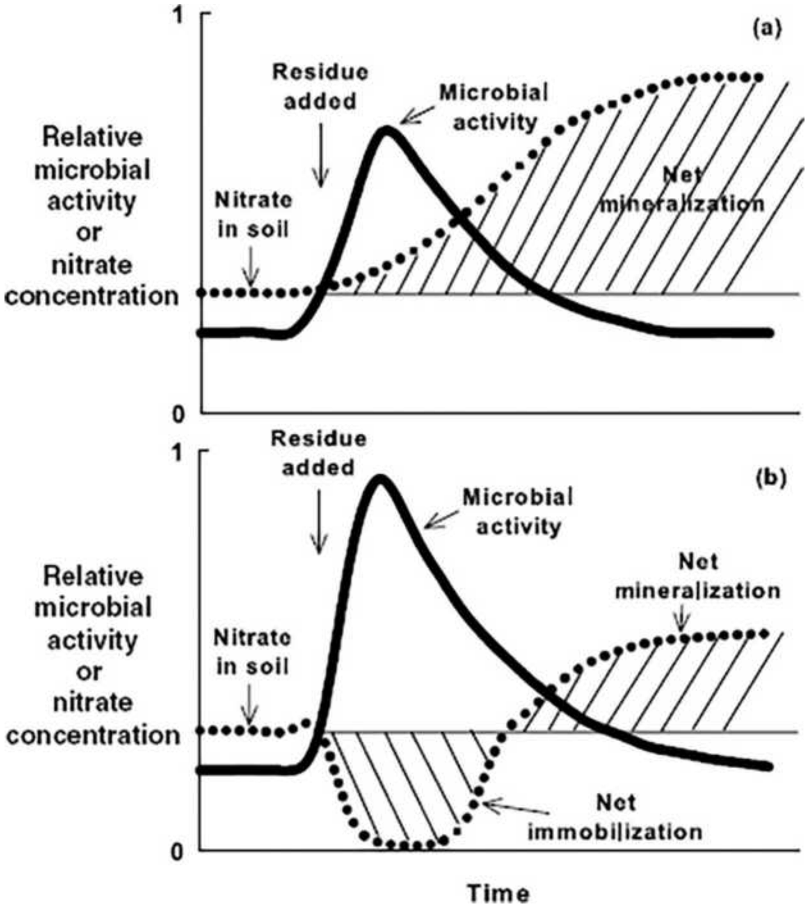

FIGURE 7 Typical responses in soil microbial activity and soil nitrate concentration with the addition of plant residue of (a) high N concentration and (b) low N concentration.

plant growth in natural and agricultural systems would provide enough demand to remobilize N into organic forms. However, NH_3^-can be used as an electron acceptor in place of O_2 under anaerobic conditions, resulting in gaseous loss of N to the atmosphere via denitrification. In temperate soils with a net negative charge on colloidal surfaces, NH_3^- can readily leach into the vadose zone and contaminate groundwater if not taken up by plants or denitrified. In tropical soils with a net positive charge, NH_3^- can be retained on anion exchange sites. Opposite behavior of the cations, NH_4^+ and NH_3^-, occurs with respect to clay mineralogy.

Humans, as well as roving animals, impose great demands on the C and N cycles. Management of agricultural and forest land for food and fiber often removes nutrients from soil for consumption and utilization elsewhere. Return of these nutrients to soil is possible when municipal and agricultural solid wastes and wastewater are applied to land. Losses of C and N from managed lands also occurs through soil erosion, which transports nutrients via 1) water from overland flow into streams, lakes, and oceans and 2) air as dust from bare land surfaces.

Volatilization of NH_3 to the atmosphere is possible when NH_4^+ is exposed to alkaline soil conditions. Significant ammonia volatilization can occur with surface application of urea fertilizer to non-acidic soils, from animal manures, and from green plant materials not incorporated into the soil.

Strategies to Mitigate Loss of Nitrogen from Agricultural Soils

Loss of nitrogen from agricultural soils occurs through harvest, runoff, leaching, volatilization, and denitrification. These losses are potential threats to the environmental quality of water and air resources, as well as to the quality of soil itself. Harvest losses of N can be accepted as practically necessary, but such losses can be partially mitigated by returning waste by-products from food processing and from animal and human consumption back to the soil as organic amendments. This recycling is an important step towards global sustainability of nutrient use and protection of the environment from nutrient loading, particularly relevant in industrialized countries, which seem to have abandoned this age-old practice.

Runoff losses of N can be controlled by protecting the soil surface from soil loss via erosion and by creating a porous surface to allow rainfall to infiltrate rather than runoff. Various conservation agricultural approaches are available to mitigate runoff losses, including reduced or no tillage (i.e., conservation tillage), intensified crop rotations to avoid bare fallow periods, winter cover cropping, crop–pasture rotation, moderate grazing of perennial pastures, and timely and deep placement of fertilizers. Loss of N in runoff can occur as part of N-rich sediment (both organic and inorganic N) and as soluble inorganic N in overland flow of water. Stopping sediment loss is most effective by protecting the soil surface with plants and surface residue, both of which mitigate the energy of rainfall impact and, therefore, avoid soil detachment. Surface application of fertilizers, whether inorganic or organic, is susceptible to runoff loss as water flows over the landscape even if soil is not detached. Therefore, timing fertilizer application to when the plant needs it the most will be an effective N-loss mitigation strategy, as well as placing fertilizer into the soil in proximity with roots with deep banding will limit access to overland flow potential.

Leaching of N through the soil profile is a concern in well-drained soils. Conditions for significant leaching often occur due to overapplication of N fertilizer and long bare-fallow periods that limit plant uptake of residual fertilizer in the soil profile. Mitigation of N leaching can be through continuous plant growth with diverse crop rotations and winter cover cropping. Perennial pastures are also often effective in mitigating N leaching, because of the extended growing season of diverse assemblages of forages. Limiting the quantity of N fertilizer applied is still a basic principle to avoid potential N leaching.

Volatilization of NH_3 can occur when sufficient NH_4^+accumulates at the soil surface from partial decomposition of animal manures and N-rich plant residues and from ammonium-based fertilizer sources. Volatilization is most prevalent in soils with high pH and when soil is rather dry. Mitigation of ammonia volatilization is possible by getting animal manure and N-rich plant residues in close proximity with moist soil and avoiding surface application of N-rich organic residues and NH_4-based fertilizers on soils with high pH.

Denitrification of $NO_3^-$to N_2 (and to N_2O or NO) is a concern in soils under the following conditions: 1) low oxygen composition of the soil atmosphere, due to either high water content or rapid consumption of oxygen by vigorous microbial activity and/or poor air exchange; 2) readily decomposable source of organic C compounds for energy; 3) abundant supply of NO_3^-; and 4) suitable temperature for microbial activity. Mitigation of N loss through denitrification is possible by keeping soil well aerated by avoiding compaction and reducing the accumulation of $NO_{3.}^-$

Chemical nitrification inhibitors have been developed to inhibit or slow down the nitrification process that converts $NH_4^+$to NO_3^-Biological approaches to control susceptibility of NO_3^- to loss via leaching and denitrification focus more on maintaining a continuously growing and diverse plant root system penetrating a soil that develops excellent tilth from a healthy and diverse soil biological community, resulting in stable aggregate structure and vigorous cycling of C and N.

Conclusion

Nitrogen is a key element for the production of high-value crops and animal products around the world. High input of N in the current industrialized model of agricultural production often leaves behind a significant amount of inorganic N, such that loss from leaching, runoff, volatilization, and denitrification can occur. Ecologically based strategies of agricultural production recognize the importance of having sufficient N for production, but rely on biological cycling among plants, animals, and soil microorganisms and fauna to synchronize the release of organically bound N into inorganic forms and avoid environmental pollution. Ecological principles of high biological diversity, continuous plant growth and soil cover, and limited soil disturbance can be used in many different climatic and ecological conditions to avoid environmental pollution by excessive N entering water bodies and air systems.

Agricultural Soils: Phosphorus

Anja Gassner and
Ewald Schnug

Introduction

Phosphorus mirabilis, the light-bearing nutrient, was probably discovered by an Arabian alchemist named Alchid Bechil, although its discovery is usually attributed somewhat later to Henning Brandt.[1] Since the early work of Justus Liebig (1803–1873), agricultural researchers have tried to tackle the mystery of phosphorus (P) availability to plants. Phosphorus research intuitively reminds one of Heisenberg's theory: "The more you see, the less you know." Despite the substantial amount of information available about the transformation products of P fertilizer within temperate[2] as well as tropical soils[3] and numerous attempts to conduct elaborate soil test methods to predict P availability to crops and algae,[2] today the management of phosphate, a finite nonrenewable resource, is far from being in accordance with the principles of sustainability.[4]

This is partly because of the still prevailing misconception that soil is a homogenous, static entity. Phosphorus is regarded traditionally as immobile, but its chemical reactivity with environmental factors, acting at different spatial scales and over different time periods, results in the formation of P species, which not only differ in their plant availability but also in their spatial distribution throughout the field. This spatial speciation[5] is the key for a new approach to assess soil analysis methods.

Chemical Speciation of Phosphorus

With the exception of small molecular organic P fractions, plants can only utilize P in its soluble form as orthophosphate.[6] Unlike carbon (C) and nitrogen (N), which can be added to the soil system from the atmosphere, the P status of natural systems is essentially controlled by the occurrence of primary apatite minerals.[7,8] Consequently, the P enrichment of soils depends directly on P inputs by mineral fertilizers and manure. Although the fate of P when applied to soil remains something of an enigma, it is widely accepted that more than 80% is immobilized by the soil because of precipitation and sorption processes,[3] whereby the limiting step to furnish crop requirements is the dissolution of initial reaction products during the cropping season.[9]

For a more practical approach, the soil P continuum is thought of as three functional pools: a readily available pool, a reversibly available pool, and a sparingly available P pool,[10] whereby the readily available P pool is related to the so-called "intensity factor," which is a measure of the gradient in the electrochemical potential of the phosphate ions across the adsorbing surfaces of plant roots and, in its simplest form, can be regarded as the P concentration in the soil solution.[11] This pool represents P that is readily accessed by plant roots. The reversibly available P denotes the soil P reserve that can be converted into soluble (readily available) P, by either living organisms or by weathering during the growth season. This pool relates to the so-called "quantity factor" or "richness factor."[12] Whereas the sparingly available P is not available on a short time scale such as one or more crop cycles, a small fraction of this pool may become available during long-term soil transformation.

Mobility of Phosphorus in Soils

As a tetrahedral oxyanion, phosphate has a very low solubility in soils and in general does not move with solvent fluxes, apart from small distance diffusion.[6] In this sense, P is regarded as an "immobile" nutrient. Thus the physical movement of P is restricted to the movement of P associated with soil particles and large-molecular- weight organic matter (particulated P) by either bioturbation, soil tillage activities, or soil erosion during flow events.[13,14] This behavior of soil P was recognized long ago by European geographers and since then has been used in archaeology to trace back ancient settlements.[15] Conway[16] introduced the use of total P distribution patterns for the analysis of small-scale occupation deposits. For example, one building showed evidence of having been demolished and partially reincorporated into the courtyard of a subsequent structure. The floor area of the remnant original structure was protected by a layer of small stones and contained high levels of P. That portion of the floor, which was subsequently converted into a courtyard, unprotected by stones, had less total P, having lost it by exposure and erosion. In an agricultural context, this translates to the following conclusions. First, as far as its total amounts are concerned, P applied with fertilizers may not move from the place it is applied to, and, second, keeping in mind that most soils are naturally poor in P, nearly all the spatial distribution of total P in agricultural soils should be more or less random, reflecting only the spatial sum of distribution faults of past anthropogenic activities (e.g., fertilization, animal husbandry). Spatial relationships may only have developed under the influence of erosion processes.[16]

Spatial Speciation of Phosphorus

During the last 10 years, the study of spatial variation of soil fertility parameters has expanded considerably, but studies that investigated the spatial distribution of soil P generally focused solely on the distribution of so-called plant-available P. The results of these studies showed that plant-available P does not fluctuate randomly, but shows distribution patterns with well-defined lag ranges, where the ranges differ, depending on the sampling procedure and scale of investigation (Table 1). For an introduction into geostatistical terminology one may consult Gassner and Schnug[17] in this issue.

Additionally, it is generally accepted that the distribution of available P does not necessarily resemble the distribution of total P.[20] It appears that the speciation of soil P is dependent on site-specific factors and, as such, is a spatial process.[21–23] In this sense, "spatial speciation" is defined as the chemical reactivity of a nutrient with site- specific environmental factors, and the subsequent formation of geochemical species that display different spatial dependencies (Figure 1).[5]

[a] Cited in Grassner[18]

Insights into the environmental processes that result in the spatial speciation of soil P and, as such, govern the behavior of applied fertilizer are necessary to predict the interconversion and equilibrium distribution of different soil P pools under specific conditions such as geomorphology, field management, and soil types.

The ratio between the readily available P pool (intensity factor) and the reversible available P pool (quantity factor), reflecting the ease of P withdrawal by the plant, is expressed as the "capacity factor."[12] The capacity factor, the P adsorption capacity of the soil, is predominantly dependent on the negative surface charges as well as the specific surface area of soil particles, and is mainly a function of the amount and nature of available adsorption sites in the soil.[24]

For a homogeneous soil, most of the potential adsorption sites will have a similar bonding energy for P. Thus the speciation of P will mainly be a function of the soil pH and the aging of initial reaction products of freshly applied fertilizer P. In this case, the spatial speciation is assumed to be low (Figure 2). For a heterogeneous soil, the nature of the chemical reactions between P and particle surface is more diverse and the chemical speciation will result in a differentiated distribution of P among soil components. In this case, the spatial speciation is assumed to be more pronounced as the distribution of different soil components with a particular bonding energy for P will result in a spatial differentiation of P species.

Apart from the site-specific adsorption capacity of a field, site-specific anthropogenic and environmental factors such as management, biological, and physical factors can result in a spatial speciation of P. Whereas the total P—and, therefore, the sparingly available P pool—is relatively inert to short-term environmental impacts, such as recent fertilizer placement or changes in tillage practices,[5,25] the reversibly available P pool is most affected by management.[26,27] Although the readily available P pool is directly influenced by crop selection and management, McDowell and Sharpley[28] showed that under similar management conditions, the specific adsorption capacity of the soil (capacity factor) controlled the rate of P release into solution.

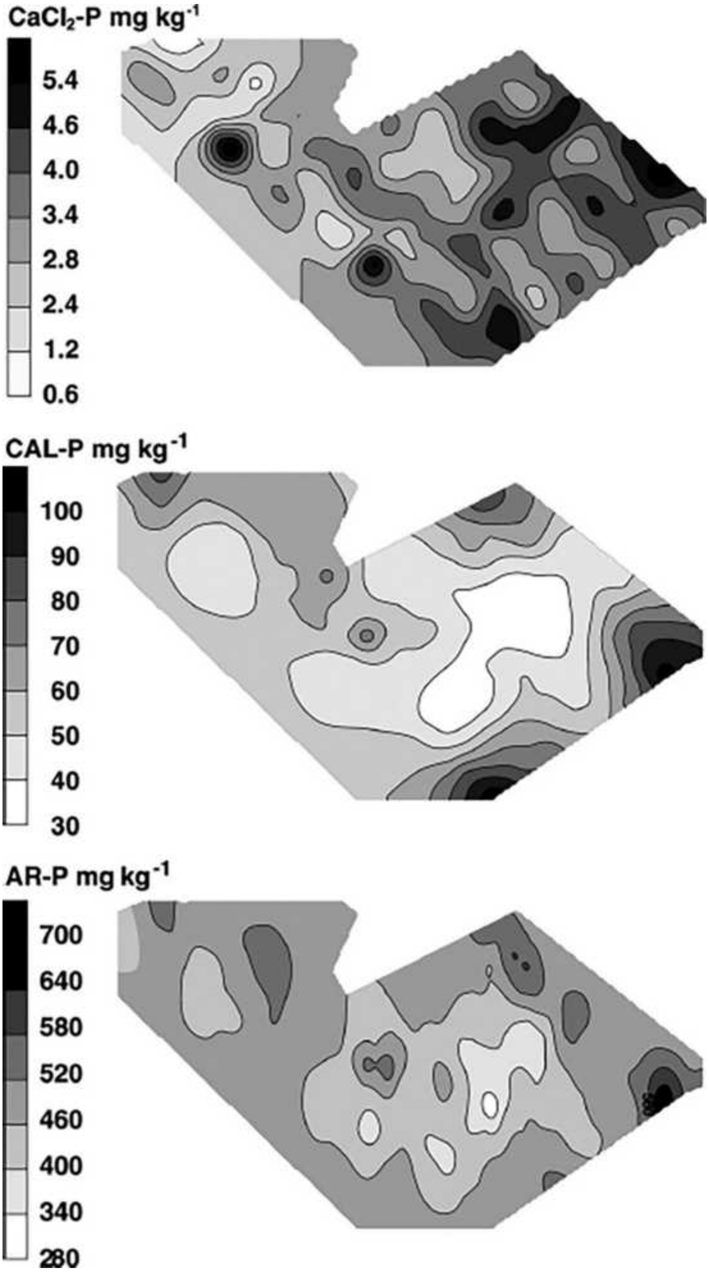

FIGURE 1 Spatial distribution of three different P fractions: $CaCl_2$ extractable P (upper map), Ca-lactate extractable P (middle map), and Aqua Regia extractable P (bottom map), at Kassow (E12°06 , N53°10), Northern Germany.

In a study investigating the spatial speciation of P at three different study sites, which differed in climate, parent material, topography, P fertilizer regime, and land management, the main environmental factors that controlled the spatial distribution of individual P pools were: soil texture for the readily available P; degree of aging of fresh soil P fractions, precipitated from application of soluble fertilizer P, for the reversibly available P; and primary P minerals and geomorphology for the sparingly available P.[18]

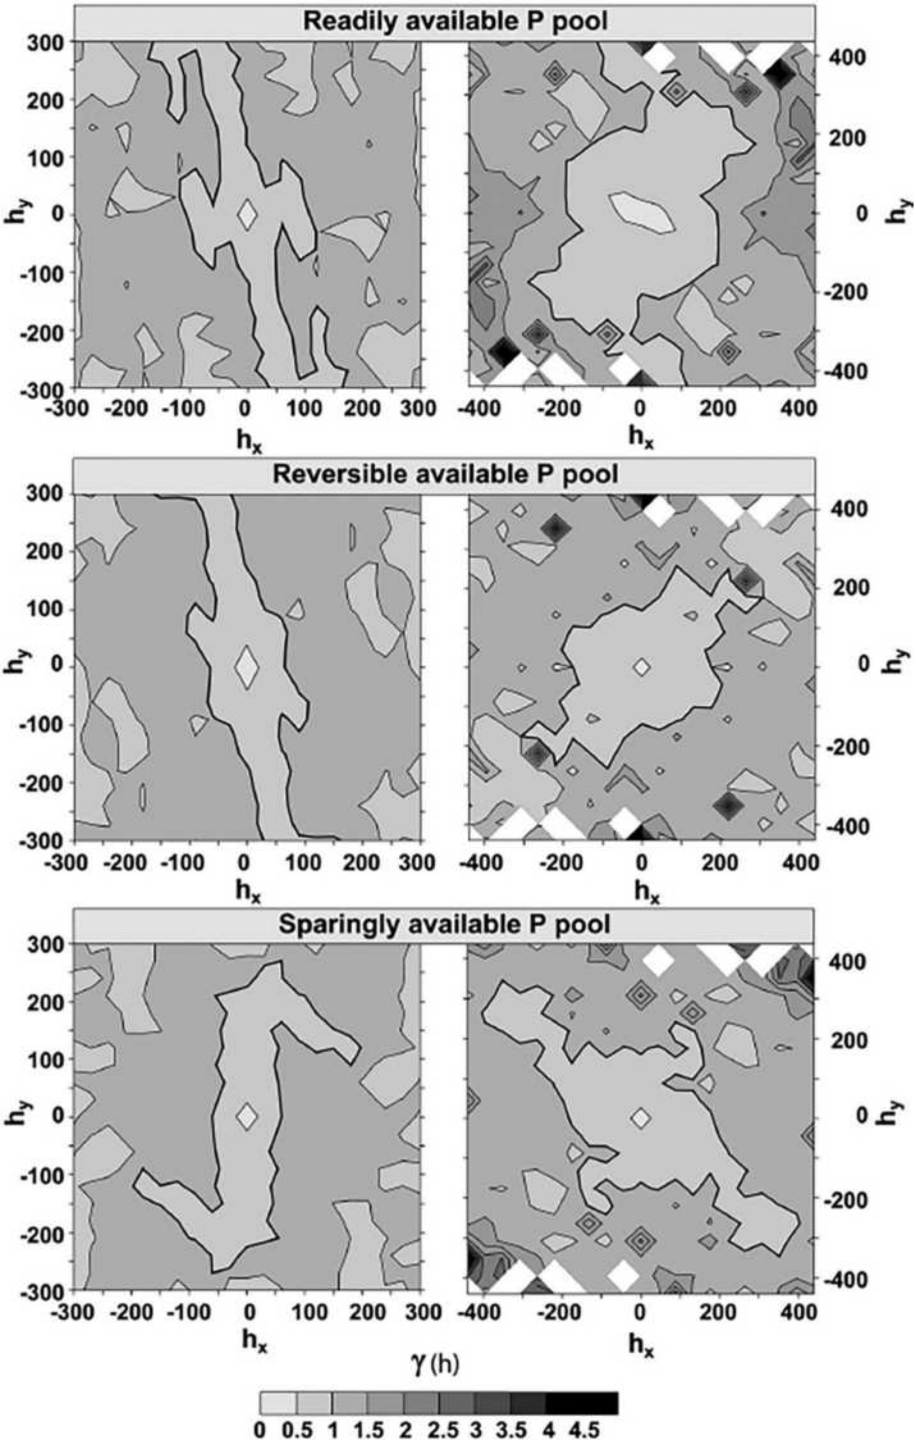

FIGURE 2 Variogram maps showing the spatial distribution of the semivariance of different P pools in a loamy sand (right) and a loamy clay (left). The semivariance is a measure of the average degree of dissimilarity between two data points.

Source: Gassner and Schnug.[17]

Conclusions

Phosphorus is present in soils not as definite and easily separated species, but as a continuum of compounds of different compositions and plant availability, in equilibrium with each other. This heterogeneous equilibrium is constantly disturbed by the uptake of the growing plant and by physical, chemical, or biochemical changes in the soil as well as fertilizer input. Within fields and across short distances, these factors can vary significantly in well- defined patterns, resulting in the spatial speciation of P. Consequently, soil P tests, evaluating the P status of a field, have to be adjusted to the site-specific soil characteristics. Furthermore, the interpretation of these results for subsequent management practices have to consider site-specific factors such as topography and past management history. Finally, the concept of spatial speciation should be applied to other nutrients.

Erosion and Global Change

Taolin Zhang and
Xingxiang Wang

Introduction

Soil erosion is the movement and transport of soil by various agents, which lead to a loss of soil, particularly by water, wind, and mass movement. It is the most serious and widespread form of soil degradation.[1] Global change is becoming a great concern since it was put forward by ICSU in 1986. Global change, as a result of physical, chemical, and biological processes in the Earth's system, particularly of interactions between humans and the environment, refers to changes in global environmental components that are vital to human survival, such as climate, land, water and air in the form of greenhouse effect, diminution of forest, depletion of biodiversity, degradation of land (desertification), and deficiency in water resources. Soil erosion is an important form of global change, and it severely threatens the quality of the soil, land, air and water resources, and hence agricultural development and human life. Soil erosion and global changes are related by bi-directional interactions,[2] and global change may exacerbate soil erosion problems.[3]

Contribution of Soil Erosion to Global Change

Extent of Soil Erosion in China and in the World

China is one of the nations that are most severely affected by soil erosion in the world. The land area affected by accelerated soil erosion is estimated at 367 Mha in 1980s, and 356 Mha in 1990s in China, including 165 Mha by water erosion and 191 Mha by wind erosion (Table 1). The annual soil loss due to soil erosion is estimated at 5000 million tons, including 2400 million tons from watershed of Yangtze River, and 1600 million tons from watershed of Yellow River.[4] The region most severely affected by soil erosion in China is the watershed of Yellow River, with area of 45 Mha and erosion modulus of

6821 $\text{tkm}^{-2}\ \text{yr}^{-1}$, especially in the Loess plateau with more than 10,000 $\text{t/ km}^{-2}\ \text{yr}^{-1}$ erosion modulus[5] (Figure 1). Fortunately, about 24% of erosion area in Loess Plateau of China has been controlled since 1980s.[6] On a global scale, total land area affected by water erosion is 1094 Mha, of which 751 Mha is severely affected, and that by wind erosion is 549 Mha, of which 296 Mha is severely affected[1,7,8] (Table 2). The annual soil loss due to soil accelerated erosion is estimated at 75 billion Mg.[9]

Soil Erosion Degrades Soil Quality, Leads to Loss of Agricultural Lands and Threatens to Global Food Security

Soil is one of the most important natural resources and a major factor in global food production. Soil erosion is widely considered as the most serious form of soil degradation, posing a significant threat to world's food production capacity and global food security.[10]

Over the past 40–50 years, the arable land has been lost due to soil erosion at a rate of 0.6 Mha per year in China and nearly one-third of the world's arable land has been lost by erosion and continues to be lost at a rate of more than 10 Mha per year at a global scale. The average rates of soil loss have been estimated at 17 t ha^{-1} yr^{-1} in the United States and Europe, and 30–40 t ha^{-1} yr^{-1} in Asia, Africa and Southern America, mainly due to inadequate agricultural land use.[9]

Soil erosion not only reduces area of arable land, but also leads to depletion of nutrient, reduction in soil organic carbon and a negative alteration of the soil physical properties in terms of nutrient and water-holding capacity, soil biodiversity, and soils become more vulnerable to diseases.[11] The negative effect of erosion on crop productivity can be assessed using field runoff plots or paired watersheds, and that of future erosion using topsoil removal and addition technique. It has been extensively researched since the turn of the 20th century, although the on-site impacts of soil erosion on productivity are easily minimized through additional external agricultural input and adoption of improved agricultural technology. The actual loss may depend on weather conditions during the growing season, farming systems, soil management, and soil ameliorative input. Partial global production loss estimates suggest that, each year farmers lose about 2.2 million Mg maize, 0.07 million Mg millet, 1.1 million Mg potatoes, 0.1 million Mg soybeans and 1.1 million Mg wheat. Erosion-caused losses of food production are most severe in Asia, Sub-Saharan Africa, and elsewhere in the tropics rather than in other regions.[10] Furthermore, as a driver of land-use change, soil erosion will induce abandonment of arable land due to declining productivity, and reduction in crop yield.[12]

Soil Erosion Deteriorates Global Environment and Influences Global Change

Soil erosion deteriorates the global environment through flood disasters, environmental pollution, desertification, etc. It aggravates flood disasters through raising riverbeds, silting lakes, and shrinking water bodies. Flood disasters increased from once per 20 years 1300 years ago to once per 1.6 years in the 1990s in the Yangtze River Basin due to soil erosion, and soil erosion played an important role in the special phenomena of the lower peak charge but highest water level in the 1998 flood, which caused at least economic losses of USD 30 billion estimated by the Washington-based World watch Institute.[13] Riverbed in lower reaches of Yellow River was raised by 8–10 cm each year due to soil erosion.[4] Soil erosion is also a cause of factor of nonpoint source pollution and siltation associated with erosion in rivers and lakes was identified as the second leading cause of water quality impairment in the U.S.[14] With an enrichment of nutrients, pesticides, salts, trace elements, pathogens, and toxic substances, soil erosion leads to contamination of surface and groundwater bodies and diminishes water quality and aquatic ecosystems stability. Meanwhile, soil erosion can also have an adverse effect on transportation, communication, and human health through increasing dust in the air. In addition, soil erosion can also be a driving force to soil desertification.

Soil erosion influences global climatic change by changing the carbon, nitrogen, and water cycles. The global soil carbon pool is about 2500 gigatons and it is 3.3 times the size of the atmospheric pool and 4.5 times the size of the biotic pool.[15] Soil erosion has a profound impact on both quality and quantity of organic matter in soils, and can be a significant factor in local carbon losses and redistribution. Small changes in the pools of carbon and nitrogen in the world soils could have large effects on atmospheric concentration of CO_2, CH_4, and NO_2. It was estimated that 4.0–6.0 Pg Cyr^{-1} was translocated by water erosion, including 2.8–4.2 Pg C redistributed over the landscape and transferred to depressional sites, 0.4–0.6 Pg C transported into the ocean and coastal ecosystems, and 0.8–1.2 Pg C emitted into the atmosphere at the global scale.[7]

Soil erosion may cause a shortage of freshwater through deteriorating soil physical structure, increasing surface runoff, and changing global water cycling. For example, 20–30 billion m^3 water was used to wash the sediments into sea to fall riverbeds in the lower reaches of Yellow River. More than 19.6 Mha arable land suffer from drought in China each year, and they are mostly located in the area severely eroded.[4]

Moreover, it may also directly lead to changes in microclimate, regional and/or zonal landscapes and ecosystems, and it may even alter the global climatic pattern. In addition, soil erosion may also lead to a change in land uses and land covers through degrading soil quality and land suitability.

Global Change May Accelerate Soil Erosion

The main factors influencing soil erosion are rainfall (amount, frequency, duration, and intensity), wind speed (direction, strength, and frequency of high-intensity events), land use and management, topography, and soils and their properties. Soil erosion forecasting is relevant at a range of time and space scale, from the field scale at which it affects the individual farmer, up to national or global scales where it can make an important contribution to planning decisions. Since the 1950s, significant advances have been made in predicting erosion risks, particularly with the development of modeling technology.[3,16–19] However, the response of soil erosion to global change is very complex temporally and spatially due to uncertainties in general circulation models (GCMs) and the complex relationships between soil erosion processes and climate, land use, and land cover.

Future changes in greenhouse gases concentration and climate will change the hydrologic cycle, and hence affect the soil–plant–water interactions, which in turn affect soil erosion. Climatic erosivity is a major determinant of soil erosion and sediment transport, and is directly affected by change in climate. Much of the increase in precipitation that has been observed worldwide has been in the form of heavy precipitation events, and climate models are predicting a continued increase in intense precipitation events during the 21st century.[20,21] The responses of models of LISEM, MEFIDIS, RUSLE, STREAM, KINESOR, SWAT, and WEEP to rainfall change indicate that soil erosion is likely to increase significantly under future climate change unless offsetting amelioration measures are taken.[19] In some regions, any increase in rainfall, weather amount, intensity, or frequency, which occurs as a result of climate change, may directly exacerbate erosion. On the contrary, in other regions a decrease in rainfall may be expected. In this case, a decline in soil moisture because of the enhanced evaporation will occur. Drought soil conditions and less vegetation can make soils more vulnerable to wind erosion. Moreover, soil erosion tends to be dominated by extreme events, which might occur only rarely. An increase in the possibility of extreme rainfall events in the future, which is suggested by several climatic change models, may accelerate soil erosion. While a large emphasis has been put on climate change and how it may impact soil erosion, other relevant global change factors may have a more profound influence on soil loss. Global change may influence soil erosion through changing temporal and spatial evolution of global soil cover, such as change in soil-forming processes and soil properties. The response of soil to the erosion process is complex, and is also influenced by soil properties such as texture, structural stability, organic matter content, clay mineralogy, and chemical constituents. All these factors are likely to change with change in climate and/or land use. Soil organic matter (SOM), which is a key element of the soil properties, is susceptible to change with changing climate. Higher temperature will usually increase rates of decomposition of organic matter, and decrease its content in soils. A decline in SOM level would cause a decrease in soil aggregate stability, lower infiltration rates, increase runoff, and hence increase the likelihood of erosion. Fortunately, the impacts of SOM on climate change and food security has been concerned and some strategy related to increase SOM has been suggested.[15]

The processes of land use and culture changes are also strongly impacted by the climatic changes. With climatic change and soil degradation, land use and land cover may be changed. A decline in forest cover due to deforestation and wildfire, especially tropical rainforests, and the conversion from forest or grassland to arable land in some areas under global change will accelerate soil erosion.

Sea level change is also an important item in global change. Recent research indicates coastal erosion is triggered by sea level rise,[22] for example, annual beach sediments loss was $1.67*10^4 m^3$ due to sea level rising in the southern Shandong sandy coast in China.[23]

Conclusions

Soil erosion is an important form of global change, and it severely threatens the quality of the soil, land, air and water resources, and hence agricultural development and human life. Soils erosion and global changes are related by bi-directional interaction, and soil erosion is likely to increase significantly under global change unless amelioration measures are taken. It is critical to take action against soil erosion under global change.

Erosion and Precipitation

Bofu Yu

Erosion is a natural process to detach soil and rock fragments for subsequent removal, or transportation, of these materials to areas of lower elevation on the surface of the earth. In the context of agriculture, the primary agents for erosion are water and wind. Climate, precipitation in particular, plays a critical role in determining where and when erosion occurs and the magnitude of erosion rate. Rainfall erosivity, i.e., the ability of rain to cause erosion, is largely a function of rain amount and peak intensity. The larger the rain amount, and/or the more intensive the rain rate, the greater the amount of water erosion would result. Low rainfall, dry soil surface, and poor ground cover are the necessary conditions for wind erosion to prevail.

Rainfall erosivity is a measure of the climatic influence on water erosion. When other variables such as topography and vegetation cover are held constant, the rate of erosion is directly related to the level of rainfall erosivity. A number of rainfall erosivity indices have been proposed so that the amount of soil eroded is linearly proportional to the rainfall erosivity index *ceteris paribus*. The most commonly used rainfall erosivity index is EI_{30}, where E is the total kinetic energy per unit area for a storm (MJ ha^{1}) and I_{30} is its peak 30 min intensity (mm hr^{-1}). Wischmeier and Smith[1] found that the combination of kinetic energy and peak intensity was most closely related to the observed amount of soil loss. The R-factor in the Universal Soil Loss Equation (USLE) and Revised USLE (RUSLE) is the mean annual sum of these EI_{30} values.[2,3] Other measures of rainfall erosivity worthy of note include the modified Fournier Index,[4,5] KE>1 index,[6] and the so-called Universal Index of Onchev.[7] Numerous other attempts have been made to search for a rainfall-based estimator of the observed amount of erosion that is superior to EI_{30}. Most of these studies have relied on restricted databases that have limited their applicability. Most of these other indices or estimators are highly correlated with each other and with EI_{30}.

Although the definition of EI_{30} is straightforward, its calculation requires long-term rainfall data at short time intervals (<30 min), which are not widely available for most parts of the world. To develop a better understanding of what is exactly involved in EI_{30}, it is helpful to examine how this index is calculated. I_{30} is the maximum intensity for any 30 min interval during a rainstorm, while the storm energy depends on how rainfall intensity varies during the event:

$$E = \int_{T}^{0} e(I)\, I\, dt \qquad (1)$$

where I is rainfall intensity, T is rain duration, and $e(I)$ is a function of rain intensity called the unit energy equation. The consensus is that the unit energy as a function of rain intensity assumes the following functional form:[3,8]

$$e(I) = e_{\max}\left(1 - \alpha e^{-I/I_0}\right) \qquad (2)$$

For RUSLE, the following was recommended: $e_{\max} = 0.29$ MJ ha^{-1} mm^{-1}; $\alpha = 0.72$; $I_o = 20$ mm hr^{-1}.[3] It can be shown from Equations 1 and 2 that the storm energy is bounded:

$$0.28e_{\max}P < E < e_{\max}P \tag{3}$$

where P is the total rain (mm). The theoretical upper and lower bounds are related to zero and infinite intensity, respectively. Analyzing 6 min rain data for a number of sites around Australia shows that the ratio of storm energy to $e_{\max}P$ ranges mostly from 0.5 to 0.8, and the ratio is slightly higher in tropical/ subtropical regions than in temperate regions (Table 1). It is also clear from Table 1 that the storm energy is always highly correlated with rain amount. Empirical study using hourly rainfall intensity data likewise indicated a strong relationship between daily rainfall and storm energy for a number of sites in the U.K.[9] Given that storm energy is primarily a function of rain total, it follows that rainfall erosivity, as defined in relation to USLE/ RUSLE, depends mainly on rain total and peak intensity and, to a much lesser extent, on rain duration.

For areas where long-term high-resolution rain data are unavailable, a simpler method to estimate rainfall erosivity in the context of USLE/RUSLE is to use the fairly consistent relationship between the mean annual rainfall and the R-factor:[10,11]

$$R - \text{factor} = 0.05(\text{MAR})^{1.6} \quad R^2 = 0.82 \tag{4}$$

where MAR is the mean annual rainfall (mm). The regression equation (Equation 4) is based on a combined database for 161 sites (132 sites in the United States and 29 sites in Australia[10,11]). MAR ranges from 67 to 2060 mm for these sites. The non-linear relationship suggests that a 1% change to MAR would lead to a 1.6% change to rainfall erosivity. This highly sensitive nature of rainfall erosivity to rainfall would have important implications for the impacts of climate change on soil erosion. Reasonably good relationships between the Modified Fournier Index and the R-factor have also been noted.[5,10] The difference between the two estimates, however, is small, and little is gained by using the Modified Fournier Index.[11] If we need to estimate the seasonal distribution of rainfall erosivity, daily rain data can be used, especially in areas with a marked wet season in winter. Monthly and annual rain totals are no longer adequate because summer rain with high peak intensity can lead to higher rainfall erosivity in the relatively drier months. Rainfall erosivity can be related to rain amount using a power function in the form:

$$EI_{30} = aP^{\beta} \tag{5}$$

The calibrated values of β for a number of sites around the world are summarized in Table 2. The β value mostly varies from 1.5 to 1.8 with higher values found largely at higher latitudes. Such relationships for daily erosivity are sufficient for determining the seasonal variation of rainfall erosivity for USLE/RUSLE. Simple sinusoidal functions to allow seasonal variation in the parameter a can be used to achieve unbiased estimates of monthly EI_{30} values.[16,21,23]

TABLE 1 Linear Relationship between Rain Amount (P) and Storm Energy (E) as in $E = \alpha e_{max}P$ for Selected Sites in Australia

Location	Climate	α	n	R2
Perth	Temperate,winter rain	0.521	2354	0.96
Melbourne	Temperate, uniform rain	0.530	1800	0.93
Brisbane	Subtropical summer rain	0.626	4088	0.96
Darwin	Tropical, summer	0.742	3701	0.98

Note: n = number of storms analyzed; R^2 = coefficient of determination, representing the fraction of the total variation in the observed E values that can be explained by rain amount.

United States	31°N–43°N	11	1.81 ± 0.16	[14]
Italy	36°N–42°N	35	1.53 ± 0.19	[15]
Equatorial (Malaysia, Indonesia, Brazil)	4°N–10°S	4	1.64 ± 0.18	[16–18]
Australia (tropical region)	10°S–25°S	41	1.49 ± 0.28	[19]
South Africa	31°S–33°S	4	1.47 ± 0.17	[20]
Australia (temperate region)	28°S–35°S	33	1.49 ± 0.25	[21,22]

Climate change has become a topic of considerable interest in recent years. In the context of precipitation and erosion, a number of attempts have been made to identify secular variation in rainfall erosivity in the recent past and the likely change to rainfall erosivity using output from global climate models. Long-term (of the order of 100 years) rainfall intensity data at short time intervals (6–10 min) can be used to detect decadal variations in rainfall erosivity.[24,25] Investigation of this nature is usually spatially restricted as data of this kind are available for a limited number of sites around the world. Annual or monthly rainfall totals have also been used to infer the likely change to rainfall erosivity at the regional or national scale.[26–28] Recorded daily rainfall totals can also be used to increase the accuracy of the estimated rainfall erosivity.[29,30] A more promising approach is to combine downscaled output from global climate models with stochastic weather generators to calculate rainfall erosivity for different climate change scenarios.[31]

Rain total and peak rainfall intensity are also key precipitation variables for a physical description of water erosion processes.[32–34] Mass balance dictates that in an area of net erosion, the amount of soil loss, SL, is given by:

$$SL = Qc \tag{6}$$

where Q is runoff amount and c is the sediment concentration. In this context, the effects of rain on erosion manifest themselves in terms of the amount of surface runoff generated and the level of sediment concentration in the runoff water. With non-climatic variables held constant, the amount of runoff is largely determined by rainfall amount and, to a lesser extent, by the rainfall intensity. Sediment concentration is related to both rainfall intensity and runoff rate. Rainfall detachment is linearly related to rainfall intensity. Shear stress or stream power commonly used to quantify flow detachment is intrinsically related to the runoff rate. Thus, in this physical framework for soil erosion, rainfall intensity plays a direct role in rain detachment. Rain amount and intensity also play an indirect role in flow detachment and transport of eroded sediments by determining the magnitude of runoff amount and runoff rate.

Precipitation is important to water erosion because soil particles and aggregates are detached by raindrops and surface runoff. A lack of precipitation, on the other hand, leads to low moisture levels near the soil surface and thus renders the soil particularly susceptible to wind erosion. Wind speed, precipitation, and potential evaporation were used to develop indices of wind erosivity.[35–37] For given wind speed and potential evaporation, wind erosivity is inversely related to precipitation. Figure 1 shows schematic relationships between precipitation and vegetation cover, rainfall and wind erosivity, and predominant erosion processes. In high rainfall areas, the rate of actual erosion is not necessarily high in spite of high rainfall erosivity unless the usually good vegetation cover is removed and the soil surface is exposed. In arid and semiarid areas with low rainfall, the combined effects of poor ground cover and dry soil surface would render the land particularly vulnerable to wind erosion.

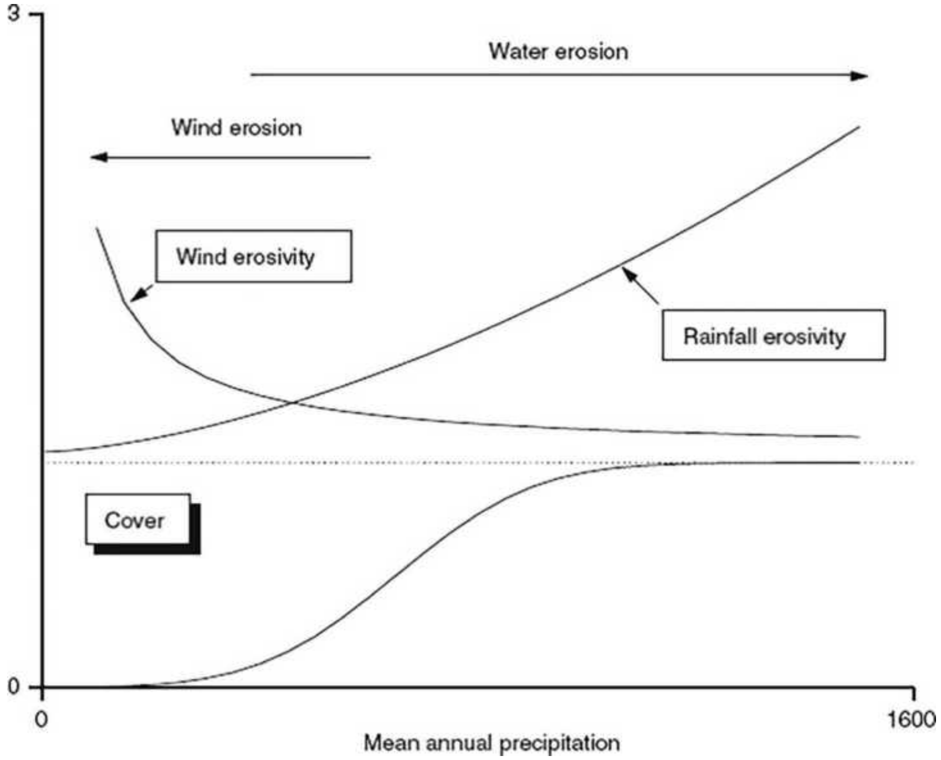

FIGURE 1 Schematic relationships between precipitation, vegetation cover, rainfall, and wind erosivity.

Precipitation is a key climatic variable that determines the type and magnitude of erosion. In the context of water erosion, rain amount and peak intensity are the most important variables in determining the erosion rate. For areas without high-resolution rainfall intensity data, the R-factor and its seasonal variation for USLE/RUSLE can be estimated from mean annual rainfall and daily rain amount. Absence of rain and concomitant dry soil surface and poor ground cover are the necessary conditions for wind to become the dominant erosion agent.

Erosion: History

Andrew S. Goudie

Introduction

Erosion is a process that has operated since the earth was created. Erosion of soil by water has likewise been a process that has been an entirely natural phenomenon ever since soils first appeared. However, during the last few millions of years that humans have inhabited the earth, their activities have caused spasms of accelerated soil erosion associated with land cover and land use changes. In classical times, it was noted that slopes in areas such as Greece, Turkey, and the Levant had been destabilized by deforestation and overgrazing. Undoubtedly, such actions as the deliberate setting of fire, adoption of pastoralism and agriculture, deforestation, urbanization, and use of machinery to move and disturb the soil have all contributed to accelerating rates. Appreciation of the nature, causes, and consequences of soil erosion has a long history, and during the 20th century, there were some notable studies of the phenomenon[1–3] stimulated by such events as the Dust Bowl in the United States and the menace of *donga* (gully) formation in Africa.[4]

However, it has never been easy to separate the role of climatic fluctuations in causing soil erosion from the role of human activities, and this has spawned long-running debates about the origin of phases of slope erosion, valley incision, and valley sedimentology in areas such as the Mediterranean basin[5,6] and the bottomlands of the western United States (see, for example, the discussion of *arroyos*[7]). Difficulties of determining how rates have been changed by human activities have also been bedeviled by an absence of direct long-term monitoring data. However, erosion leads to sedimentation, and so the study of rates of sediment accumulation in lakes, swamps, estuaries, reservoirs, and river floodplains provides a means of obtaining long-term data from which erosion rates can be inferred.

Deforestation

Deforestation[8] has been a crucial cause of accelerated soil erosion in many areas (Figure 1). Forests protect the underlying soil from the direct effects of rainfall, generating an environment in which erosion rates tend to be low. The canopy shortens the fall of raindrops, decreases their velocity, and thus reduces their kinetic energy. Most canopies reduce the erosion effects of rainfall. The presence of humus in forest soils[9] absorbs the impact of raindrops and gives them extremely high permeability. Thus forest soils have high infiltration capacities. Forest soils also transmit large quantities of water through their fabrics because they have many macropores produced by roots and their rich soil fauna. They are also

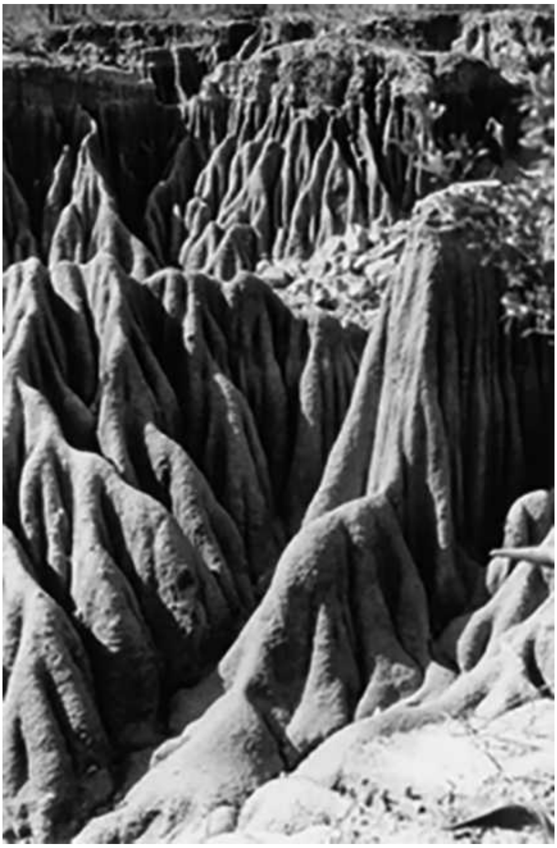

FIGURE 1 An erosional badland (donga) in Swaziland, Southern Africa. It may date back to deforestation in the Iron Age.

well aggregated, making them resistant to both wetting and water drop impact. This superior aggregation is a result of the presence of considerable organic material, which is an important cementing agent in the formation of large water-stable aggregates. Furthermore, earthworms also help to produce large aggregates.

It is therefore to be expected that with forest removal, rates of soil loss will rise and mass movements will increase in magnitude and frequency. The rates of erosion will be high if the ground is left bare; under crops, the increase will be less marked. Furthermore, the method of plowing, the time of planting, the nature of the crop, and the size of the fields will influence the severity of erosion.

Sedimentation Rates

A good example of using long-term sedimentation rates to infer long-term erosion rates is provided by a study[10] of the Kuk Swamp in Papua New Guinea. This identified low rates of erosion until 9000 BP, when, with the onset of the first phase of forest clearance, they increased from 0.15 to about 1.2 cm/1000 years. Rates remained relatively stable until the last few decades when, following European contact, the extension of anthropogenic grasslands, subsistence gardens, and coffee plantations produced a rate that is very markedly higher: 34 cm/1000 years.

A further long-term study of the response rates of erosion to land cover changes is provided by a study undertaken on the North Island of New Zealand.[11] During the last 2000 years of human settlement, catchments underwent a change from indigenous forest fern/scrub following Polynesian settlement (c. 560 years BP) and then a change to pasture following European settlement (AD 1878). Sedimentation rates under European pastoral land use were between 5 and 6 times the rates that occurred under fern/ scrub and 8–17 times the rates under indigenous forest. A broadly comparable study[12] looked at rates of infilling of an estuary fed by a steepland catchment in another part of New Zealand.

In pre-Polynesian times, rates of sedimentation were 0.1 mm year^{-1}, during Polynesian times, the rates climbed to 0.3 mm year^{-1}, while since European land clearance in the 1880s, the rates have shot up to 11 mm year^{-1}.

Major changes in rates of erosion have also taken place in Australia as a result of European settlement over the last two centuries.[13] Particularly important was the introduction of grazing stock.

There is increasing evidence to suggest that silty valley fills in Germany, France, and Britain, many of them dating back to the Bronze Age and the Iron Age, are the result of accelerated slope erosion produced by the activities of early farmers.[14] Indeed, in recent years, various studies have been undertaken with a view to assessing the importance of changes in sedimentation rate caused by humans at different times in the Holocene in Britain. Among the formative events that have been identified are initial land clearance by Mesolithic and Neolithic people; agricultural intensification and sedentarization in the late Bronze Age; the widespread adoption of the iron plow in the early Iron Age; settlement by the Vikings; and the introduction of sheep farming.

A core from Llangorse Lake (Brecon Beacons, Wales)[15] provides long-term data on changing rates of sedimentation. The 13-fold increase in rates after 5000 BP seems to have occurred rapidly and can be attributed to initial forest clearance. The second dramatic increase of more than 4-fold took place in the last 150 years and is a result of agricultural intensification.

The work on the lakes of the Peten region of northern Guatemala (Central America), an area of tropical lowland dry forest, is also instructive with respect to early agricultural colonization.[16] Combining archaeology and lake sediment stratigraphy, the diverse environmental consequences of the growth of Mayan civilization were reconstructed.

This showed a dramatic growth after 3000 years BP, but collapsed in the 9th century A.D. The hypotheses put forward to explain this collapse include warfare, disease, earthquakes, and soil degradation. The population has remained relatively low ever since, and after the first European contact (A.D. 1525), the region was virtually depopulated. The period of Mayan success saw a marked reduction in vegetation cover, an increase in lake sedimentation rates and in catchment soil erosion, an increased supply of inorganic silts and clays to the lakes, a pulse of phosphorus derived from human wastes, and a decrease in lacustrine productivity caused by high levels of turbidity.

Serious sedimentation of bays and estuaries has been caused by human activity on the eastern coast of the United States. Gottschalk[17] calculated that at the head of the Chesapeake Bay, 65 million m^3 of sediment was deposited between 1846 and 1938. The average depth of water over an area of 83 km^2 was reduced by 0.76 m. New land comprising 318 ha was added to the state of Maryland and, as Gottschalk remarked, "the Susquehanna River is repeating the history of the Tigris and Euphrates." Much of the material entrained by erosion on upper slopes as a result of agriculture in Maryland, however, was not translocated as far as the coast. Only about one-third of the eroded material left the river valley.[18] The remainder accumulated on floodplains as alluvium and colluvium at rates of up to 1.6 cm/year. Similarly, an intensive augering survey of floodplain soils in Wisconsin established that, since the development of agriculture, floodplain aggradation had proceeded at a rate of approximately 0.85 cm/year.[19] Channel and floodplain aggradation caused the flooding of low alluvial terraces to be more frequent, extensive, and deeper. The rate of sedimentation has since declined[20] because of less intensive land use and the institution of effective erosion control measures on farmland.[21]

Various attempts have also been made to establish rates of accelerated erosion on the plainlands of Russia.[22] It has been calculated that during the period 1696–1796, a total of 19.5×10^9 m^3 of soil was mobilized by sheet and rill erosion; for 1796–1887, it was $36.7\times10^9 m^3$, and for 1887–1980, it was $42.5\times10^9 m^3$. This increasing trend was a result of an increase in the area under cultivation and the assimilation of land more prone to erosion.

Conclusion

Accelerating rates of soil erosion are neither inevitable nor universal. In some parts of the world (e.g., New England or steep slopes in some of the Mediterranean countries[23]), the agricultural frontier has retreated and pressures on the soil have been reduced. Elsewhere, a whole range of soil conservation techniques has been introduced with some success. Nevertheless, accelerated soil erosion has a number of adverse consequences: loss of soil resource, sedimentation behind dams and in lakes, and a loss of water quality because of turbidity and other effects.

Erosion by Wind: Global Hot Spots

Andrew Warren

Natural Erosion

The Sahara, the Central Asian Deserts, and the Chinese deserts are the sites of very high rates of "natural" erosion. Much more sediment leaves the Sahara in wind than in water. Contemporary outputs from the Sahara are of the order of 10^9 tons per year.[1] Dry Australia, the southwestern United States, and southern South America are less important, but still significant natural hot spots. The dust reaches far into the oceans and beyond, as from northern African to the United States, and from Australia to New Zealand (Figure 1). Marine and land sediments (loess and stabilized sand dunes) show that the hot spots were hotter in the Pleistocene, and that they got hotter as it progressed. In the central Sahara, Egypt, western

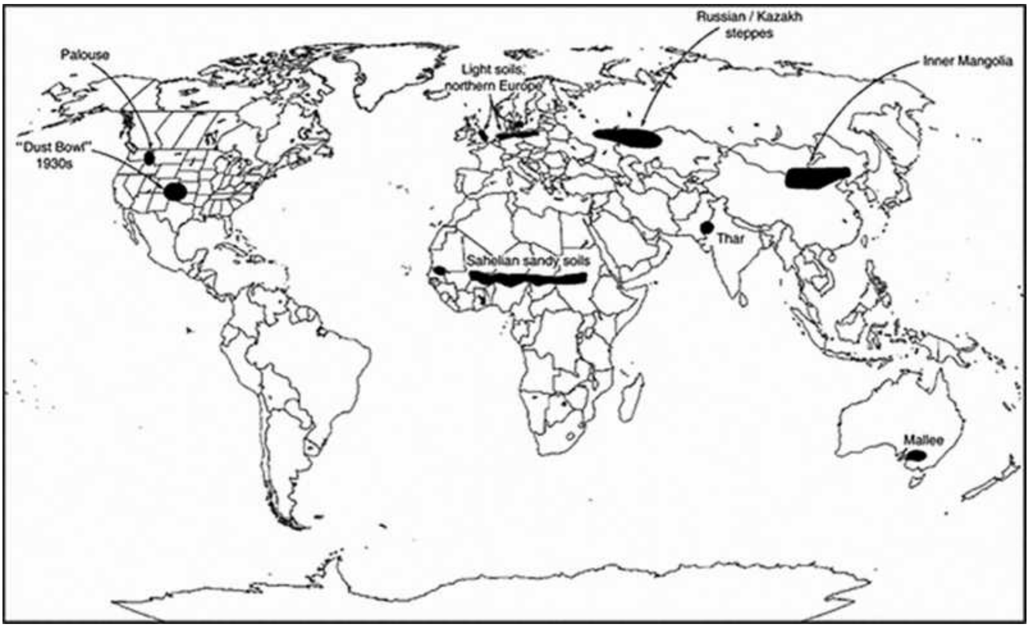

FIGURE 1 Global hot spots for wind erosion.

Argentina, eastern Iran, and parts of western China, great grooves were cut at those times by wind erosion, some in hard rock. There were also more hot spots, as in parts of northern Europe and central North America. Ice-core data from Greenland, the Tibetan Plateau, and the Antarctic corroborate the picture. The contemporary global source areas are all very dry. Explanation of the temporal change is more disputed.[2]

Seen at a finer scale, most "natural" erosion in these deserts occurs in soft sediments, particularly those in ancient, dry lake basins. The northern Chad Depression in the central Sahara and the Lake Eyre basin in central Australia are major natural hot spots.[3] In the late Pleistocene, the bare outwash plains round glaciers were the sources of loess, and of sand that formed dunes (now mostly stabilized) in northern Europe, Asia and northern Canada. People have little influence on rates of wind erosion in deserts. There are exceptions. Off-road vehicles create a minor hot spot in the Mojave of southern California; and wars and training for wars has created others in North Africa during the 1940s, and during the Gulf War.[2]

Induced Erosion

Identifying global hot spots of induced wind erosion is more problematic. Measurements of emissions are very few indeed, measurements of rates of erosion are even fewer, and measurements of economic impact are the rarest of all. This leaves some results from modeling, historical accounts built on disparate evidence, and informed guesses. Modeling and measurement suggest short-term rates of the order of 30–60 t ha^{-1} yr^{-1} on dry high plains sites, depending on winds, rainfall, and land use. Caesium-based measurements in the Sahel of West Africa, on sandy soils under fallow-cultivation cycling, and with mean annual rainfalls of about 550 mm give rates of up to 40 t ha^{-1} yr^{-1} over a 30 years period.[4]

Some historical accounts are well documented and compelling. The Dust Bowl of the American Great Plains in the 1930s was an undisputed hot spot.[5] Dust storms were more frequent and violent and many farmers went out of business, though more from drought than erosion. There were renewed hot spots here in the 1950s, 1960s, and 1970s, on the evidence of agricultural surveys and dust emissions. Probably more serious, though less well documented, at least in English, were the hot spots in the Soviet Union, especially northern Kazakhstan and neighboring parts of Russia, at about the same time[6] (although the earliest recorded paper in Russian on wind erosion control was written in 1768). More surprising, even to some experts, are histories of wind erosion in Western Europe. An even earlier paper on wind erosion, titled "A curious and exact relation of a sand cloud which hath lately overwhelmed a great tract of land in the county of Suffolk" appeared in the *Philosophical Transactions of the Royal Society of London* in 1669. In Sweden, no less a person than the great naturalist Linnaeus recorded destitution because of wind erosion in Skania in the 18th century. There is similar evidence in northern Germany, the Netherlands, Denmark, Poland and Hungary. Archaeology now shows that there were hot spots as far back as the Neolithic when ancient farms were buried in sand in southeastern England and the Netherlands. In all these areas, it was and is sandy soils, inherited from glacial outwash, that are the most susceptible. Much more recently, the period of desiccation in the Sahel of West Africa is said to have been a hot spot for wind erosion. Some evidence lies in dust-storm data,[1] and, as in the Great Plains of the 1930s, there was undoubtedly great hardship. However, here too, the exact role of wind erosion is debatable. Much of the dust may have come from quite small perimeters round dust-measuring stations, and the hardship was to do more with drought than erosion.

Informed guesses are a more dubious source. The literature is no great help, even with the wind erosion bibliography (listing works till 1995) and its 2700 odd entries.[7] It is undoubtedly biased toward work in English, toward areas where funds have been more available and to places where there has been a strong scientific tradition. For example, research in the USA, and the Great Plains in particular, where massive funds for research were released and maintained after the 1930s, overwhelms the bibliography, yet the aforementioned historical evidence suggests that the problem may have been more serious in the USSR. Indeed, Petrov's bibliography of relevant work in Russian (1768–1950) has 852 entries. Germany, with its long scientific tradition, apparently dominates research in Europe, yet it is known that the problem is as serious in neighboring counties. Southeastern Australia is also, by this evidence, a hot-spot,[8] yet in terms of damage to cropland, the Sahel of West Africa is probably more of one (the Sahel is only belatedly receiving scientific attention). Using the literature, Crosson[9] estimated that the Sahel was a major wind erosion hot spot, yet there are few data on which to base this conclusion.[4]

Only one systematic attempt at informed guessing on a worldwide scale has been made. This is GLASOD (The global assessment of soil degradation). It is most accessible in the *World Atlas of Desertification,* which is now in its second edition.[10] The assessment was for "polygons" of the order of size of southeast England, the province of Skania in Sweden, or a quarter of an average US State. Experts who knew each polygon were asked a set of carefully constructed questions about the extent and severity of soil degradation, including wind erosion. The result is the best guess we have of the severity of wind erosion globally. But it has serious flaws: in Africa and many other parts of the world, there were no measurements at the time of the questionnaire against which to compare the guesses; the distinction between induced at natural erosion is unclear; some experts have interpreted the questions differently from others; the identifications are generally of potential rather than actual erosion; the polygons are huge.

The expert opinion used in GLASOD is based on our present scientific knowledge about wind erosion. If, as a simple framework, we take the factors in the famous Wind Erosion Equation of Woodruff and Siddoway, we can follow it in predicting the hot spots.[11] Three factors are almost equally important. First is the Climatic (C) factor. Most induced wind erosion occurs in areas with semi-arid climates, as corroborated by maps of the C factor in the Sahel of West Africa, and in the United States. This is also true in the USSR, Australia, and northwestern Europe. However, wind erosion can and does take place in much wetter climates. In Wales and in the Pennine Hills of England peat is blown away after fires and in long dry spells. Erosion occurs in parts of England where the mean annual rainfall is of the order of 1500 mm. At roughly the same mean annual rainfall, there is also significant wind erosion on the coastal plain of South Carolina. Wind erosion is reported in the Austrian Tyrol, where rainfalls approach 2000 mm. Even in Iceland, where evapotranspiration is very low, there is some serious wind erosion. The C factor is also important in the temporal dimension: when there are dry years, wind erosion hot spots appear, as in the Dust Bowl and the Sahel.

The K, or soil, factor in the Wind Erosion Equation is the second important control, for wind erosion rarely affects fine-texture soils, although a few may be "pelletized" into aggregates of sand size, which may then be moved by the wind. Areas with agriculture on sandy soils are, worldwide, the common locations of hot spots, because they lack binding agents for aggregation. Peats, which also may be loose, are also eroded in Western Europe and Florida when they are drained, cleared, and cultivated. Light loess soils, as in the Palouse of Washington State, parts of the Great Plains and the Russian steppes, are other hot spots.

The last crucial factor is vegetation cover, and this is the most susceptible to management. The plowing, or harrowing of a field can raise considerable quantities of dust,[12] but it is clearance of vegetation in dry and windy seasons that is the more generally damaging. The reasons why farmers clear susceptible fields are exceedingly complex. Ignorance may sometimes produce a minute hot spot, but it is an inexperienced farmer indeed who does not realize that erosion follows clearance. In the Sahelian hot spot, for example, the laying of millet (*Pennisetum glaucum*) stalks to counter erosion is standard practice. Economic forces produce the main hot spots for induced erosion. In Europe, at least, the short-term economic impact of wind erosion does not provide a strong enough incentive to persuade farmers to manage it. Worster believed that the huge hot spot in the US Dust Bowl was mainly due to farmers being driven to cultivate by other economic forces, in this case the need to pay off loans from banks and from machinery salesmen. The massive Soviet hot spots are said to have been the result of yet another kind of economic force: centralized and ill-informed attempts to reach US standards of economic output. In our study of a village in Niger, economics takes yet another guise: wind erosion is the outcome of a gamble by those farmers who can afford to lose a crop, because they have other economic options.[13]

Erosion by Wind: Principles

Larry D. Stetler

Erosion Processes

Erosion of fine-grained sediment and soil particles by wind is a natural geologic process occurring worldwide on a nearly continuous basis. Throughout the geological record evidence of wind processes eroding, transporting, and depositing sediment exists primarily as vast accumulations of eolian (wind-blown) sand—both modern sand dune fields and ancient eolian sandstone formations—and loess (wind-blown silt). Currently, about 30% of the total land surface of the planet consists of semi-arid and arid lands which give rise to most of the transported sediment and dust. Modern agriculture and industrial activities are also a significant contributor to transported sediment and dust due to induced or mechanical destabilization of the land surface.

Conceptually, mobilization of loose sediment and soil particles occurs during wind storms or wind "events," where the mean wind speed exceeds a critical threshold value based on some erodible fraction of the sediment. Individual wind events may be of short (less than one to a few hours) or long (multiple hours to days) duration. In terms of distance and total mass moved, a typical erosion event will transport the greatest mass a short distance and a significantly lesser mass a greater distance. Perception of moving sediment, however, may make this statement appear to be contradictory since there is, generally, an abundance of the smaller and lighter particles which are visually acute when airborne. Exceptional, or non-typical, wind events are able to transport fine particles across entire continents and oceans to distant lands where visual impacts to air quality may be readily observed.

Knowledge of particle entrainment and transport studies was greatly advanced through the work of Bagnold who used field observations in the deserts of Egypt and later wind tunnel studies to detail the mechanics of the erosional and transportation process. This work resulted in his well- known and widely used treatise *The Physics of Blown Sand and Desert Dunes.*[1] He observed that once a particle begins to move it will be transported by one of three modes: creep, saltation, or suspension. The primary difference in these three transport modes is a relatively simple relation between the particle size and the wind force which, unfortunately, becomes a complex mechanical problem that is today still not fully understood.

Wind Dynamics

Wind is by nature a random process and as such, the internal structure of a natural wind contains random variations known as turbulence (except in possibly very stable conditions). Turbulence develops in natural flows as inertial forces, which provide forward momentum (motion), react to viscous forces, which impede motion due to fluid properties. This results in a flow that is strongly sheared.

The unit of measure for wind speed is the mean wind velocity, $\bar{U}$, defined as an average value for a continuous time series of instantaneous velocities (Figure 1):

$$\overline{U} = \frac{\sum u_1 + u_2 + \ldots + u_i}{T} \tag{1}$$

where

$u_1 + u_2 + \ldots + u_i$ = components of instantaneous velocity
T = time interval over which velocity values are summed

As shown in Figure 1, at every instant a fluctuating component of velocity, u'_i exists defined as the difference between the instantaneous and the mean velocity values:

$$u_i^{'} = u_i - \overline{U} \tag{2}$$

It is these velocity fluctuations, whether positive or negative in regard to the mean velocity, that give rise to flow instability and thus, turbulence. As such, turbulence is not a property of the fluid but of the flow of the fluid. Turbulent flows are, therefore, unique in their ability to mix momentum and kinetic energy and to erode and transport particles.

Particle Entrainment

Bagnold described the instant of initial particle motion by a threshold fluid velocity which represents the wind speed at which the most susceptible particle becomes entrained. As a flow passes over a stationary particle, turbulent kinetic energy is imparted to the grain which builds a reservoir of stored potential energy.[2] Further increases in this energy reservoir cause the grain to oscillate and at the critical point

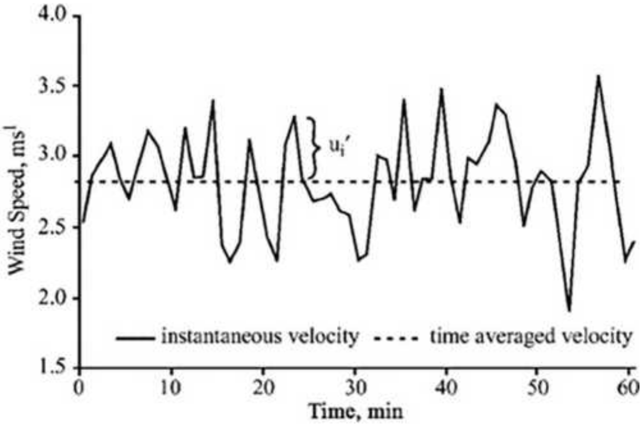

FIGURE 1 Time series of one min wind speeds illustrating principles of determining mean wind speed, instantaneous and fluctuating values. Unpublished data from author.

where potential energy exceeds the energy of adherence, the grain lifts, or more accurately is ejected in a near vertical trajectory away from the surface[2,3] initiating saltation. For a single grain of diameter d, Bagnold showed that the threshold fluid velocity, v_t, required to initiate saltation motion is related to particle diameter by:

$$v_t = 5.75A\sqrt{\frac{\rho_p - \rho_f}{\rho_p} - gd\,\log}\,\frac{z}{k} \tag{3}$$

where

A = Empirical constant = 0.1 for fully turbulent flows
ρ_p = Particle density
ρ_f = fluid density
g = gravity force
z = height for which threshold velocity is being calculated
k = Surface roughness height equal to about 1/30 the surface grain diameter.

For the case of a naturally irregular surface, such as a field or a sand dune, fluid threshold is not defined by a single wind speed or particle size but by a continuum of wind speeds over a length of time where grains of various diameter become entrained almost simultaneously.[4]

Once these grains are ejected into the overriding flow they attain a high-energy ballistic trajectory that depends upon particle size and wind velocity,[1,5,6] (Figure 2). Heavier and larger particles will travel relatively close to the surface (A) contrasted to lighter and smaller particles that initially are ejected higher into the wind profile (B). At some distant point downstream these grains (impactors) will impact on the sediment bed and either rebound upward again (C), eject new impactors (D), or lodge in the loose sediment. In either case, it is probable that upon impact sufficient kinetic energy will be transferred to one or several additional grains that are "splashed," or dislodged a short distance (E) known as reptation,[5,6] a low-energy process that includes a small number of grains traveling upstream. Reptation includes what Bagnold referred to as creep— grains that are too large to be entrained aerodynamically and move by rolling or sliding along the surface. Impact force is also a primary method leading to disaggregation of larger particle agglomerates by breaking particle bonds or the particles themselves into smaller pieces, enabling aerodynamic transport.

Saltation, which is defined as movement in a series of short hops, includes particles in the high-energy population (A, B, C, and D). These particles are initially moved by wind speeds exceeding the fluid threshold and subsequently through surface impacts that eject new particles at a point known as the impact threshold. Bagnold suggested that the impact threshold involves the same mechanics included in Equation 3 except $A = 0.08$. In other words, after saltation is initiated, additional grains are placed in motion at the threshold impact velocity that is about 80% of the threshold fluid velocity. This infers that once motion has begun, further motion can be sustained at wind speeds less than those required for initial grain motion.

The third transport mode, suspension, occurs in grains that are small enough to respond directly to turbulent fluctuations and thus, are lofted above the surface saltation layer.

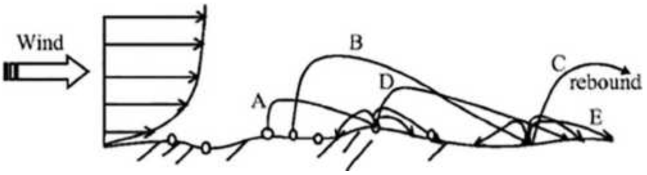

FIGURE 2 Particle transport paths in response to the wind profile (at left). A, B, C, and D are high-energy impacting grains moving in saltation. E are low-energy reptating particles including those moving by creep.

Self-Balancing Concept

Energy required to transport particles comes from extraction of turbulent momentum contained in the flow and a reduction in shearing forces near the surface.[7,8] Thus, as the flow adjusts to the presence of particles, a self-balancing condition in mass flux develops downstream of the point of initial grain motion.[9] In other words, the carrying capacity of the wind has been realized. This does not imply additional particles are not eroded but that as larger grains become deposited behind surface roughness elements, the loss of mass is balanced by erosion of new grains from the surface, primarily by impact and abrasion forces.

The self-balancing concept for maximum horizontal mass flux, $f_{\max}$, has been analyzed by Stout,[8] reducing to:

$$f_x = f_{\max}\left(1 - e^{\frac{x}{b}}\right) \tag{4}$$

where

f_x = horizontal mass flux at downstream distance, x, from a non-eroding boundary
b = length scale for stability in horizontal mass flux

and is applied to height-specific mass flux measurements. In utility, Equation 4 states that beginning from a non-eroding boundary at $x = 0$, f_x increases with x until $f_{\max}$ is attained. Downstream of this point, horizontal mass flux is relatively unchanged. Typical vertical and horizontal mass flux profiles from two wind events are shown in Figure 3.[10] Two components require discussion. First, vertical mass flux profiles, from 0.1 to 1.5 m height, show mass decreases with height. This is consistent with the discussion above, e.g., saltating particles having less mass loft higher into the flow. For any single profile, mass is greatest near the surface and decreases vertically. Second, horizontal mass flux increases downstream until the maximum transport capacity is reached. In the figure, mass continues to increase downstream not yet having attained $f_{\max}$.

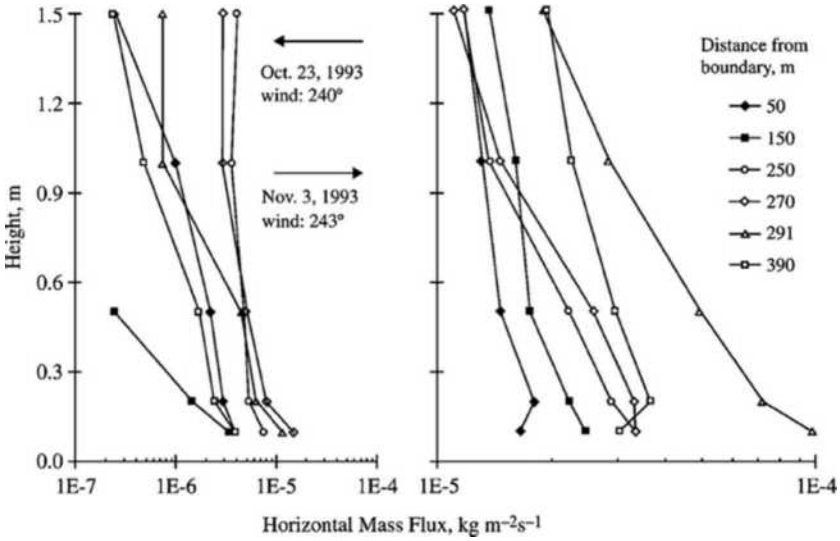

FIGURE 3 Vertical and horizontal mass flux profiles for two wind events illustrating the decrease and increase of mass with height and downstream distance, respectively.
Source: Stetler and Saxton.[10]

Conclusions

Complications to the above processes arrive due to numerous natural and human-induced conditions including: soil type, particle size distribution and fraction of erodible particles, climate, and land use. In cultivated fields, surface roughness is a primary consideration complicating the entrainment process as well as the establishment of the saltation layer. Rough surface elements have the effect of reducing wind shear forces thereby limiting erosion contrasted to a smoother surface that is favorable for a higher erosion rate.[11] Surface roughness can be either from soil clods, vegetation, or a combination of both.[12] Additionally, given all the factors discussed above, increases in soil moisture will cause an increase in the wind speed required to initiate grain motion.[13]

Prediction of wind erosion is, therefore, an inexact science, even with the advent of sophisticated computer models. The numerous and complex relations between all the critical parameters imply a degree of uncertainty, even in the best of calculations. The remaining entries will address some of these parameters more specifically.

Erosion: Snowmelt

Donald K. McCool

Introduction

In many areas of the world, winter hydrology is an important part of the annual erosion process; in some regions it is the primary cause of erosion. Sharratt et al.[1] indicate that about half of the Earth's land surface is frozen at some time during the year. In this topic, we will consider winter processes to include a range of conditions from those where the soil freezes and thaws diurnally and is subjected mainly to rainfall to those where the soil remains frozen for several months and precipitation occurs as snow or in other solid form during all or part of the winter season. In areas where daily minimum temperatures are rarely below 0°C, winter erosion processes are of relatively minor importance as compared to spring, summer and autumn erosion. At the other end of the spectrum are areas where the soil freezes in the autumn and stays frozen until spring and the ground is blanketed with snow for the entire winter.

FIGURE 1 Erosion on fall seeded winter wheat in eastern Washington caused by rain and snowmelt on thawing soil. Measured rill erosion was 200 metric tons per hectare.

Erosion is then confined to a period of spring snowmelt. Some areas such as the Palouse region of eastern Washington, northern Idaho, and northeastern Oregon are subjected to several runoff and erosion events each winter because the winter temperatures and precipitation patterns lead to multiple soil freezing and thawing occurrences each winter with accompanying rain or snowmelt events. The result of a particularly severe rain and snowmelt event when the soil had thawed at the surface on a fall-seeded field is shown in Figure 1.

Precipitation

Precipitation in areas where winter processes are important can occur as rain, or in solid form as sleet or snow. Rain can cause erosion due to splash and runoff detachment whereas sleet and snow cause detachment by runoff as they melt. In general, winter rainfall intensities are lower than summer rainfall intensities because of the lack of thunderstorm activity in the winter. However, the frequency and duration of precipitation are commonly greater. Since water loss from the soil is considerably lower during the winter due to lower mean temperatures and the absence of actively growing crops, even low intensity rainfall can increase the moisture content of soil rather quickly with a resultant dramatic increase in its susceptibility to erosion. The kinetic energy and intensity associated with rainstorms are not direct factors in snowmelt erosion. Snowmelt erosion is more closely related to volume and peak rate of runoff, which can be strongly influenced by rainfall when it occurs concurrently with the snowmelt.

Soil

The phase of the water in the surface layer of the soil is important in the winter erosion process. When soil water is frozen, erodibility, the susceptibility of the soil to erosion, is very low and erosion rates under sheet flow conditions are generally quite low. However, when runoff concentrates in small channels, the flow may cut into and through the frozen layer, leaving gullies and deeply incised channels. Soils that have been frozen and are thawing from the surface are weakened due to water expansion during the freezing process. Lee[2] cited a number of studies that indicate an increase in water content as water moves to the freezing front from deeper in the soil because the area where the soil is freezing is at very high water tension. The soil will regain strength after the frost has thawed and the soil reconsolidates as water drains from the soil.[3]

FIGURE 2 Gully erosion from snowmelt runoff in northern Idaho.

Water content of the soil at the time of freezing is important to the permeability of the soil and the opportunity for infiltration and deep percolation. Lee[2] found a linear relationship with a negative slope between the ratio of frozen soil infiltration hydraulic conductivity to the unfrozen soil infiltration hydraulic conductivity. Soil frozen at water content near saturation is frequently impervious and runoff can be nearly 100% of the rainfall or snowmelt,[2] thus leading to severe concentrated flow and gully erosion (Figure 2).

Effect of Snow and Freezing Conditions

During the nonwinter period or in climatic regions where winter erosion processes are not a factor, the only type of water erosion that occurs is rainfall on unfrozen soil. Winter erosion is more complex because there are seven basic types of erosion events:

1. Rain on frozen soil
2. Rain on thawing soil
3. Rain on unfrozen soil
4. Snowmelt on frozen soil
5. Snowmelt on unfrozen soil
6. Rain on snowmelt on frozen soil
7. Rain on snowmelt on unfrozen soil

Snowmelt on thawing soil and rain on snowmelt on thawing soil are not listed because, as discussed later, these conditions generally do not occur due to the insulating properties of snow. Further complicating these various types of events is that they typically do not stand alone but occur in some combination and how they combine will dictate the severity of any resultant erosion.

A blanket of snow on the soil surface can have positive as well as negative effects with regard to soil erodibility. Snow is an excellent insulator; the deeper the snow the better the insulation. Thus, a snow layer prior to or concurrent with freezing conditions can retard or prevent frozen soil. However, this insulating property also works extremely well at preventing frozen soil from thawing from the surface down (though thawing will occur in an upward direction due to deeper, warmer unfrozen layers if above ground temperatures are favorable). Snow cover on frozen soil typically results in the soil surface remaining frozen until bare soil begins to appear as the snow melts with warming temperatures, at which time the exposed soil begins to thaw from the surface down (Figure 3). The potential for severe

FIGURE 3 Melting snow exposes bare soil to thaw and increases erodibility.

erosion can be quite high with the presence of snow and depends on how all the contributing factors come together. If rainfall accompanies the warming temperatures required for snowmelt, runoff can be initiated over the frozen soil beneath the snowpack. If these conditions persist as patches of soil begin to be exposed and surface thawing follows, soil erosion will begin. The nature and severity of the erosion will be determined largely by the intensity and duration of the rainfall and to a lesser degree by temperature which affects the rapidity of the thawing process.

Runoff Events

It is difficult to ascribe a single set of characteristics to describe winter hydrology events on hillslopes or small watersheds. Events from rainfall on frost-impacted soil can be of very short duration whereas events resulting from extended periods of snowmelt can be of much longer duration. Events involving rainfall without snowmelt are usually brief although erosion rates can be high if the soil is thawing from the surface. Events involving snowmelt alone are extended in nature; runoff may fluctuate diurnally as air temperature dips below freezing at night. Erosion resulting from snowmelt alone is generally not severe. The highest runoff rates and flooding result from a combination of rainfall and snowmelt with high air temperatures. As long as the soil is frozen, sheet and rill erosion rates may be quite small, although concentrated flow erosion may be significant. When substantial quantities of bare soil appear, and the soil frost starts to thaw from the surface, erosion rates may increase dramatically. Sediment concentration graphs may lead or lag hydrographs under winter conditions. When there is no snow and the soil has thawed at the surface, a small amount of rainfall may lead to very high sediment concentration that occurs early in the event. When snow melts and the soil is not frozen, the sediment concentration and hydrographs may coincide. When snow melts over frozen soil, there may be little sediment until a portion of the soil is bare and melts. Then the runoff from the melting snow will detach and transport sediment, leading to a significant lag of peak sediment concentration.

Modeling

Erosion models are used to estimate location specific soil losses under various management systems within different land uses. They are also used to estimate expected amounts of sediment and chemicals that may be associated with those sediments. Models may be empirical in nature, such as the universal soil loss equation (USLE)[4] or the revised universal soil loss equation (RUSLE),[5] or they may be process based such as WEPP.[6] The inclusion of winter erosion processes even in empirical models such as USLE or RUSLE complicates the models. Erosion relationships based on runoff characteristics rather than rainfall characteristics may be more appropriate, creating the need to estimate runoff. Process-based models require inclusion of soil freezing and thawing, snowfall and snowmelt, and movement of water into frost impacted soil. Simple soil frost models are driven by air temperature, but more complex models consider radiation and other methods of energy transfer. It is difficult to strike a balance between excessive data requirement and adequate performance for applied use.

Amelioration

Preventing erosion damages from winter processes is similar to preventing erosion damages in other seasons. Cropland and rangeland are best protected by crop and surface cover. Snow collected in standing residue can prevent soil freezing and the creation of an impermeable condition. Surface cover protects from splash detachment, insulates the soil, and slows runoff. No till practices produce root channels and other pores that enable infiltration when the soil is frozen. Likewise, for areas where frost depth seldom exceeds 30–40 cm, deep ripping, chiseling, or slot mulching to expected frost depth can prevent formation of a continuous frost layer and lead to increased infiltration.

Erosion: Soil Quality

Craig Ditzler

Introduction

Soil erosion involves the detachment and removal of soil material from one site and its transport to another location. Soil erosion usually degrades soil quality and a soil of poorer quality is less able to withstand further erosion, thus creating a downward spiral of soil degradation. When the surface soil is removed through erosion, organic matter and clay particles may be lost, with consequent reductions in fertility, biological activity, aggregation and rooting depth. Other potential effects of erosion on soil quality include reduced porosity and infiltration, formation of crusts on the soil surface, changes in soil texture, and compaction. These changes in turn reduce the capacity of the soil to supply and cycle nutrients, filter and degrade toxic materials, store and supply moisture and sustain plant and biological productivity. They may also result in increased runoff, less biomass production and plant cover, and greater susceptibility to further erosion. Erosion increases the variability in soil quality across a field and, on a broad scale, is associated with widespread loss of agricultural productivity and declining water quality.

Soil erosion is a natural process by which soil particles are detached and moved by water, wind, gravity, or ice. All soils have an inherent erodibility, or natural susceptibility to erosion, based on soil features, topography, and climate. However, human activities, such as logging, livestock grazing, tillage, removal of vegetation, and urban development, can greatly accelerate natural rates of erosion. Cleared and managed as they are for crop and livestock production, agricultural soils are particularly susceptible to wind and water erosion (Figures 1 and 2), and also to a recently recognized process known as tillage erosion—the loosening of soil by tillage equipment and its downslope movement under gravity.[1]

Eroded soil may move only a few meters in a field and come to rest in lower positions, resulting in increased variability of surface soil properties across the field as subsoil becomes exposed in some places and surface layers are buried and over-thickened in others. It may also move great distances, being deposited in neighboring fields, roadside ditches, and water bodies. In some cases of wind erosion, fine soil particles may travel many kilometers before being deposited.

Effects of Soil Erosion on Soil Quality

The loss of surface soil in a landscape may impair soil function, and thus soil quality, through adverse effects on many physical, chemical, and biological properties of the soil.[2] Table 1 summarizes some of the effects of erosion on the soil quality functions listed by Gregorich.[4]

FIGURE 1 Deposition of wind-blown soil material. (From USDA, Natural Resources Conservation Service—Soil Quality Institute.)

FIGURE 2 Severe erosion by water has removed all of the surface layer and much of the subsoil. (From USDA, Natural Resources Conservation Service—Soil Quality Institute.)

TABLE 1 Some General Effects of Soil Erosion on Soil-Quality Functions

Erosion Effects	Soil-Quality Functions Affected
Reduced cation-exchange capacity	Sustaining plant growth and animal life Buffering or filtering Regulating energy
Formation of surface crusts	Regulating water, gases, and energy Sustaining plant growth and animal life
Changes in rooting volume Changes in surface layer texture	Sustaining plant growth and animal life Sustaining plant growth and animal life
Loss of organic matter	Regulating water and gases Sustaining plant growth and animal life
Compaction	Regulating energy Regulating water and gases
Deterioration of soil structure	Sustaining plant growth and animal life Regulating water and gases
Exposure of subsoil material	Sustaining plant growth and animal life Sustaining plant growth and animal life Regulating water, gases, and energy

Physical Effects

Erosion selectively removes the finer, lighter particles from the soil surface, leaving coarser particles behind. Depending on the severity of erosion, an eroded soil may become very coarse in texture, sometimes with a gravelly surface. The deposition of the eroded material in lower topographic areas may result in a thickening of the topsoil and an increase in rooting volume.

Tillage of eroded soils may result in a mixing of subsoil with the surface soil, altering its composition. For example, cultivation of eroded soils having clay-enriched subsoils may increase the clay content of the surface soil. As erosion progresses, plant roots must enter progressively deeper into the subsoil layer to obtain nutrients and water. Where subsoil layers restrict root growth because of their physical and/or chemical properties, the depth of rooting is reduced, along with the capacity of the soil to supply water and nutrients to plants.

Individual soil particles are held together in aggregates, which form the structural fabric of the soil. Soils with good structural arrangement of aggregates and the pore spaces between them provide good aeration for soil roots and microbes; allow ready movement and storage of water and plant nutrients in the pore spaces; and retain their structure when exposed to stresses such as cultivation and the impact of raindrops.[3,4] Abrasion by wind, rain, and tillage can disintegrate aggregates at the soil surface, and the resulting fine particles can plug larger soil pores and form a hard, thin crust on the surface. This crust seals the surface and limits the infiltration of air and water, as well as impedes the emergence of seedlings. Finer soil particles are also more easily compacted as the pore spaces between them are reduced under the pressure of farm machinery. Deteriorating soil structure further increases the risk of soil erosion—fine soil particles created by the breakdown of aggregates at the soil surface are especially vulnerable to wind and water erosion. Furthermore, compacted, crusted soils resist the infiltration of water, increasing the volume of surface runoff and compounding the effects of erosion. Thus, erosion reduces soil quality, making the soil prone to further erosion and further degradation.

Chemical Effects

Organic matter and clay are important sites of cation exchange in the soil. Cation-exchange capacity is a measure of negatively charged sites on the soil particles that are capable of holding positively charged ions, including many plant nutrients. As organic matter and clay particles are lost from the soil surface through erosion, attached nutrients are relocated in the landscape, often to adjacent water bodies where they contribute to declining water quality. Loss of these fine soil particles also impairs the ability tostore nutrients, reducing soil fertility. This effect is more pronounced in sandy soils containing small amounts of clay, though it may be offset to some degree if erosion causes the surface layer to become more clayey. Where subsoils are more enriched in clay than the surface soil, the clay particles may form chemical bonds with phosphorus, fixing it into forms not easily available to plants and thus reducing fertility.

For some acid soils with subsoil pH <5.0, concentrations of available aluminum may be at levels toxic to plant roots and removal of surface soil by erosion can effectively reduce the rooting depth of the soil.

Subsoil layers having pH >8.5 often contain high levels of sodium. Surface soil removal and subsequent exposure of these subsoils to rainwater or irrigation waters with low ionic concentrations can lead to dispersion of clay particles, loss of soil structure, surface sealing, and greatly reduced water infiltration.

Biological Effects

Removal of organic matter and nutrients from the soil surface by erosion reduces the food and energy supply needed to sustain healthy populations of soil organisms and support plant growth. Soil organisms are the agents of organic matter decomposition and nutrient cycling in soil. In addition, they play an important role in the stabilization of soil aggregates through the production of binding agents such as roots, fungal hyphae, polysaccharides, gums, and complex molecules consisting of humic substances combined with iron, aluminum, or aluminosilicates.[5,6] So, as erosion proceeds, the food source for organisms is reduced, leading to declines in populations. Soil structure and stability then deteriorate, the soil becomes more susceptible to further erosion, and the cycle continues.

Conclusions

The interaction of accelerated soil erosion and soil quality is complex. Soil erosion usually reduces soil quality, and a soil of poorer quality is less able to withstand erosion, thus creating a downward spiral of soil degradation. However, many soil-conservation practices have been useful in mitigating the effects of erosion. Reduced tillage systems limit soil disturbance and build soil structure. Crop residue management, under seeding, cover cropping, and permanent cover (e.g., pasture) protect the soil from the action of wind and water. Contour cultivation, grassed waterways, and terracing alter the flow of surface water, curbing water erosion. Herbaceous wind barriers and woody windbreaks and shelterbelts help to control wind erosion. Nevertheless, large tracts of agricultural land throughout the world are still subject to the unsustainable loss of soil as a result of erosion, and continued adoption of preventive methods are needed to protect and restore soil quality.

Farming: Organic

Brenda Frick

Introduction

IFOAM, the International Federation of Organic Agriculture Movements, defines organic agriculture as follows: "Organic agriculture is a production system that sustains the health of soils, ecosystems and people. It relies on ecological processes, biodiversity and cycles adapted to local conditions, rather than the use of inputs with adverse effects. Organic agriculture combines tradition, innovation and science to benefit the shared environment and promote fair relationships and a good quality of life for all involved."[1]

IFOAM identifies four overlapping principles for which organic agriculture strives:[2]

- "The principle of ecology: the desire to work with, emulate and help sustain living ecological systems and cycles.
- The principle of care: management in a responsible manner protecting the well-being of people and environment.
- The principle of health: sustaining and enhancing the health of soil, plant, animal, human and planet.
- The principle of fairness: ensuring fairness among people and in relationship to other living beings."

Organic Farming Standards

Organic standards around the world share a vision of the farm as an ecological system. They emphasize holistic management through biological and ecological processes, soil building, suitable crop rotations, humane handling of livestock, and a thorough audit trail to assure consumers of the integrity of the process. Organic standards generally prohibit genetically modified organisms, synthetic fertilizers, pesticides, growth regulators, and antibiotics. Some organic standards include social justice standards as well.[3,4]

Organic production is a long-term commitment. Farms must meet the regulations for a minimum period of time, generally 3 years, before they qualify for organic status. They must have a farm plan that includes proactive techniques to improve the farm's environmental status, build soil fertility, and reduce the impacts of non-beneficial organisms.

In recent years, certification standards have become mandatory in many countries.

In the United States, the Organic Foods Production Act was passed in 1990, enacting a standard that was built with an unprecedented amount of input from farmers, processors, and consumers. The standard was fully implemented in 2002. Now any products sold in the United States that are labeled "organic" must be in compliance with the standard.[5]

The Canadian Organic Products Regulation was enacted in 2006 and came into force July 2009. Products labeled as organic in Canada must meet the standard.[6]

Europe has the EU standard, EEC No. 2092/91, as well as smaller national or private standards. Japan also has a national standard.[7]

Products sold across boundaries must meet the standards of the importer. Canada and the United States signed equivalency agreements to recognize each other's standards in 2009. The two sets of standards differ in only a few "variances." A product that is certified organic in one of these countries is approved as organic in the other after an inspection verifies that it also meets the variance requirements. In practice, this additional step is generally included with the annual inspection process. Equivalency is intended to ease trade between these two major trading partners. Similar agreements will likely follow for other countries.[8,9]

Soil Building

Soil is literally the foundation on which all agriculture is based. In organic agriculture, healthy soils are seen as the key to healthy plant growth, which in turn is the key to healthy livestock and healthy people.

Soil management in organic systems is a matter of fostering biological processes in the soil, rather than applying synthetic off-farm inputs. Synthetic nitrogen fertilizers are made in an energy-intensive process generally starting with natural gas. By eliminating synthetic nitrogen sources, organic farming can significantly reduce energy consumption 30%–50% in field crops (less where nitrogen fertilization is less).[10,11] Synthetic nitrogen and phosphorus fertilizers are primary pollutants of rivers and estuaries downstream from agricultural cropland. By using less leachable, biological sources of fertility, organic farms are responsible for less nutrient pollution.[12]

In organic systems, biological processes in the soil are encouraged by practices such as use of green manures, cover crops, and mulches. Tillage is used judiciously when needed to manage weeds and pests or to prepare a seedbed.[13]

Green manures are crops that are grown to provide food and habitat for soil organisms, rather than products for harvest. Legumes are especially useful green manures, as they can partner with *Rhizobia,* which capture nitrogen from the air and make it available to the legumes. When these legumes are incorporated into the soil, soil organisms release the nitrogen in a form that other plants can use. Legumes and many other plants can also form beneficial relationships with mycorrhizae. Mycorrhizae form extensive networks of filaments throughout the soil and can "capture" soil nutrients from a much larger volume of soil than the plant roots could access on their own. Again, these nutrients are released in an accessible form when the green manure plants break down in the soil. Other green manure plants, such as cereals, provide "fiber," or soil organic matter, which is crucial to soil organisms involved in nutrient cycling.

Cover crops are used to reduce erosion potential and nutrient loss between crops. For instance, a cover crop of rye might be seeded after the harvest of a summer annual crop. The rye would act to stabilize the soil during the erosion-prone fall and spring. In the case of a legume crop, the cover crop could also act to sequester the nitrogen released from the legumes, so that it would not leach away.

Mulches can be living short-statured plants that grow between the rows of the desired crop, providing shade for the soil. This reduces moisture loss, temperature fluctuation, and germination of weed seed. It increases the potential activity of beneficial insects and soil organisms. Mulches can also be killed plants.

Some cover crops can be killed and seeded into in one pass of a roller crimper (see Rodale's No-till+).[14] This technology reduces the problematic effects of tillage and uses less energy by combining operations. Mulches of straw or other plant residues can also be used in smaller-scale operations.[15]

Organic systems tend to have greater soil biological activity as a result of these practices. In a study conducted across the Canadian prairies, soils from organic rotations had greater aggregate stability, a key in reducing erosion potential, than conventional rotations. This may arise from greater mycorrhizal fungi, which produce "sticky" polysaccharides that bind soil particles together.[16]

Farm operations that include livestock can use these livestock to improve soil fertility. Grazing green manures, for instance, can improve the economic value of the green manure while releasing most of the nutrients in a form that is very effectively used by the soil organisms. This method also reduces off-farm energy consumption, by allowing the animals to harvest the material themselves. Intensive rotational grazing systems can rejuvenate soils by releasing nutrients from the standing vegetation back into a soil-available form. Grazing pigs essentially "till" soil, loosening and aerating it. They can also clean up culls or fallen grain. When natural animal activity replaces some of the tractor-based tillage, energy is saved.

Genetically Engineered Organisms

Organic systems prohibit genetically engineered products. The results of moving genetically engineered products into our food system are, as yet, unknown. In North America, governments are reluctant to label food products containing the products of engineering. Thus, for those who wish to avoid this form of contamination of their food system, organic foods are their safest course.

Pest Management Practices

Organic systems prohibit synthetic herbicides and pesticides. They thus eliminate the concern of off-target losses of these products. Significant levels of biocides are detected in the air and water globally, especially near agricultural fields.[17–19] Exposure to these biocides is linked directly to poisoning of aquatic systems and of pesticide handlers and indirectly to increasing levels of human cancer and other diseases.[17]

Organic production instead chooses a systems approach to farming. Producers strive to understand the ecological relationships that influence the abundance of the various species in their systems and to avoid outbreaks of those species that harm the crop. Many of the methods used to favor the crop in the ecological community can be summarized by good crop husbandry—avoidance of pests through sanitation and quarantine; seed cleaning; management of soil fertility; selection of locally adapted and competitive crops and crop cultivars and breeds of livestock; appropriate timing, depth, and rate of seeding; and integration of cropping and livestock and judicious use of off-farm in- puts.[20] Use of farm-grown seed and closed herd management reduce immigration of pests. Where problems arise, introduction of new genetics may be warranted. Mechanical and biological pest controls are used as necessary but only as a last resort.[16,21]

Rotation is one of the strongest tools that the producer uses. A diverse crop rotation increases microbial and mycorrhizal activity in the soil and improves crop vigor. Populations of crop-specific pests, such as many diseases and insects, are severely reduced by years when a given crop is not grown.[22] Crop rotations alter the timing and competitive relationships of crops and reduce the build-up of weed communities adapted to any given management practice. Crop and cultivar selection is also very important. Matching crops to fields improves their competitive relations with weeds, and helps them to resist both insect and pathogen attacks.

Similarly, rotation of livestock is important to maintain quality of grazing lands. Multiple species increases diversity and reduces problems. For instance, chickens following beef animals can reduce fly larvae; sheep and cattle can graze different plant species and different forage heights.

Weeds

In organic systems, weeds are considered to be a part of the ecological system. They can be beneficial in moderating the soil environment, providing habitat and food for micro- and macrofauna, moving soil nutrients to the surface, and indicating soil or management problems. Of course, large weed populations are often detrimental. Weed management begins with avoidance, includes managing the crop and weed environment to minimize weeds, and only lastly involves direct weed control.[16]

A strongly competitive crop is an excellent defense against weeds. Competitive crops, such as fall rye and sweet clover, and perennial crops, such as alfalfa, are particularly effective at reducing the weed community. Less competitive crops, such as flax and lentil, are best seeded in less weedy fields, following strongly competitive crops.[16] Crop competition can be increased by appropriate cultivar selection and by crop management techniques. One of the most effective of these is increasing the seeding rate.[16] Heavier seeding rates are more effective in weedy situations. Organic recommendations are generally 1.5 to 2 times the seeding rates recommended when herbicides are applied. When used in combination, cultural techniques such as appropriate cultivar, diverse rotation, and increased seeding rate increased crop yield and reduced weed competition.[16]

Tillage can be used to reduce weed populations. Tillage can be used after harvest, before seeding, and in fallow years. Concerns over the negative effects of tillage on soil quality, especially on erosion potential, have reduced the frequency of fall and fallow tillages, though these may be cautiously used for perennial weed control.[23] Delayed seeding after spring tillage remains an important tool. Early tillage stimulates the germination of volunteer crop and weed seeds. These are destroyed with a second tillage at or before seeding. This strategy has been especially effective at reducing the abundance of early emerging species such as wild oats, *Avena fatua,* and winter annual weeds such as stinkweed *(Thlaspi arvense)*.[16]

Harrowing after seeding or even after crop emergence can also be effective. This strategy is most effective for weeds that emerge from shallow depths, such as green foxtail, in crops that have large, deeply placed seeds. For row crops, interrow cultivation can be effective. The combination of early harrowing across the rows and interrow cultivation can offer good weed control. Other mechanical weed control techniques include flaming, burning, and mowing. Chaff collection at harvest can remove significant numbers of weed seeds. It is most effective for volunteer crop seeds, and weed seeds such as lambsquarters *(Chenopodium album),* that are largely retained on the plant at a height above the stubble.[16]

Organic farmers are increasingly seeking ways of reducing tillage, substituting machinery such as noble blade cultivators, which kill weeds but leave them standing, and roller crimpers, which crimp weeds but leave them attached to the soil, and mowing. All these methods reduce erosion potential and soil disturbance relative to cultivation. Their efficacy for weed control is still under investigation. Use of forages, silage crops, and direct stubble grazing or green manure grazing further varies the rotation, allowing better weed control with less tillage. For many organic farmers, there is a trade-off between reducing tillage and increasing weed pressures. Further research is needed in this area.[16]

Biocontrol of weeds includes the use of livestock, weed-eating insects, and weed-suppressing diseases. Livestock can be used for grazing or to consume mowed weeds. Livestock can also be used to consume chaff or seed screenings. Biocontrol insects generally target perennial weed species. For instance, the black dot spurge beetle has been released for control of leafy spurge. Few fungal biocontrol agents are available. Examples include DeVine® for strangler vine, Collego® for northern joint vetch, Biomal® for round-leaved mallow, and *Phoma* for dandelion. Beneficial organisms can be encouraged by practices such as reducing tillage, maintaining shelterbelts, and growing crops (such as legumes and some cereals) that encourage mycorrhizae. These can also be effective for weed control.[21]

Insects and Other Invertebrates

A majority of insects found in crop fields are beneficial or are of no economic importance. Diversity of habitat and wildlife encourages positive interactions among species and reduces the potential for outbreaks of insect pests.

Organically grown crops may be less attractive to insects than crops grown with abundant synthetic fertilizers. Synthetic fertilizers may result in the accumulation of excess nitrate in plant tissue; composted manure and green manures release nitrogen more slowly, reducing the potential for this accumulation. Excess nitrate makes plants more attractive to insect pests and can increase the reproductive rate of some insects, thus increasing the severity of an insect outbreak.

Crop rotations can be effective against insect pests with limited dispersal capabilities, such as the corn rootworm. For these types of insects, reducing crop residues and volunteer crop are also important.

For widely dispersed insects that are attracted to specific crops, large-scale cropping diversity is important. Monocultures favor these insects. Increasing the presence of non-attractive plant species reduces the incidence of attack. Practices such as strip cropping and intercropping can reduce the attraction of insect pests by diluting the aroma of the crop or confusing the insect's search image. For instance, underseeding canola with yellow sweet clover may reduce the incidence of flea beetles. Even weed populations may function this way. For instance, weeds in alfalfa may increase the habitat for parasitic wasps that control alfalfa caterpillars. Barrier strips of an unattractive crop around the outside of the susceptible crop may prevent insects from crossing into the susceptible crop. For instance, a border strip of peas may reduce the movement of grasshoppers into wheat. Trap strips of an attractive crop may be sown. After insects accumulate there, it can be mowed or cultivated, thus destroying many of the insects. Small-sized fields also limit the problem of insect outbreaks.

The time of seeding can sometimes be altered to avoid insect pests. For instance, late seeding of canola can reduce the severity of flea beetles, and early seeding of wheat can reduce the attack of wheat midge.

Cultivar selection may help prevent insect problems. Wheat cultivars differ substantially in their susceptibility to wheat midge, in large part due to their rate of development.

Biocontrol agents are available for some insect pests. Predators such as ladybugs and lacewings can be used to reduce aphid populations. *Bacillus thuringiensis* strains have been developed for control of several insects, including caterpillars and beetles.[24] Some of these control organisms can be purchased. Maintaining a varied habitat in and around the crop field can also help to harbor such natural organisms.

Pheromone traps may be used to lure insects away from crops. Sticky traps can also be used. These trapping methods are particularly appropriate to monitoring insect populations.[24] They are less effective at large-scale insect removal. In high-value crops, such as potatoes or strawberries, insect "vacuums" can be used for larger insects such as Colorado potato beetles or lygus bugs.

A few products can be used under organic certification standards. Soaps and oils can be used to suffocate insects such as aphids. Diatomaceous earth can be used to discourage soft-bodied insect larvae, rusty grain beetles, and slugs and snails. Natural products such as pyrethrum and rotenone are also acceptable under most certification standards.

Diseases

As with insects, many fungal and bacterial species are beneficial or benign. Practices that increase biodiversity will likely increase species that compete with or prey on disease species and thus reduce the outbreak of disease epidemics. The severity of disease can be limited by reducing the population of the pathogen or the susceptibility of the host or by changing environmental conditions that favor infection.

Rotation is an important key to reducing disease by reducing the inoculum level of the pathogen. Crop rotation is effective when pathogens are obligate and host specific, with low dormancy and poor aerial spread. Leaf blights of cereals and ascochyta blights of lentil can be reduced by rotations that include different crops. Crop rotation alone is not sufficient to eliminate diseases in perennial crops; diseases such as common root rots and seedling blights with a wide host range; diseases that persist in soil, such as *Fusarium* wilt of flax; diseases with rapid spread, such as powdery mildew of peas; or diseases that are widespread in the air or by insect vectors, such as cereal grain rusts and aster yellows.

Straw, residue, and weed management can be important. Straw is a primary inoculum for some disease species. Incorporation of residues speeds their decomposition and thus reduces the pathogen population. The risks to soil quality with excess tillage need to be balanced against the risk of leaving inoculum in the field. Other sources of infection include volunteers of the target crop and weeds that are closely related to it. These sources of inoculum can reduce the effectiveness of a rotation away from the target crop.

Where diseases spread slowly from adjacent fields, field edges can be treated separately. Barrier strips or early swathing or mowing of the severely affected area may reduce the spread of disease into the crop.

Seed quality can impact disease potential. Reducing seed damage during harvest, storage, and seeding can reduce the susceptibility to disease, especially seedling blights. This is especially important for seeds such as flax, rye, and pulses. Disease-free seed reduces the spread of seed-borne diseases into new areas.

Host susceptibility can be reduced by the selection of appropriate cultivars. Resistance or relative tolerance to a number of diseases varies greatly among cultivars. Differences among cultivars in disease susceptibility may reflect differences in their rate of growth; differences in their architecture and thus canopy humidity; or physical, biochemical, or genetic properties that restrict disease entry. Crop timing may also be important. For instance, earlier seeding may reduce the incidence of diseases such as barley yellow dwarf, powdery mildew of pea, and pasmo of flax. Late seeding of fall-seeded crops can reduce spread of disease by reducing their overlap with similar spring-seeded crops. Late seeding into warm soil can increase seedling vigor and thus reduce crop susceptibility to seedling blights. Reduced seeding rates can reduce the spread of disease by reducing contact among plants and by altering the environment in the canopy. Intercropping or strip cropping can be effective as well.

Some environmental manipulations can make disease frequency less severe. Selection of an appropriate field for a given crop can be important. Nutrient imbalance can make diseases such as take-all in cereals more severe. The incorporation of manure and green manures in rotations can reduce the severity of disease by encouraging microbes that are antagonistic to crop pathogens.

Future Concerns

Organic farming has many of the concerns that plague conventional farming: an aging cohort of farmers; a scarcity of reliable information sources; an economic system that puts little value on ecological services provided by farmers and farmland; and increasingly, commoditization of organic products.

Despite strong organic regulations, there is evidence that many consumers are not well informed. This leads to copycat items in the marketplace, claiming organic attributes without the rigor behind the organic claims.

There is concern among organic producers that the popularity of biotechnology in crop breeding will result in the abandonment of traditional breeding programs. If all or even most future genetic disease and insect resistance is incorporated into a genetically modified background, it will be unavailable to organic producers. This will greatly reduce their pest management options.

Farmers are forced to make compromises between the soil benefits of reducing tillage and the efficacy of tillage for weed control. Most organic farmers export products while attempting to cycle materials internally. Erratic weather threatens cropping; immature market infrastructure creates volatility in farm income. Farming of any sort is financially risky relative to most other professions. Poor crops and poor markets cause people to seek off-farm income. This and a local labor shortage reduce the ability of many farms to access the benefits of integrating livestock into their cropping systems.

Organic producers have pioneered a path away from high-energy-consuming and polluting synthetic fertilizers and biocides. They have chosen to emulate nature, fostering natural ecosystem processes and biological cycling. It seems they are on a path toward sustainability, but further development is needed on this path.

Global Climate Change: World Soils

Rattan Lal

Introduction

Earth's vast reservoir of carbon (C) is contained in four distinct pools (Table 1). The soil C pool comprises both organic and inorganic forms. Soil organic carbon (SOC) is estimated at 1,550 Pg (1 Pg=petagram=10^{15} g=1 billion metric tons) and soil inorganic carbon (SIC) at 940 Pg.[1] The atmospheric pool contains 820 Pg of C, and the vegetation for the biotic pool amounts to about 620 Pg of C.[2] The pedologic or soil C pool, with a total reserve of about 2,490 Pg to 1 m depth in both organic and inorganic forms, is about 3.5 times the atmospheric pool and 3.8 times the biotic pool.[1–6]

In addition to being the largest terrestrial pool, world soils also play a major role in the global C cycle (Figure 1).[3,4] The SOC pool is highly dynamic, concentrated near the soil surface, and comprises material of plant and animal origin at various stages of decay and decomposition. A large part of the SOC pool is held in the organic soils of tundra and boreal forest ecosystems.[5] It is this dynamic SOC pool

TABLE 1 Global Pools of C

Pool	Amount (Pg)
Ocean	
Intermediate and deep ocean	38,100
Surface ocean	1,020
Dissolved organic carbon	700
Surface sediment	150
Marine biota	3
Soil (1 m depth)	
SOC	1,505
SIC	940
Vegetation	620
Atmosphere	760

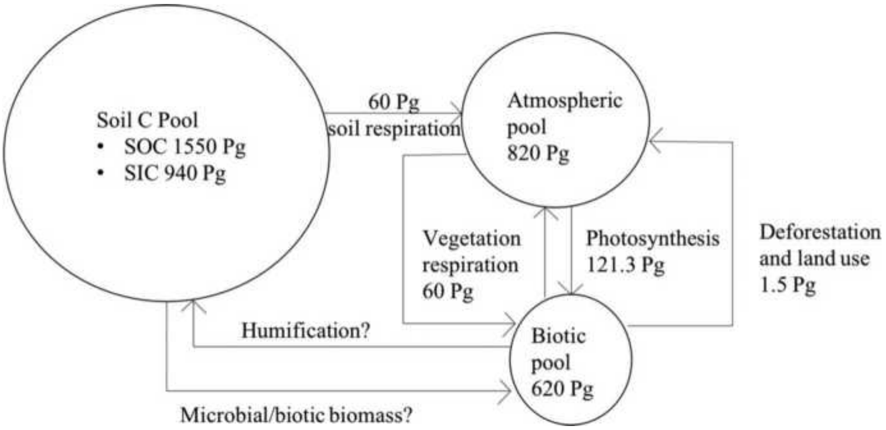

FIGURE 1 Interactive effects among the three C pools (soils, biota, and atmosphere) have led to a steady increase in the atmospheric pool at the expense of the soil and biotic pools. Values in the arrow indicate direction and magnitude of the known fluxes (Pg/yr), while the question mark indicates the lack of information.
Source: Lal,[3] Jansson et al.,[2] and Le Quéré et al.[7]

that is intimately connected with the projected global warming or the accelerated greenhouse effect. Change in soil C pool by 1 Pg is equivalent to 0.47 ppm change in atmospheric concentration of CO_2.[6]

These global pools are interconnected through fluxes of C (Figure 1). Sources and sinks of carbon for the decade of 2008–2017 are shown in Table 2. The two principal sources are fossil-fuel combustion (9.4 Pg/yr) and deforestation and soil disturbance (1.5 Pg/yr). The two proven sinks are atmosphere (4.7 Pg/yr) and ocean (2.4 Pg/yr). The unknown sink for the remaining 3.2 Pg/yr is most likely the world soils and other terrestrial ecosystems.[7] The exchanges occur between (1) world biota and the atmosphere with an annual flux of 121.3 Pg photosynthesized by plants and returned to the atmosphere in equal amounts through plant and soil respiration; and (2) oceans and the atmosphere amounting to an annual net increase of the ocean sink by about 2.4 Pg/yr.[7]

There has been a steady increase in the atmospheric concentration of greenhouse gases (GHGs—CO_2, CH_4, and N_2O) since the beginning of agriculture,[10] but more strongly with the onset of the industrial revolution in the 1850s. This increase is primarily due to human activities, e.g., industry-based fossil-fuel

TABLE 2 Sources and Sinks of Atmospheric CO_2 for the Decade of 2008–2017

Source/Sink	Flux (Pg C/yr)
Source	
Fossil-fuel combustion	9.4, 0.5
Deforestation, land use, and world soils	1.5, 0.7
Total	10.9
Sinks	
Increase in atmospheric concentration	4.7, 0.02
Ocean uptake	2.4, 0.5
Total	7.1
Land	3.2, 0.8
Imbalance	0.5

Source: Le Quéré et al.[7]

consumption, and agriculture-based deforestation and conversion to cultivable land involving intensive use of fertilizers and manures. The CO_2 concentration in the atmosphere has increased from 280 ppmv in the 1850s to about 405.5 ppmv in 2017, and is increasing at the rate of 0.55% per year.[11]

Agricultural Activities and Greenhouse Gas Emissions

GHGs are emitted by numerous agricultural activities (Figure 2). Agricultural sources of CO_2 are deforestation, land use conversion, biomass burning, soil plowing and other mechanical disturbances of the topsoil, and fossil-fuel consumption. Among principal sources of CH_4 are enteric fermentation in ruminant animals, cultivation of rice paddies, anaerobiosis in poorly drained soils, and biomass burning. Atmospheric concentration of CH_4 has increased from 722 ppb during the pre-industrial era to 1,859 ppb in 2017, and is increasing at the rate of 0.7 ppb/yr.[11] Use of nitrogenous fertilizers and manures is the principal source of N_2O emission. Concentration of N_2O in the atmosphere has increased from 270 ppb in pre-industrial era to 330 ppb in 2017, and is increasing at the rate of 0.9 ppb/yr.[11] Soil management plays a major role in the type and amount of emission of GHGs.[4]

The rate of oxidation or mineralization of the SOC pool depends on its composition and numerous other factors. Factors that increase oxidation are soil disturbance, high soil temperature, lack of protective vegetal cover, and risks of soil erosion and degradation. In contrast, factors that decrease oxidation are minimal soil disturbance, low soil temperature, presence of protective vegetal cover, and high soil resilience. The annual flux of CO_2 from soil to the atmosphere, about 60 Pg, is due to soil respiration and its rate increases with increase in soil temperature. The mean resident time of SOC in soil is about 32 years, but some resistance humic substances can stay in soil for thousands of years. Losses of SOC pool by oxidation are accentuated by soil erosion of water and wind,[12–14] and other degradative processes.

Introduction of mechanized agriculture (e.g., tractor-based plowing and other farm operations causing soil disturbance) has accentuated losses of SOC pool from cultivated soils. Some soils lose as much as 25% of their SOC pool within 1 year after deforestation and cultivation.[15] The rate of loss of SOC

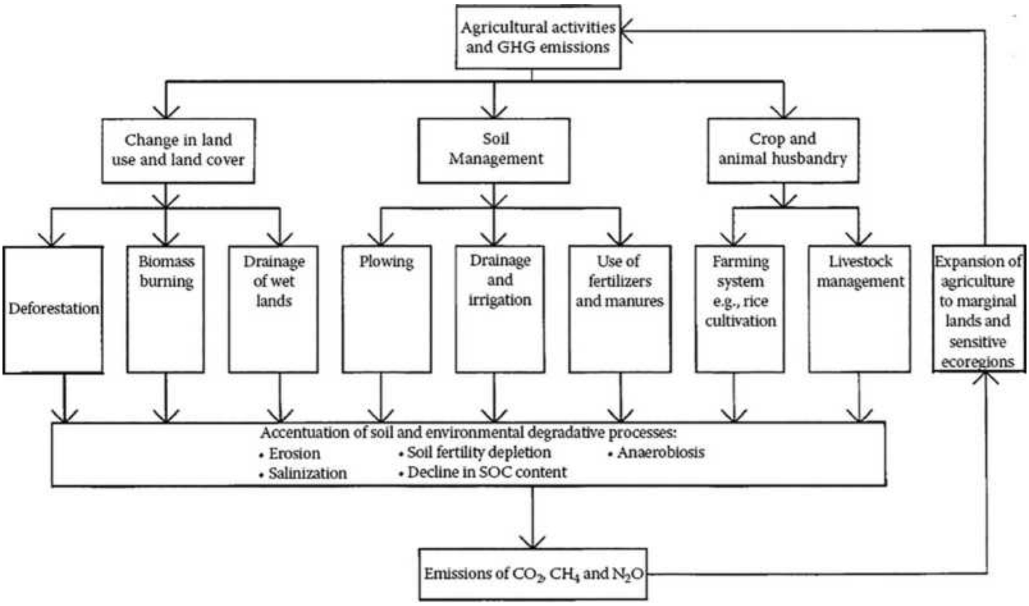

FIGURE 2 Agricultural activities and emission of GHG from soil to the atmosphere.

content is more in the tropics than that in the temperate climate. Some tropical soils, cultivated for millennia in Asia, have extremely low levels of remaining SOC content (as low as 0.2%). These soils have probably lost 75%–80% of their antecedent SOC content. It is likely that as much as 135 Pg of C in the atmospheric pool has been contributed by world soils.[3]

In addition to being a source of atmospheric C (as CO_2, CH_4, or CO), world soils are also a major source of N_2O. The relative contribution of N_2O has also increased because of the intensive use of nitrogenous fertilizers since World War II. The magnitude of N_2O emission varies among soils, type of nitrogenous fertilizer used (formulation), climate, land use, and soil and crop management.[16]

Potential of World Soils as C Sink

The SOC in most agricultural soils is below their potential capacity. Assuming a considerable part of atmospheric CO_2 has come from world soils, it is possible to reverse the trend and store C back into the soil. Increase in SOC content, through change in land use and farming practices, could slow the rate of increase of atmospheric CO_2 and provide a negative feedback to the greenhouse effect. Because of their vast pool, it is very likely that terrestrial ecosystems are the unknown sink for 3.2 Pg of C/yr (Table 2), of which soils are a major component.[3]

Principal mechanisms by which soils can be used as an effective sink for some of the atmospheric CO_2 through increase in SOC content include (1) conversion of biomass into resistant humic substances with long turnover time, (2) aggregation or formation of stable organo-mineral complexes that render SOC inaccessible to microbes, and (3) deep incorporation of SOC below the plow layer through deep root system development and translocation by leaching. These mechanisms can be set-in-motion through adoption of proper land use, choice of appropriate farming/cropping systems, and use of judicious soil and crop management practices.[3,4]

The potential of C sequestration in world soils depends on the current land use, present level of SOC content, the initial SOC content prior to soil disturbance by deforestation and conversion to other land uses, climatic or ecoregional characteristics, and farming systems. Among all land uses, the largest potential increase in SOC content is in arable lands. If the SOC content of the world's agricultural land can be increased at the low rate of 0.04% per year to 40 cm depth, which may be difficult to achieve for soils of arid and semiarid regions, the C sequestration potential of such a possibility is about 2.5 Pg/yr (Eq. 1). These calculations, based on the assumption that the mean bulk density of soils is 1.25 Mg/m^3, are mere examples of what may be possible. The estimates thus computed are not indicative of what is happening now nor what may happen in the future.

Thus, an example of the estimation of C sequestration potential of $5{,}000 \times 10^6$ ha of world agricultural land to 40 cm depth.

Managing World Soils for Mitigation of the Greenhouse Effect

There are several soil management practices that can be used to increase SOC content and reduce the risk of accelerated greenhouse effect (Figure 3). These practices can be grouped under two broad categories: (1) those that decrease losses due to soil degradative processes and (2) those that increase SOC content through soil restorative processes (Table 3). The principal strategy is of agricultural intensification through adoption of appropriate land use and recommended agricultural practices.

A tremendous potential of mitigation of the greenhouse effect exists through restoration of degraded and drastically disturbed soils. It is estimated that the area of the degraded soils of the world is about 2.0 billion ha.[23] These soils include the presently cultivated land area, pastoral land areas, and other managed and natural ecosystems. Restoration to improve soil quality can lead to an increase in ground biomass production (both above and below the ground), increase in SOC content, and strengthening of a negative feedback to the greenhouse effect. An example of calculating the sequestration potential of restoration of degraded soils is shown in Eq. (2).

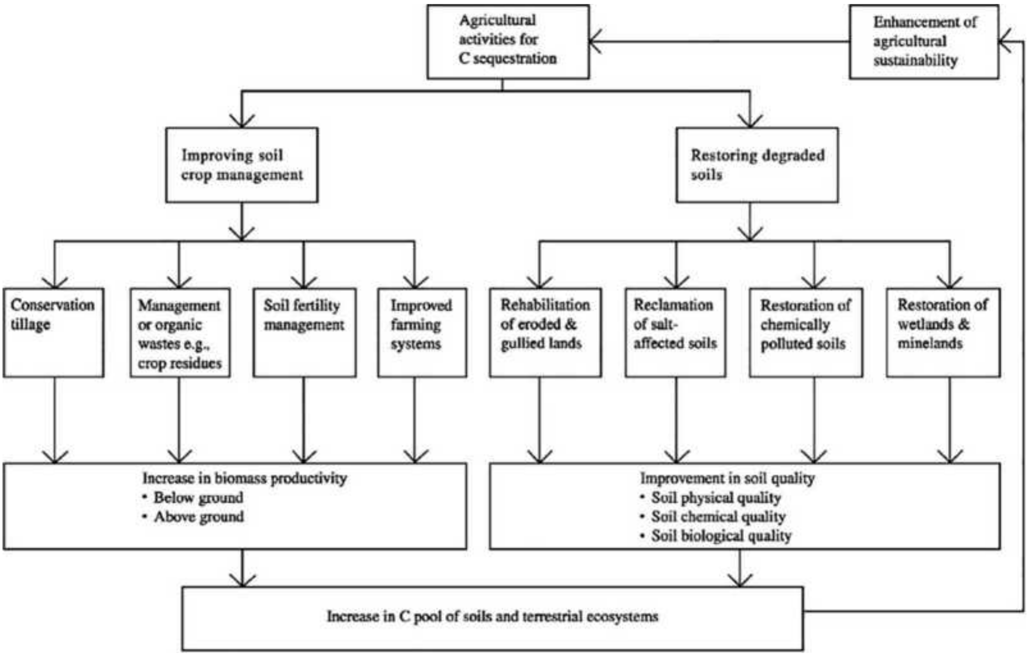

FIGURE 3 Agricultural activities with a potential of sequester C in world soils that decrease the risks of the greenhouse effect.

TABLE 3 Strategies for Increasing SOC Content for Mitigation of the Greenhouse Effect

Practices That Decrease Loss of SOC Content	Practices That Enhance SOC Content
Soil erosion control techniques	Improved soil fertility and integrated nutrient management
1. Conservation agriculture	1. Precision farming
Residue management Terraces and vegetable contour barriers Improved cropping systems Afforestation	Nutrient cycling Application of biosolids and biological nitrogen fixation
2. Decreasing losses of organic carbon through erosion, mineralization, and leaching	2. Restoration of degraded soils Eroded soils Mineland and drastically disturbed soils Salt-affected soils
	3. Water management (controlled drainage and drip subirrigation)

C sequestration potential of restoration of degraded

(2)

These calculations are based on the assumption that mean soil bulk density to 0.4 m depth is 1.25 Mg/m^3. It is also assumed that the potential, 1 Pg/yr of restoring degraded soils combined with 2.5 Pg C/yr of managing all agricultural land at 3.5 Pg C/yr, can be realized over 25–50 years. Realization of this potential requires development of strict land care ethics and global soil policy that must be strictly adhered to. While attempts at decreasing the emissions due to fossil-fuel combustion must be continued, it is important that the vast potential of world soils in C sequestration may be realizable through adoption of known and proven technologies. The attainable potential of world soils for C sequestration is 0.6–1.2 Pg C/yr.[4]

Conclusions

World soils constitute a major terrestrial C pool, and even a small change in the C pool of world soils can lead to a substantial change in the atmospheric C pool. A considerable increase in atmospheric C pool, since the industrial revolution, has come from the soil and biotic pools. Agricultural activities that lead to emissions of CO_2 and CH_4 from soil to the atmosphere include deforestation, biomass burning, and plowing. Gaseous emissions are accentuated by soil degradative processes including accelerated erosion and structural decline.

Conversion to an appropriate land use and adoption of judicious management can reverse the trend by making world soils a major sink for C. The SOC content of agricultural soils can be maintained or enhanced by use of conservation agriculture, application of crop residue mulch, and judicious use of chemical fertilizers and organic amendments which enhance soil quality. Total potential of agricultural soils (~5 billion ha) and degraded soils (~2 billion ha) of 3.5 Pg C/yr, merely an example of calculation, necessitates land use planning and the appropriate policy implications.

Integrated Farming Systems

John Holland

Introduction

The system of agricultural production has undergone immense changes in the past three decades.[1] Crop yields have increased through a combination of plant breeding, intensive use of pesticides and inorganic fertilizer, and greater mechanization. Farming systems based on high inputs of agrochemicals and intensive tillage are now recognized as being unsustainable because they cause soil erosion, soil nutrient depletion, environmental pollution, increased pest problems, and public health hazards. In addition the profitability of cereal and oil crop production also declined at the end of the 20th century forcing farmers to examine ways of reducing their production costs.[1] As a consequence farming is facing economic, political, environmental, and social pressures that are forcing changes in the methods of crop production. In response, a range of different production systems has evolved that try to address these issues. The most extreme are the organic or biological systems in which agrochemical use is almost eliminated. Various systems have been defined that are between the extremes, such as integrated farming systems, and these aim to use lower inputs and as such are regarded as being more sustainable.[2] Many definitions exist for integrated farming but the most appropriate is all encompassed in the description by El Titi[3] "*an holistic pattern of land use, which integrates natural regulation processes into farming activities to achieve a maximum replacement of off-farm inputs and to sustain farm income.*" Integrated farming therefore incorporates the principles of integrated crop management (ICM) and integrated pest management (IPM) but takes a long-term, whole-farm approach that considers all aspects of crop production and land management.[2] The emphasis is on preserving farm profitability by optimizing inputs, although consequently there may be ecological benefits and overall greater sustainability.[4]

What Is Forcing the Changes?

The driving forces where integrated farming has been adopted vary between countries and farmers. The main influences are outlined below.

Legislation

The withdrawal of many pesticides (e.g., in Denmark) has led to some farmers having no option but to adopt integrated or organic systems. Some countries (e.g., the Netherlands) have set targets for national conversion to sustainable agriculture based on integrated farming.[5]

Economic Pressure

Recent declines in cereal and oil seed values and price support has made European farmers look closely at their variable and fixed production costs and therefore a more integrated approach. Agrienvironment payments encourage better habitat management. Cross compliance, modulation, etc., if adopted may force more widespread changes.

Green Marketing Incentive

Crop assurance schemes may include integrated practices. These may provide a premium over conventionally produced food or are a requirement for the larger supermarket retailers.[5]

Environmental

The widespread decline in farmland wildlife is now recognized by governments, farmers, environmental organizations, and the general public.[1,6] To mitigate some of these changes farmers are adopting some of the principles of integrated farming, especially with respect to pesticide use and management of their ecological infrastructure.

Agronomic

When pesticide resistance reaches such levels that chemical control is no longer possible or economical then farmers have to look for alternative solutions.[7]

Development of Integrated Farming

The integrated approach incorporates all aspects of farm management and therefore requires knowledge of the interactions between components in the system, before the concept can be promoted to farmers. In many countries, long-term farm studies have been conducted to develop an integrated system and in some cases economic and environmental comparisons were made with the conventional approach.[4,8] Overall integrated farming proved equally profitable.[4,8] Lower yields could be expected, but this loss was compensated for by using lower inputs of agrochemicals and energy. In the United Kingdom results from nine farm-scale studies in which integrated and conventional farming was compared were pooled for analysis. In the integrated system substantial reductions in inputs were achieved without losing crop quality (Table 1).

The reduction in agrochemical inputs is likely, but as yet not satisfactorily proven to reduce the risk of pollution and toxic or sublethal effects to nontarget organisms. Nevertheless, some environmental benefits were attained.[1,6] Some studies reported greater numbers and diversity of soil fauna where an

TABLE 1 Integrated Farming Inputs and Their Costs as a Percentage of Conventional Systems

Input	% Change in Quantity of Use	% Change in Cost
Fungicides	−50	−41
Herbicides	−42	−32
Insecticides	−40	−42
Fertilizers	−18	−15
Seeds	+10	+12
Operational	–	−9

Source: Adapted from Integrated Farming: Agricultural Research into Practice; MAFF Publications: London, 1998.

integrated system was used, although this was not always apparent. Beneficial insects vary naturally in their abundance between years, fields, and different crops and these fluctuations were usually greater than those between the two farming systems. In small-scale (often <5 ha) trials conventional inputs appeared to have few long-term, direct effects on nontarget arthropods, however, farm-scale monitoring in the United Kingdom for the past 20 years has indicated that many arthropods have declined since the advent of intensive farming and are showing little sign of recovering.[1] In all farming system experiments weed, disease, and insect pest infestation levels were routinely monitored to aid crop protection decisions. Most studies reported lower disease and insect pest incidence, but higher weed burdens in the integrated system, although rigorous experimental appraisals were seldom given.

Principles of Integrated Farming

Arable crops are complex ecological systems[1] and consequently a blueprint for their management using an integrated approach cannot be applied universally. Each farm, crop, and even each field must be considered separately based upon the previous history, current crop monitoring, and the farmers' individual objectives. There are, however, some broad principles that apply.[2,3,5,7,9]

Multifunctional Crop Rotation

Rotation is the core of any integrated system with a minimum of four different crops, although a longer rotation may add more opportunities to build soil fertility and prevent disease and pest carryover. Although the choice of crops will depend on locality, markets, and prices, there are some broad principles. Crops that build soil fertility (leguminous crops and those with high inputs of organic matter, e.g., grasses) must be alternated with those that reduce soil physical and chemical fertility (root crops with low input of organic matter, e.g., potatoes and sugar beet). The sequence of each crop can also be used to ensure there are opportunities to control grass weeds in broadleaved crops and that pest organisms are kept below economic thresholds by ensuring that no single type or group of crops are grown in succession. There may have to be compromises and the rotation chosen will reflect the economic, agronomic, or environmental priorities of individual farmers.

Integrated Nutrient Management

Inputs of inorganic fertilizers are essential to maintain yield and quality but must be balanced to ensure supply does not exceed demand by more than 10%. Excessive nutrient supply encourages weeds, pests, and diseases and causes pollution. Application should maximize uptake by the crop and minimize loss to the environment. Where possible inorganic fertilizer should be replaced with animal and green manures. This has many benefits:

Improved soil nutrient supply and physical structure
Encouragement of beneficial organisms such as predatory invertebrates and microbials
Lower cost
Savings in nonrenewable resources

Optimizing nutrient supply through judicious use of off-farm inputs, organic manures wherever possible, and choice of a nutrient-supplying crop rotation will generate economic benefits for the farmer and the environment, especially water quality.

Minimum Soil Cultivation

Soil cultivations require high inputs of energy and machinery, are damaging to beneficial soil fauna, and encourage erosion and nutrient leaching. Adopting a soil cultivation system to minimize these effects is an essential component of any integrated system. The type and intensity of cultivation must be chosen according to soil type and agronomic concerns (e.g., weed species composition). Conservation tillage/noninversion tillage in combination with mulching should be maximized thereby concentrating soil organic matter in the upper soil layers. This improves soil structure and workability, decreases erosion and leaching, improves drought tolerance, and creates more favorable conditions for beneficial predatory invertebrates, soil microorganisms, and earthworms. Weeds may be encouraged but these may be overcome by utilizing the benefits of rotation and targeted weed control. Considerable cost savings may be made and this is the driving force behind the recent interest in the noninversion tillage in Western Europe.

Integrated Crop Management

Integrated crop management encompasses IPM but extends the principles to the control of weeds and diseases. The approach maximizes natural regulatory mechanisms through adoption of the above components and uses plant resistance, time of planting, economic thresholds, and the most environmentally safe pesticides. This requires more intensive crop monitoring and in some cases greater tolerance of pests. Mechanical weed control combined with low doses of herbicide may be appropriate. Encouragement of pest predators through provision of suitable habitat and trap cropping is also recommended.

Ecological Infrastructure Management

This is the provision of a suitable proportion of noncrop or ecological areas that if correctly managed can

Provide a source of beneficial species for pest control;
Act as buffer zones along ecologically sensitive areas such as watercourses preventing nutrient loss and soil erosion;
Provide a refuge from which reinvasion may occur after any adverse agricultural operations;
Prevent weed ingress into fields; and
Act as a source of biodiversity.

These areas may be field margins, hedgerows, fence lines, grass, or herbaceous strips arranged to ensure the maximum connectivity while keeping individual field size to a minimum. A minimum area of 5% of cropped land is recommended[3] although the ecological gains will be dependent on the quality of these areas. Research has identified the potential of different ecological areas to provide pest control and act as buffer zones.

Implementing an Integrated System

The approach requires considerable knowledge and commitment by the farmer. A whole farm evaluation helps the transition from high to lower inputs. On-farm trials may be needed to ascertain the most effective system. Extension services are needed for the transition period and afterward if it is to remain successful.[2] New technology, such as decision support and precision farming techniques, are advocated.

Organic Soil Amendments

Philip Oduor-Owino

Introduction

Modern agriculture is faced with the challenge of becoming more productive and yet more sustainable. One important goal toward this end is to boost crop production through proper management of weeds, insect pests, and plant pathogens. These management tactics must be implemented without adversely affecting the ecosystem. Therefore, there is a need to change from the use of pesticides to safer pest management practices, which can be adopted in integrated pest management (IPM) programs. The use of organic soil amendments for the control of plant pathogens and/or pests may provide a viable alternative.[1–3]

Organic Soil Amendments and Their Mechanisms of Action

Amending soil with organic matter such as chitin, oil cakes, compost, animal manures, and other industrial by-products in pest management studies is well recognized.[4,5] However, effects of these materials on disease development are not clear, and have been attributed, in part, to the factors discussed below.

Impacts of Organic Soil Amendments on Plant Health and Weeds

Soil amendments improve plant growth by enhancing plant nutrition.[1] The levels of nitrogen, phosphorus, potassium, and other essential elements are increased when organic matter is added to soil and is associated with better crop performance.[1] Changes in physical characteristics of soil may also enhance plant growth and the associated weeds, an attribute that should be utilized in disease management. Healthy plants produce higher yields, compete with weeds, and tolerate fungal, nematode, and insect damage better than unthrifty plants.[1,6]

Organic Soil Amendments and Plant Resistance

Materials such as oil cakes and sawdust have high phenolic content and alter the attractiveness of host plants to nematodes.[7] For example, seed treatment with ground oil cakes boosts plant resistance to *Tylenchulus semipenetrans* Cobb and root-knot nematodes due to increased levels of phenols in treated citrus and tomato roots, respectively.[4,7] In contrast, organic materials from *Tithonia diversifolia* (Hems) and chicken manure increase the severity of dry root-rot of French bean (*Phaseolus vulgaris* L.cv. Monel) caused by *Fusarium solani* f.sp. *phaseoli* (Mart) Sacc. (Table 1). This has been attributed to the formation of stimulatory ammonium compounds during decomposition.[8]

Release of Compounds Toxic to Insects and Plant Pathogens

Some organic materials release insecticidal, nematoxic, and/or fungitoxic chemicals during decomposition, for instance, neem oil and neem cake powder from the neem tree, *Azadirachtin indica.* A. Juss contains the limonoid azadirachtin, which is nematoxic and insecticidal in nature.[6,9] The black bean aphid, *Aphis fabae* (Scop), has been successfully controlled by this product (Table 2). The nematicidal activity of marigolds (*Tagetes* spp.) and castor (*Ricinus* spp.) has also been recognized, but in this case

the toxic principles are Polythienyls and ricin, respectively.[4,7] Antimicrobial chemicals such as nitrites and hydrogen sulfide are also produced during decomposition and play an important role in disease control. Unfortunately, various changes in quality and quantity of these chemicals occur over time, making it difficult to obtain more than circumstantial evidence that any one compound is responsible for disease suppression.[2]

Stimulation of Antagonistic Microorganisms

The hypothesis that organic soil amendments stimulate the activity of antagonistic microorganisms was proposed over 50 years ago.[5] When organic matter is added to soil, a sequence of microbial changes is initiated, none of which should be viewed in isolation. It is possible that the ability of nematophagous fungi such as *Paecilomyces lilacinus* Thom. (Samson) and *Verticillium chlamydosporium* (Goddard) to destroy/parasitize eggs of root-knot nematodes is stimulated by soil amendments.[2,10] Egg parasitism of up to 37% has been achieved with organic matter from castor plant or chicken manure (Table 3). Besides egg parasitism, the diverse range of microorganisms in amended soils competes with nematodes and other invertebrate pests for space and oxygen, thereby creating unfavorable anaerobic microsites in the soil. Bacteria such as *Streptomyces anulatus* (Beijerinck) Waksman, the collembolan, and *Entomobyroides dissimilis* (Moniez) are good examples.[5] *Armillaria* root rot of fruit and forest trees, caused by *Armillaria mellea* Vahl ex.fr, is minimized using coffee pulp that stimulates the antagonistic effects of *Trichoderma viride* link ex. Fries against a wide range of *Armillaria* spp.[11]

In conclusion, it is evident that various activities of soil microorganisms contribute significantly to the detrimental effects of organic matter on plant pathogens. However, it is difficult to determine whether any one activity or group of organisms is directly responsible for the suppression of specific diseases. The evidence available remains largely circumstantial.

Use of Organic Soil Amendments in the 21st Century

Studies on the efficacy of organic soil amendments against plant pathogens should be intensified worldwide. Organic plant materials such as chitin, compost, and oil cakes have great nematode control potential but have remained unutilized in biological control systems due to inadequate and inconsistent information on their efficacy and compatibility with antagonistic microorganisms.[10,12] It is not known if these organic materials and fungal antagonists/predators can successfully be integrated into the same pest control systems. The future challenge in this case is to determine ways of boosting the antagonistic potential of specific beneficial organisms by using locally available amendments in quantities realistic for broad-scale agricultural use. The complexity of the soil environment may thwart efforts to achieve this, but previous studies[4,5,7] and recent work on the interaction between nematodes and organic soil amendments[1–3,13] suggest that this is a promising area for further research.

Future Concerns

Organic soil amendments have a positive future in pest and disease control.[10,14] However, recent techniques used in the fields of biotechnology and molecular genetics[15] may dominate biological control research with a view of alleviating problems that are presently confronting researchers in an attempt to look for safe pest control alternatives. It is important that scientists, in their eagerness to embrace these new technologies, do not lose sight of the fact that the ultimate objective is the development of environmentally friendly pest control systems that can be applied in the field. We must strike the right balance between theoretical investigations and the more applied biological control studies aimed at developing viable pest management options.

Pasturelands, Rangelands, and Other Grazing Social-Ecological Systems

Radost Stanimirova
and Rachael Garrett

Introduction

Approximately 26% of Earth's land (excluding Antarctica) is occupied[1] by grazing systems, making them the largest non-forest land use on the planet (Erb et al. 2017, FAO 2011). A defining feature of livestock production is that ruminants (e.g., bovines, sheep, and goats) spend at least some of their lifetime grazing; however, there are several terms used to refer to large grassy areas depending on the intensity of use: grasslands, rangelands, pasturelands, and grazing lands. Practitioners and researchers usually distinguish among natural grazing lands (also called rangelands) and improved grazing lands (also called pasturelands) (Allen et al. 2011, Garnett et al. 2017). While the term "grasslands" describes ecological communities that are dominated by grasses, the term "grazing lands" refers to the potential or realized use of grasslands to humans. Rangelands are dominated by natural vegetation whose species composition has not been altered to boost livestock productivity (Allen et al. 2011, Garnett et al. 2017)

---

[1] Though the land occupied for grazing may include multiple non-grazing uses as well, just as grazing may occur in areas not primarily devoted to livestock production.

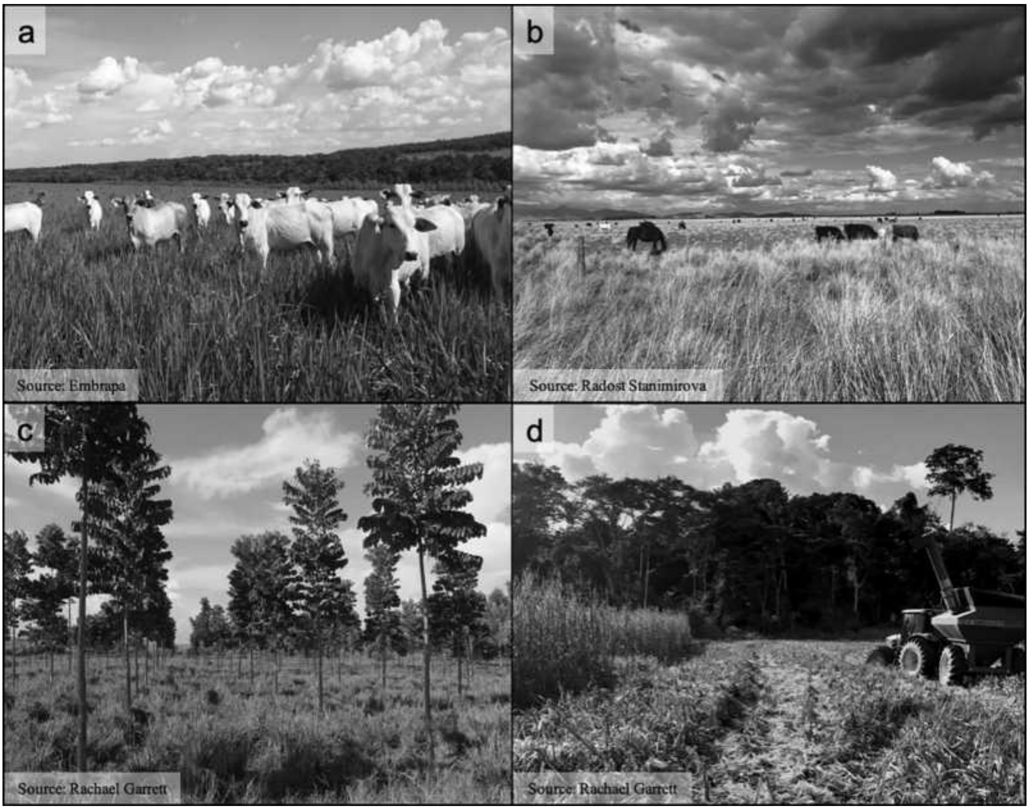

FIGURE 1 Examples of (a) pastureland (i.e., intensively managed planted grassland), (b) rangeland (i.e., extensively managed natural grassland), (c) silvo-pastoral system, and (d) integrated crop-livestock system.

(Figure 1b). Rangelands can be characterized as grasslands, shrub steppe, shrublands, savannas, and deserts that are managed to provision ecosystem services to benefit human well-being. Pasturelands, on the other hand, are more intensively managed by planting nutrient-rich grasses and legumes, or by using fertilizer and other amendments (Allen et al. 2011, Garnett et al. 2017) (Figure 23.1a). Heretofore, we refer to rangelands and pasturelands together as grazing lands or grazing systems.

Ecosystem Services Provided by Grazing Systems

There are four different categories of ecosystem services: provisioning, regulating, supporting, and cultural (MA 2005, Sala et al. 2017). Because grazing systems are heterogeneous, they provide numerous ecosystem services in addition to provisioning feed for livestock, and food and fiber for the world's pastoralists (Sala et al. 2017). In the case of grazing lands, *provisioning services*, which are the products that can be directly harvested and have market value, are freshwater and forage for livestock to produce meat, milk, wool, and leather (Sala and Paruelo 1997, Sala et al. 2017). The main ecosystem *regulating service* in grasslands is soil carbon sequestration. *Supporting services* enable the production of all other ecosystem services such as nutrient cycling, conservation of soils, habitat, and biodiversity (MA 2005, Sala and Paruelo 1997). Lastly, *cultural services*, which are the nonmaterial benefits that humans obtain from grazing lands, include social status, traditional lifestyles, and tourism (Sala et al. 2017). From local-to-global scales, ranchers, commercial entities, and the public sector all benefit from the ecosystem services that are provided by grazing lands.

Provisioning Services

Grasslands are a key feed resource, accounting for close to 50% of feed use in livestock production systems globally (Herrero et al. 2013). While in many parts of the world, grassland provisioning services are directly traded in markets, in other places pastoralists depend on provisioning services for their livelihoods. Specifically, the livestock sector provides income for approximately 1.3 billion people worldwide and food for approximately 800 million food-insecure people (Herrero et al. 2013). Globally, the livestock sector produced approximately 586 million tons of milk, 59 million tons of beef, and 11 million tons of small ruminant meat in 2000 (Herrero et al. 2013). Although most rangeland-based systems occupy less productive lands compared to pasturelands, they provide a key source of livelihood for pastoralists in regions that rely on extensive livestock production. Indeed, rangeland-based systems account for the majority of small ruminant meat production, for local production of beef in Latin America and Oceania, and for small ruminant milk production in sub-Saharan Africa (Herrero et al. 2013).

Regulating Services

Grassland soils contain one-third of the terrestrial soil organic carbon pool because they are geographically extensive and have relatively high per unit area carbon storage (Garnett et al. 2017, White et al. 2000). However, the ability of grasslands to sequester carbon is limited due to variability in many factors (e.g., soil type, nutrient availability) that determine if organic matter is converted to stable belowground carbon. Planting deep-rooted grasses and legumes, adding manure to soils, stimulating forage productivity, and changing the timing and intensity of grazing can potentially increase the rate of soil carbon sequestration (Batjes 2014, Garnett et al. 2017). Good grazing management at the right stocking rate can maintain or even increase soil carbon sequestration by stimulating plant growth, which can lead to an increase in the proportion of organic matter that's partitioned belowground (Batjes 2014, Garnett et al. 2017). Although soil carbon stocks can quickly increase after an improvement in management, especially in degraded grazing lands, the rate of increase progressively declines as the system approaches an equilibrium (Smith 2014). As a result, while managing for land-based carbon sequestration in grazing systems is useful, it only plays a minor role in offsetting greenhouse gas emissions to which the livestock sector itself is a significant contributor.

Supporting Services

Wildlife Habitat and Biodiversity

Maintaining biodiversity in grazing systems is key not only to sustaining grassland flora and fauna but also to delivering all other ecosystem services. Managing for grassland structural heterogeneity, for example, can improve forage availability, enhance ecosystem functionality, and increase habitat availability for different plant, insect, bird, and mammal species (Fuhlendorf et al. 2006, 2017, Tews et al. 2004). There are two aspects of biodiversity that appear to be critical for provision of ecosystem services and resilience to environmental change: functional-group diversity and functional-response diversity (Elmqvist et al. 2003, Folke et al. 2004). While functional-group diversity refers to groups of organisms that perform different functions in an ecosystem (i.e., graze, fix nitrogen), functional-response diversity refers to the ability of species from the same functional group to respond differently to environmental change (i.e., rainfall, grazing). Loss of both types of functional diversity can cause dramatic alterations in ecosystem functioning (Chapin 1997, Duffy 2002, Jackson 2001).

Soil Conservation and Nutrient Cycling

Globally, grassland soils are very diverse and their characteristics and functions are critical determinants of the ecosystems services that grazing systems can provide. Grassland soil structure and biogeochemical cycles are controlled by three major functional groups of organisms: vascular plants, biological soil crusts, and soil microbial communities (Evans et al. 2017). In addition, soil biogeochemical cycles (i.e., water, carbon, and nutrients) vary as a function of precipitation, phenology, disturbance regimes, and management practices (Evans et al. 2017). Rangelands, in particular, are a critical component of global biogeochemical cycles because they are globally extensive and sensitive to changes in resource availability caused by ecosystem drivers (Donohue et al. 2013, Poulter et al. 2014). In grazing lands, the quality and productivity of forage and, in turn, livestock are determined by the efficiency of these nutrient cycles. Managing these ecosystems for soil conservation and nutrient cycling involves controlling livestock density to minimize soil compaction and overgrazing, maintaining plant diversity, planting legumes, and incorporating manure and fertilizers to the soil according to a comprehensive nutrient management plan (Bellows 2001).

Cultural Services

While the provisioning, regulating, and supporting services that grazing lands provide often translate into material benefits to farmers (i.e., food and income), many land use choices are driven by the nonmaterial benefits these systems provide (Garrett et al. 2017). The degree to which different nonmaterial outcomes result in improved well-being is related to cultural preferences. Many farmers choose grazing systems as a livelihood due to the low and less seasonal labor demands relative to most systems of crop production (Hecht 1993, Muchagata and Brown 2003), a desire to pursue a lifestyle independent of markets and governments (Skaggs 2008, van der Ploeg 2010) and as a status symbol (Hoelle 2011, Walker et al. 2000). For example, the persistence of low-income cattle ranching in the Brazilian Amazon and Cerrado has been linked to its cultural importance as a source of social status and a tranquil lifestyle (Garrett et al. 2017, Wilcox 2017). Grazing lands and the biodiversity they harbor also provide aesthetic and spiritual values, including a sense of place, to both inhabitants and visitors (Knight 2002). These cultural values are reflected in the value of tourism activities and land prices, which often exceed the income provided by livestock rearing (Skaggs 2008).

It is important to note that while grassland ecosystems provide cultural services, cultural traditions also shape ecosystem services by determining land use diversity and intensity. In the Swiss Alps, for example, Romanic, German, and Walser villages exhibit very different land use configurations resulting in different levels of plant diversity within similar types of grazing systems (Maurer et al. 2006). Among Old Order Amish farmers in the United States, cultural preferences toward autonomy, social controls on the introduction of new technologies (e.g., synthetic inputs, heavy machinery), and a refusal of government assistance, such as subsidized insurance (Stinner et al. 1989), have helped protect grazing systems within increasingly homogenized cropland landscapes (Garrett In Review, Parker 2013).

Management of Grazing Systems

Climate is a major driver of ecosystem structure and function in grasslands, with near-term precipitation being the dominant climatic control and antecedent precipitation being secondary (Knapp and Smith 2001, Sala et al. 2012, Wu et al. 2015). As a result, the timing and amount of precipitation are key factors that limit soil moisture availability and annual vegetation productivity, and subsequently constrain grazing livestock density (Sala et al. 2012, Sloat et al. 2018, Wilcox et al. 2017). Changes in water availability due to drought, for example, have negative impacts on the provision of grassland ecosystem services, with especially profound response in soils where microbial activity, nutrient availability, and soil carbon sequestration depend on soil moisture (Evans et al. 2017).

In addition to climate variability, vegetation dynamics and productivity in *rangelands* (i.e., *extensively managed systems*) are also driven by livestock density (Briske et al. 2003, Ellis and Swift 1988, Gaitán et al. 2014, Sala et al. 2012, Wilcox et al. 2017). Specifically, while grazing primarily affects the long-term structure and composition of rangelands, precipitation variability primarily affects yearly plant production and forage availability (Briske et al. 2003, Ellis and Swift 1988, Fernandez-Gimenez and Allen-Diaz

1999). In many regions of the world, continuous, unconstrained grazing (i.e., overgrazing) on rangelands with already poor soils or in climates with long dry seasons has led to degradation (decreased water infiltration and surface organic material leading to a loss of soil structure, nutrients, and water availability, and encroachment by invasive species) (King and Hobbs 2006, Perkins and Thomas 1993). Recent sustainable rangeland management approaches have focused on reversing land degradation and restoring overgrazed ecosystems (Bestelmeyer et al. 2012, Briske et al. 2008). Specifically, resilience-based rangeland management aims to maintain desirable ecological states (i.e., grasslands) in order to avoid ecological thresholds that lead to less desirable ecological states (i.e., desert shrubland) (Bestelmeyer et al. 2012, Briske et al. 2008, Elmqvist et al. 2003).

In *pasturelands* (i.e., *intensively managed systems*), climate is also a major driver of productivity. Yet, human interventions such as irrigation, rotational grazing (frequently moving cattle through smaller paddocks to avoid grazing beyond an optimal threshold), applying soil correctives and fertilizer, and intercropping leguminous plant species (e.g., forage peanut) are mechanisms that can outweigh climatic effects on grass productivity while also improving animal nutrition (Condron et al. 2014, Nobilly and Bryant 2013, Valentim and Andrade 2005). Grazing duration and intensity can also be managed to optimize productivity and economic returns. Other important improved grassland systems include integrated crop-livestock systems (planted pastures that are rotated with cropland) (Figure 1d) and silvo-pastoral systems (planted or natural pastures that are intercropped with tree species) (Figure 1c). These systems rely on synergies between the cropland, tree, and grazing land uses to increase nutrient availability and improve soil structure when livestock are kept at low to moderate grazing intensities (Carvalho et al. 2014, Lemaire et al. 2014, Ryschawy et al. 2017). These synergies can reduce needs for external inputs while maintaining or increasing productivity and profitability (Garrett et al. 2017, Gil et al. 2018, Schiere et al. 2002). While mixed and integrated crop-livestock production systems are common in sub-Saharan Africa and Southeast Asia (Robinson et al. 2011), they remain very rare in the Global North and other important grazing regions (Garrett et al. In Review).

Collectively, these management decisions can substantially increase the amount of forage produced, as well as the number of cattle that can be supported, while decreasing the amount of time it takes the cattle to achieve slaughter weight. In Brazil, for example, existing ranching management practices in Brazilian Cerrado are highly extensive, and the current productivity of these pastures is only 32%–34% of its potential (Strassburg et al. 2014). Studies have shown that introducing rotational grazing can double the amount of protein produced per hectare, while integrated crop and livestock systems can increase the amount of protein produced by nearly 700% (Gil et al. 2018).

Traditional approaches to grazing system management have focused on the provision of food and fiber but have often been inadequate in guiding the provision of other ecosystem goods and services (Sala et al. 2017). For example, despite management efforts, rangelands have remained vulnerable to accelerated soil degradation, which impairs their ability to provide both regulating and supporting ecosystem services (Sala et al. 2017). At different temporal and spatial scales, climate variability, land degradation, and the feedbacks between these two processes can reduce the ability of grazing systems to maintain ecosystem services.

Challenges in Grazing Systems

Quantifying the susceptibility of grazing systems to climate variability and land degradation is critical for anticipating grassland feed shortages and for monitoring regions that are vulnerable to desertification and woody encroachment. However, modeling the response of these ecosystems to climate variation, for example, is challenging because they are actively grazed by livestock and managed by humans, which means that their dynamics are influenced by grazing, soil amendments, and precipitation at multiple spatial and temporal scales. The interacting dynamics of climate variability, land degradation, and management shape the demand and provision of ecosystems services of grazing social-ecological systems (Figure 2).

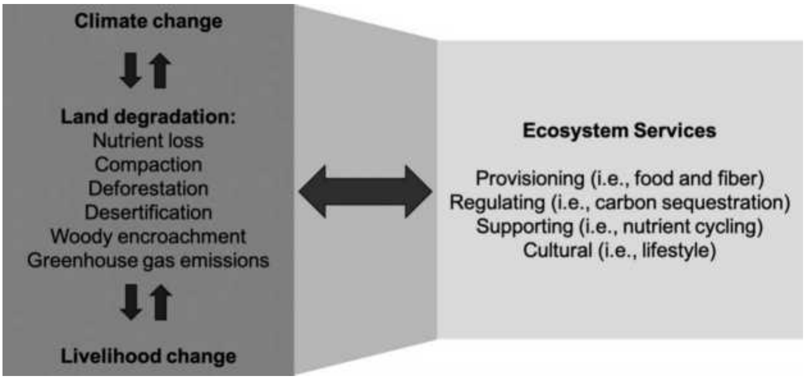

FIGURE 2 Generalized diagram of ecosystem services and challenges in grazing social-ecological systems. Humans and the environment interact to shape the demand and provision of ecosystem goods and services.

Climate Change

In the coming decades, the responses of ecosystem processes to changes in the frequency and intensity of drought are likely to be exacerbated by rising temperatures (Huang et al. 2016, Polley et al. 2017). Recent studies suggest that up to 66% of global land areas are experiencing drying, and precipitation events in arid and semi-arid regions are forecast to become shorter, less frequent, and less widespread (Huang et al. 2016, Reeves et al. 2014). When combined with overgrazing, a warmer and drier climate can ultimately result in decreased productivity and directional shifts in the cover and composition of plant communities in grazing systems (Polley et al. 2017). If realized, then these changes pose a significant threat to the sustainability of these systems, especially in arid and semi-arid regions.

Desertification

Twenty to thirty-five percent of the world's pastures are in poor condition and show signs of degradation, especially when compared to natural grasslands (non-pasture) where direct human impacts are limited (Conant 2010, Garnett et al. 2017). Dryland ecosystems are especially vulnerable to degradation due to multiple biophysical and social stressors that exert pressure at different temporal and spatial scales: climate, land use, economic and institutional factors, national policies, and population growth (Geist and Lambin 2004, Reynolds et al. 2007). When degradation is characterized by severe reductions in biological activity and by a persistent state change, a regime shift, it is also known as desertification. Desertification often happens when poor management practices such as depletion of water resources and overgrazing are compounded by exploitative and distant economic and political systems (Bestelmeyer et al. 2015, Reynolds et al. 2007). Most dryland livelihoods depend closely on highly variable biophysical drivers such as precipitation, which means that there is great uncertainty in detecting thresholds of state change and maintaining the sustainability and future of these social-ecological systems.

Woody Encroachment

In drylands, woody encroachment is often an example of desertification because continuous grass cover is replaced by patchy vegetation cover with increased proportion of bare soils, which leads to increased water and wind erosion, and nutrient loss for the soil in plant interspaces (Barger et al. 2011, D'Odorico et al. 2012, Evans et al. 2017). Encroachment is likely to result in degradation of value for cattle and sheep production, but does not necessarily result in degradation of structural and functional capacities of the ecosystem (Eldridge et al. 2011). The drivers of woody encroachment are complex and vary greatly by region and ecological zone but often reflect an interaction among climate (i.e., intensity and frequency of precipitation), land use (i.e., grazing), atmospheric chemistry (i.e., CO_2 concentrations), soil properties (i.e., texture and depth), and disturbance regimes (i.e., fire frequency and intensity) (Archer et al. 2017, Briggs et al. 2005). Robust generalizations about the importance of the different drivers remain unavailable due to context-dependent factors that co-occur and interact to promote or constrain woody cover (Archer et al. 2017, D'Odorico et al. 2012). In the past few decades, brush management of woody encroachment has focused on reversing the directional shifts in vegetation with the goal of improving livestock production (Archer et al. 2017).

Poverty and Food Insecurity

Grazing systems are the most common forms of agricultural production in the developing world, in terms of both the total land area and the number of people supported (Herrero et al. 2012). In Africa, for example, livestock production systems cover 73% of the land area (Thornton 2014). Since livestock provides a critical source of income and food in livestock-dependent communities, interactions between land degradation and climate change that reduce grazing land productivity are an existential threat to many of the world's poor (HLPE 2012). There are various adaptation strategies that can help reduce livestock-dependent communities' vulnerability to climate change, including improved grazing, soil, and nutrient management (Thornton 2014). Yet, existing institutional and household asset constraints typically limit farmers' abilities to pursue these activities and lock farmers into the extensive practices that contributed to land degradation in the first place. These social-ecological dynamics create what are known as "resource degradation poverty traps", whereby human behaviors erode natural capital and reduce land productivity, food production, and income, leading to further constraints on the range of behaviors possible, further degradation, and greater poverty (Barrett 2008).

Nutrient Loss due to Runoff, Leaching, and Erosion

In grasslands, rainwater and snowmelt can remove nutrients from soils via runoff, leaching, and erosion (Bellows 2001). Runoff and erosion transport either dissolved nutrients or nutrients attached to soil particles over the soil surface to streams, rivers, and lakes. Leaching, on the other hand, is the downward transport of dissolved nutrients through the soil profile, out of reach of plant roots, and into groundwater (Bellows 2001). Leaching is more likely to happen when the number of cattle herd exceeds the assimilative capacity of the land (Billota et al. 2007). All three processes are detrimental to livestock production and environment health because they deplete nutrients that could be used for forage production and contaminate water bodies (Bellows 2001). High nitrate levels in drinking water can cause health problems for animal and human infants, while high phosphorous levels in streams and lakes can lead to eutrophication.

Maintaining adequate livestock density, planting deep-rooted and prostrate vegetation, and keeping plant residue cover can enhance water infiltration and provide good protection against nutrient loss (Bellows 2001, Billota et al. 2007). In addition, maintaining a healthy and diverse population of soil organisms helps incorporate nutrients into soil, reducing the risk of runoff, leaching, and erosion. Finally, protection of riparian areas surrounding streams and rivers is essential to minimizing broader ecosystem pollution (Dosskey et al. 2010, Osborne and Kovacic 1993).

Compaction

Soil compaction reduces the ability of nutrients, water, and roots to move through the soil (Bellows 2001). Soil compaction is caused by animals or equipment continuously moving across the soil, pressing down on the soil, and squeezing soil pore spaces together. The likelihood of compaction increases as soil moisture, animal weight, animal numbers, and the duration of grazing increase (Billota et al. 2007). Soil compaction makes vegetation susceptible to disease, restricts root growth, reduces nutrient availability for plant uptake, increases the potential for runoff and erosion, and reduces forage yields (Bellows 2001).

The likelihood of compaction can be reduced by (i) maintaining a diverse population of soil organisms that burrow in the soil and form soil aggregates, (ii) not grazing animals on wet or poorly drained soils, and (iii) decreasing the number of animals and/or the time they spend in each paddock (Bellows 2001).

Greenhouse Gas Emissions and Deforestation

Regardless of whether they are "conventional" or grass fed, most ruminants spend a majority of their life grazing and a relatively short period at the end of their life in a forage or feed-based finishing system. Consequently, a majority of their emissions from digestion (i.e., enteric fermentation) are associated with grazing. For example, a study in Alberta, Canada, found that across the entire cattle production life cycle, the reproduction and grazing period associated with calf–cow production contributed 80% of the greenhouse gas emissions for each finished steer (Beauchemin et al. 2010). Consequently, these authors recommend that interventions to reduce the greenhouse gas footprint of beef production from enteric fermentation should focus on improving forage quality within cow–calf grazing systems. Conversely, extending the amount of time that cattle spend grazing, i.e., in fully grass-fed systems, would substantially increase the amount of greenhouse gas emissions associated with beef production (Hayek and Garrett 2018).

Grazing on lower productivity rangelands and grasslands, including degraded systems, lowers animal weight gain. The longer it takes to raise a ruminant for slaughter, the more methane it will produce over its lifetime as part of its normal digestive processes. Land degradation can also contribute to greater greenhouse gas emissions via deforestation. When lands become degraded, they may be abandoned, leading farmers to clear new land that has more fertile soil (Balbino et al. 2011, Dias-Filho 2014, Walker et al. 2000). This is a major sustainability challenge throughout much of Latin America. In the Brazilian Amazon, for example, pastures accounted for 59% of the cleared forest area in 2012 and 22% of these areas were in some degree of degradation (INPE 2012). Improved pasture management, including better grass varieties, rotational grazing, and integrated systems, can reduce deforestation and spare land for biodiversity by increasing production on existing cleared lands (Cohn et al. 2014, Gil et al. 2018, Strassburg et al. 2014). Since land cover change is one of the leading sources of greenhouse gas emissions (Houghton et al. 2012), improved pasture management can be an effective way to mitigate climate change (Strassburg et al. 2014), so long as it is coupled with stringent conservation policies (Garrett et al. 2018).

Major Knowledge Gaps in Grazing Systems

Despite the fact that livestock grazing is the largest land use activity on the planet (Erb et al. 2017, Herrero et al. 2013) and that it is important in tackling climate change and improving food security, quantitative global analyses of the spatial patterns, and dynamics of grazing are rare (Erb et al. 2017, Kuemmerle et al. 2013). While there is some knowledge on the biogeochemical and biophysical aspects of livestock management, there is a lack of robust global datasets on the extent and intensity of grazing systems and associated management practices (Erb et al. 2017). Spatially explicit, consistent, and comprehensive global grazing data are crucial for doing social-ecological research. Data gaps are largest in developing countries, which are currently experiencing rapid land use change that is likely to accelerate in the coming decades.

Aside from spatially explicit information on grazing area and management and associated biomass production and use, there are many additional knowledge gaps related to fundamental processes and outcomes in grazing social-ecological systems. Very little is known about animal outcomes, including welfare, behavior, genetics, reproduction, and health under different management and environmental conditions. While much progress has been made in measuring ecosystem services and livelihood outcomes in grazing systems, there has not been sufficient study of landscape scale outcomes across these two interrelated sets of factors to understand how grazing systems can be improved to achieve more win-wins (and fewer trade-offs). These knowledge gaps become even more prominent when considering the complex ways that climate change may alter both human management and ecological responses in grazing systems. Finally, greater social research is needed to better understand the multiple livelihood and community uses and resulting social values of grazing systems.

Conclusions

Grazing systems are extensive and heterogeneous; they provide numerous ecosystem services in addition to provisioning feed for livestock, including carbon sequestration, habitat for diverse species, regulation of biogeochemical cycles, and maintenance of traditional lifestyles. While livestock rearing has important cultural significance and provides income and nutrition in areas that cannot support any other livelihoods, the livestock production sector poses some challenges to the sustainability of our planet as a result of deforestation, habitat and land degradation, water pollution, and greenhouse gas emissions. Ensuring food security, satisfying increased demand for meat and dairy, and protecting grassland ecosystems in an era of climate change are significant scientific and societal challenges. Given the complex and multi-dimensional social-ecological processes that shape grazing systems, there is an urgent need to improve our understating of the biophysical and biogeochemical aspects, and spatially explicit dynamics of grazing in order to devise and apply sustainable management practices.

Salt-Affected Soils: Physical Properties and Behavior

Hwat Bing So

Introduction

Apart from gravel and stones, soils consist largely of a mixture of sand, silt, and clay particles, held together as aggregates by organic matter, iron-aluminum oxides, and/ or electrostatic forces between clay particles mediated by the cations adsorbed on the negative charges of the clay surfaces. The proportion of sand, silt, and clay particles is referred to as the texture of the soil, which imparts certain fundamental properties onto the soil, e.g., a sandy soil behaves quite differently from a clayey soil. These particles are generally organized as compound aggregates and the arrangement of these aggregates and particles is known as the structure of the soil, which modifies and imposes properties other than those resulting from its texture, e.g., a well-structured or -aggregated clay soil will hold water well but will also transmit water and drain readily, while a poorly aggregated clay soil of the same texture will drain slowly and tends to waterlog following rainfall as water content remains above field capacity (upper limit of the non-limiting water range) for excessively long periods.

As part of the soil structure, soil particles and aggregates are generally arranged in a hierarchical order, where the lower orders tend to have higher densities and greater internal strength than the higher orders.[1,2] At the lowest order, clay particles (<2 microns) tend to form clay domains (packets of parallel clay sheets of around 5–7 sheets). Several domains form clusters, followed by several orders of clusters, microaggregates (approximately 20–250 microns), and macroaggregates or clods as the highest order. Only the larger microaggregates and macroaggregates are visible to the naked eye. The hierarchical nature implies that destruction of a lower order will result in the destruction of all higher orders, and therefore, the stability of these clay domains are fundamental in determining the stability of the aggregates and, hence, soil structure, except where the bonding at the higher orders are extremely

strong. The higher orders are physically held together by organic matter and/or iron-aluminum oxides, while the lower orders and domains are predominantly held together by electrostatic forces between clay particles (flocculation). The breakdown of the higher orders (macro- to microaggregates) is defined as slaking, while the breakdown of the lower orders (microaggregates to individual clay particles or domains) is termed dispersion (see Figure 1).

Good structural stability is essential for a biologically productive soil, to maintain adequate transmission and supply of water, adequate drainage and aeration, and adequate chemical fertility in terms of cations adsorbed on the clay surfaces. Roots must be able to grow through the soil to access water, nutrients, and oxygen, and this can occur only in soils with sufficiently large pores and low mechanical resistance, such as found in structurally stable soils.

Cations such as sodium, potassium, calcium, magnesium, aluminum, and hydrogen are commonly found in the soil as adsorbed or exchangeable cations on the surfaces of the colloidal clay particles. In alkaline soils, the first four are the predominant cations, while in acid soils, hydrogen and aluminum become increasingly dominant as the acidity increases or the pH decreases. By virtue of their small ionic radius and/or their high valency, calcium, aluminum, and hydrogen tend to impart high stability onto the aggregates as the clay domains remain stable and clay particles remain flocculated. Sodium and potassium, due to their large ionic radii and low valency, tend to cause clays to swell and disperse, which leads to various problems that can potentially limit plant growth. An exception occurs with Potassium fixation on some clay minerals, where potassium act as a very strong bonding agent. Despite being divalent, magnesium tends to have a higher ionic radius than calcium and tends to have an adverse effect on dispersion, particularly in combination with high sodium concentration.

In most soils, sodium is present only in small quantities in the soil, and these soils generally exhibit good aggregate stability. However, when the exchangeable sodium in the soil is present in sufficiently high quantities, it disperses a proportion of the clay domains, producing sufficient quantities of dispersed clay to block the soil's transmission pores to the extent that it affects other soil properties that limit plant growth, and the soil is then considered to be sodic.[3] Thus, sodic soils are also equated with dispersive soils, although dispersive soils are not necessarily sodic.

Sodic soils are found in every continent (Table 1).[3,4] High concentrations of sodium in the soil are generally associated with the presence of sodium salt in the soil or groundwater, in particular under arid or semiarid climatic conditions and sometimes under humid conditions.[5] High evaporative demand in combination with limited rainfall tends to concentrate sodium salts in the surface soil, which gives rise to high exchangeable sodium on the clay and colloidal fractions in the surface soil. Therefore, sodic soils are generally considered as a subset of saline soils.[3] It is a natural feature of particular soil types,

TABLE 1 Global Distribution of Sodic Soils

Continent	Estimated Area[a] (Million ha)	Land Area[b] (Million ha)	% of Land Area
North America	9.6	2,425.6	0.4

but it may also be a consequence of human activities, such as irrigation practices and clearing of native vegetation on the upper slopes. Both activities give rise to increasing salinity associated with rising saline water tables and commonly referred to as secondary salinity. As irrigation practices are expanding globally to feed the growing population, and some with poor-quality water, secondary salinity and sodicity are becoming increasingly important as a production constraint. In Australia alone, approximately 2.5 million ha of arable land are affected by secondary salinity, costing an estimated $200 million in lost production annually.[6] Although sodic soils are found in every continent, they generally cover small proportions of the total land area, except on the Australian continent, where they occur over approximately 44% of the land area (Table 1).[3,7,8]

Measurement of Sodicity and Definition of Sodic Soil

The sodicity of the soil is most commonly measured as the exchangeable sodium percentage (ESP), which is given as

$$\mathrm{ESP} = 100\left(\text{exchangeable Na/CEC}\right) \tag{1}$$

where the cation exchange capacity (CEC) is generally determined at a reference pH of 7[9] or as the sum of exchangeable cations (Ca+Mg+Na+K) at a pH of 8.2.[10] These methods gave acceptable results for non-saline soils; however, for saline soils, the extraction process will result in dilution of the soil solution and change the ESP. A correction should be made by subtracting the soluble cations from the total extractable cations.[11]

Other less commonly used measures of sodicity are the exchangeable sodium ratio (ESR)[12] and exchangeable sodium content (ES)[13,14] of the soil, which are given as

$$\mathrm{ESR} = \text{exchangeable Na/exchangeable}\left(\mathrm{Ca} + \mathrm{Mg} + \mathrm{K}\right) \tag{2}$$

and

$$\mathrm{ES} = \text{exchangeable Na}\left(\text{cmole}\right)/\text{kg soil.} \tag{3}$$

As sodicity is inextricably linked to salinity, it is also important to define the sodium hazard of the irrigation water or soil solution commonly expressed as sodium adsorption ratio (SAR), which is given as

$$\mathrm{SAR} = \left[\mathrm{Na}\right]/\left(\left[\mathrm{Ca} + \mathrm{Mg}\right]/2\right)^{0.5} \tag{4}$$

where the brackets [ ] denote concentrations in mmol+/L.

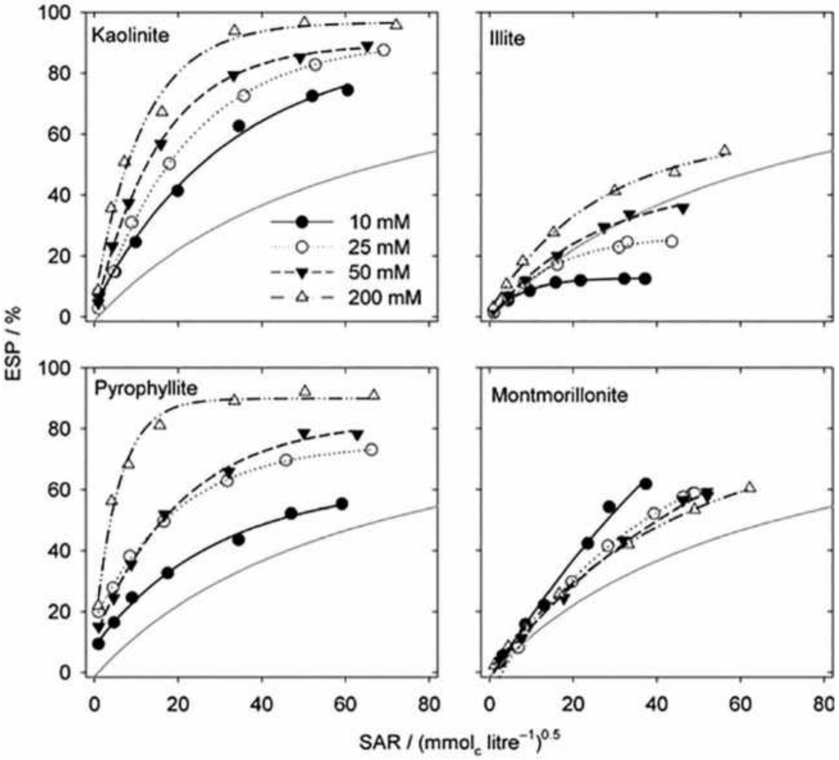

FIGURE 2 Changes in exchangeable sodium percentage (ESP) in four clay minerals (kaolinite, illite, pyrophyllite, and montmorillonite) following equilibration with solutions of various sodium adsorption ratios (SARs; as calculated by analysis of the entrained solution) at various ionic strengths. The solid line without data represents the average relationship for 59 salt-affected soils for the western United States.
Source: Adapted from Kopittke et al.[6]

As exchange reactions take place between the exchange phase and the soil solution, the ESP of the soil can be derived from the SAR of the soil solution as saturated paste, a 1:5 soil solution extract,[15] or irrigation water. The ESP–SAR relationship for all soils used to be assumed constant for all soils based on the soils of the Western United States,[12] but in reality, it is dependent on the clay mineralogy and the ionic strength, as shown in laboratory studies (Figure 2).[6]

In the selection of an appropriate parameter for sodicity, it should be noted that ESP is a parameter associated with the active clay and colloidal fraction of the soil and is useful when relating this parameter to other properties of that fraction, such as the dispersion ratio of clay (DRC), while ES is a bulk soil parameter and will be more suitable when we are concerned with bulk soil properties, such as dispersible clay content (DC) and hydraulic conductivity (K). The effect of increasing sodium on the amount of dispersed clay in 128 vertisols from the Darling Downs in Queensland, Australia, is shown in Figure 3.[13,16] Although it is common to relate sodium content as ESP to the amount of dispersed clay as DRC, a much better relationship was obtained for the same dataset when expressed as DC and ES, both expressed as a proportion of the bulk soil. Clearly, sodicity is better expressed as ES, at least for vertisols, and the regression is

$$\mathrm{DC} = 9.15 + 8.67(\mathrm{ES}) \quad \mathrm{R}^2 = 0.71^{***} \tag{5}$$

where *** indicates significance at p<0.001

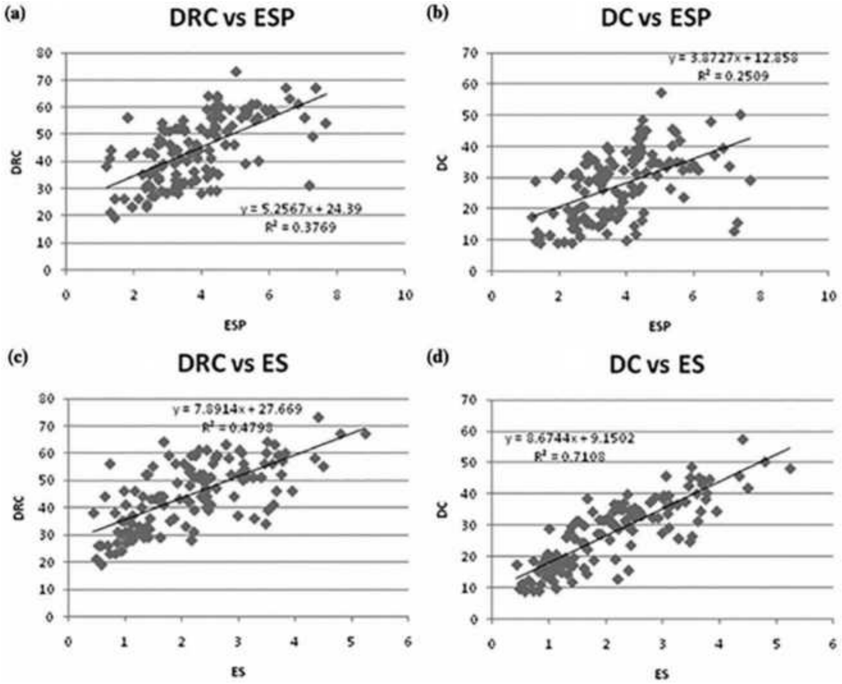

FIGURE 3 The relationship between dispersed clay and exchangeable sodium on 128 soil samples from 2 vertisols from the Darling Downs, Queensland, Australia. Dispersed clay is expressed as (a) dispersion ratio of clay (DRC) vs. exchangeable sodium percentage (ESP); (b) dispersed clay content(DC) vs. ESP; (c) DRC vs. ES; and (d) DC vs. ES.
Source: Adapted from Cook.[13]

For the same soils, DC and ES are strongly related to the soil's hydraulic conductivity, and all are bulk soil properties, while ESP would be a very poor predictor of hydraulic conductivity for these soils (Figure 4). A review of 15 published works to compare the abilities of ESP and ES to explain variation in soil structural stabilities across different soil types concluded that ES is a better index of sodium levels than ESP.[17]

How is a sodic soil defined? Generally, when the exchangeable sodium in the soil is present in sufficient quantities to influence its behavior, the soil is considered to be sodic.[18] However, defining whether a soil is sodic or not implies that there is a threshold ESP where the soil properties change dramatically. Although there is some evidence that this concept may apply in the laboratory,[19] the majority of work in the laboratory and in the field shows that there is little evidence of a threshold ESP and that sodium exerts a progressively increasing influence as ESP increases, as shown in Figure 4. However there is a need to develop a criterion to assist in the classification of soil as sodic if the probability of detrimental effects of sodicity is sufficiently high. The United States Salinity Laboratory (USSL) determined this criterion as an ESP of 15,[12] while in Australia,[20] the criterion is an ESP of 6 (highly sodic when the ESP reaches 15 or higher). Differences between the two criteria are due to the electrolyte levels of the water used at the time for deriving the ESP of the soils. The tapwater used in Riverside, California, United States, had a concentration of 3–10 mmol/L, while in Adelaide, Australia, the tapwater used at the time had a concentration of 0.7 mmol/L.[15,21,22] Furthermore, the Australian opinion was based on experience with many clay soils, whereas the U.S. experience was based on soils with textures lighter than sandy loam.[23] This again illustrates the strong interaction between clay type, electrolyte concentrations (or salinity in its extreme) and sodium levels, and this interaction is an important factor in the management of sodic soils.[24,25]

Chemistry of the Clay–Cation Interaction and Its Effect on Swelling and Dispersion

In the soil, cations are attracted onto the negative clay surfaces, resulting in a diffuse double layer (DDL) where the cation concentrations near the surface are higher than in the bulk soil solution.[15,26,27] Conversely, the concentrations of anions near the clay surface are lower than in the bulk solution. The net positive charge of the DDL counteracts the net negative charge of the clay surfaces, thereby maintaining electro-neutrality of the system. The thickness of the DDL represents the hydration layer of the clay surface and is strongly affected by the valency of the cations in the DDL and the ionic concentration of the bulk solution. The DDL determines the degree of swelling and whether the clay domains disperse or remain flocculated. The DDL tends to be expanded with low-valency cations such as Na or K and/or low ionic concentration of the bulk solution. On the other hand, it tends to be compressed with high-valency cations such as Ca, Mg, and Al and/or high ionic concentrations in the bulk solution.

In homoionic montmorillonitic clay systems, Ca-clay systems exhibit limited swelling, with a maximum water content of 0.8 cm^3/g, and remain flocculated. Na-clay swells considerably more than Ca-clay (Figure 5), and this is shown by the very high water content (>1 cm^3/g) at a pF of 1 and a solution concentration of 0.01 mol NaCl/L or less, which is approximately similar to normal soil solution concentrations.[18,28] Swelling in Na-clay increases rapidly as the electrolyte concentration decreases and clay particles become detached from each other and exhibit spontaneous dispersion. Figure 5 shows clearly the combined effect of the valency of the dominant cation and the electrolyte concentration of the soil solution on the swelling and dispersion of the clay particles. In summary, high Sodium and low EC represent excessive swelling and dispersion, while high Ca and high EC represent limited swelling and flocculation.

In field soils, the clay fraction is associated with a mixture of cations, which is generally dominated by Ca and Mg, with a smaller complement of Na and K ions, and Al ions in acid soils with a pH less

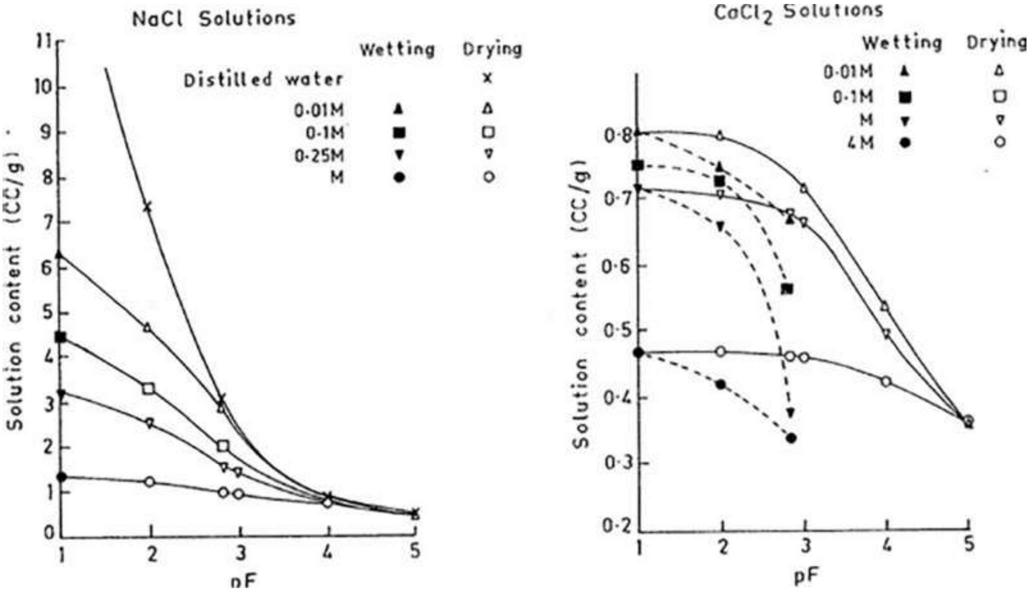

FIGURE 5 Swelling of Na and Ca montmorillonite clay, as a function of solution content and water potential expressed as pF.
Source: Adapted from Aylmore and Quirk.[28]

than 5.5. The principal effect of a high proportion of sodium in field soils is the swelling of some of the clay fraction following wetting associated with the hydration of the Sodium ions, which leads to slaking of the aggregates and dispersion of a proportion of the clay size fraction. These dispersed materials are effective in the blockage of pores, leading to a reduction in transmission pores (>15 µm corresponding to field capacity), which in turn affects the hydrologic and mechanical properties and behavior of the soil.[2] The severity of the effect of dispersion is partly dependent on the clay content of the soil; a small percentage of dispersion can result in large decreases in soil's hydraulic conductivity.[29] At lower clay contents (<30%), the soil matrix is sandy with inherently large transmission pores and high hydraulic conductivities. In contrast, soils with higher clay contents (>30%) have a clayey matrix, and the number of transmission pores is determined by the degree of structural development. The same degree of dispersion tends to have a greater effect on soils with a clayey matrix compared with soils with a sandy matrix.

The combined effect of electrolyte concentration and sodium on clay dispersion and hydraulic conductivity was first established by Quirk and Schofield[24] on illite dominated soils. They used the reduction in hydraulic conductivity to separate soils that are unstable and likely to be affected by dispersion from soils that are stable. This was later refined using actual dispersion measurements and resulted in a classification scheme for the illite dominated red-brown earths of southern Australia as shown in Figure 6.[25] This classification used the SAR of a 1:5 soil water extract as a measure of the exchangeable sodium of the soil, as this is strongly related to ESP, and the total cation concentrations (TCCs) in mmol +/ L as the measure of electrolyte concentration. It classifies soils as dispersive soils, potentially dispersive soils, and flocculated soils. The spontaneously dispersive soils have high exchangeable sodium levels and low electrolyte concentrations, except where SAR is less than 3, as these soils do not spontaneously disperse, because its TCC is always above 0.6 mmol+/L and requires a small external energy to disperse. The potentially dispersive soil requires an external energy to disperse the soil, e.g., cultivation or raindrop impact. The flocculated soil does not disperse even with the input of external energy. Similar classification can be developed for other soil types. In Figure 6, the dotted line through SAR 3 was drawn to indicate that in low-sodium soils, dispersion is less likely to be a problem.

Effect of Sodicity on the Soil's Physical Property and Behavior

Sodic soils are structurally unstable, and the effect on the soil's physical property and behavior is shown conceptually in the diagram in Figure 7.

Slaking and dispersion are the fundamental processes of degradation of structurally unstable sodic soils. Slaking alone is generally not adequate to cause deleterious effects (self-mulching vertisols in the virgin state are highly productive soils, (they slake when wetted), but when followed by dispersion, it generally results in a decrease in soil's productivity. It is important to note here that dispersion for class 1 and 2 soils in Figure 6 is strongly affected by an external energy input, such as rapid wetting, cultivation under wet plastic conditions, or raindrop impact. It is also strongly affected by the electrolyte concentration and the sodium–calcium ratio of the soil solution. Rapid wetting (on surface soils under rainfall or irrigation) is a particularly destructive force associated with the rapid release of heat of wetting, which pushes the clay domains apart. However, when wetting is done slowly, the integrity of the domains and aggregates are often maintained, and the soils are able to maintain their transmission pores. Slow wetting occurs in the subsoil, on soil under a reasonably thick mulch or under low-energy/low-output spray irrigation (e.g., fine spray or mist).

In the field, sodicity is most problematic when it occurs on the surface, where the soil is almost always subjected to rapid wetting from rainfall. Sodicity in the subsoil is less of a problem and is much easier to manage, and these subsoils should not be exposed to the surface unless it is ameliorated.

Effect on the Hydrologic Properties and Behavior of Soils

The first and foremost effect of slaking and dispersion is the formation of a surface seal and the subsequent reduction of the soil's hydraulic conductivity (K) associated with blockage of transmission pores between the larger particles or stable aggregates. A small increase in dispersion may result in large

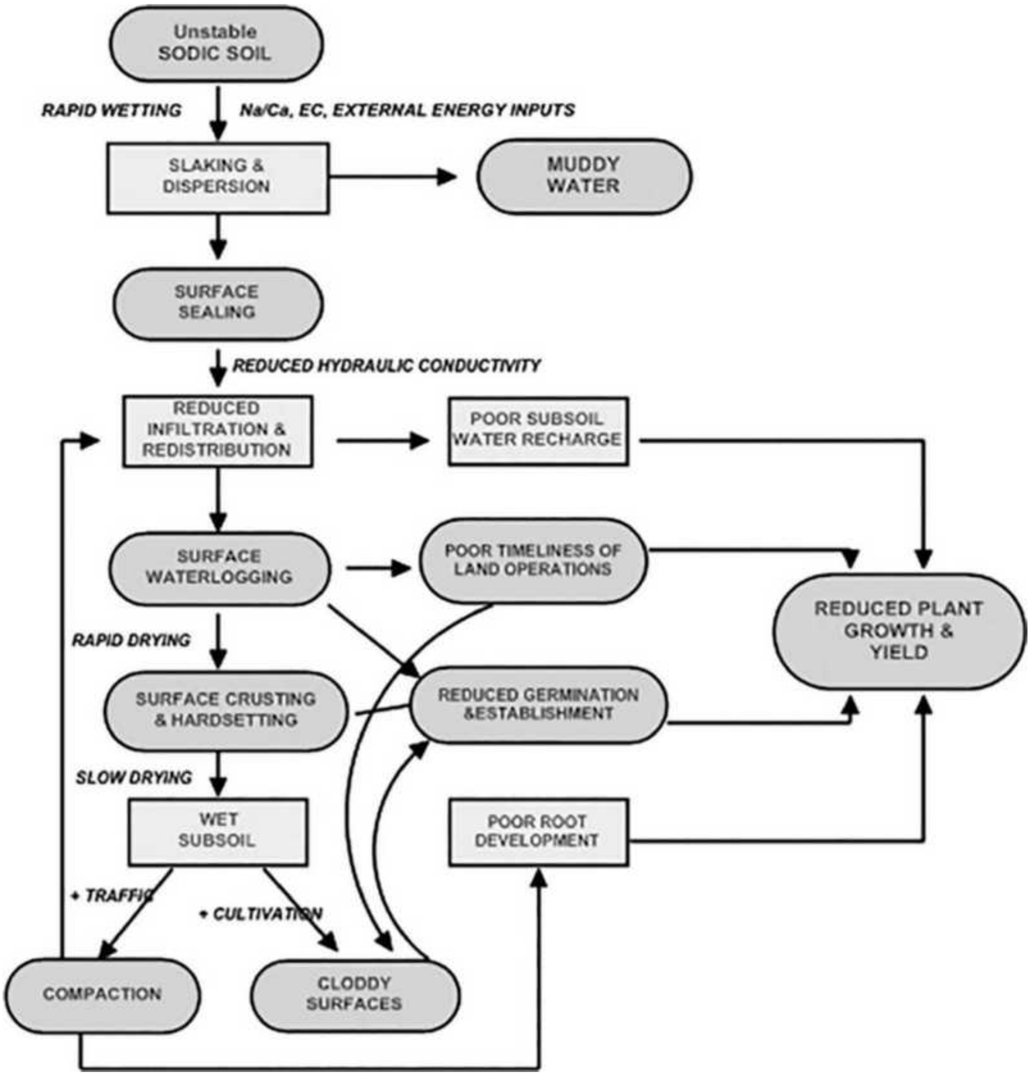

FIGURE 7 Diagram showing how slaking and dispersion associated with excessive sodium results in a range of seemingly independent soil physical problems in the field.
Source: Adapted from So.[2]

decreases in K[16,29] These processes are associated with many soil physical problems observed in the field that affect plant growth or soil behavior, shown in shaded oval shapes in Figure 7.[15,22] Waterlogging, low infiltration, crusting, hardsetting, poor timing of farming operations, and poor germination and seedling establishment are generally perceived as distinctly different problems in the field, but as shown in Figure 7, they have a common cause in slaking and dispersion and can therefore be corrected using the same treatment. This also applies to non-sodic dispersive soils. Hence, an ameliorative treatment applied to reduce or prevent dispersion and to correct one particular problem will also correct many of the other physical problems shown in Figure 7.

The degree of slaking and dispersion can be readily assessed in the field with the Emmerson dispersion test[30] or its modified versions.[31,32] These quick field tests rely on visual assessments and scoring of the degree of slaking and dispersion (Plate 1) of natural aggregates or remolded aggregates in water. Remolding is conducted at field capacity to simulate the application of external energy such as tillage under wet conditions or raindrop impact. The resulting scores from these tests have been successfully related to crop yields.[33,34]

Field assessment of the extend of degradation associated with sodium is generally based on whether there are detrimental effects on the soil's productivity, which is principally affected by the amount of plant-available soil water (ASW) over the crop growing season. The ASW is the difference between water input, controlled by the soil's infiltration rate, and the water output from the root zone, controlled by the drainage rate, and both rates are affected by the soil's hydraulic conductivity. As K decreases, the soil's infiltration and drainage rates also decrease. Hence, as sodicity increases, the recharge of the soil water storage maybe reduced but may initially remain adequate for the requirement of the plants. However, at the critical ESP or above, the reduction in K becomes sufficiently large to reduce the subsoil water recharge (Figure 7) or the amount of available soil water storage such that crop growth becomes affected. Therefore, the critical ESP should vary with the prevailing seasonal rainfall, irrigation, and soil type,[34] but a general relationship between these factors has yet to be quantified. As mentioned earlier, the most common critical level of sodicity used to indicate the probability of such reduction is ESP of 15% in the United States and 6% in Australia.

A reduction in the rate of drainage in sodic soils will increase the probability of surface waterlogging following rainfall or irrigation, which may significantly reduce germination and establishment of seedlings (see Figure 7).

Effect on the Mechanical Properties and Behavior of Soils

Surface waterlogging would reduce soil strength and its ability to support mechanical loads, and therefore, its trafficability is reduced. This increases the time when the soil is in a plastic state and not suitable for tillage; therefore, its workability is also reduced. These two conditions lead to poor timeliness of land operations (Figure 7).

Upon drying, the surface seal forms a crust or a hardsetting surface depending on the texture and structural status of the soil. At this stage, drying would occur at a high rate, and the thickness of the crust will depend on this rate of drying, being thicker the slower the rate of drying. The thickness of the crust will also depend on the size of the dry aggregates.[35] Furthermore, the higher the ESP, the harder is the crust formed, as shown in Figure 8.[18,36] The development of surface crusting leads to a reduction in the evaporation rate, leading to a subsoil below the crust that remains wet for longer periods. When the soil is subjected to traffic under this condition, the load transmitted to this wet subsoil will lead to compaction, while cultivation leads to cloddy surface conditions, which are not conducive to seed germination and establishment. This in turn leads to reduced crop growth and yield.

In contrast, fine sandy or silty soils are dominated by particles that are sufficiently large to have very low or no surface activity and therefore tend to remain as individual particles. On the other hand, they are small enough to block transmission pores. Therefore, soils with a high content of fine sand and silt in the surface horizon are inherently unstable; their aggregates readily slake and disperse throughout this horizon when wet, particularly when they are also sodic. Under wet conditions, these soils are very soft and highly susceptible to deformation and compaction. Because of the low water holding capacity associated with the predominance of coarse particles, these soils rapidly dry to create a hardsetting soil and are sometimes referred to locally as a "Sunday soil," being too wet for cultivation on Saturday and too dry on Monday. As conditions suitable for cultivation are restricted, sodic hardsetting soils tends to give rise to cloddy seedbeds. Cultivation when it is too wet will compress the soils into large clods, while cultivation when it is too dry with a high tensile strength will also result in cloddy seedbeds. Both conditions will require additional cultivation and energy to create a suitable seedbed. In practical terms, this means increased cost of production.

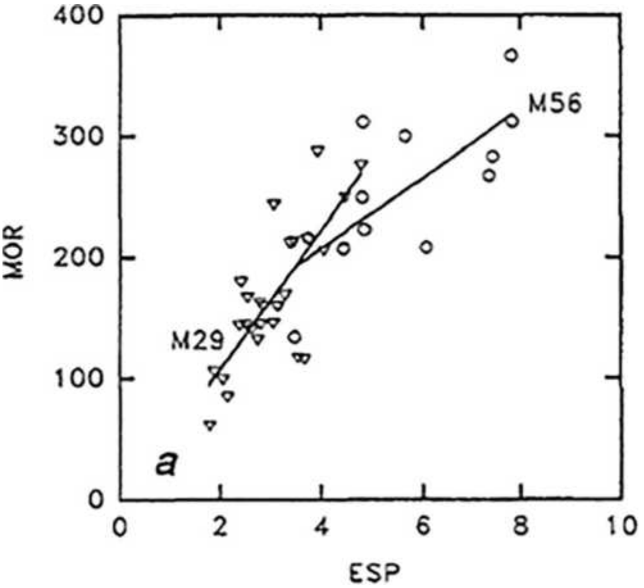

FIGURE 8 Modulus of rupture (MOR), a measure of crust strength, as a function of ESP for two clay soils from Western Australia.
Source: Adapted from So.[2]

High ESPs are associated with lower liquid and plastic limits and would require more energy to cultivate[37] and lead to the perception of a soil with a heavier texture than indicated by its particle size distribution. The use of gypsum to ameliorate the effect high ESP on clay soils increases the ease of tillage due to a reduction in soil strength.[38]

Management of Sodic Soils

The management of sodic soils is fundamentally based on the management of the slaking and dispersion processes in the soil. Table 2 lists a range of management options that have been used in the field to control these processes.

Slaking can be managed at the macroaggregate level by avoiding or minimizing the breakdown of existing bonds (organic matter) through minimizing soil disturbance (zero or minimum tillage practices) and/or through the addition of surface mulch or aggregate bonding materials such as organic matter,[39] polymers [polyvinyl alcohol (PVA), polyacrylamide (PAM)], and calcium carbonates (lime). It can also be achieved by incorporating grasses into the existing crop rotation as grass roots and associated fungal hyphae bind microaggregates into macroaggregates.[40]

On the other hand, dispersion can be managed at the clay domain and microaggregate level by using divalent cations and/or high EC in the soil solution or a combination of the two. The most popular ameliorant used is gypsum ($CaSO_4.2H_2O$), which provides Ca^{2+} and a continuous presence of adequate EC levels associated with its limited solubility (2.2dS/m in water at 25°C). The solubility of gypsum in soils is less than in water[41] and is dependent on the particle size of gypsum. Ca^2+ replaces Na^+ from the clay exchange sites (the exchangeable cation effect), which represents a permanent or residual effect of gypsum. The presence of a high electrolyte concentration where free gypsum is present provides the dominant initial effect of gypsum. It represents the temporary electrolyte effect of gypsum.[41] Lime will provide a similar effect but is a much slower acting ameliorant, while slaked lime is a fastacting soluble ameliorant.

TABLE 2 Strategies for Managing Slaking and Dispersion

Problem	Aggregate Hierarchical Level Affected	Action Required	Management Options
Slaking	Macroaggregates	Prevent breakdown of bonds	1. Zero tillage or minimum tillage 2. Surface mulch 3. Slow wetting during irrigation 4. Reduce droplet energy during spray irrigation
		Increased aggregate bonding and bonding strength	1. Incorporate organic matter 2. PVA 3. PAM 4. Lime or calcium carbonates 5. Introduce grasses in crop rotation
Dispersion	Microaggregates and clay domains	Increase flocculation by replacing monovalent cations with di- or polyvalent cations (exchangeable cation effect)	1. Gypsum application (S or H_2SO_4 application produce $CaSO_4$ in the soil) 2. Lime application (slow response) 3. Slaked lime [$Ca(OH)_2$] application (quick response) 4. $CaCl_2$ application (expensive and mostly confined to laboratory trials)
		Increase flocculation by increasing electrolyte concentrations (temporary electrolyte effect)	1. Gypsum application 2. Slaked lime [$Ca(OH)_2$] application 3. $CaCl_2$ application

Source: Adapted from So.[2]

Conclusion

Sodic soils are generally associated with the presence of high concentrations of sodium salts and considered as a subset of saline soils. The presence of high sodium concentrations may be a natural feature of the landscape but can also be associated with human activities, in particular, clearing of native vegetation on the upper slopes of the landscapes and irrigation. The need for increasing food production to feed the growing population leads to the conversion of marginal lands, including naturally sodic soils, and the introduction of more irrigation with poor-quality water.

The fundamental problem associated with sodic soils has been shown to be related to the basic processes of slaking and dispersion, which in turn may lead to a variety of field problems that affect plant growth and yield, such as crusting and hardsetting, waterlogging, lack of subsoil water, compaction, cloddy surfaces, poor germination, and seedling establishment. Sodic soils can be managed effectively at the macro scale to minimize or prevent slaking through addition of aggregate bonding materials (organic matter, PVA, PAM, lime, or $CaCO_3$) or to slow the process of wetting. Alternatively, it can be managed at the micro scale by targeting the dispersion process with the use of divalent cations in combination with high electrolyte levels (gypsum, slaked lime).

Sodic Soils: Properties

Pichu Rengasamy

Introduction

Sodic soils are those with a high proportion of sodium adsorbed to the soil particles compared to other cations such as Ca, Mg, and K. Exchangeable sodium percentage (ESP) is a criterion used to identify sodic soils. When a soil with high ESP is wetted, the bonds between soil particles are weakened. As a result, the clay particles swell and often become detached and disperse at high water content. This leads to poor physical properties of soils. In classification system developed in U.S.A., a soil with an ESP >15 is considered as "sodic," and in Australia, the criterion is >6. These differences are owing to the influence of several soil factors including salt levels, pH, organic matter, and clay mineralogy on the adverse effects of ESP on soil properties. Sodic soils are widespread in arid and semiarid regions of the world extending up to 30% of the total land area (Table 1). Use of saline water, including waste and effluent waters containing sodium salts, for irrigation induces sodicity in soils. Sodicity is a latent problem in many salt-affected soils where deleterious effects on soil properties are evident only when salts are leached below a threshold level.[2] While soil salinity reduces plant growth, directly affecting physiological functions through osmotic and toxicity effects on plants, sodicity causes deterioration of soil physical properties indirectly affecting plant growth and survival. Sodic soils are subjected to severe structural degradation and exhibit poor soil-water and soil-air relationships; these properties (Table 2) adversely affect root growth, thereby restricting plant production and making it difficult to work in soils when they are wet or dry.

Yield Decline in Sodic Soils

Sodic soils make the paddocks prone to waterlogging, poor crop emergence and establishment, gully erosion, and in some instances tunnel erosion. Because of the heterogeneity in the accumulation of sodium by soil particles, these symptoms may be observed only in certain parts of the paddock. Generally, patchy growth and barren patches are visible in a number of spots in a paddock, while the rest of the field may look normal. However, the effects of sodicity are fully realized in the harvested yield. The actual yield obtained in sodic soils is often less than half of the potential yield expected on the basis of climate,

TABLE 1 World Distribution of Sodic Soils

Continent	Country	Area of Sodic Soils (000 ha)
North America	Canada	6,974
	U.S.A.	2,590
South America	Argentina	53,139
	Bolivia	716
	Brazil	362

particularly rainfall and evapotranspiration.[3,4] Relative yield of cereals grown in dryland sodic soils in Australia in relation to average root zone ESP is given in Figure 1.

Swelling and dispersion of sodic aggregates destroy soil structure, reduce the porosity and permeability of soils, and increase the soil strength even at low suction (i.e., high water content). These adverse conditions restrict water storage and transport. Soils are, therefore, either too wet immediately after rain or too dry within a few days for optimal plant growth. Thus, the range of soil water content that does not limit plant growth and function ("nonlimiting water range") is very small.[5] Dense, slowly permeable sodic subsoils reduce the supplies of water, oxygen, and nutrients needed for obtaining maximum potential yield. During the rainy season, even with prolonged ponding of water on the surface, only a small increase in water content occurs in subsoil. The low porosity leads to slow internal drainage and water redistribution within the profile.[6] This reduction in water storage causes crop water stress during prolonged dry periods. Subsoil as a source of water and nutrients becomes more important in dryland cropping regions than in irrigated soils.

TABLE 2 Physical and Chemical Properties of a Typical Sodic Soil Profile in South Australia

Properties	0–20 cm	20–40 cm	40–100 cm
Chemical properties			
$pH_{1:5}$ (water)	7.9	8.9	9.2
EC_e (dS/m)	0.4	3.8	4.9
Organic carbon (%)	1.2	0.6	0.3

Final infiltration rate in the field (mm/hr)	0.2		

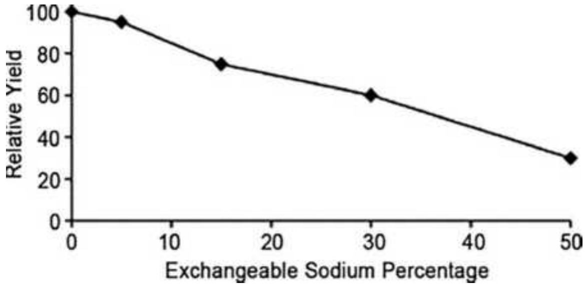

FIGURE 1 Relative yield of cereals grown in Australian sodic soils in relation to average root zone ESP.

Salt Accumulation in Root Zones of Sodic Soils

Soils with sodic subsoils are characterized by moderate to high exchangeable sodium and, in many cases, with high pH (>8.5) where carbonate and bicarbonate minerals are present. Subsoil sodicity restricts drainage beyond the root zone and as a result salts accumulate in this zone. The concentration of accumulated salts fluctuates with rainfall pattern, input of salt from agronomic practices, and soil weathering, as schematically explained in Figure 2. Dryland salinity or “seepage salinity” in many countries is associated with rising saline groundwater tables. However, the extent of subsoil salinity, also called “transient salinity,” not associated with saline groundwater is large in many landscapes dominated by subsoil sodicity. A relationship between rainfall, subsoil ESP, and ECe for northeastern Australian soils has been reported.[7] In dryland regions with annual rainfall between 250 and 600 mm, sodic subsoils have an EC_e between 2 and 20 that can dramatically affect crop production through osmotic effects during dry periods. Laboratory measured EC_e will increase several folds under field conditions as the soil layers dry in between rainy days. The combination of poor water storage and osmotic stress enhance water stress to crops under dryland cropping.

Root Zone Constraints in Dryland Sodic Soils

Multiple problems occur in soils with subsoil sodicity. Soil compaction, crusting, and induration of subsoil layers re quire “physical” reclamation. Sodicity, salt accumulation, and alkaline pH require “chemical” reclamation. All of these conditions cause, in addition to water stress, macro- and micronutrient deficiency, and toxicity owing to Na^+, Cl^-, HCO_3^-, CO_3^{2-}, B, $Al(OH)_4^-$, and others. Low organic matter and biological activity compound these problems encountered in sodic subsoils.

Management of Dryland Sodic Soils

Major criteria in increasing productivity in dryland sodic soil are improved water storage and transport in the root zone and crop water use efficiency. More information is available on agricultural management in sodic soils that is more relevant to irrigated lands.[6] Reclamation procedures involving high costs are prohibitive in dryland regions because of low benefit/cost ratio.

Diagnosis of multiple problems with large variations, vertically and horizontally across the paddock, is primarily important. Gypsum is the most commonly used compound to reclaim sodic soils. Subsoil reclamation may involve higher rates of gypsum application or deep placement of gypsum by deep ripping or deep plowing. Salt-tolerant plant species may alleviate subsoil salinity. Plants that can tolerate ion toxicity such as boron, carbonate, sodium, and chloride have also been identified. Strategies to improve subsoil fertility may include 1) mechanical means of placing nutrients deeper in the profile; 2) using nutrient sources of lower or higher mobility; 3) using deep-rooted legumes to fix nitrogen at depths; and 4) selection of plant species and genotypes better suited to acquiring nutrients from subsoils. Future research is needed on developing plants that modify the rhizosphere and adapt to edaphic conditions. Farming systems should be developed to prevent accumulation of salts and toxic elements in the root zone of sodic soils.

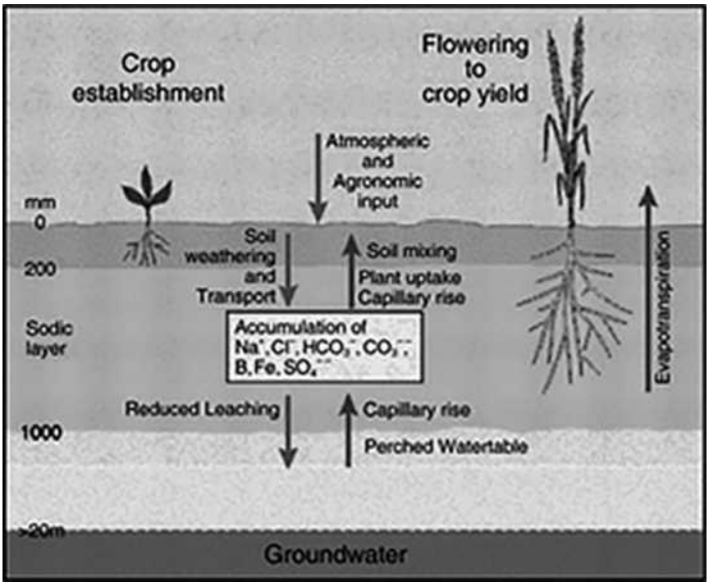

FIGURE 2 Salt accumulation in sodic subsoils.

Conclusions

Soils with a high proportion of exchangeable sodium are considered as sodic soils. On wetting these soils, clay particles swell and disperse degrading soil structure, and on further drying soils become dense. Poor water storage and restricted movement of air and water in soil profile lead to yield decline of many crops. Sodic subsoils cause accumulation of salts in the rootzone. In dryland sodic soils multiple problems such as salinity and toxic elements in addition to sodicity occur making management decisions difficult. Soil amelioration with gypsum and choice of tolerant crops are useful in farming these soils.

Soil Degradation: Global Assessment

Ahmet Çilek,
Suha Berberoğlu,
Erhan Akça, Cenk Dönmez, Mehmet Akif Erdoğan,
Burçak Kapur, and
Selim Kapur

Introduction

One of the major challenges facing humanity in the coming decades is the need to increase food production in limited soil sources to cope with the ever-increasing population, which is indeed the greatest threat for food/soil security.[1] Although estimates on the prevalence on land degradation vary from 1 to 6 billion ha,[2] Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES)[3] reported that the worldwide degraded land is reached to 75% which now threatens 3.2 billion of people well-being in spite of the strict laws enacted for environmental protection. This is an unpalatable but important indicator of high external input dependent on global food, fiber and biofuel production, and a corresponding increase in soil/land damage, reflecting the expensive agricultural production.[4] Global efforts are in an increasing trend for achieving sustainable soil use in the world and the Global Soil Partnership established in 2012 as a mechanism to develop a strong interactive partnership and enhanced collaboration and synergy of efforts between all stakeholders for the protection of the soils against main soil degradation threats.[5] It is based upon the concept of soil multifunctionality and recognizes the various soil functions relevant for global economy and the environment. These functions are under threats of losses in soil organic carbon and soil biodiversity, soil sealing, nutrient imbalance, salinity-alkalinization, and pollution that are severely limiting soil functionality and therefore socioeconomic growth. Soils in the world are recognized as being the result of millennia of human interaction with the landscape and have never been as fragile as today.[6]

Background

Soil can even degrade without actually eroding. It can lose its nutrients and soil biota, and can become damaged by waterlogging and compaction. Erosion is only the most visible part of degradation, where the forces of gravity, water flow, or wind actively remove soil particles. Rather than taking the classical view that soil degradation was, is, and will remain an ongoing process mainly found in countries of the developing world, this phenomenon should be seen as a worldwide process that occurs at different scales and different time frames in different regions.[7] The causes of biophysical and chemical soil degradations are enhanced by socioeconomic interventions, which are the main anthropogenic components of this problem, together with agricultural mismanagement, overgrazing, deforestation, overexploitation, loss of soil organic carbon soil sealing, and pollution as the main reasons for erosion and chemical soil degradation.[5]

Soil degradation, the threat to "soil security," is ubiquitous across the globe in its various forms and at varying magnitudes, depending on the specific demands of people and the inexorably increasing pressures on land. Europe provides many telling examples of the fragile nature of soil security and the destructive consequences of a wide range of soil degradation processes. Asia, Africa, and South and North America are not only partly affected by the non-resilient impacts of soil degradation but also experiencing subtler destruction of soils via political developments, which seek to provide temporary relief and welfare in response to the demands of local populations. Several diverse data sets were used in this research (Table 1). The modeling of land degradation adopted here is based on soil types, water and wind erosion, land cover, terrestrial net primary productivity (NPP), percent tree cover, aridity, and chemical deterioration.

The global *soil map* derived by the United States Department of Agriculture/Natural Resources Conservation Service (USDA-NRCS, Soil Survey Division) was used as one of the inputs in this study. This map was produced in September 2005 and was based on a reclassification of the Food and Agriculture Organization of the United Nations Educational, Scientific and Cultural Organization (FAO-UNESCO) Soil Map of the World combined with a soil climate map. The soil map shows the global distribution of major soil types. The scale of the global soil map is 1:5,000,000.

The global *water erosion vulnerability map* was based on a reclassification of the global soil climate map and global soil map of the USDA-NRCS. The global soil climate map comprises the major biome types at the global scale, which was derived using global land cover maps of the European Space Agency. The global water erosion vulnerability map consisted of four vulnerability classes of the water. These classes were also based on soil climate and soil classification of the USDA-NRCS, Soil Survey Division. This map was produced in 1998 with a scale of 1:5,000,000.

The global *wind erosion vulnerability map* was derived using soil and soil climate maps of the USDA-NRCS, Soil Survey Division. The map was 1:5,000,000 scale and comprised four vulnerability classes.

The global *land cover map* was derived by ESA Climate Change Initiative—Land Cover led by UCLouvain. The land cover map was derived using AVHRR HRPT (1992–1999), SPOT-Vegetation (1999–2012), and PROBA-V (2013–2015) at 1 km spatial resolution, and comprises 22 land cover classes

TABLE 1 The Data Sets Used in the Modeling of Land Degradation

Chemical deterioration map	LADA

defined according to the UN Land Cover Classification System. This set of cover types included 11 categories of natural vegetation covers.[8]

The global NPP map indicated the net amount of carbon from the atmosphere into green plants. NPP is an important ecological variable that measures the energy input to the biosphere and terrestrial carbon dioxide assimilation and shows ecosystem performance. The Global NPP map was gathered from The Oak Ridge National Laboratory Distributed Active Archive Center (ORNL DAAC) for biogeochemical dynamics, which is one of the National Aeronautics and Space Administration-Earth Observing System Data and Information System (NASA-EOSDIS) data centers managed by the Earth Science Data and Information System (ESDIS) Project. This map was derived by using the NASA-CASA (Carnegie Ames Stanford Approach) NPP Model Approach.

The *percent tree cover map* was gathered from the Global Land Cover Facility/University of Maryland. It illustrates the global cover of woody vegetation, on a continuous scale from 0% to 100%. Advanced very high-resolution radiometer (AVHRR) images were used to derive the percent tree cover map at 1 km spatial resolution. The percent tree cover was estimated using the linear regression method. This map comprises three classes, namely, the (1) 10%–80% tree cover, (2) non-vegetated land, and (3) tree cover less than 10%.[9]

The global *aridity index map* was gathered from the -Consultative Group for International Agricultural Research – Consortium for Spatial Information (CGIAR-CSI). Aridity is expressed as a function of precipitation, potential evapo-transpiration (PET), and temperature, and is classified according to the climatic zones proposed by the UNEP.[10] The Aridity Index is used to quantify the precipitation deficit over atmospheric water demand. The Aridity Index map was derived using MODIS images with 1 km spatial resolution. The climate data sets were obtained from the WorldClim data set,[11] and the map was estimated with the following equation:

$$\text{Aridity Index (AI)} = \text{MAP} / \text{MAE},$$

where MAP is the mean annual precipitation and MAE is the mean annual evapotranspiration.

The *chemical deterioration map* was obtained from the Land Degradation Assessment in Drylands (LADA) organization. The chemical deterioration map used in this study comprised four main classes: (1) fertility decline and reduced organic matter content (not by erosion)—leaching, nutrient mining, oxidation, and volatization (N); (2) acidification—decreased soil pH; (3) soil pollution—soil contamination with heavy metals and toxic components; and (4) salinization/alkalinization—a net increase in salt and sodium contents of the (top) soil leading to a productivity decline.

Standardization and weighting of these inputs were the two critical steps while modeling the land degradation within a Geographical Information System (GIS) environment. The inputs were scaled between 0 and 1 in standardization using sigmoidal functions. The fuzzy approach was used in standardization to evaluate the possibility that each pixel belongs to a fuzzy set by evaluating any of a series of fuzzy set membership functions. The sigmoidal, J-shaped, and linear functions were controlled by four points ordered from low to high on the measurement scale. Factor-by-factor weighting was done (i.e., weak NPP will have the higher score and risk than dense NPP areas) following standardization. All factors were evaluated through overlapping each other.

Europe

The major problems concerning the soils of Europe are the quality and quantity loss of soils due to erosion, sealing/urbanization, flooding, loss of fertility due to deep ploughing, removing crop residues, mono-culture, decline in organic carbon and biodiversity along with local and diffuse soil contamination especially in industrial and urban areas, and soil acidification (Figure 1).[12,13] Salinity, although not widely distributed in Europe, is seen in some parts of Western and Eastern Europe,[14] whereas urbanization and construction of infrastructure at the expense of fertile land are widespread in Europe,

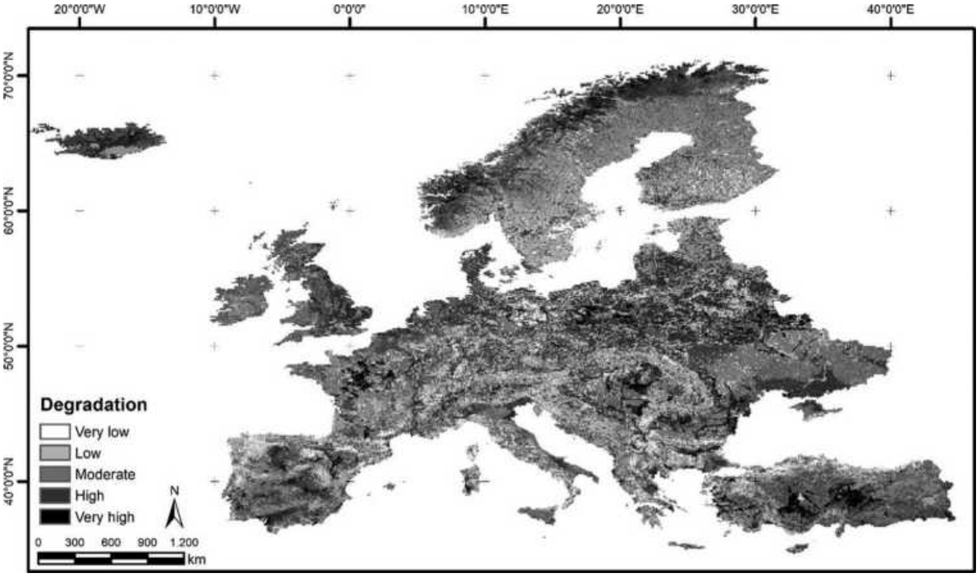

FIGURE 1 Soil degradation map of Europe.

particularly in the Benelux countries, France, Germany, and Switzerland, and such effects are most conspicuously destructive along the misused coasts of Spain, France, Italy, Greece, Turkey, Croatia, and Albania. The EU average soil sealing from 2000 to 2006 was 3%, but this figure raises to approximately 14% in Ireland, Cyprus, and Spain.[15] The drastic increase in the rate of urbanization since the 1980s is now expected to follow the Plan Bleu,[16] which seeks to create beneficial relationships between populations, natural resources, the main elements of the environment, and the major sectors of development in the Mediterranean Basin and to work for sustainable development in the Mediterranean region. The very appropriate term "industrial desertification" remains valid for the once-degraded soils of Eastern Europe, under the pressure of mining and heavy industry, as in the Ukraine where such land occupies 3% of the total land area of the country.[17]

There are three broad zones of "natural" erosion across Europe, including Iceland: (1) the southern zone (the Mediterranean countries); (2) a northern loess zone comprising the Baltic States and part of Russia; and (3) the eastern zone of Slovenia, Croatia, Bosnia-Herzegovina, Romania, Bulgaria, Poland, Hungary, Slovakia, the Czech Republic, and Ukraine (Figure 1). Seasonal rainfalls are responsible for severe erosion due to overgrazing and the shift from traditional crops. Erosion in Southern Europe is an ancient problem and still continues in many places, with marked on-site impacts and with significant decreases in soil productivity as a result of soil thinning. The northern zone of high-quality loess soils displays moderate effects of erosion with less intense precipitation on saturated soils. Local wind erosion on light textured soils is also responsible for the transportation of agricultural chemicals used in the intensive farming systems of the northern zone to adjacent water bodies, along with eroded sediments. The high erodibility of the soils of the eastern zone is exacerbated by the presence of large state-controlled farms that have introduced intensive agriculture at the expense of a decrease in the natural vegetation. Contaminated sediments are also present in this zone, particularly in the vicinity of former industrial operations/deserts, with high rates of erosion in Ukraine (41% of the total land area) and Russia (57% of the total land area) whose agricultural land has been subjected to strong water and wind erosion ever since the beginning of industrialization.[17]

Localized zones of likely soil contamination through the activities of heavy industry are common in northwestern and central Europe as well as Northern Italy, together with more scattered areas of known and likely soil contamination due to the intensive use of agricultural chemicals.[21] Sources of

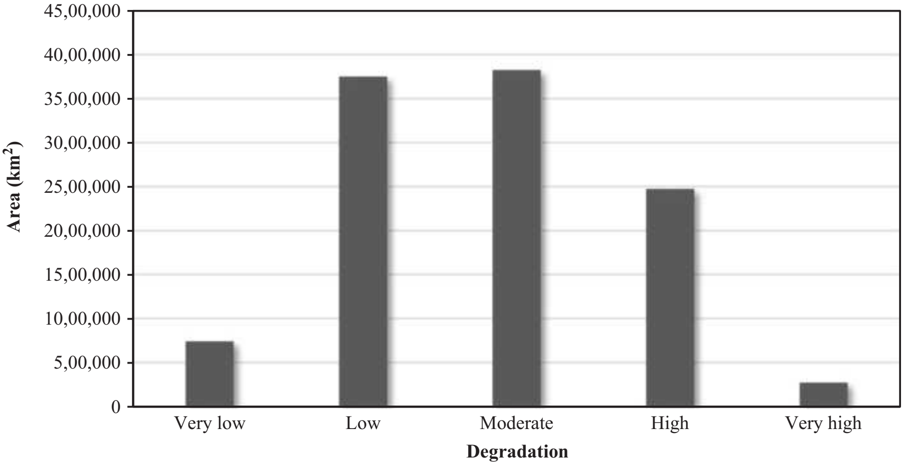

FIGURE 2 Distribution of soil degradation rates in Europe.

contamination are especially abundant in the "hot spots" associated with urban areas and industrial enclaves in the northwestern, southern, and central parts of the continent (Figure 1). Acidification through deposition of windborne industrial effluents and aerosols has been a long-standing problem for the whole of Europe; however, this is not expected to increase much further, especially in Western Europe, as a result of the successful implementation of the emission-control policies over 40 years.[18]

The desertification of parts of Europe has been evident for some decades, and the parameters of the problem are now becoming clear, with current emphasis on monitoring of the environmentally sensitive areas[19] on selected sites, seeking quality indicators for (1) soil, (2) vegetation, (3) climate, and (4) human management throughout the Mediterranean Basin. Apart from the human factor, these indicators are inherent. Nevertheless, the majority of the lands/soils in Europe are under the threat of low and moderate degradation levels as compared with other continents that have suffered extensive and very high degradation, especially through erosion, salinity, and loss of nutrients (Figure 2).

Asia

The most severe aspect of soil degradation on Asian lands has been desertification due to the historical, climatic, and topographic character of this region as well as the political and population pressures created by the conflicts of the past 500 years or so. At least US $10 billion is lost annually as a result of losses resulting from land degradation in India, Pakistan, Bangladesh, Iran, Afghanistan, Nepal, Sri Lanka, and Bhutan. FAO, UNDP, and UNEP estimated that this figure is equal to 2% of the region's Gross Domestic Product, which is about 7% of the value of its agricultural output.[20] Salinization caused by the rapid drop in the level of the Aral Sea and the waterlogging of rangelands in Central Asia due to the destruction of the vegetation cover by overgrazing and cultivation provide the most striking examples of an extreme version of degradation—desertification caused by the misuse of the land. Soil salinity has had severe effects at the northern and western parts of the Caspian Sea, north of India and Pakistan, Laos, Myanmar, and Thailand[21] mainly due to the shift to irrigated agriculture and destruction of the natural vegetation (Figure 3). A major threat to the Asian environment has occurred through the accumulation of soluble salts, mainly deposited from saline irrigation water or through mismanagement of available water resources, as in the drying Aral Sea and the Turan lowlands as well as the deterioration of the oases in Turkmenistan, with excessive abstraction of water in Central Asia (Figure 3).[21] Soil salinity costs Uzbekistan about US $1 billion annually.[21] Moreover, as soil salinity decreases plant productivity, it has negative effect on soil organic carbon inputs which lead to low soil organic carbon contents.

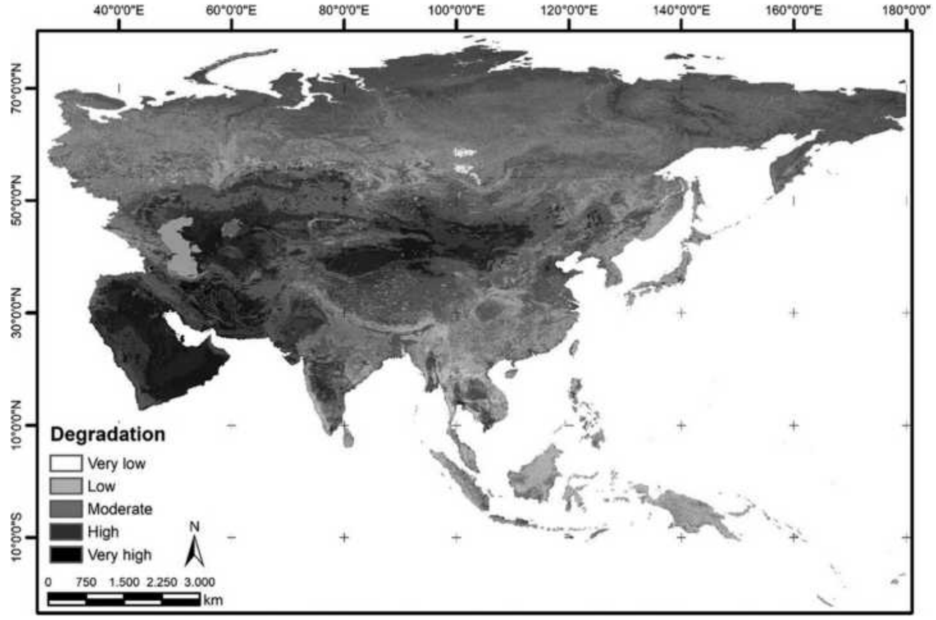

FIGURE 3 Soil degradation map of Asia.

The drylands of the Middle East have been degrading since the Sumerian epoch, with excessive irrigation causing severe salinity and erosion/siltation problems,[22] especially in Iraq, Syria, and Saudi Arabia. Iraq has been unique in the magnitude of the historically recorded buildup of salinity levels, with 8.5 million ha saline land, which is 64% of the total arable land surface (i.e., 90% of the land in the southern part of that country). The historical lands of Iran, Pakistan, Afghanistan, India, and China are also subject to ancient and ongoing soil/land degradation processes, which are subtle in some areas but evident and drastic in others (Figure 3). All ongoing contemporary loss of soil and land in the Asian continent is at an increasing trend even to the presence of the extensive untouched natural forest areas of the north of the continent (Figure 4).

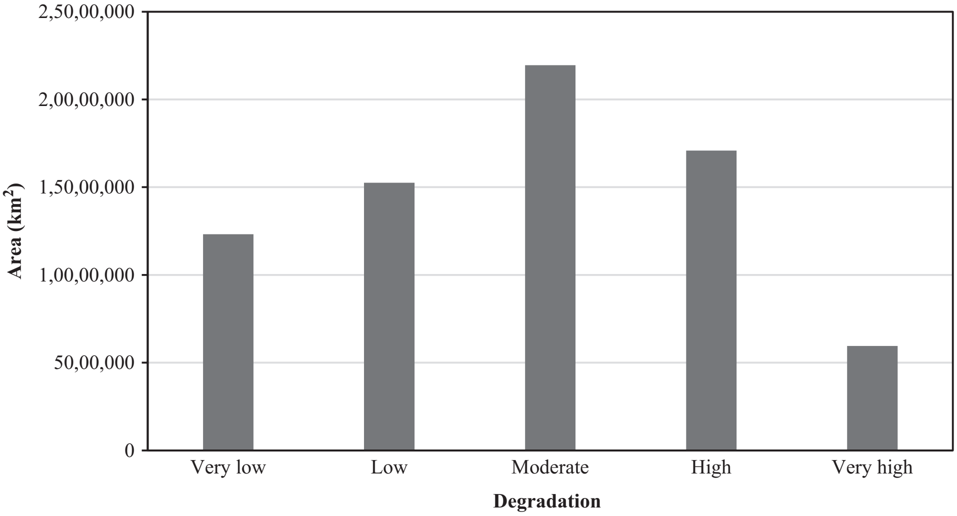

FIGURE 4 Distribution of soil degradation rates in Asia.

Africa

Africa's primary past and present concern has been the loss of soil productivity by nutrient depletion, i.e., the decreasing NPK levels (in kilograms per hectare) in cultivated soils following the exponential growth in population and the resulting starvation and migrations at high levels in the northern, central, and southern parts of the continent (Figure 5). Intensification of land use to meet the increased food demands combined with the mismanagement of the land leads to the degradation of the continental soils. Central African forests are converted to low productive agricultural lands and are used for charcoal and fuelwood production. Moreover, urbanization and uncontrolled mining are other major threats to African forests. This poses the ultimate question of how the appropriate sustainable technologies that will permit the increased productivity of the soils can be identified. This problem is illustrated by the example of the Sudan, where nutrient depletion has steadily increased through

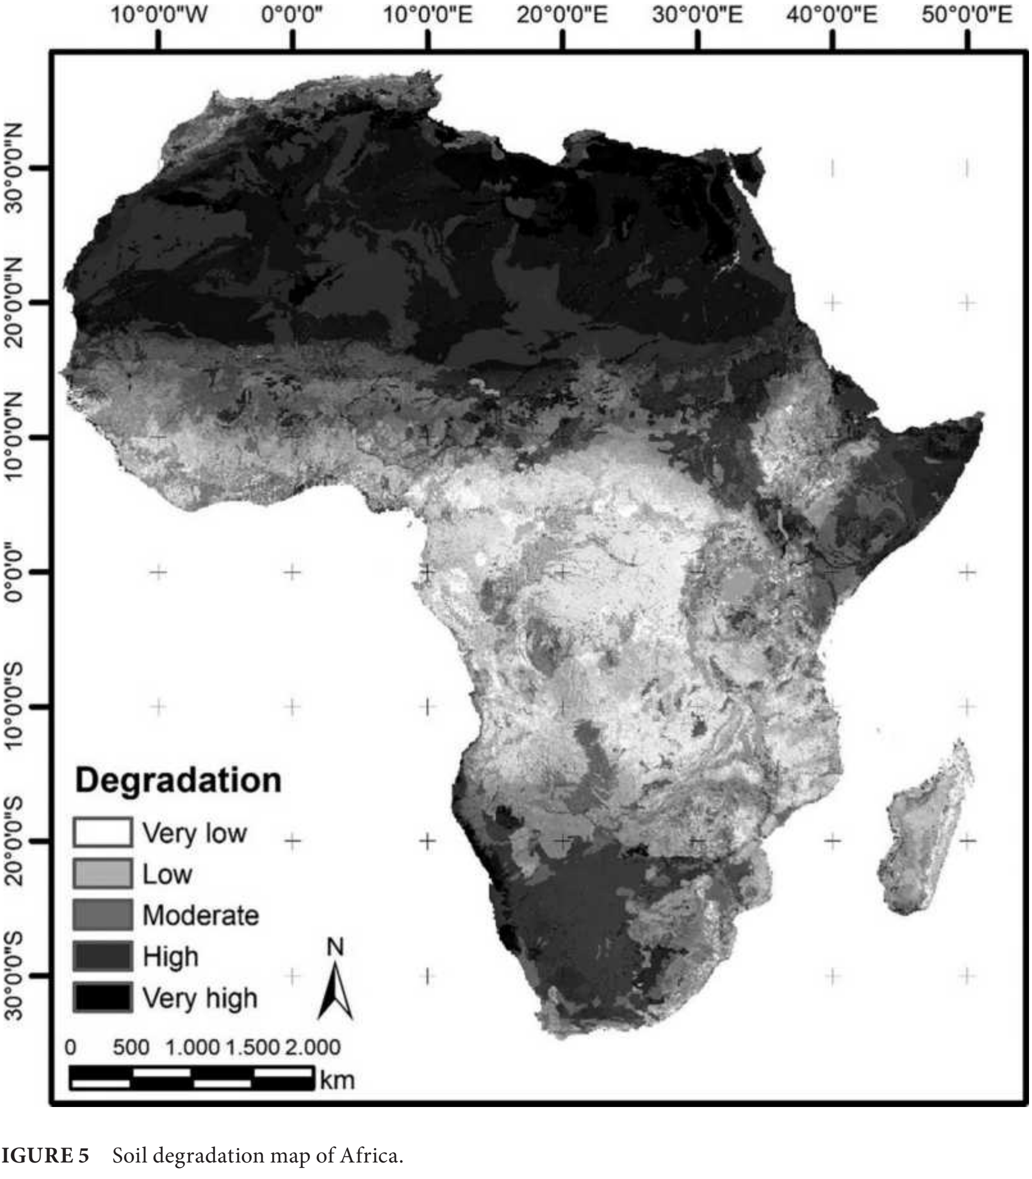

FIGURE 5 Soil degradation map of Africa.

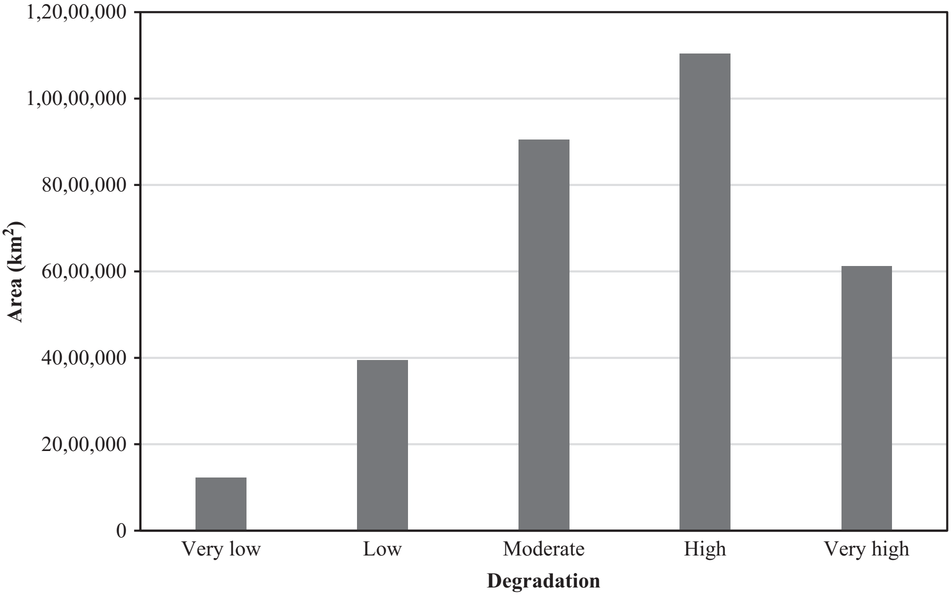

FIGURE 6 Distribution of soil degradation rates in Africa.

more mechanized land preparation, planting and threshing without the use of inorganic fertilizers, and legume rotations. Thus, aggregate yields have been falling as it became more difficult to expand the cultivated area without substantial public investments in infrastructure. In Burkina Faso, and in the other lands of Africa located around the southern and northern fringes of the Saharan desert and the desert margins, the decreased infiltration and increased runoff causing erosion is a further consequence of repeated cultivation. Thus, the technological measures to be identified for Burkina Faso and similarly to other African countries must be smart agriculture. This includes development of water retention technologies, while polyculture/rotations with proper manuring and fertilization for cost-efficient provisions of N and P by preferably green manuring are major actions to be taken. These actions in the Sudan and likewise other parts of Africa will provide balanced management of soil moisture, nutrients, and organic matter by enhancing C-sequestration in soil, which is the main goal for sustainability based on the sustainable management of the land, to ensure the security of both the soil and the global climate.[23,24] Salinity is progressively menacing the lands of the African continent by the increased salt accumulation in the soils of the Sahel (especially in Libya) and parts of the Sahara, which is irrigated and/or excess irrigated by fossil water.

The land area of the African continent that is highly and very highly affected by land/soil degradation is estimated to be above 17 million km^2, 1.7 times larger than 10 million km^2 Europe continent, which is mainly caused by depletion of the nutrients and increase of soil salinity (Figure 6). The slight erosion determined on the Saharan lands reflects a mere reality, i.e., the ultimate fate of the land depends on strict conservation measures, as well as detailed research on any fossil water considered for use. Only by such means can stable ecosystems be conserved in such water–soil poor regions.

South America

Water and wind erosion on the eastern and western coastal/ inland areas of the South American continent are the dominant soil degradation processes in these regions and have caused the loss of the topsoil at alarming rates due to the prevailing climatic and topographic conditions. Almost as important is the loss of nutrients from the Amazon Basin[13] (Figure 7). Graesse et al.[25] calculated 17% of new cropland and 57% of new pastureland replaced forests in Latin America from 2001 to 2013. These deforestations and overgrazing effects caused the degradation of 576 million ha of potential agricultural land, an area almost equal to the very high, high, and moderately high degraded land/soil areas (Figure 8). Another important factor has been the ever-increasing introduction of inappropriate agricultural practices derived from the so-called imported technology, which has not been properly adapted to indigenous land-use procedures. The traditional methods of permitting the land to recover naturally have been almost totally abandoned and has been replaced by unsuitable technological measures designed to maintain production levels (temporarily) and to overcome the loss of soil resilience, thus increasing chemical inputs.

The rapid industrialization/urbanization of the limited land resources in the Caribbean has been expelling agricultural communities to remote and marginal regions that are at present rich in

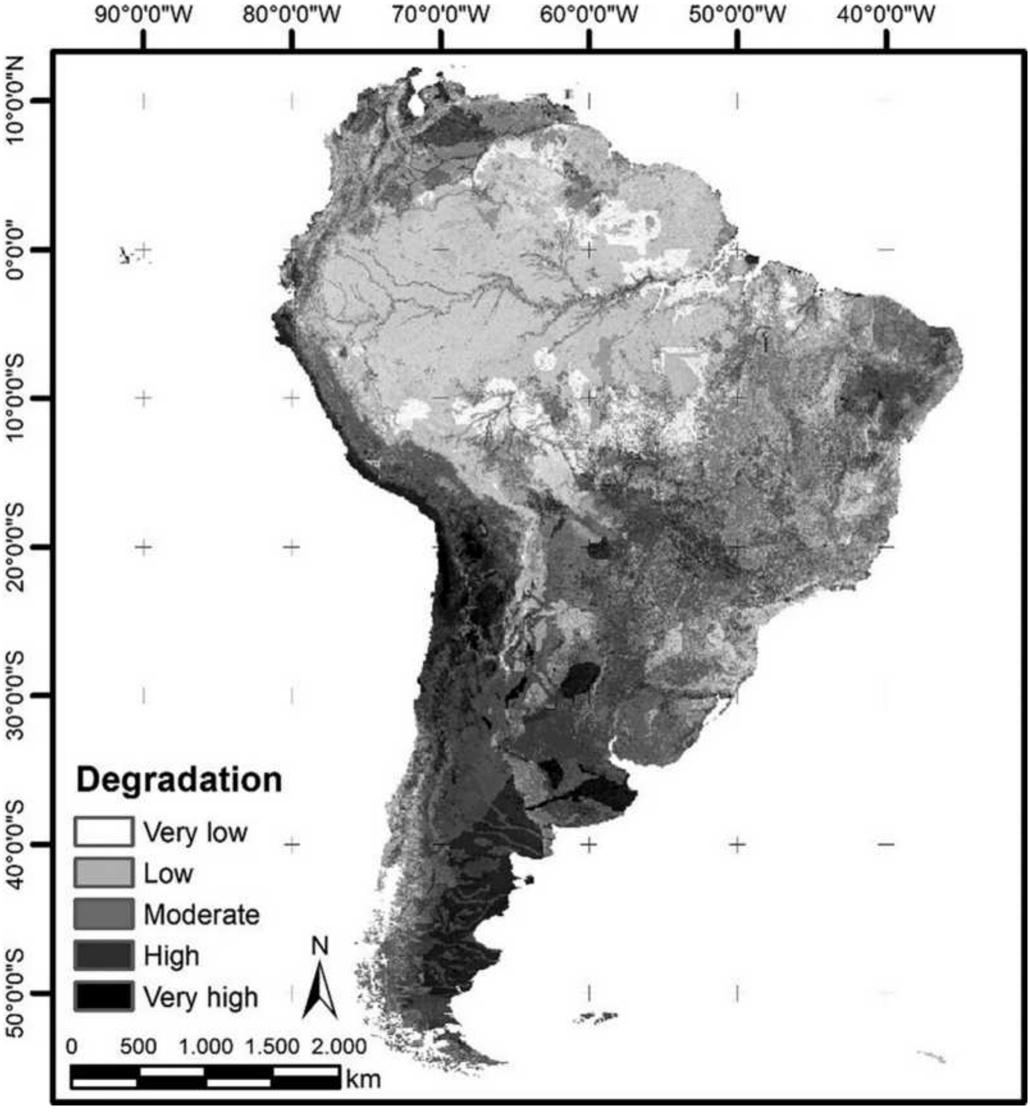

FIGURE 7 Soil degradation map of South America.

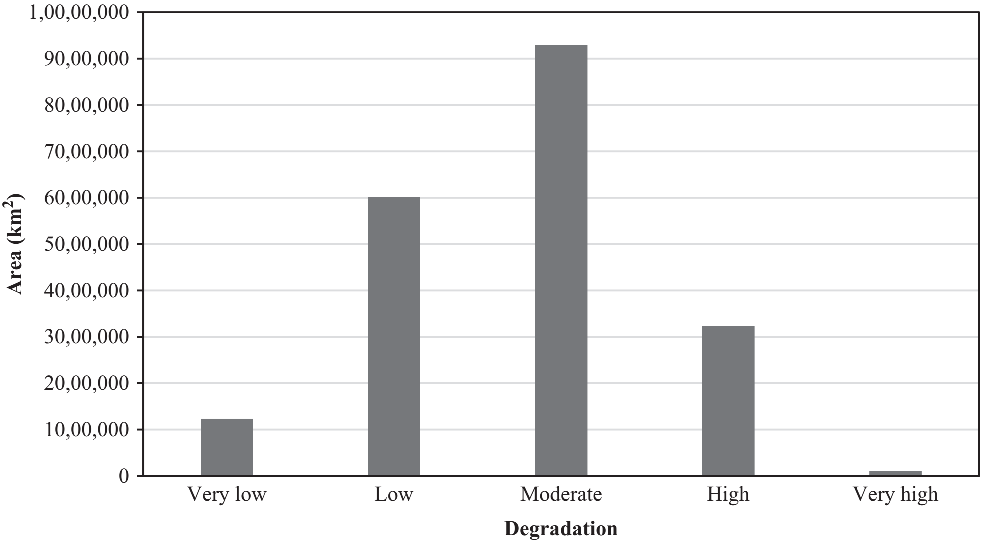

FIGURE 8 Distribution of soil degradation rates in South America.

biodiversity and biomass—a major global C sink. Moreover, large-scale livestock herding in Central and South America is also a major threat to soil security and has been responsible for degrading 35% of the pasture lands of Argentina.

North America, Central America, and the Caribbean Islands

The most prominent outcome of soil/land degradation (or more correctly desertification) in the United States is exemplified by the accelerated dust storm episodes of the 1930s—the Dust Bowl years, marked by the "Black Blizzards," which were caused by persistent strong winds, droughts, and overuse of the soils. These resulted in the destruction of large tracts of farmland in the south and central United States. Recently, salinization has become an equally severe problem in the western part of the country (Figure 9) through the artificial elevation of water tables by extensive irrigation, with associated acute drainage problems. An area of about 10 million ha in the west of the United States has been suffering from salinity-related reductions in yields, coupled with very high costs in both the Colorado River basin and the San Joaquin Valley.[26] Unfortunately, new irrigation technologies such as the Center-Pivot irrigation system (developed as an alternative to the conventional irrigation systems that caused the salinity problems) has caused a decline of the water table levels in areas north of Lubbock, Texas, by around 30–50 m, leading to a dramatic decrease (by 50%) in the thickness of the well-known Ogallala aquifer. In some areas, this has been followed by ground subsidence, which is an extreme form of soil structure degradation, i.e., loss of the physical integrity of the soil.

Loss of topsoil, as the result of more than 200 years of intensive farming in the United States, is estimated to vary from 25% to 75% and exceeds the upper limit in some parts of the country.[27,28] The United States provides good examples of the difficulties involved in erosion control, with its large-scale intensive agriculture damaging soil structure and also increasing the erosion of susceptible soils. This problem could be greatly mitigated by strict enforcement of the no-till system. Such no-till areas have increased tremendously in the United States and are forecast to increase in linear fashion.[29] Conservation farming is practiced in only about half of all US agricultural land and on less than half of the country's most erodible cropland. Conservation farmers are encouraged to use only the basic types of organic fertilizers, such as animal and green manure together with compost, mulch farming, improved pasture management, and crop rotation to conserve soil nutrients. In Alaska, scientists have identified a

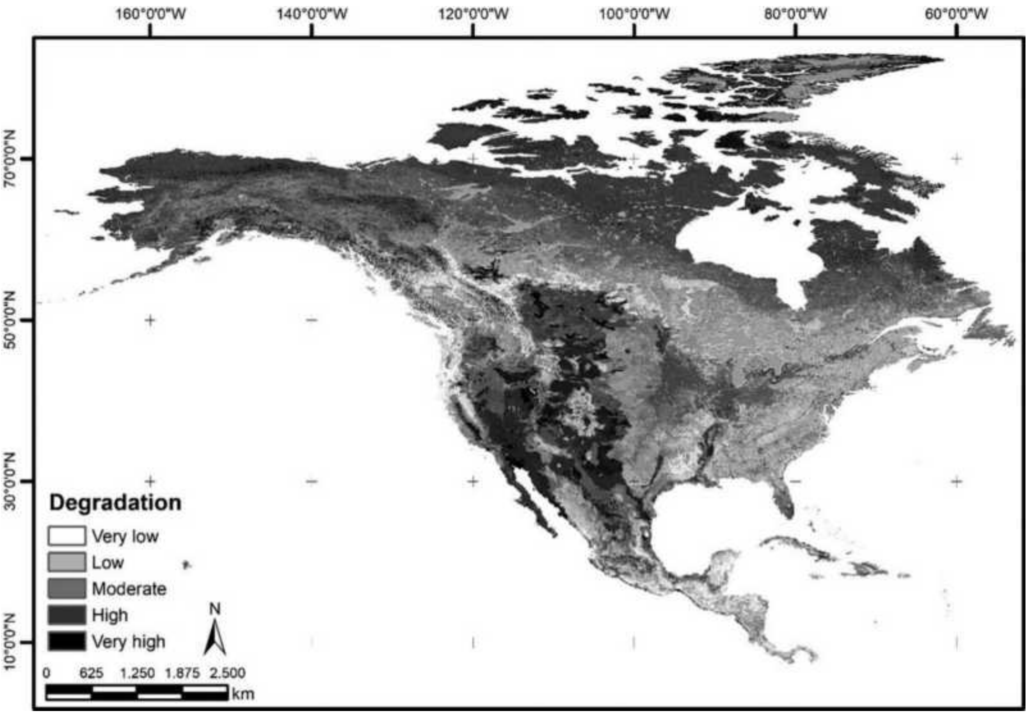

FIGURE 9 Soil degradation map of North and Central America and the Caribbean islands.

number of events that may have been the cause of a severe and rapid soil erosion, where the northern ice sheet is diminishing and consequently causing the increase of water temperatures, which means the increased development of storm events, more precipitations, and higher waves with a potential of eroding some 14 m of coastline each year, which is a much higher rate than the 6.1 m erosion recorded in the mid-1950s.[30] Jones et al. state that this might be a new era in ocean–land interactions and the reshaping of the Arctic coastline by erosion. Furthermore, they claim that the warming sea-surface temperatures and the rising sea level will most probably act to reduce the permafrost-dominated coastline and thaw the ice-rich bluffs and consequently increase erosion and degrade Arctic landscapes together with the long-standing cultural sites.

Canada is a large country where half of the 68 million ha of available land is cultivated, with an average farm size of 450 ha. It is reported that Canada has experienced annual soil losses on the prairies (through wind and water erosion) that are similar to the Asian steppes, amounting, respectively, to 60 and 117 million tons. These annual rates are much higher than the rate of soil formation, resulting in an annual potential grain production loss of 4.6 million tons of wheat. With regard to primary soil salinity, during historic times, the prairies have experienced steady increases, related partially to increasing groundwater levels. Major problems of secondary salinity are estimated to affect 2.2 million ha of land in Alberta, Saskatchewan, and parts of Manitoba, with an immense economic impact each year.

Central America is drastically suffering from soil erosion, where almost 26% of the territory is strongly affected via this irreparable menace caused mainly by overgrazing, which almost adds up to a total of 58% of the overall degradation in the southern tip of North America (Figure 10). Concrete precautions are being taken in the whole region by implementing the “Quesungual” agro-forestry method, concerning the planting of trees between the dispersed natural forest tree communities, converting pastures to forests (World Bank Project), and implementing ambitious projects such as the Lake Managua Watershed drainage to avoid landslides—a major component of degradation in Nicaragua.[31]

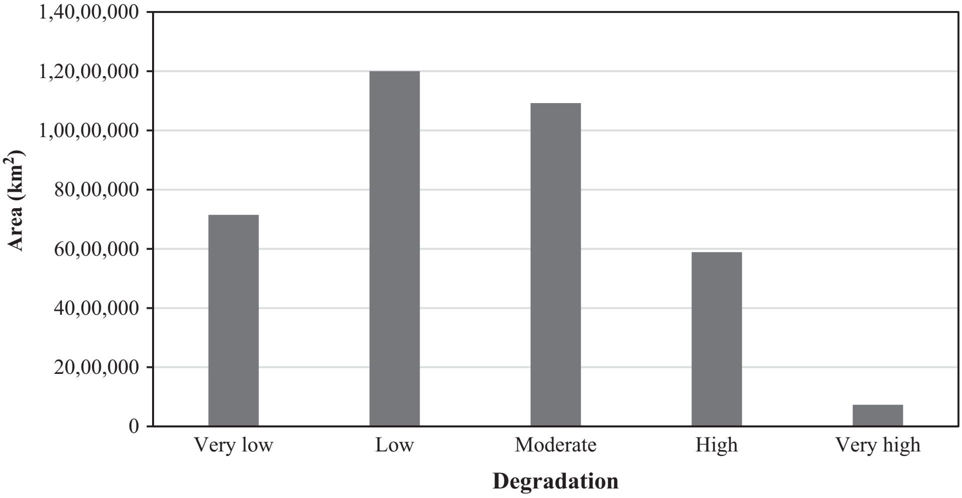

FIGURE 10 Distribution of soil degradation rates in North and Central America.

The Caribbean islands and the lands of Central America have long faced a common fate of soil degradation via intense conversion of forests to cultivated soil, i.e., deforestation, causing flooding, landslides, and development of land surfaces prone to erosion and degrading the cycles of carbon and water—the wonders that sustain our living globe. Costa Rica loses about 860 million tons of valuable topsoil every year.[32] Earthquakes of the Caribbean and Central America were/are followed primarily by volcanic eruptions with immediate and dramatic changes in the environment, where lava buries soils that would be covered for at least a generation-long period before developing into fertile lands rich in nutrients. Drastic examples reveal the inappropriate soil use systems imposed by the colonial powers of Europe back in the 16th century based on the creation of extensive deforestation areas replaced by sugar cane fields, which has been the beginning of the soil degradation era, particularly in Haiti in the Caribbean islands. Precautions to combat the vast ongoing soil erosion in the Caribbean islands, especially in Haiti, seek the development of tree plantations and in particular bamboo crops to overcome the soil-degradation- and political-unrest-oriented contemporary poverty in the country. The high rates of erosion, as sediment depositions in the sea, are also threatening one-third of the coral reefs around the Caribbean islands. High turbidity of inshore water and elevated algal cover on reefs are linked to the impacts of coastal development inducing erosion, with soil/sediment deposition being a major influence on the conditions of reefs.[33,34] The Caribbean Environment Program is active in the region, seeking to mitigate soil and land degradation by developing projects primarily on the "Best Management Practices in Agriculture" and "Integrating Watersheds and Coastal Areas Management—IWCAM" via the Global Environment Facility (GEF) included in National Programs of Action.[35]

Australia

The Australian agricultural/soil resource base has been long endangered by the "business as usual" concept on the continent aiming to achieve temporary economic betterment,[36] *which, in contrast, induced soil degradation.* Identification of the different types of soil degradation in Australia reveals that erosion has been the main component, primarily via dust storms, which still are a serious problem, especially where cropping practices do not include retention of cover and minimum tillage methods. Water erosion effects are also particularly severe in areas of summer rainfall and topographic extremities (Figure 11). Remedial actions for this include the well-known measures of maintaining adequate

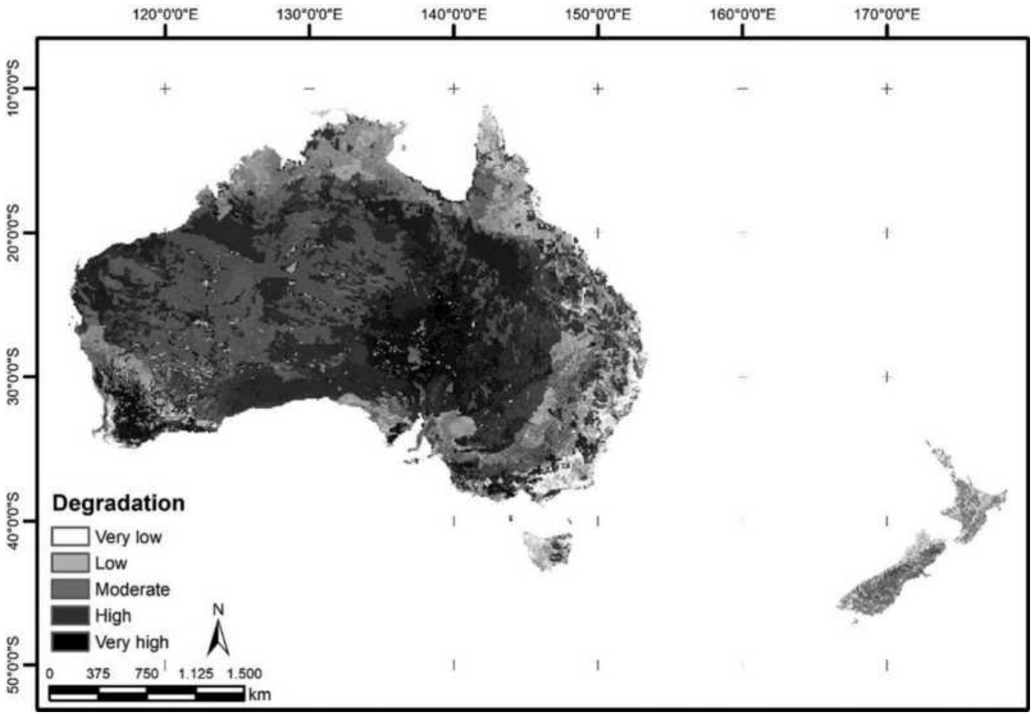

FIGURE 11 Soil degradation map of Australia and New Zealand.

cover and changing prevailing altitudes towards stock management, storage feed, redesign of watering sites, and management of riparian areas.

Part of the excess salinity in Australia is of primary origin and was retained in the subsoil by trees, which have now been cleared to create soil surfaces for cropping and pastures, allowing penetration of water to the saline subsoil, then followed by abstraction from the water table, thus leading to serious problems in the southwest, east, and central-eastern parts of the country (Figure 11). About 30% of Australia's agricultural land is sodic, creating poor physical soil conditions and impeded productivity. This problem can only be alleviated by massive revegetation programs and by taking extra care of the water table and plant cover. Despite the introduction of costly conventional measures for reclamation, salinity levels continue to increase across Australia in the dry and irrigated soils. The dryland salinity in the continent affects about 2.5 million ha of farmland and is expanding at a rate of 3%–5% yr^{-1} which may sum up to 8.8 million ha (33%) by 2050.[37]

The retardation of the organic matter levels also requires remediation measures, with economically justified fertilizer use strategies to be utilized throughout the continent. Moreover, overgrazing has resulted in the impoverishment of plant communities and loss of habitats as well as the decline in the chemical fertility of the soil by progressive depletion of organic matter in the topsoil, followed by deterioration in soil structure.

Acidification caused by legume-based (clover, etc.) mixed farming plus use of ammonia-based fertilizers threatens 55 million ha of Australian land, which is about one-half of the degraded land areas (high, moderate, and very high, respectively) of the continent (Figure 12). Liming seems to be the most effective present remedy, but this is costly, does not lead to rapid recovery, and is impractical for subsoil acidity. Thus, the precise remedies have yet to be developed for the conditions on this continent, utilizing careful, long-term monitoring and the experience of farmers to devise specific treatment and conservation procedures. Despite the common view that reflects the absence of soil loss in

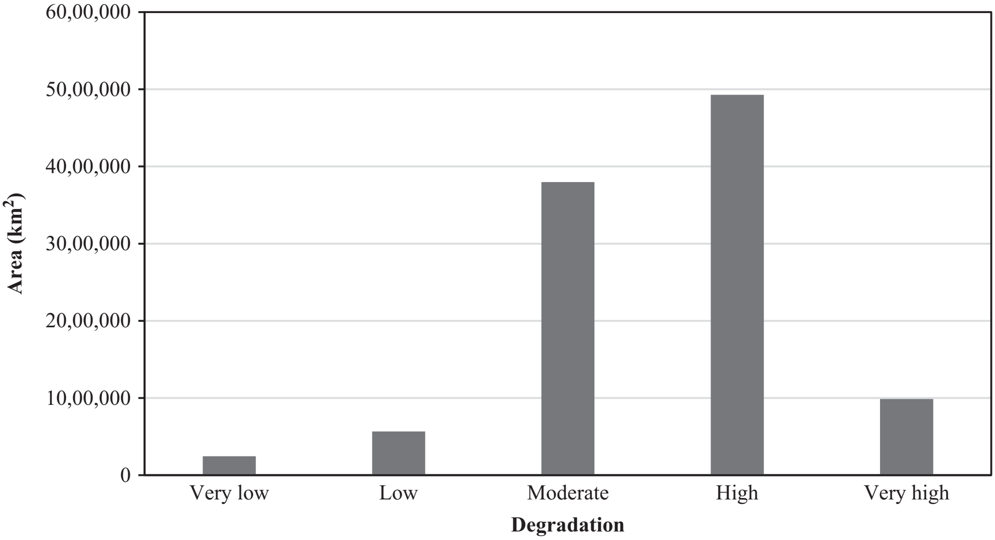

FIGURE 12 Distribution of soil degradation rates in Australia and New Zealand.

New Zealand due to the presence of the widespread forests, soil erosion has been a major threat to the natural resources as being accelerated by early colonial and contemporary deforestation followed by the unwise land-use practices such as overgrazing. Accelerated erosion is the most serious and the least reversible of soil degradation problems encountered in the country. The main forms of erosion in New Zealand are, namely, the mass, fluvial, surface, and stream-bank transportation of the soil in the hilly country, in the Marlborough and Manawatu regions, in the lands outside the hill country, and at the unstable areas cleared of tree cover. The long-standing experience and research provided the relevant bodies dealing with erosion in New Zealand, with the appropriate techniques to reduce the impacts of erosion in the pastoral lands. These techniques include the maintaining of the adequate vegetative cover (e.g., avoiding overgrazing and maintaining a dense pasture sward through regular applications of fertilizer and grass seed), the spaced or close tree planting, retiring the land from pasture, fencing off and planting riverbanks, and building debris dams to slow water flows in gullies. A similar system to the Australian "National Landcare Organisation" is being implemented in New Zealand in 1996 as the "New Zealand Landcare Trust" which is a nongovernmental organization facilitating sustainable land management (SLM) and biodiversity initiatives at a community-driven basis, in order to effective catchment management to improve the land and water quality of the country. The Landcare Trust seeks the assurance of implementing land management more sustainably.[38]

Conclusions

The state of soil/land degradation and its remediation through a multifunction–multi-impact approach has been defined through a driving force–pressure–state–impact–response (DPSIR) matrix developed by the European Environmental Agency[39] (Figure 13) leading to SLM[40–42] measures to be taken for the future. SLM is concerned with more soil/land-friendly farming practices that minimize the erosion potential of soils, together with the adoption by landholders of property management planning procedures that involve community actions, such as the Landcare Program of Australia.[38] Moreover, as Smyth and Dumanski[40] have stated, this approach combines socioeconomic principles with environmental concerns to enable production to be enhanced alongside a reduction in the level of risk to the sustenance of natural resources. Thus, degradation of soil and water quality, which have negative

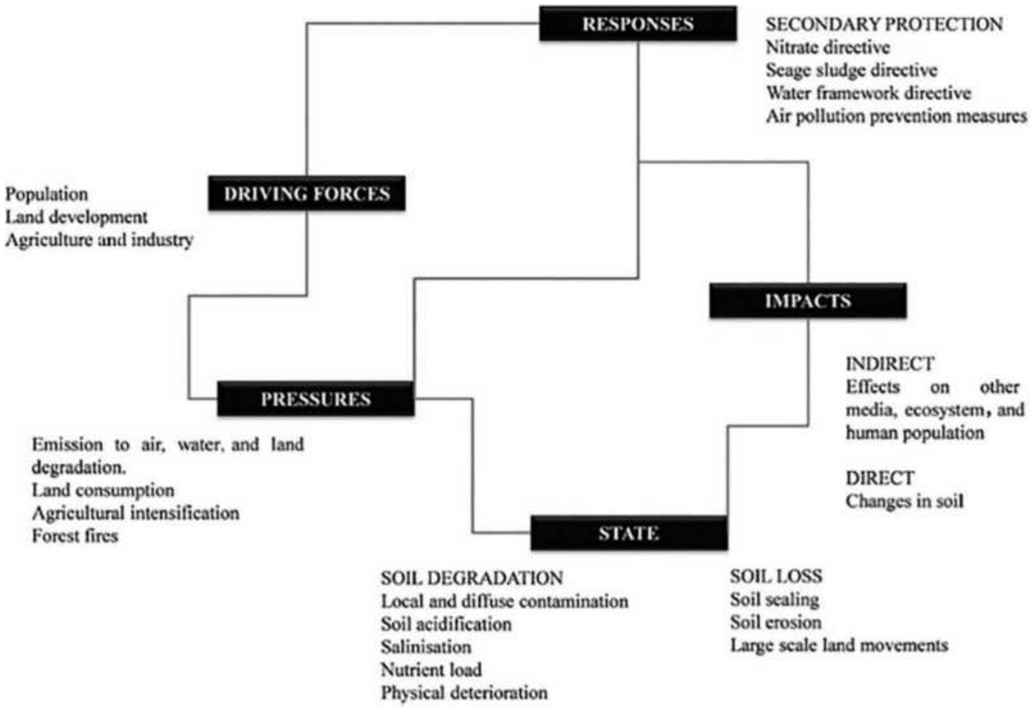

FIGURE 13 DPSIR framework applied to soil.
Source: UNEP/EEA.[39]

effects on climate[43] and biodiversity, can be prevented or minimized in a manner that is acceptable to the farming community. The methods to be adapted for SLM via community actions include contour farming, terracing, vegetative barriers, and other land-use practices amalgamated with indigenous (traditional) technical knowledge (ITC)[44,45] as applied to farming and landscape preservation. The impetus for the use of ITK by scientists and local communities in creating new strategies for sustainable resource management was provided in the United Nations Conference on Environment and Development (UNCED) held in Rio de Janeiro (Brazil) in 2012. Thus, at the 13th meeting of the Parties to the United Nations Convention to Combat Desertification, 113 countries had agreed to specify solid targets with clear indicators, to rehabilitate degraded lands and reverse degradation, which currently affects more than third of the world's prime land resources.[46] This approach was widely accepted and endorsed as the Land Degradation Neutrality approach for a primary solution to the degradation of global soil/land resources in the new UNCCD 2018–2030 Strategic Framework[47] in order to meet UN Sustainable Development Goals aimed to be achieved by 2030 for the global welfare and peace.

Soil Erosion and Carbon Dioxide

Pierre A. Jacinthe
and Rattan Lal

Introduction

The projected warming of global climate and the degradation of land resources by erosion are among the most pressing environmental challenges of the modern era. The recent warming trend in the world's climate is linked to the accumulation of radiatively active gases (CO_2, N_2O, CH_4) in the atmosphere.[1,2,3] Atmospheric CO_2 concentration has been increasing at a rate of 2.2 ppm C y^{-1},[4] which, if maintained, could profoundly alter the chemical composition and the energy balance of the Earth's atmosphere. Although fossil fuel burning is the primary contributor to the current atmospheric CO_2 buildup, it is estimated that agriculture and land-use change contributed 24% of total anthropogenic emissions of CO_2.[5] In soils, evolution of CO_2 occurs through soil respiration which includes root respiration and the microbial decomposition of crop residues and soil humus.

The soil organic carbon (SOC) content is positively related to structural stability and negatively related to the susceptibility of soils to erosion.[6,7] Cultivation reduces the stability of aggregates,[6] thereby increasing the erodibility of soils.[8] The effect of SOC on susceptibility to erosion is best exemplified by the use of SOC content in determining the soil erodibility factor (K) in the universal soil loss equation (USLE).[7] Worldwide, an estimated 1.11×10^9 ha of land are affected by water erosion,[9] resulting in the annual transport of $20–25\times10^9$ Mg of sediment to rivers and oceans.[10,11] While much is known about the protective role of SOC against soil erosion, information is limited regarding the fate of SOC mobilized by erosion. It is estimated that as much as 1.1 PgC [1 Pg$=10^{15}$ g$=$billion metric ton] may be emitted into atmosphere by erosion by water.[12] In this entry, we deliberate that water erosion, as a mechanism for SOC removal, has a profound effect on the global CO_2 budget, and we present an approach to assess erosion-induced CO_2 emission into the atmosphere.

Eroded Soil Organic Carbon: State of the Knowledge

Water erosion involves the detachment of soil aggregates, the release of aggregate-protected SOC, and the translocation and deposition of detached soil particles. Globally, estimates of SOC displaced in terrestrial ecosystems by water erosion are in the order 57 Pg of Cy^{-1}.[13,14] There is considerable uncertainty regarding the fate of the eroded SOC, however. The Intergovernmental Panel on Climate Change (IPCC) echoed this uncertainty in its handbook for conducting national greenhouse gas inventory by stating that the net effect of erosion on CO_2 evolution is unclear at the present time.[15]

The fate of SOC mobilized by erosion can include redistribution, long-term storage in aquatic and terrestrial systems, and mineralization during transport and deposition leading to emission of CO_2 (production of CH_4 possible depending on oxidation status).[14] During transport, detached soil particles are hydrodynamically sorted and redistributed over the eroding landscape as determined by flow condition, surface roughness, particle size, and geomorphology. Between 80% and 90% of the total soil mass mobilized by water erosion remains near the site of erosion.[15] A fraction of the eroded SOC is exported to streams, rivers, and lakes. Several publications have documented the magnitude of these exports which are in the order of 0.6–0.8 Pg C y^{-1} [16,17] or more.[12,14]

Eroded SOC in runoff is also retained in the low-lying portions of the eroding landscape, but the fate of SOC entrapped in these terrestrial deposits is also not fully understood. On the premise that the decomposition process may be O_2-constrained, it has been suggested that entrapment of eroded SOC in terrestrial deposits can be a mechanism for C sequestration.[18,19] It is estimated that a sequestration of 0.6–1.5 Pg C y^{-1} may be possible via this mechanism.[19]

Eroded soil materials typically contain twice as much (or more) C than the average topsoil.[18] In addition, these materials are enriched in labile C.[20] Given the propensity of these SOC fractions to be associated with the lighter and most erosion-prone soil particles, mineralization of eroded C during transport and deposition is a reasonable expectation. A study comparing CPMAS^{13}C-nuclear magnetic resonance spectrometry data of eroded and deposited soil samples indicated that 70% of SOC in eroded soil could be decomposed during transport and deposition.[21] A recent review suggests a lower (20%) mineralization rate.[13]

The information presented above clearly underscores the need for better quantitative assessments of the various fates of eroded SOC. Of particular interest is an assessment of water erosion's contribution to atmospheric CO_2. At the present time, there are few if any experimental data to support such an evaluation. However, an indirect determination of CO_2 production during transport and deposition of eroded SOC is possible using literature data pertaining to the other pathways identified above.

Assessment of Erosion-Induced Carbon Dioxide Fluxes from Existing Data

Conceptual Framework and Description of the Mass Balance Approach

In order to estimate CO_2 production during transport and deposition of eroded SOC, a mass balance approach, described in Figure 1, is proposed. This approach assumes a steady-state equilibrium with respect to SOC content. Augmentation of the initial pool of SOC via humification of crop residues compensates for SOC losses, which include soil respiration, leaching, and SOC translocation with runoff waters. It follows that

$$C_0 + h \cdot C_A = C_t + S_R + E \tag{1}$$

$$S_R = k \cdot C_t \tag{2}$$

$$E = L_C + S_w + E_W + S_L + E_L \tag{3}$$

$$\frac{E_L = (C_0 - C_t)}{t + h \cdot C_A - k \cdot C_t - (L_C + S_w + E_w + S_L)} \tag{4}$$

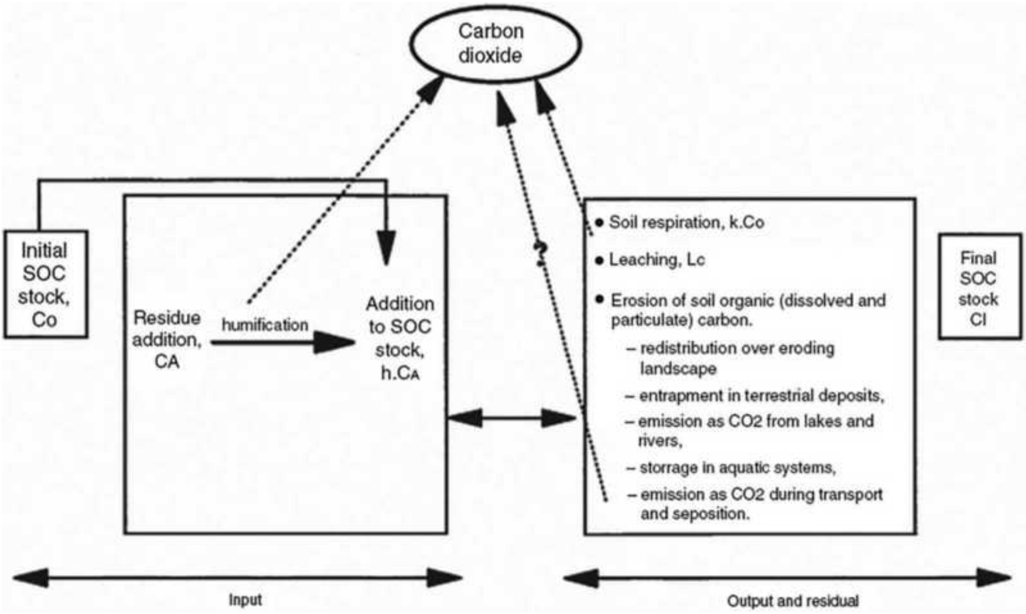

FIGURE 1 A conceptual mass balance model of SOC evolution in soils.

where C_0=initial SOC stocks, h=humification rate, C_A=annual residue addition, C_t=the SOC stocks after t years, S_R=annual SOC mineralization, k=coefficient of SOC mineralization, L_C=leaching loss of SOC, S_w=terrestrial C delivered to lakes and oceans, E_w=CO_2 evasion from aquatic systems (lakes, rivers, streams), S_L=C storage in terrestrial deposits, and E_L=mineralization and CO_2 evolution during transport and deposition of eroded SOC. The coefficients h and k are in units of y^{-1}, C_0 and C_t are in g C m^{-2}, and the other parameters are in units of g C m^{-2} y^{-1}.

Using Eq. (4), CO_2 evolution during transport and deposition of eroded SOC (E_L) can be computed. Values for the parameters in Eq. (3), assembled from various regional and global scale studies, are summarized in Table 1. We used the mass balance model and data from several long-term studies of SOC evolution to estimate EL.

TABLE 1 Estimates of the Major Pathways of Soil Organic Carbon Exported from Agricultural and Forested Watersheds

Description of SOC Loss Pathway	Symbol	Range (g C m^{-2} y^{-1})
Leaching of organic carbon in forest and cropland	L_C	0.5–5[a]
Terrestrial carbon delivered to lakes, rivers, and oceans	S_W	10–25[b]
Evasion CO_2 from aquatic systems	E_W	0.2–3.6[c]
Organic carbon storage in terrestrial deposits	S_l	6–15[d]

[a] Data from Guggenberger and Kaiser.[29]

[b] Terrestrial C delivery to the ocean [computed using global C input to the ocean (750×10^{12} g C/yr from Ludwig et al.[17]) and the total area of river draining to the ocean (89×10^{12} m^2 from Stallard[19])] was added to accumulation rate of terrestrial C in freshwater systems and man-made reservoirs (2–10 g C m^{-2} y^{-1} from Mulholland and Elwood[30]).

[c] Adapted from Spitzy and Leenheer.[31]

[d] Estimate computed using global C storage in terrestrial sediments ($0.6–15\times10^{15}$ g C y^{-1} from Stallard[19]) and total area of river basins (10^{14} m^2 from Meybeck[32]).

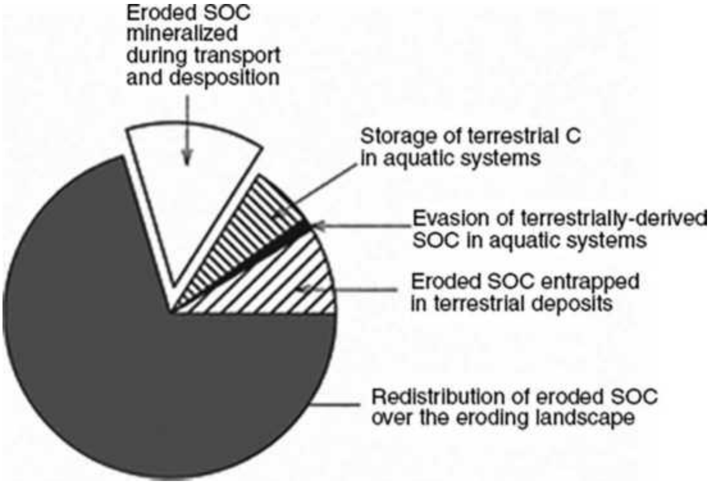

FIGURE 2 A hypothetical distribution of erosion-mobilized SOC among various possible fates.

Estimates of Erosion-Caused CO_2 Emissions

Analyses of the data available in the literature show that estimates of CO_2 production (E_L) during transport and deposition of eroded SOC range between 6 and 52 g C m^{-2} y^{-1} (Table 2). These estimates are necessarily crude given that the values assigned to the model parameters were obtained from different studies. It is important to note, however, that our parameter estimates (e.g., S_W, E_W) were similar to direct measurements made in studies conducted in various geographical regions including the United States,[22] Europe, and New Zealand.[16] Assuming a sediment delivery ratio of 15%[11] and a C-enrichment ratio of 2 for eroded soil material,[18] the total C exported from a typical eroded field averages 30% of the total C mobilized during erosional events. Using the C export data in Table 1, estimates of total C mobilized by water erosion range between 56 and 168 g C m^{-2} y^{-1}. Similar estimates (40 and 190 g C m^{-2} y^{-1}) of SOC mobilization are also obtained by assuming that computed E_L values represent 20% of the total SOC displaced by water erosion.[12] Using these ranges of erosion-induced SOC mobilization and the data in Table 1, a hypothetical distribution of eroded SOC among several pathways is presented in Figure 2. For example, for a soil containing $4–5\times10^3$ g C m^{-2}, the loss and redistribution of 1%–5% of the total SOC might go unnoticed for some time. Removal of SOC via sheet erosion could be particularly difficult to detect in the short term, hence a possible dismissal of water erosion as an important mechanism for SOC loss.[23] However, field study data support the view that erosion is a significant contributor to SOC decline and sometimes contributes more to SOC depletion than soil respiration.[24,25]

If the data in Table 2 are extrapolated to the global cropland (1.5×10^9 ha),[26] erosion-induced global CO_2 fluxes to the atmosphere ranging between 0.12 and 0.55 Pg C y^{-1} can be computed. These fluxes could represent up to one-third of the annual CO_2 emission (1.6 Pg C y^{-1}) due to deforestation and land-use change in the tropics.[13]

Conclusions

The information presented in this entry supports our contention that sizable amounts of CO_2 can be produced as a result of SOC mobilization by water erosion. Moreover, water erosion could elicit profound disturbances in the plant–soil–atmosphere segment of the global C cycle through a cascading process involving nutrient depletion, decreased biomass production, and alteration of the radiative and thermal properties of soils. The strong control of temperature on CO_2 emission[21] and the higher temperature

usually recorded in eroded soils[22] also indicate a shortened residence time of photosynthetically fixed C in the soil system. Although many of the effects remain to be evaluated experimentally, available information suggests a positive feedback of water erosion on atmospheric CO_2 and climate warming.

Soil Quality: Carbon and Nitrogen Gases

Philippe Rochette,
Sean McGinn, and
Reynald Lemke

Carbon Gases

Carbon is a major constituent of biomass and soil organic matter. However, more than 99% of global carbon is locked into sediments and fossil forms and is not available for biological processes. The small remaining active fraction of global carbon transits between atmospheric CO_2, biomass and soil organic matter, and detritus in the so-called carbon cycle (Figure 1). The carbon cycle is driven by photosynthetic fixation of atmospheric CO_2 by plants. In global terrestrial ecosystems, it is estimated that plant photosynthesis fixes more than 200 Gt of CO_2 every year.[1] Eventually, similar amounts are returned to the atmosphere by the respiration of animals and by the aerobic heterotrophic decomposition of soil organic matter and plant litter. In the absence of oxygen and other electron acceptors, CH_4 is the final product of soil organic matter decomposition. Human activities, including changes in land use and soil management, are contributing to unprecedented rapid increases in atmospheric CO_2 and

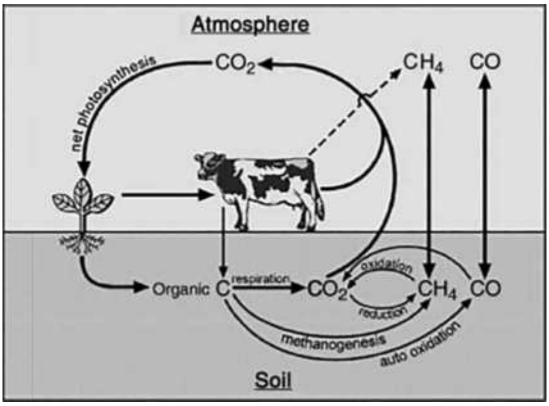

FIGURE 1 The soil carbon cycle. In well-aerated soils, decomposition of soil organic matter produces carbon dioxide. Significant amounts of methane are produced only under highly anaerobic (waterlogged) soilas.

CH_4 concentrations, which may result in important modifications of the Earth's climate. In dry soils, auto-oxidation of organic compounds can produce carbon monoxide (CO). Carbon monoxide can also be biologically oxidized to CO_2 in moist but well-aerated soils.

Carbon Dioxide

Soil-surface emitted CO_2, or soil respiration, is the sum of the CO_2 produced by root respiration and heterotrophic decomposition of root exudates, soil organic matter and plant litter. Decomposition processes, while dominated by soil microbes, are the result of complex interactions between soil fauna, fungi, actinomycetes, and bacteria. During decomposition, complex molecules like cellulose, hemicellulose, proteins, and lignin are broken down into low molecular weight substances and oxidized to CO_2 to produce energy and C for the growth of organisms.[2,3] The rate of decomposition is regulated by the quality and quantity of organic substrates and by physical/environmental properties of soil, such as temperature, moisture, and aeration.[4]

When ecosystems are in equilibrium, soil CO_2 emissions are the result of the natural recycling of nutrients and equal the amount of atmospheric CO_2 fixed by plant photosynthesis. However, in the past 150 years, human activity has broken this equilibrium by burning fossil carbon reserves and by decreasing soil organic matter through land- use changes. During this period, the additional CO_2 that entered the carbon cycle could not be completely absorbed by increases in autotrophic activity and atmospheric CO_2 concentrations increased from 280 to 365 ppm.

Several measures have been identified to reduce net CO_2 emissions from soils. Among them, it is believed that modifications in agricultural and forest management practices could result in increased C storage in soils as organic matter. Converting cultivated land into natural ecosystems usually increases soil carbon content because of increased return of plant litter and decreased decomposition. Also, tillage breaks down aggregates and increases soil carbon losses by exposing organic matter to microbes that decompose it. Therefore, reducing tillage intensity, fallow frequency, and the amount of cultivated land (by increasing productivity), and increasing perennial crops in rotation and permanent grasslands are seen as potential management practices for mitigating global warming.[5]

Methane

Methane is produced in soils by the decomposition of organic matter and by the reduction of CO_2 under highly anaerobic environments. Such conditions are found in wetlands and in rice paddies that, together with landfills, contribute about half of the total emissions of anthropogenic CH_4. Methane is stable in waterlogged soils and can be emitted to the atmosphere via diffusion, ebullition, and transport through plants. In the presence of oxygen, certain bacteria can oxidize CH_4 to CO_2 (Figure 1).[6]

Human intervention can greatly influence CH_4 production or consumption in soils. Flooding of soils in natural or agricultural ecosystems usually results in increased emissions[7] while drainage of wetlands can turn a source of methane into a sink.[8] Flooded rice fields are a major source of anthropogenic CH_4. Management practices have been proposed to reduce CH_4 emissions from rice paddies, including draining the fields during the growing season, replacing urea by other types of nitrogen fertilizers, and reducing the input of crop residues by using new cultivars and alternative cultural practices.[5] Reduced rates of CH_4 oxidation in well-aerated soils have been observed following cultivation and addition of nitrogen fertilizers.[9]

Nitrogen Gases

The passage of nitrogen (N) through ecosystems can be represented as a "loop-within-a-loop" (Figure 2). Nitrogen enters ecosystems primarily through biotic or abiotic processes that "fix" (convert molecular nitrogen [N_2] to biologically available forms) N_2 from the atmosphere. Within the soil-plant system, N

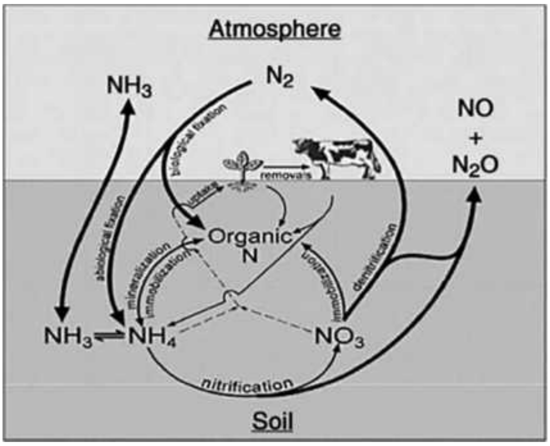

FIGURE 2 Schematic representation of the nitrogen cycle depicted as a “loop-within-a-loop.” The outer loop traces the passage of N from the atmosphere through ecosystems and back to the atmosphere, while the inner loop traces the interconversion of N between organic and inorganic forms within the soil–plant system.

undergoes a complex series of transformations, resulting in a continual transfer of N between inorganic and organic forms—the inner loop (Figure 2). Nitrous oxide and NO_x are both produced and consumed during these transformations. With time, most of the N entering ecosystems returns to the atmosphere as N_2, but an important fraction is emitted as gaseous NH_3, NO_x, and N_2O. More than 70% of the estimated 18 Tg N_2O–N entering the atmosphere each year is emitted by soils.[1,10] Above plant-canopy emissions of NO_x from soils are probably in the range of 3.3–21 Tg N yr^{-1}.[11,12] This exchange of N between the atmosphere and the soil-plant system— the outer loop—strongly mediates atmospheric concentrations of NH_3, NO_x, and N_2O.

Nitric and Nitrous Oxides

The majority of soil-emitted NO_x is nitric oxide (NO);[13] therefore, the rest of this discussion will focus on nitrogen gases other than nitrogen dioxide (NO_2). Nitric oxide is derived primarily via autotrophic nitrification,[14,15] whereas N_2O emissions can be a product of autotrophic nitrification,[15] denitrification,[16] or a combination of both.[14] Nitrous oxide, and particularly NO, may also be emitted from various chemical reactions collectively known as chemodenitrification.[17]

The magnitude of N_2O and NO emissions is strongly influenced by site-specific variables—most particularly soil attributes—and human intervention. Given that both gases are produced primarily during microbial transformations of inorganic N, the potential of a soil to produce and emit N_2O or NO increases with increasing N availability.[18] Anthropogenic activities that increase the flow of N into the system also increase emissions of N_2O and NO. Such activities include, for example, the cultivation of legume grain or forage crops,[19] and intensive use of nitrogen fertilizers.[20]

Total N_2O emissions tend to increase as soil organic carbon (SOC) content increases. This is understandable, since N turnover is closely tied to SOC turnover, and the amount of carbon (C) available to drive microbial processes is directly related to the quantity and quality of SOC. The relative availability of C and N is of particular importance when livestock manure or sewage sludge is added to soils. The addition of both C and N tend to increase N_2O and NO emissions more than N alone, particularly in C limited systems.[21,22]

Agricultural management practices that minimize soil disturbance tend to increase soil water status and soil bulk density, favoring the development of anaerobic conditions and higher N_2O[4] but possibly lower NO emissions.[23] Conversely, equal or lower emissions of N_2O have also been reported in no-tillage systems compared to conventional tillage systems.[24] In this instance, reduced soil disturbance appeared to alter N cycling, resulting in lower NO_3^- availability—hence lower N_2O emissions—during the spring thaw period.

In general, soil conditions or management that lead to accumulations of NH_4^+, NO_3^-, and particularly NO_2^-, favor gaseous N losses. This may happen if N is released during soil C mineralization at a time when plant uptake is absent or minimal, an example being bare soil fallow periods commonly employed in the semiarid regions of North America, or if fertilizer or organic N is added at a time when crop growth is not vigorous. Low soil pH levels (<5) inhibit NO_2^- oxidizers more than NH_4^+ oxidizers, resulting in accumulations of NO_2^- and abiotic production of NO.[25] The latter may occur even in near-neutral soils as a result of very high concentrations of NH_4^+ localized in urine patches, or concentrated in bands or nests of ammonium based fertilizers.[26]

Ammonia

The production of ammonia (NH_3) in soils is closely linked to the accumulation of ammonium (NH_4^+) resulting from the mineralization of organic matter (ammonification) by soil microbes. In agricultural soils, the NH_4^+ content is enhanced where inorganic nitrogen and livestock manure fertilizers are used. In soil solution, NH_4^+ dissociates and forms an equilibrium with NH_3, which can volatilize to the soil air and eventually reach the atmosphere [Eq. (1)]. Ammonium is also bound to negative exchange sites on soil organic matter and clay minerals (exchangeable NH_4^+) and can be "fixed" within clays. The latter is released slower than exchangeable NH_4^+.[27] Ammonium is converted through biological oxidation (nitrification) by soil bacteria (nitrifiers) to nitrate (NO_3^-) which is taken up by plants. Atmospheric NH_3 and NH_4^+ can be recycled back to the soil through dry and wet deposition (Figure 2).

$$\begin{array}{l} NH^+_{4(\text{solution})} \Leftrightarrow NH^+_{4(\text{exchangeable})} \Leftrightarrow NH^+_{4(\text{non-exchangeable})} \\ \Updownarrow \\ NH_{3(\text{solution})} \Leftrightarrow NH_{3(\text{soil air})} \Leftrightarrow NH_{3(\text{atmosphere})} \end{array}$$

The volatilized NH_3 from soil is not only a loss of valuable nitrogen for crop growth [28] but is a significant source of atmospheric NH_3[29,30] which can damage plants[31,32] and contribute to odor nuisances that are associated with the application of manure to soils. In the atmosphere, NH_3 neutralizes atmospheric acids and the resulting aerosols contribute to atmospheric haze. Atmospheric NH_3 can also cause acidification of ecosystems by augmenting the capture of sulfur dioxide in clouds[33] and through nitrification of deposited NH_4^+ and NH_3.[34]

Most management techniques that relate to minimizing NH_3 emissions pertain to managing inorganic and livestock manure fertilizers, which are the most significant sources of this gas.[30,35] The key to these techniques is to reduce exposure of the amendment to the atmosphere either by limiting the amount applied or by injection/incorporation of the amendment. Manipulating the chemistry of the soil can also be used to control NH_3 emissions especially in amended soils.[36,37] For example, the addition of acids to fertilized soils can potentially reduce NH_3 emissions. Adding heavy metals or organic compounds with urea fertilizer can inhibit the conversion of urea to NH_4^+ by retarding urease enzyme activity. There is also the potential of adding Ca or Mg salts with urea fertilizers to reduce NH_3 emissions.

Meteorological and soil conditions also modify the emission of NH_3. Application of manure when soil moisture is initially high but subject to rapid drying can result in higher than normal emissions of NH_3.[36,38] High soil moisture content would put more NH_4^+ into solution near the soil surface and increase volatilization. However, irrigation or rainfall following application can leach nearsurface NH_4^+ and decrease volatilization.

Conclusions

Soil quality and carbon and nitrogen gas dynamics are closely linked. In general, high-quality soils have high nutrient availability and aeration, good infiltration and retention of water, and a stable structure, all of which are factors that control the production and consumption of gases in soils. Improving soil quality through higher soil organic C content or better soil structure often results in a reduction of net emissions of greenhouse gases into the atmosphere. Also, soil degradation increases emissions of greenhouse gases as a result of greater use of nitrogen fertilizers, erosion, denitrification, deforestation, and grassland cultivation.[39] Therefore, adoption of most management practices aimed at improving soil quality also help to improve atmospheric quality.

Sustainable Agriculture: Soil Quality

John W. Doran and
Ed G. Gregorich

Introduction

Growing human populations, diminishing nonrenewable resources, social and political instability, and environmental degradation threaten the natural processes that sustain the global ecosphere and life on Earth.[1,2] With losses of farmland to degradation and urbanization and little new agricultural land to develop, meeting the needs of future populations for food, fiber, and other agricultural products depends on a significant increase in crop yields. Under current food production practices, this yield increase spells greater use of inputs (e.g., energy, fertilizer, pesticides), and raises the question of the environmental costs of increased production.

Agriculture and Environmental Sustainability

To a large extent, the economic and social viability of agriculture depends on the sustainability of the resources that agriculture both depends on and affects. Farmers have always intuitively known that good soil quality underpins the success of their operations, and soil conservation programs in many countries throughout the last century supported this recognition. Since the late 1980s, interest has grown in a fuller accounting of the environmental costs of agricultural production. These costs include declining water quality and competition for finite water resources, declining air quality, emission of greenhouse gases, loss of wildlife habitat, and decline in species and genetic diversity.[3] To a large extent, conserving and enhancing soil quality can mitigate these costs.

Soil

Agricultural land management in the past has taxed the soil system, often withdrawing more than it has returned. In particular, mechanical cultivation and the continuous production of row crops has resulted in the displacement and loss of soil by erosion, large decreases in soil organic matter, and a concomitant release of carbon as carbon dioxide into the atmosphere.[4] Within the last decade, inventories of soil productive capacity indicate human-induced degradation on nearly 40% of the Earth's arable land as a result of land clearing, extensive soil cultivation, soil erosion, atmospheric deposition of pollutants, over-grazing, salinization, and desertification.[5] The projected doubling of the human population in the next century threatens even greater degradation of soils and other natural resources.[6]

Water

Intensive farming practices have, in many parts of the world, jeopardized the quality of surface water and groundwater through the addition of agriculturally derived nitrate nitrogen, phosphorus, pesticides, sediment, and pathogens (e.g., bacteria from manure). Agriculture is considered the most widespread contributor to nonpoint-source water pollution in the U.S.[7] The major agricultural water contaminant in North America and Europe is nitrate nitrogen derived from atmospheric deposition, livestock manures, and commercial fertilizers. Human alterations of the nitrogen cycle have almost doubled the rate of nitrogen input to terrestrial ecosystems over the past 30 years, resulting in large increases in the transfer of nitrogen from land to the atmosphere and to rivers, estuaries, and coastal waters.[8–10]

Agriculture, competing as it does with many other uses of fresh water, is also at the heart of current discussions of water quantity and is a key consideration in the trend toward demand management, rather than supply management, of water resources. Global warming scenarios predict water shortages in some existing agricultural areas in the world, and water surpluses in others. Changing conditions will call for new ways of farming and of resolving conflict among water users.

Controlling soil erosion reduces the amount of sediments entering waterways, along with the chemicals (e.g., pesticides) and pathogens they carry. Nutrient management plans that account for all sources of nitrogen and phosphorus and match nutrient application more closely to plant needs reduce the risk of nitrogen and phosphorus entering groundwater and surface water. Maintaining soil quality improves the ability of soil to receive and partition water, making the most efficient use of this resource.

Air and Atmosphere

Atmospheric concentrations of greenhouse gases—particularly nitrous oxide, methane, and carbon dioxide—have been increasing dramatically over the past 20 years, enhancing the greenhouse effect by which the Earth's atmosphere is warmed. Agriculture is a significant contributor of these gases to the atmosphere; in Canada, for example, agriculture accounted for about 10% of total 1996 emissions of these gases, an increase of about 4% since 1981.[11] Soil management practices such as tillage, cropping patterns, and the use of manure and commercial fertilizers influence atmospheric quality through changes in the soil's capacity to produce or consume greenhouse gases.[12,13] Under the United Nations Framework Convention on Climate Change and its Protocols, signatory countries are considering ways to reduce emissions, including those from agriculture, and also to capitalize on agricultural sinks of greenhouse gases, such as by carbon sequestration in agricultural soils. The present threat of ozone depletion and global climate change necessitates a better understanding of the influence of land management on soil processes.

Agricultural emissions of ammonia (from fertilizer and manure) and particulate matter (dust released during soil tillage and subsequent erosion) have been linked to various environmental effects, such as acidification, eutrophication, and smog. Reducing the emission of these substances involves improving the quality of soils so that they are more resistant to erosion, reducing tillage and increasing the amount of soil cover, and practicing better nitrogen management (both manure and commercial fertilizer).

Agroecosystem Biodiversity

Agriculture benefits from biodiversity in many ways, but it has also reduced biodiversity over the years, mainly through the conversion of natural habitats, but also through effects on soil and water quality.

Improving soil quality not only maintains a healthy biological community in the soil itself, along with the functions these organisms carry out, but also supports the other flora and fauna dependent on this community. Soil quality improvements that benefit water quality can also improve the viability of aquatic ecosystems.

Assessment of Soil Quality

Assessment of soil quality or health is invaluable in determining the sustainability of land management systems.[14] Soil quality is the major link between the strategies of conservation management practices and the achievement of the major goals of agriculture.[15,16]

Assessment of soil quality can be used to identify problem production areas, make realistic estimates of food production, monitor changes in sustainability and environmental quality as related to agricultural management, and assist government agencies in formulating and evaluating sustainable agricultural and land use policies (Figure 1). Using simple indicators of soil quality and soil health that have meaning to farmers and other land managers is likely the most fruitful means of linking science with practice in assessing the sustainability of land management practices.[17]

Doran et al.[18] stressed the importance of holistic management approaches that optimize the multiple functions of soil, conserve soil resources, and support strategies for promoting soil quality. They proposed a basic set of indicators to assess soil quality and health in various agricultural management systems. Many of these key indicators are very useful to specialists (e.g., researchers, consultants, extension staff, and conservationists) but are beyond the expertise or time constraints of the producer to measure. Success in developing and implementing standards for assessing soil quality and sustainability hinges on partnership with agricultural producers, who are the primary stewards of the land and the chief decision makers regarding land use and management. In light of this consideration, Doran et al.[18] also presented strategies for sustainable management that include a more generic set of indicators to assess soil quality and health that are practical for producers (Table 1). A study conducted in the northern U.S. corn and dairy belt used a similar approach to determine how farmers assess soil quality and health and found that they ranked soil organic matter, crop appearance, and risk to erosion as the three most important properties for describing soil health and sustainable management.[17] Such strategies maximize the benefits of natural cycles, reduce dependence on nonrenewable resources, and help producers

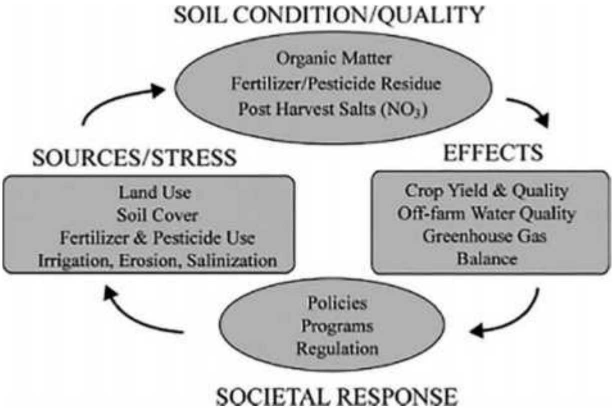

FIGURE 1 The politics of soil health. The assessment of soil condition/quality is needed to monitor changes in sustainability and environmental quality as related to agriculture management and to assist governmental agencies in formulating realistic agricultural and land use policies.

TABLE 1 Strategies for Sustainable Agricultural Management and Proposed Indicators of Crop Performance and Soil and Environmental Health

Sustainability Strategy	Indicators for Producers
Conserve soil organic matter through maintaining soil C and N levels by reducing tillage, recycling plant and animal manures, and/or increasing plant diversity where C inputs C outputs	Direction/change in organic matter levels with time (visual or remote sensing by color or chemical analysis), specific organic matter potential for climate, soil, and vegetation, soil water storage
Minimize soil erosion through conservation tillage and increased protective cover (residue, stable aggregates, covercrops, green fallow)	Visual (gullies, rills, dust, etc.) Surface soil properties (topsoil depth, organic matter content/texture, water infiltration, runoff, ponding, % cover)
Balance production and environment through conservation and integrated management systems (optimizing tillage, residue, water, and chemical use) and by synchronizing available N and P levels with crop needs during the year	Crop characteristics (visual or remote sensing of yield, color, nutrient status, plant vigor, and rooting characteristics) Soil physical condition/compaction Soil and water nitrate levels Amount and toxicity of pesticides used
Better use of renewable resources through relying less on fossil fuels and petrochemicals and more on renewable resources and biodiversity (e.g., crop rotations, legumes, manures, integrated pest management)	Input and output ratios of costs and energy Leaching losses/soil acidification Crop characteristics (as listed above) Soil and water nitrate levels

Source: Postel et al.[2]

identify long-term goals for sustainability that also meet short-term needs for production. Soil quality assessment must be directed at the financial survival of the farm as well as environmental preservation.

Although much remains to be done, useful models exist for translating soil science into practice. For example, Gomez et al.[19] provide a practical framework for determining the sustainability of hill country agriculture in the Philippines. It uses indicators that satisfy both the needs of the farmer (e.g., productivity, profitability, stability, and viability) and the conservation of soil and water resources. Threshold values for sustainability are identified relative to the average local conditions for crop yield, profit, risk of crop failure, soil depth, percent soil cover, and soil organic matter content. This conceptual framework for assessing sustainability could be expanded to include other needs of society and environmental conservation. In particular, adding a category for balancing energy input and output, as well as monetary costs, would better assess the short- and long-term sustainability of management and the value of greater reliance on renewable resources and less dependence on fossil fuels and petrochemicals in enhancing economic, ecological, and environmental resources. Expanding the list of resource conservation variables to include leachable salts (especially nitrate), measured as soil electrical conductivity at the time of fertilization and after harvest, would permit land managers to better quantify the impact of agricultural practices on air and water quality.

Confirmation of the effectiveness of systems for residue management, organic matter formation, nitrogen and carbon cycling, soil structure maintenance, and biological control of pests and diseases will assist in discovering approaches that are both profitable and environmentally sound. The challenge in the future will be to better use the diversity and resiliency of the soil biological community to maintain a quality ecosystem, thus fostering sustainability. Sustainability strategies must be fine-tuned using such practices as crop rotation for greater crop diversity and tighter cycling of nutrients, reduction of soil disturbance to maintain soil organic matter and reduce erosion, and development of systems that make greater use of renewable biological resources. Ultimately, the indicators of soil quality and strategies for sustainable management must be linked to the development of management systems that foster reduction in the inputs of nonrenewable resources, maintain acceptable levels of productivity, and minimize impact on the environment.

Drought and Agricultural Production in the Central Andes

Claudia Canedo-Rosso, Ronny Berndtsson, and Cintia B. Uvo

Introduction

Agricultural production is highly sensitive to climate hazards, including droughts. Losses due to drought events represent a significant challenge to farmers, agricultural stakeholders, and policymakers worldwide (UNISDR, 2015). The scientific community predicts an intensification of negative impacts due to future climate change (IPCC, 2013). The UN Sustainable Development Goals (SDGs) state that the priority areas for adaptation to climate change are water and agriculture. These, in turn, are related to the largest climate hazards that are drought, floods, and higher temperature (UN, 2016). Droughts originate from the lack of precipitation during a specific period of time, resulting in water shortages in a specific region (Wilhite and Glantz, 1985). The rainy season in the Central Andes generally occurs during the austral summer (DJFM). In this period, the position of the Atlantic intertropical convergence zone (ITCZ) and the formation of the Bolivian High result in a prevalence of easterly winds over the Central Andes (Garreaud et al., 2003). Easterly winds transport humid air from the lowlands east of the Central Andes to the region, while the prevalence of westerly winds inhibits moisture transport (Lenters and Cook, 1999; Thibeault et al., 2012; Vuille et al., 2000). The summer rainfall represents more than 70% of the total annual precipitation (Canedo-Rosso et al., 2019b; Garreaud et al., 2003). Spatially, precipitation in the Central Andes presents a northeast-southwest gradient with annual precipitation above 800 mm in the northeastern decreasing to below 200 mm in the south-western Central Andes (Vuille et al., 2000).

Agricultural production is directly affected by climate hazards in the Central Andes, and drought conditions may lead to shortage of food for humans and animals (Garcia, 2003; Garcia et al., 2007). This is the case for the most important crops in the Central Andes: quinoa and potato, which are affected by precipitation variability, and losses in crop production are connected to drought (Garcia et al., 2003). Precipitation in the Central Andes is strongly associated with the El Niño Southern Oscillation (ENSO), which warm phase is connected to droughts (Garreaud and Aceituno, 2001; Thompson et al., 1984; Vicente-Serrano et al., 2015). The ENSO is a periodical variation in sea surface temperature (SST) over the tropical Pacific Ocean with intervals of 2–7 years and may be represented by three phases: neutral, warm (El Niño), and cold (La Niña) phases. In Bolivia, large socio-economic losses have been experienced in the past due to ENSO. For example, El Niño 1982–1983 affected 1.6 million people in rural areas (mainly Potosí and Oruro), 85% of potato and 50% of quinoa production were lost due to decreasing water supply, and a total loss of USD 400 million was estimated (Mariscal et al., 2011). In 1997–1998, 135,000 people were affected and USD 515 million loss was estimated (UNDP, 2011). More recently, during the 2015–2016 El Niño, 665,000 people were affected and over USD 450 million of losses were experienced (Guha-Sapir et al., 2016). To lessen the long-term impacts of similar events, the Bolivian national government has allocated large budget amounts for emergency operations to compensate part of the losses, which are usually evaluated in an ex-post fashion. Important in this context is that Bolivia has implemented a national program for risk disaster management that includes an early warning system informing about disaster occurrence a few days ahead of the event.

Precipitation Variability

Principal component analysis (PCA) was applied to the summer precipitation (DJFM) and Nino3.4 for seeking their relationship. The monthly precipitation at El Alto, Patacamaya, Oruro, and Potosi (Los Pinos) was obtained from the National Service of Meteorology and Hydrology (SENAMHI) of Bolivia from 1948 to 2016 (Figure 1). And, ENSO, Nino3.4 data were obtained from Rayner et al. (2003) for the region 3.4 for the same time period (see https://www.esrl.noaa.gov/psd/gcos_wgsp/Timeseries/Nino34). El Alto and Oruro datasets had no missing data. Patacamaya and Potosi time series had less than 10% missing data. The data gaps of the time series were replaced with the monthly mean of each time series. The summer precipitation (DJFM) totals for El Alto, Patacamaya, Oruro, and Potosi and the summer average of Nino3.4 from 1948 to 2016 were used in this study. Prior to the PCAs, all seasonal data were standardized to zero mean and unit standard deviation. PCA was developed by Pearson (1901) and Hotelling (1933). It reduces data dimensionality and concentrates variance into a small number of variables. All numerical computations were performed using the MATLAB software.

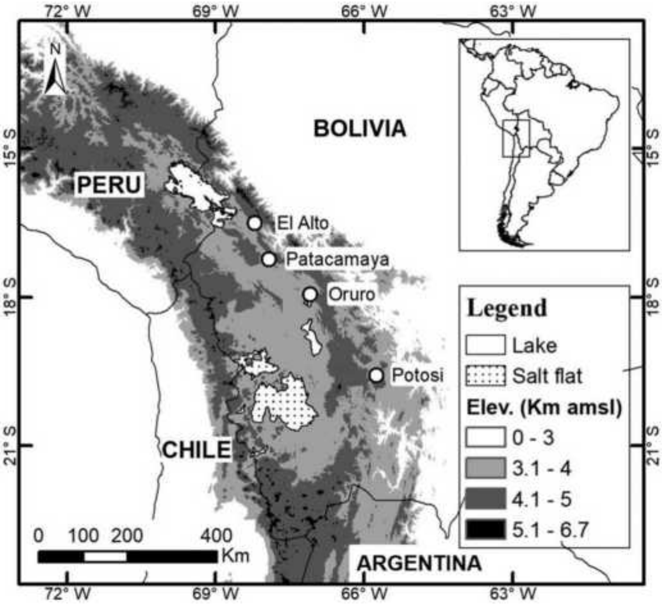

FIGURE 1 The Central Andes of South America.

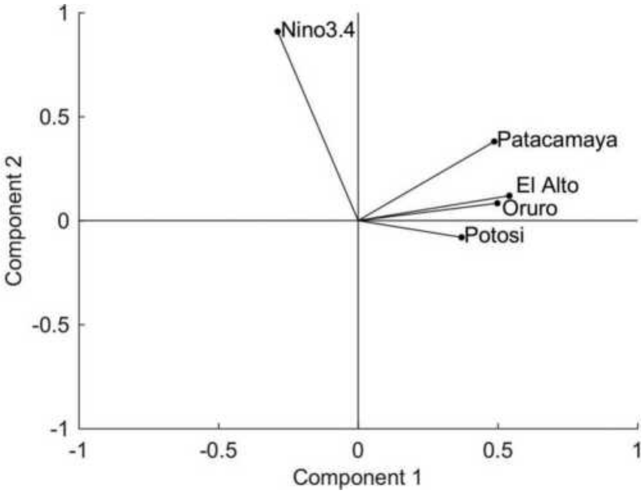

FIGURE 2 Biplot of the first and second modes for the PCA for the summer precipitation and Nino3.4.

The results of the PCA show that the first two modes explain about 70% of the total variance (Figure 2). The first mode explains about 50% of the variance and shows a negative relationship between summer precipitation and ENSO for all studied locations. The correlation coefficients of the first mode are 0.5 for El Alto, Patacamaya, and Oruro; 0.4 for Potosi; and −0.3 for Nino3.4. These results confirm previous findings that there is a negative relationship between precipitation and ENSO (see Canedo-Rosso et al., 2019b; Garreaud et al., 2003; Garreaud and Aceituno, 2001; Thibeault et al., 2012). This means that less rainfall occurs during warm ENSO phases, and this condition could exacerbate the occurrence of drought. The second mode explains about 20% of the total variance and shows a difference for summer precipitation pattern in the studied region. Patacamaya shows a larger variation of precipitation compared to the other locations, with a correlation coefficient of 0.4. The heterogenic topography could be a factor that increases variance of precipitation in the studied region. The Central Andes is divided into two mountain ranges, and between these is the Altiplano high plateau. El Alto, Patacamaya, and Oruro are located on the plateau, and Potosi is located on the eastern range of the Central Andes. This could explain the slight negative relationship between the precipitation for Potosi and the other locations.

Impacts of El Niño – Southern Oscillation on Crop Yield

Precipitation dependency by rainfed agriculture and frost risk limit farming production to the austral summer (Condori et al., 2014; Garcia et al., 2007). Due to the fact that farming is mostly rainfed, weather-related phenomena are very important for crop production. The ENSO impact on crop yield was analyzed using two-sample t-test and Wilcoxon's rank-sum tests for La Paz (including El Alto and Patacamaya), Oruro, and Potosi from 1981 to 2017. The crop yield for potato and quinoa was standardized and filtered by PCA, and the time series were reconstructed keeping about 90% of their original variability to reduce noise. To test the relationship, crop yield during neutral/moderate years was compared with crop yield during strong and very strong El Niño years (warm ENSO phase) (see Table 1). The results showed that quinoa yield during warm ENSO phase and neutral/moderate years presents a significant difference at 95% confidence level except for Oruro. The average yield during neutral/moderate years is higher compared to El Niño years in La Paz and Potosi. The crop yield during El Niño years is lower than the mean in Oruro, except for 1982–1983 and 2015–2016. This contradicts previous findings that reported large agricultural losses during 1982–1983, 1997–1998 (Mariscal et al., 2011; Santos, 2006),

TABLE 1 Classification of ENSO

Strong and [a]Very Strong El Niño	Neutral and Moderate	Strong La Niña
1982–1983[a]	1981–1982	1988–1989
1987–1988	1983–1987	1998–1999
1991–1992	1989–1991	1999–2000
1997–1998[a]	1992–1997	2007–2008
2015–2016[a]	2000–2007	2010–2011
	2008–2010	
	2011–2015	
	2016–2017	

Strong and very strong El Niño (≥ 1.5°C), strong La Niña (≤ –1.5°C), and neutral/moderate (–1.4 to 1.4°C) years for the time period from 1981 to 2017.
[a] Very strong El Niño years. From Null (2018).

and 2015–2016 (Valdez, 2017). On the other hand, the quinoa yield has constantly increased during the last years, mainly in Oruro. This could be explained by employment of advanced crop management strategies (e.g., selected crop varieties and application of agricultural innovations), as Oruro is one of the largest producers of quinoa in Bolivia and the world (Ormachea and Ramirez, 2013).

Despite the quinoa's high tolerance to environmental stress including droughts (Jacobsen et al., 2005; Jacobsen et al., 2003), it generally showed large losses during El Niño events (Figure 3). This may be due to the crop´s sensitivity for water stress during specific stages of the growing season, and the most sensitive stages are the emergence, flowering, and grain development (Geerts et al., 2008, 2009). The risk for crop yield reduction could be reduced here with irrigation during the sensitive phases of the quinoa crop development. A strategy like deficit irrigation could be employed (Geerts et al., 2008; Talebnejad and Sepaskhah, 2015). Another strategy to mitigate the crop yield reduction is implementation of crop varieties more resistant to water stress (Sun et al., 2014).

The t-test and rank-sum test results showed that potato yield during neutral/moderate and El Niño years is significantly different at 95% confidence level except for La Paz. The results showed that production during neutral/moderate years is higher in Oruro and Potosi. All regions showed the lowest potato yield during strong El Niño 1982–1983, with a yield reduction of four standard deviations below the mean. The yield reduction during El Niño events seems to have a larger effect in Oruro. In La Paz, potato yield showed lower vulnerability to El Niño, except during the strong events of 1987–1988 and 2015–2016 (Figure 3). This could be explained by closeness to the Lake Titicaca and other water bodies that might be used as a water source during precipitation deficit. Similar strategies for drought mitigation (e.g., irrigation and resistant crop varieties) could be implemented in order to avoid large crop losses. However, knowing that a very strong El Niño could lead to large agricultural losses, insurance policy could be assigned to farmers in order to manage the risk before the occurrence of a drought event (Canedo-Rosso et al., 2019a). For the implementation of any drought mitigation strategy, identification, evaluation, and monitoring of drought risk are crucial. Especially important are our findings that ENSO must be taken explicitly into account in such considerations.

As mentioned before, ENSO is the most important climate phenomenon that affects the variability of precipitation in the Central Andes (Canedo-Rosso et al., 2019b; Garreaud et al., 2003; Garreaud and Battisti, 1999; Vuille, 1999; Vuille et al., 2000), and it is known that its warm phase is connected to dryer and warmer conditions in the Central Andes. This information could be used for the development of seasonal forecast of precipitation and temperature over Central Andes as ENSO forecasts are developed at major global research and operational centers (e.g., International Research Institute for Climate and Society and Climate Prediction Center). When an El Niño is predicted, it is possible to assume that less

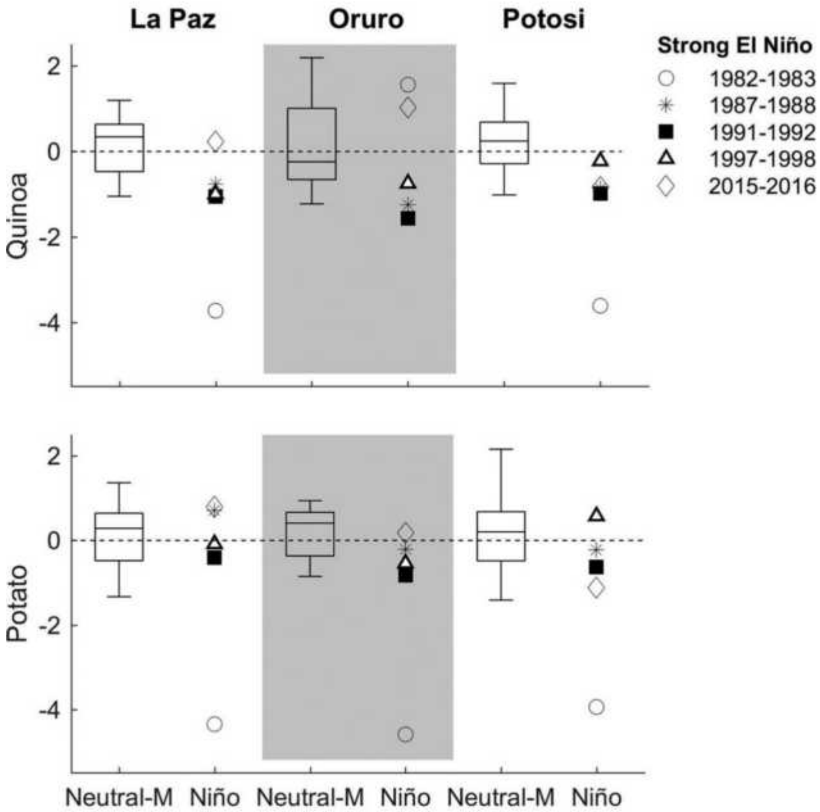

FIGURE 3 Crop yield during neutral/moderate and ENSO years. (Boxplots of quinoa and potato yield anomalies for neutral and moderate (Neutral-M) years for La Paz, Oruro, and Potosi. Crop yield anomalies during strong El Niño years (markers). Based on Canedo-Rosso et al. (2019a).)

precipitation and higher temperature could eventually lead to drought occurrence in the Central Andes during the growing season. Moreover, higher temperatures increase evapotranspiration rates and loss of water content in the soil. For a scenario of high probability of drought occurrence, the application of ex-ante strategies could mitigate its negative effects. Thus, in agriculture, these strategies could reduce crop production losses (Canedo-Rosso et al., 2019a). There are several ex-ante strategies for drought management in agriculture. Examples of these are as follows: use crop or varieties resistant to drought, install irrigation systems, and allocate financial compensation or insurance policy to farmers. For the implementation of any drought mitigation strategy, identification, evaluation, and monitoring of drought risk are needed.

Conclusions

Droughts in the Central Andes are generally driven by ENSO warm phase, and they affect the agricultural production by lowering quinoa and potato yields by decreasing summer precipitation. Regions that presented accessibility to other water supply sources than precipitation or have a better crop management showed lower influence of drought events. It is important to consider the implementation of ex-ante strategies (such as irrigation, agricultural technology, and insurance), in order to decrease the agricultural loss due to climate hazards in the region. Moreover, the evaluation of causes and consequences of droughts could support seasonal forecasting, drought risk reduction, and sustainable water management.

Mines: Rehabilitation of Open Cut

Douglas J. Dollhopf

Introduction

Mining directly disturbs approximately 240,000km^2 of the Earth's surface.[1] Surface mining methods may be classified as: 1) open pit mining; 2) strip mining; 3) dredging; and 4) hydraulic mining.[2] Open pit mining includes quarries used to produce limestone, sandstone, marble, and granite; pits used to produce sand, gravel, and bentonite; and large excavations used to produce talc, copper, gold, iron, silver, and other metals. This mining method is distinguished by having one large pit or numerous small pits across the landscape. State or federal governments establish regulations that require the operator to restore the land to an approved land use(s) that is equal to or better than the premine land use. The approved postmine land use(s) is instrumental in determining the final graded topography and vegetation community.

Landscape Regrading

Reclamation of an open pit mine must address the open pit itself, waste rock removed from the pit to gain access to the ore, tailing impoundments, and access roads (Figure 1). For open pit mines, complete backfilling of the pit is not usually economically feasible. Because the pit remaining after mineral extraction may be hundreds of feet deep, the cost of moving waste rock back into the depression is prohibitive. Surface and groundwater may flow into the depression after mining is terminated and an impoundment develops. Pit slopes should be reduced to the limits required for safe access for humans, livestock, and wildlife. Pit slopes should not be permitted at gradients that jeopardize the success of postmine reclamation.

FIGURE 1 Large open pit mine in the U.S. with water impounded in bottom.

Coversoil Resources

Successful plant community establishment on an open pit mine site is a direct function of the coversoil quality applied. Coversoil suitability criteria vary in the US from state to state, but are similar to those presented in Table 1. The coversoil resource emanates from two procedures: 1) salvaging the natural soil resource from the area to be disturbed and 2) mining unconsolidated geologic stratum when the soil resource is absent. Under present US federal and state mine regulatory programs, all portions of the soil resource shall be salvaged in a project area if it meets physicochemical suitability criteria. Soil materials that do not meet these suitability criteria are generally not used since they may impair plant establishment and growth. Once the soil resource is salvaged, it should be directly hauled to an area that has been backfilled and is ready to receive coversoil. Direct hauled soil contains a viable seed bank, mycorrhizal associations, organic matter, and nutrients that aid in plant establishment. Conversely, if the soil resource is stockpiled, these resources will deteriorate with time.

Prior to implementation of mine land reclamation regulations during the 1970s and 1980s, open pit US mine operations often did not institute land reclamation. The soil resource was not salvaged, the disturbed landscape was not graded to the approximate original contour, and the site was not seeded. Consequently, the soil resource was lost. Today, these lands are being coversoiled using unconsolidated geologic stratum. Valley fill areas adjacent to the disturbed landscape often contain alluvial materials beneath the soil resource that meet all soil suitability criteria (Table 1), except organic matter is absent. This alluvial stratigraphy may be 10–30 m thick or more. Earth moving equipment is used to stockpile

TABLE 1 Coversoil Suitability Criteria

Soil Parameter	Suitability Criteria
pH	>6.5 and <8.0 standard units
Electrical conductivity	<4.0 dS/cm
Exchangeable sodium percentage	<12%
USDA textural classes (12 types)	All suitable except clay, loamy sand, sand
Rock content (particles >2mm diameter)	
Slope gradients <25%	<35%, weight basis
Slope gradients >25%	>35 and <60%, weight basis
As, Cd, Cu, Pb, Zn, other metals	Near back ground levels, i.e., no enrichment
Organic matter	>0.5%, weight basis

the soil resource, separating true topsoil (A-horizon) from subsoil (B- and C-horizons), to enable excavation of deeper alluvial material. Following placement of this alluvial coversoil on the disturbed landscape, the pit created is contoured and the stockpiled soil resource is replaced. Lands receiving coversoil emanating from a geologic stratum should have organic matter applied to expedite establishment of nutrient cycles in the plant root zone. Cattle manure and municipal compost are two sources of organic matter used in land reclamation projects.

Coversoil Thickness Requirements

The thickness of coversoil required for maximum vegetation performance is dependent on several factors including the 1) vegetation species present; 2) local climate; 3) coversoil quality; and 4) physicochemical quality of the substrate beneath the coversoil. The maximum rooting depth of many rangeland ecosystem plant species is less than 45 cm and generally does not exceed 100 cm.[3] Investigators found that a minimum of 40 cm to a maximum of 150 cm of coversoil is needed for optimum plant growth.[4–8] This wide variation of findings is a function of site specific conditions identified before. The Barth[4] investigation is representative of most research. This investigator found that generic spoil, defined as nonalkaline and nonsaline loams with sodium adsorption ratio (SAR) below seven, showed an increase in plant production up to a coversoil depth of approximately 50 cm. Sodic spoil, or material with SAR of 26 or higher, required a minimum of 70 cm of coversoil to reach maximum cool season grass production. Coversoiled acid spoils, defined as spoils exhibiting pH values between 3.6 and 4.3, revealed increased grass production up to the maximum coversoil depth used in this study (152 cm).

In Situ Soil Reclamation

In situ soil reclamation at open cut mine sites means no coversoil resource is used. Chemical and/or organic amendments are applied to the graded spoil, tailings, or waste rock landscape to enable plant establishment and growth.

In Situ Sodic Minesoil Remediation

Thousands of hectares of land in Wyoming and Montana were open pit mined for the mineral bentonite prior to passage of state regulations requiring land reclamation. The absence of a soil resource to reclaim these lands means the plant ecosystem must be established on graded spoils. Spoils are overburden materials cast aside to access the underlying mineral, bentonite. These overburden materials have a sodic condition (ESP 20–40), clay texture (60% clay) dominated by swelling clay minerals such as smectite, and preclude plant establishment and growth. In situ soil remediation requires a two-fold approach: 1) permanently reduce exchangeable sodium percentage (ESP) to less than 10 within the 0–30 cm soil profile and 2) provide an organic amendment to immediately prevent soil crust development and increase water infiltration. Crust development in these clayey-sodic soil systems is precluded with applications of wood chips from saw mill waste or manure.[9] Applications of gypsum, calcium chloride, magnesium chloride, and sulfuric acid to these sodic soils have been shown to be effective at reducing the ESP to acceptable levels in minesoils and provide a root zone suitable for plant growth.[10]

In Situ Acid Minesoil Remediation

Open pit mines associated with gold, silver, and metal extraction from sulfide ore bodies frequently produce tailings impoundments and waste rock areas that are acidic (pH 2.5–5.5) and fail to support plant growth. Soil acidity is formed when sulfide minerals, such as pyrite, are exposed to oxidizing conditions in the presence of water. In the absence of a coversoil resource, tailings and waste rock material are treated with alkaline amendments to permanently neutralize the soil acidity. Soil analysis of the acid base account and active acidity enable determination of the calcium carbonate requirement.[11] Amendments used include calcium carbonate, calcium hydroxide, and calcium oxide. In situ treatment with amendments should be at least to the 45 cm soil depth and special engineered plowing equipment is required to attain this depth of incorporation.[12]

Acid Mine Drainage

Upon exposure of open pit mine wastes to water and oxygen, sulfide minerals oxidize to form acidic, sulfate rich drainage.[13] Iron-oxidizing bacteria, e.g., *Thiobacillus ferrooxidans,* expedite the acid producing reaction rate up to a million times. Metal composition (Al, Cu, Fe, Mn, Pb, Zn, and others) and concentrations in acid mine drainage (AMD) depend on the type and quantity of sulfide minerals present. Approaches to prevent or treat AMD include: 1) removal of air and water from the sulfide body that is disturbed; 2) wetland construction to precipitate contaminants with oxidation ponds and anaerobic-microbial reactions in plant root zones; 3) underground anoxic-and above ground open-limestone drains to raise water pH; and 4) treatment of drainage with neutralizing chemicals such as hydrated lime, quicklime, soda ash, caustic soda, and ammonia.[14]

Steep Slope Reclamation

Open pit mines are frequently located in mountainous terrain and reconstructed slopes may have gradients as steep as 50%. Sediment yields tend to increase linearly with slope gradient. There is an inverse relationship between soil loss on slopes and rock cover.[15] High rock content in soils increases infiltration rate and surface roughness decreasing runoff and soil loss. As erosion occurs on rocky soil, rock cover increases as the coarse fragments below the surface are exposed. This armoring of the soil surface can help reduce soil erosion. It has been reported that plant growth may be impaired when soil rock content exceeds 35%.[16] High rock contents of 35%–60% applied on steep slopes (Table 1) may impair plant growth, but are considered a best management practice to facilitate plant establishment and slope stability.

Construction of shallow pits across steep slopes is commonly practiced to increase water storage on the slope and minimize runoff. Pitting techniques using equipment referred to as Dammer–Diker, gouger, and dozer basin blade have been shown to be effective in controlling sediment loss.[17]

Conclusions

During these past 30 years, land rehabilitation sciences at open pit mines developed at an exponential rate. Grading the mined landscape to the approximate original contour, use of adequate amounts of—and quality of—coversoil, and development of in situ soil treatments at sites where coversoil resources were absent have all provided means to establish a diverse plant community. Techniques have been developed to revegetate and stabilize slopes approaching a 50% gradient, which is an asset for mines located in mountainous terrain. Methods to control and treat AMD from open pit mines continue to improve, but this impact to surface water resources remains unresolved. Future research is required to develop better AMD treatment methods.

Bioenergy Crops: Carbon Balance Assessment

Rocky Lemus and
Rattan Lal

Overview

Global production and use of bioethanol, derived from corn and sugarcane, doubled between 2007 and 2016.[1] Annual bioethanol production was 103 billion liter in 2016 and increased to 106 billion liter in 2017.[2] Several herbaceous species have been assessed as potential energy sources and for carbon (C) sequestration since the 1990s. Switchgrass (*Panicum virgatum* L.), a herbaceous species, and two short-rotation woody crops (SRWCs), hybrid poplar (*Populus* spp.) and willow (*Salix* spp.), are promising for C sequestration and biofuel production. Using these species as energy crops can partly offset CO_2 emitted by fossil fuel combustion. However, biomass yield of these promising species depends on environmental differences across years and across sites along with differences due to application of nitrogenous fertilizers.[3]

There are approximately 60 million ha (Mha) of degraded soil (severely eroded and mined land) in the United States that can be sown to bioenergy crops to decrease soil erosion and increase C sequestration.[4] The Midwest and the Southeast regions of the United States are the potential areas where bioenergy crops are most likely to compete with other traditional crops for land resources.[5] The use of bioenergy crops in these areas offers an opportunity to replenish the soil organic C (SOC) pool depleted by tillage and soil degradation.

Biomass fuels used in a sustainable manner can result in no net increase in atmospheric CO_2 and thus are C neutral. Indeed, sustainable use of biomass can result in a net decrease in the rate of enrichment of atmospheric CO_2. This is based on the assumption that all the CO_2 emitted by the use of biomass fuels is absorbed from the atmosphere by photosynthesis. However, the water and C footprint of bioethanol may vary widely. For example, Brazilian bioethanol from sugarcane has a better energy balance (17.7 MJ/L) and lower C footprint (38.5 gCO_{2e}/MJ) than corn-based ethanol in the United States (11.2 MJ/L and 44.9 gCO_{2e}/MJ, respectively).[1] Externalities associated with life-cycle emissions from corn-based ethanol must be addressed.[6,7] Increased substitution of fossil fuels with biomass-based fuels reduces the risk of global warming by enrichment of atmospheric CO_2. This entry discusses the importance of energy crops in offsetting fossil fuel combustion through C sequestration in biomass and soil.

Influence of Bioenergy Crops at the Temporal Scale

Long-term tillage and continuous cropping can reduce SOC pool[8,9] and increase atmospheric concentration of CO_2 (Figure 1).[10] Conversion of natural to agricultural ecosystems results in the net release of C into the atmosphere.[11] Conservation practices, such as the introduction of perennial crops on degraded agricultural soils and growing bioenergy crops, constitute a direct link between sink (SOC) and the source of CO_2 (fossil fuel). Bioenergy crops are the sink/source transition because the C incorporated into their biomass and root system has a high potential of being incorporated into the SOM pool. Most of the C is incorporated into the biomass and soil by the deep and extensive root systems. The SOC pool attains a new equilibrium after grassland restoration, but the time required for SOC to reach equilibrium is variable, especially under diverse climatic conditions.[12,13,14] Most models used to estimate C sequestration in bioenergy crops suggest that a period longer than 10 years may be necessary for pronounced soil-quality improvements.

Benefits of Bioenergy Crops

The SOC pool and its dynamics are the major indicators of soil quality and crop productivity.[13,15] Bioenergy crops can improve soil quality through increase in SOM, nutrient dynamics, erosion control, and improvement in soil structure and porosity. Most perennial crops and SRWCs have extensive root systems that reduce soil erosion and nonpoint-source pollution.

A shift from traditional agricultural crops into perennial bioenergy crops stabilizes agricultural soils, reduces erosion, and improves water quality.[14,16,17] Most of these benefits are due to the elimination of tillage leading to a significant decrease in both erosion and chemical runoff especially nitrate (NO_3–N). Soil erosion and nitrate runoff are reduced in 2-year-old stands of switchgrass when compared to no-till corn (Table 1). Conservation effectiveness of switchgrass is attributed to high root biomass, which stabilizes the soil,[18] depletes excess N and P,[19] and increases microbial activity.[20]

[a] The ratio SWG/NTC of <1 indicates conservation effectiveness of a SWG system during the second and third years of its establishment.

Potential of C Sequestration

Bioenergy crops have the potential to store large quantities of C. Exploring their biomass potential through N fertilization and soil management are some of the proposed strategies to offset CO_2 emissions by fossil fuel combustion. However, a bioenergy crop is not a closed system and only some portion of the C sequestered might be conserved through the production-utilization cycle. Most of the C sequestered in the biomass is utilized for energy production allowing some C release back into the atmosphere. This system does not cause negative impacts as most of the C returned to the atmosphere is recaptured by the plants during the subsequent season.

Assessing the net C sequestration of bioenergy compared to agricultural crops requires analyses of C sequestration across the soil profile. Carbon sequestration is influenced by biological processes such as root biomass and crop species, and by soil physical and chemical aspects such as texture, bulk density, and pH. The amount of C in these types of management options is affected by soil perturbation which could increase SOM oxidation, exacerbating losses, especially at the soil surface. Estimations of C sequestration on land under the Conservation Reserve Program (CRP) have ranged from 0.6 to 1.0 Mg C ha^{-1} yr^{-1} in SOM,[21] compared to 2.0 Mg C ha^{-1} yr^{-1} in SRWC.[22] Root biomass and its relationship to SOC are always positive but may be influenced by soil depth and plant species.[23] Switchgrass improves soil quality via reduced nutrient loss (especially NO_3–N) and increases C sequestration through its deep rooting system, high biomass production, and perenniality.[24] Switchgrass root biomass can be as high as 16.8 Mg ha^{-1} up to 3.3 m deep with some root mass variability among soil type.[20]

The sustainability of soil and crop systems is typically affected by changes in the SOC pool. The largest gain in SOC pool occurs in the upper 30-cm layer. There are differences in the amount of C being sequestered by herbaceous crops and SRWCs, but they have the potential to increase C both in the soil and aboveground biomass. The data in Figure 2 show that after 5 years, SOC pool at 60-cm depth was 97.5 Mg ha^{-1} under willow, 80.5 Mg ha^{-1} under switchgrass, and 78.5 Mg ha^{-1} under corn. The mean rate of SOC sequestration, vis-à-vis corn, over 5 years was 3.8 Mg C ha^{-1} yr^{-1} under willow and 0.4 Mg C ha^{-1} yr^{-1} under switchgrass (Figure 2). The SOC fluctuations are more drastic in the top soil layers, probably because of the greater effect of precipitation, soil temperature, larger root biomass, and greater microbial activity. Long-term experiments on switchgrass in the United States indicate that it is productive and sustainable on rainfed and marginal lands east of the 100th meridian and stands can last up to 10 years with N input of 10–12 kg/ha.[26]

Conclusions

Bioenergy crops can influence the global C cycle. An important challenge in using bioenergy crops is assessing how much C is being sequestered and how much is being put back into the atmosphere by the cofiring process to produce electricity or other sources of energy. Available data indicate that perennial crops are moving in the right direction in improving soil quality while providing an alternative energy

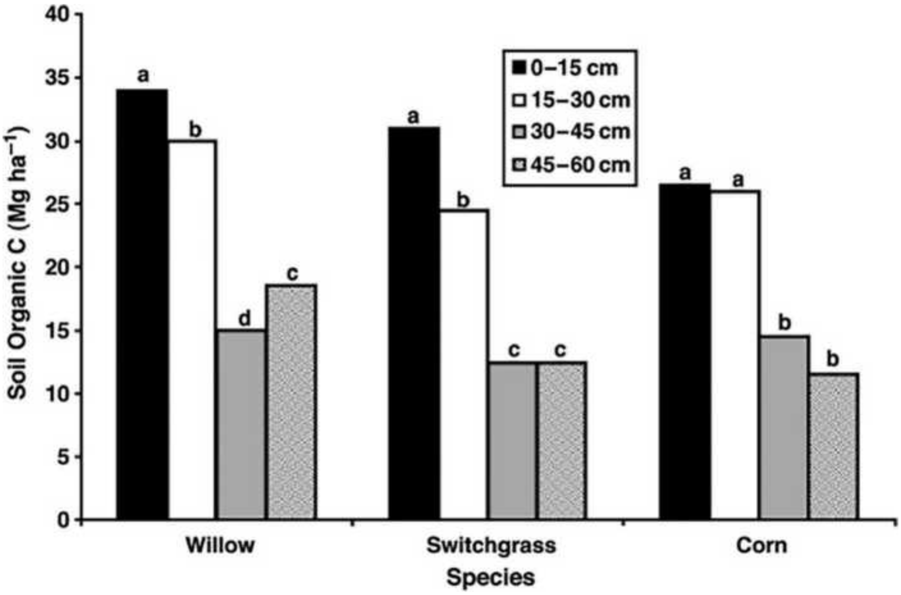

FIGURE 2 Comparison of C sequestration between bioenergy crops and corn at different soil depths 5 years after establishment.
(**Source:** Mehdi et al.[25])

source. A combination of soil C sequestration and bioenergy crops with high biomass capability and deep perennial root systems is a useful strategy of reducing the rate of enrichment of atmospheric CO_2. The use of bioenergy crops increases soil C and improves soil quality by eliminating C losses associated with annual cultivation. However, these improvements depend on the rate of soil C additions, the long-term capacity of the soil for C storage, and the stability or permanence of the sequestered C overtime.

Erosion by Water: Amendment Techniques

X.-C. (John) Zhang

Introduction

Soil erosion by water and wind is a worldwide problem. For example, approximately 36 billion tons of soils were removed from global lands in 2012.[1] Soil erosion is perhaps the major environmental threat to profitability, sustainability, and resilience of world agriculture. This entry focuses on soil erosion by water and its control with various amendment techniques. Soil erosion by water is defined as the amount of soil lost or removed in a specified time over an area of land by the action of raindrops and surface flow of water. Fundamental erosion processes involve detachment, transport, and deposition of soil particles by the two erosive agents. Detachment is the dislodging of soil particles from the soil mass, which is bound together by physical and chemical bonding forces. Transport is the movement of detached soil particles over the soil surfaces. Deposition is the downward motion of sediment particles settling out of the surface flow of water. Deposition occurs when sediment load in the surface flow is greater than the maximum carrying capacity of the flow due to a decrease in surface flow power or velocity.

Based on the predominant erosion forms and mechanisms, erosion by water may be categorized as splash, interrill, rill, ephemeral gully, gully, and stream-channel erosion. Raindrop impact is the primary force causing soil detachment in areas between rills (i.e., interrill area), while net downslope transport by raindrop splash due to the slope effect is very small. Erosive power of the shallow sheet flow in the interrill areas is mostly too low to detach the cohesive soil but high enough to carry the detached soil particles to rills with the assistance of raindrop agitation. Rills are small channels (usually 50–300 mm wide by 50–150 mm deep)[2] normally formed by the incision of concentrated flow and can be obliterated by tillage. Detachment and transport in rills are primarily by flowing water without aiding of raindrop impact. Flow in rills often converges in a few larger channels before leaving the field boundaries. These channels are ephemeral gullies, which are generally shallow and wide (a few meters) but can still be tilled across.[2] When concentrated flow erodes channels deeper than can be crossed with farm equipment, the eroded channels are called gullies.[2] Another important sediment source is erosion in streams, including downward cutting and bank erosion. However, gully and stream erosion are not discussed in this entry because they cannot be directly controlled by any amendment technique. In contrast, upland erosion, which includes splash, interrill, rill, and ephemeral gully erosion, is primarily a soil surface phenomenon and therefore can be effectively controlled by surface treatments with various types of soil amendments. Upland erosion has both on-site and off-site consequences. The main on-site impacts are loss of soil productivity and reduction of soil quality, while the main off-site effects are discharge of sediment and agricultural pollutants (e.g., nitrogen, phosphorous, pesticides, and herbicides) into streams and other surface water bodies. Thus, controlling upland erosion is of great importance in both preserving land productivity and protecting surface water quality.

Material added to soil to benefit soil or plant is called a soil amendment.[3] Soil amendments generally fall into two groups: inorganic and organic. Inorganic amendments include lime, gypsum, coal combustion by-products, stone, gravel, sand, and many others. Organic amendments comprise manure, compost, municipal and industrial wastes such as sewage sludge and paper mill sludge, synthetic polymer, various plant-derived mulches (e.g., crop residue, stubble, sawdust, woodchips, straw, leaves, and barks), etc. Soil amendments, based on their origins, may be arbitrarily grouped into five different categories: mined or mineral, synthetic polymer, manure and compost, municipal and industrial wastes, and mulches. Technically, chemical fertilizers are soil amendments, but conventionally they are not referred to as such. Many materials provide multiple benefits or functions to the soil and crops. Thus, soil amendments cannot be strictly defined. For example, manure has traditionally been used as a fertilizer for centuries, but it also conditions soil by improving its physical, chemical, and biological properties. This is true for almost all organic amendments, either raw or composted, which eventually decompose and release nutrients into soil through nutrient cycling. For comprehensiveness, manure, compost, and organic urban and industrial wastes are considered as soil amendments in this entry.

A closely related term to soil amendment is soil conditioner, which is a subset of soil amendments, aimed at creating favorable physical environments for plant growth such as improving aeration, water infiltration, water holding capacity, soil bulk density, aggregate stability, soil structure, resistance to erosion, and tilth. Soil amendments are either incorporated into the soil or applied on the surfaces. Incorporated materials intend to alter soil properties in the tillage layer, while surface-applied materials are used to primarily protect properties of the soil surface. For centuries, soil amendments such as animal waste, farmyard manure, green manure, crop residues, and composts derived from these materials are often incorporated into soils to recycle plant nutrients and to improve soil structure and tilth. During the past half-century, surface-applied mulches, notill mulches, stubble mulches, and living mulches have been widely used to protect the soil surface from wind and water erosion.[4] In the past decades, agricultural land applications of municipal and industrial wastes, such as sewage sludge, paper mill sludge, and coal combustion by-products have increased dramatically due to increasing landfill costs.[5] More recently, new and inexpensive polymer products have revived the interests in using synthetic polymers to reduce water runoff and soil erosion.

Overall, soil amendments impart beneficial effects on soil physical, chemical, and biological properties and promote plant growth.[3–5] Most amendments are also important agronomic measures for soil erosion control. Soil amendments are often chosen to increase soil aggregation and soil structural stability,[6] increase soil's resistance to erosion, protect soil from raindrop splash erosion, reduce surface seal formation (a thin, dense surface layer with very low water permeability, resulting from raindrop impact), increase water infiltration, decrease surface runoff volume, obstruct water flow, and therefore reduce soil erosion. The specific benefits for erosion control are derived from the decreased erosive power of both raindrop impact and flowing water as well as the increased soil's resistance to erosion. Thus, most amendments are effective in reducing soil erosion by water, though only a few (e.g., standing residue cover, living mulches) are effective in controlling erosion by wind.

Types of Amendment and Erosion Control

Lime

Liming materials such as quicklime (CaO) and limestone minerals are the most widely used amendments that are mined. Liming soil has a long history in the United States. Early settlers started to lime soil from the beginning of the 19th century. By the early 20th century, liming had become a routine agricultural practice to raise soil pH and increase crop productivity. Liming soil generally improves soil physical and chemical properties[3,7] in two ways. First, it neutralizes soil acidity, which reduces phytotoxicity of Al, Mn, and H ions and increases plant availability of Ca and many nutrients and microbial nutrient cycling processes. Second, it promotes soil aggregation and soil structural stability by increasing Ca^{2+} in soil solution and on soil exchange sites. However, overliming can result in soil clay dispersion and aggregate disintegration in highly weathered, high-Al^{3+} low-pH soils. Liming reduces soil erosion by improving soil aggregation and structural stability and by increasing surface cover due to enhanced plant growth. Lime has also been successfully applied as a soil stabilizer and cementing agent to control side sloughing of canal embankments and to prevent subsurface (piping) erosion on earthen dams, which are composed of highly dispersive and expansive clays.[3,8]

Gypsum

Mined and by-product gypsum are widely used as soil amendments to improve soil physical and chemical properties, reduce soil erosion, and increase nutrient availability of calcium and sulfur. Gypsum has been successfully used for decades to correct structurally unstable, high-Na^+ soils (e.g., saline and sodic soils). Because soil clay and organic matter are primary structural components (cementing agents) for aggregate formation, the displacement of clay by dispersion often leads to breakdown of soil aggregates and deterioration of soil structure, while clay flocculation promotes soil aggregation and structural stability. The beneficial effects of gypsum addition on controlling soil erosion result from increased stability of soil aggregates and structure due to elevated electrolyte concentration in soil solution and the predomination of calcium ions on the exchange sites of soil clays.

Cation charge and electrolyte concentration are the two major factors influencing clay flocculation or dispersion.[9] When two clay particles approach each other, their electric double layers (a negatively charged clay surface surrounded by a compensating cation cloud) begin to repel each other when the two cation clouds overlap. The cation cloud is pushed toward the particle surface when electrolyte concentration is increased or when a divalent cation replaces a monovalent cation. The reduction in the cloud thickness results in a decrease in this repulsive force. When a critical electrolyte concentration is reached, van der Waals' attractive force overcomes the repulsive force resulting in a rapid flocculation of clay particles. This concentration is termed critical flocculation concentration (CFC). Because cation charge has a more dominant effect on clay flocculation than electrolyte concentration, Al salts such as alum have been widely used to flocculate suspended particles in many water treatment plants. Among the common soil cations (e.g., Al^{3+}, Ca^{2+}, Mg^{2+}, K^+, Na^+, and H^+), Ca^{2+} has the greatest flocculation power apart from Al^{3+} (Al^{3+} is only significant in weathered, acid soils), while Na^+ has the least. This is why sodic soils have poor aggregate and soil structure stability, and gypsum addition to these soils helps to improve soil structure. Based on these principles, clay particles flocculate when electrolyte concentration is greater than CFC; otherwise, dispersion takes place. A visual demonstration of clay flocculation is illustrated in Figure 1. After 6-hour settling, more dispersed clay particles have formed into microaggregates and settled out to the bottom as solution concentrations of gypsum increase.

It is well known that soils having high concentration of Na^+ are not structurally stable. However, low-Na^+ soils can also be destabilized and dispersed by external forces such as raindrop impact due to low electrolyte concentration in rainwater,[10–12] resulting in seal formation on the soil surface. Clay dispersion and soil aggregate breakdown by raindrop impact are the two primary processes causing seal formation on soil surfaces. Surface seals often have water hydraulic conductivities several orders less than the same non-sealed soils. Thus, surface application of gypsum can prevent clay dispersion, reduce seal formation, increase infiltration, and reduce erosion of easily dispersed soils.

Overall, gypsum addition is effective in preventing clay dispersion, stabilizing soil aggregates and structure, reducing surface seal formation, increasing water infiltration, and reducing soil erosion by water.[3,10,11] It is well documented that gypsum can reduce soil erosion by (1) promoting water infiltration and reducing erosive power of runoff, (2) increasing soil resistance to erosion by increasing aggregate

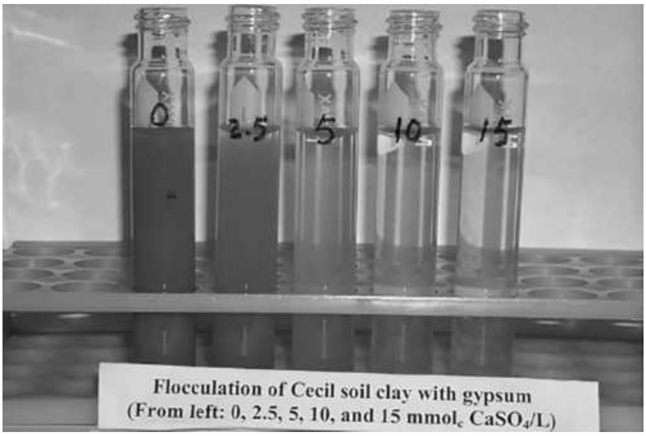

FIGURE 1 Gypsum flocculation test series after 6-hour settling of the Cecil soil clay in gypsum solution.

size and stability, and (3) enhancing flocculation and deposition of clay particles suspended in runoff.[13] Based on field experiment conducted in many countries, surface application of 3–10 Mg/ha of gypsum would considerably reduce surface runoff and soil erosion in most soils for several months after application or until mixed into soils by tillage.[14] If it is applied as a source of fertilizer calcium and sulfur, 0.1–0.5 Mg/ha is often adequate.

Synthetic Polymer

Polymers are repeated monomers chained together to form long extended molecules and are characterized by their molecular weight, configuration, and charge properties. Polyacrylamide (PAM) and polysaccharide are widely studied and used as soil conditioners. They can be cationic, nonionic, and anionic, among which anionic PAM is most widely used. The effectiveness of polymers in altering soil properties is related to their chemical properties, water quality (ionic type and strength), and soil characteristics. The irreversible interaction between polymers and fine soil particles, especially clays, lays the foundation for its ability to stabilize soil aggregates, promote water infiltration, and therefore reduce surface runoff and soil erosion.

The use of synthetic polymers to improve soil physical properties began in the 1950s. In early agricultural studies, polymers were usually incorporated into the entire plow layer to promote structural stability and water permeability. During the 1950s, reports that polymers were effective in reducing erosion, improving water infiltration, and increasing crop yields stimulated a great deal of interest among agriculturists. However, the widespread use of synthetic polymers available at the time was restrained by high cost and large quantities needed for soil incorporation.

Since the 1980s, new polymer products and new application strategies have rekindled interest in these soil conditioners. Only a small amount of polymer, when sprayed on the very soil surface or dissolved in irrigation water, can reduce surface seal and crust formation by preventing clay dispersion and stabilizing soil aggregates, increase water infiltration, and reduce soil erosion.[3] When surface applied, these new polymer products are especially effective with unstable, sealing-prone soils. The thread-like large polymer molecules or interwoven polymer nets are adsorbed strongly (often irreversibly) to soil aggregates and clay particles. The adsorbed polymer nets that surround soil aggregates physically protect them from disintegration by raindrop impact or shear force imparted by flowing water. Polymers can also chain clay particles together to promote flocculation. Polymers have been used to remove fine particles from water body in water treatment plants and in sedimentation ponds.

Anionic PAM, being similar to soil humus in charge property, is most extensively used as soil conditioners. The effectiveness of anionic PAM is usually improved by adding a source of cation such as gypsum because cations are essential for building cation bridges between negatively charged clay particles and PAM molecules. Anionic PAM has also been successfully used to reduce soil erosion in furrow and sprinkler irrigation, on construction sites, and on steep slopes such as road banks.[15] Generally, application rates vary with PAM properties, soil characteristics, and specific goals of a particular treatment. To enhance infiltration and reduce soil erosion in flood and sprinkler irrigation, normally less than 5 kg/ha when dissolved in irrigation water would be sufficient.[3] When sprayed on soil surfaces to control surface seal formation, rates of 10–30 kg/ha are adequate for most soils. To control erosion on steep slopes such as road embankments or on construction sites, greater amounts up to 100 kg/ha may be needed. The effectiveness of PAM in reducing runoff and soil erosion can last several weeks or even months following application.

Manure, Compost, and Organic Sludge

Animal, farmyard, and green manures have been used as organic soil amendments to improve soil productivity for many centuries. Since the 1990s, application of municipal biosolids (sewage sludge) and industrial waste compost such as paper sludge to agricultural lands has increased dramatically. These materials have the ability to increase soil aggregate stability, porosity, and water holding capacity; reduce water runoff and soil erosion; improve soil tilth; increase plant nutrient availability and soil cation exchange capacity; and elevate soil microbial activities.[3] Decomposed organic substances such as humus along with soil clays are primary binding agents for soil aggregation. An increase in soil organic matter content often leads to increases in soil aggregation and structural stability. Thus, addition of organic materials such as manure and compost reduces soil erosion by water by improving soil aggregation, reducing runoff, and increasing soil resistance to erosion. In addition, improved soil conditions and fertility enhance root and plant growth, resulting in greater plant cover and root biomass, which further protect soil and reduce soil erosion. Large amounts of these organic amendments must be applied over decades to substantially increase soil humus levels.

Organic and Inorganic Mulches

Most mulch materials used for runoff and erosion control are naturally occurring. Both inorganic and organic mulches have been used. Inorganic mulches include stone, gravel, sand, and many others, while organic mulches are normally undecomposed materials derived from living matter such as crop residue, hay, leaves, woodchips, and sawdust.[3] These materials dissipate raindrop impact energy, protect surface soil aggregates from disintegration by raindrop impact, prevent surface seal formation, increase water infiltration, reduce the sediment-carrying capacity of overland flow by obstructing flow, and reduce soil erosion.

One of the key benefits of mulches is erosion control. The great benefit of erosion control results from the ability of surface mulches to reduce not only soil detachment by raindrop impact and flowing water but also the sediment-carrying capacity of overland flow. Surface-applied mulches of crop residue, no-tillage mulches, and stubble mulches are found to be the most effective agronomic measures in controlling soil erosion.[16,17] Moreover, living mulches, such as cover crops that are later turned into soil as an organic amendment, permanent grass buffer/filter strips, and grass waterways, are even more effective than residue mulches in controlling soil erosion. These living mulches can increase soil organic matter and nutrient cycling, reduce soil splash by canopy cover, reduce downward scouring of concentrated flow by interlocked root networks, enhance sediment deposition by slowing down water flow, and reduce pesticide and chemical movement to surface waters by adsorption and filtration.

Overall, surface mulches are very effective in reducing surface runoff and soil erosion by water. Many studies have shown that both runoff volumes and soil loss rates decrease rapidly (often exponentially) with increases of surface mulches.[4,16,17] Buried or incorporated residues are also effective in reducing soil erosion, especially rill erosion. However, the reduction is generally less as compared to surface residues. In addition, all mulches that cover the soil surface (gravel) or anchor the soil (stubble) are also effective in reducing soil erosion by wind. Furthermore, organic mulches eventually decompose into humus and impart to the soil all the beneficial qualities derived from traditional organic matter additions as discussed earlier.

Conclusion

Soil amendments are generally used to improve the chemical, physical, and biological properties of the soil and therefore to promote plant growth. Lime neutralizes soil acidity, remedies Al and Mn toxicity, enhances microbial activity, increases plant availability of many nutrients, and promotes soil aggregation and structural stability. Gypsum and synthetic polymers prevent clay dispersion, reduce surface seal formation, protect and stabilize soil aggregates and structure, reduce soil erodibility, increase water infiltration, and reduce soil erosion by water. Organic amendments such as animal manure, compost, and municipal and industrial wastes add organic matter to soils, increase microbial activity, enhance nutrient cycling and availability, improve soil tilth, increase aggregate stability and water holding capacity, enhance water infiltration, and reduce surface runoff and soil erosion. Inorganic mulches like stone and sand physically prevent dislodgement and breakdown of soil surface aggregates by raindrop impact, reduce surface seal formation, suppress soil evaporation, increase water infiltration, obstruct overland flow, and reduce sediment transport capacity and soil erosion. Organic mulches such as crop stubble and grass filter strips impart to the soil the combined benefits of the inorganic mulches and organic amendments as discussed above. Being the most important and most effective agronomic measures for erosion control, organic mulches not only protect soil from detachment by raindrop impact and flowing water shear but also reduce the sediment-carrying capacity of the flow by impeding it.

Erosion by Water: Assessment and Control

José Miguel Reichert, Nadia Bernardi Bonumá, Gustavo Enrique Merten, and Jean Paolo Gomes Minella

Introduction

Soil water erosion is the process of detachment and transportation of soil particles from the point of origination by the action of rainfall and runoff. Although erosion is a natural process, human activities have increased erosion either due to inappropriate agricultural and deforestation practices or due to constructions and mining activities without considering the soil characteristics. Land degradation and water pollution owing to erosion have become severe problems worldwide. In order to assess and prevent the environmental impacts due to soil erosion, several control measures can be used, but first, it is necessary to understand the sources and factors affecting the erosion process. The specific objectives of this entry are to discuss 1) the causes of water erosion and the link between on-site and off-site environmental impacts as a result of soil losses; 2) erosion assessment by monitoring, use of mathematical models, and indicators; 3) the erosion control practices; and 4) an integrated environmental management and the role of farmers, constructors, scientists, and managers in order to reach a sustainable strategy to control soil erosion.

Erosion Problems

Soil erosion by water is the most significant land degradation problem worldwide.[1] Even though erosion is a natural geomorphic process occurring continually over the earth's surface,[2] human activities can magnify, minimize, or prevent the operation of this natural process.[3] Man has been the most active agent linked to accelerate erosion either due to inappropriate agricultural and deforestation practices or due to constructions and mining activities without considering the soil characteristics.

Each year, 75 billion tons of soil are removed due to erosion, with most coming from agricultural land, and around 20 million ha of land are lost.[4] In the United States, according to the U.S. Environmental Protection Agency and the federally mandated National Pollution Discharge Elimination System, soil erosion is considered the biggest contributor to nonpoint source pollution.[5] In the European Union, the main problems for soils are contamination and losses due to increasing soil erosion.[6] In the developing world, soil erosion is the single most important environmental degradation problem, which has far-reaching economic, political, social, and environmental implications due to both on-site and off-site damages.[4]

In agricultural areas, according to Renschler and Harbor,[3] farming operations directly affect soil movement through activities such as tillage,[7] root crop harvesting, and the trampling of soil and removal of vegetation by livestock.[8]

Soil losses from agriculture are of concern because of both agricultural on-site and environmental off-site impacts.[9] The agricultural on-site impacts are related to soil degradation and include increased bulk density, reduced aggregate stability, and depletion of nutrient and carbon content,[10] and consequently reduced soil productivity.[1] The problem may become so severe that the land can no longer be cultivated and must be abandoned, which have practical and economic implications for land managers.[6]

The environmental off-site impacts are the increase in sediment and other pollution loads in receiving waters.[1] Excessive sediment inputs to rivers can cause physical problems of turbidity in the water column and sedimentation in channels, reservoirs, estuaries, harbors, and the near-coastal zone. In turn, this sedimentation may affect channel morphology and behavior, and navigation.[11] The cost of dredging the several billion tons of sediment from rivers and harbors each year is about 15 times more than the cost of holding the soil on the land from which it eroded.[12] Sediment is also a pollutant in its own right and, through the chemicals adsorbed to it, can increase the levels of nitrogen and phosphorus in water bodies and result in eutrophication.[9]

Sources of Erosion and Sedimentation

Soil water erosion is the process of detachment and transportation of soil particles from the point of origination by the action of rainfall and runoff. Water erosion of soils starts when raindrops strike bare soil peds and clods, separating particles and causing the finer particles to move with the flowing water as suspended sediments.[12] Sources include agricultural lands; disturbed forest lands; construction sites; roadway embankments, cuts, and ditches; surface mines; and natural geological eroding "badlands."[13]

Erosion can happen within rills, interrill (the area between rills), tunnels, gullies, and stream channels. Interrill erosion process is rainfall dominated, whereas rill erosion is mostly defined by runoff. Rills are such small concentrations of running water that they can be completely removed by normal cultivation methods, whereas gullies cannot be.[14] Gully erosion is defined as the erosion process whereby runoff water accumulates and often recurs in narrow channels and, over short periods, removes the soil from this narrow area to considerable depths.[15] Tunnel erosion may occur in soils with sublayers that have a greater tendency to transport flowing water than does the surface layer.[14] Stream channels can be sources (stream channel erosion) or sinks of sediments (sedimentation).

Erosion Assessment

To address soil erosion processes and risk, scientists and engineers from various fields have developed physical parameters, equations, and models with the intention of implementing assessment tools for educational, planning, and legislative purposes.[3]

Monitoring

The purpose of the assessment and the size of the area (scale) will strongly influence the approach. Time scale and funding will influence the methods that can be used.[16] Field measurements may be classified into two groups: those designed to determine soil loss from small areas or erosion plots and those designed to assess erosion over a large area such as a drainage basin.[10]

Field Plots

In order to describe the factors that cause the erosion process and the effectiveness of erosion control techniques, several studies on experimental plots have been done.

The experimental plots may be soil pans or field plots. Single or several pans may be used in a static or mobile position.[17] Field erosion plots may be subject to natural or simulated rainfall. On small plots, a rotating simulator (Figure 1) can be set up between two plots, which can be rained on at the same time.[18] The standard plot is 22 m long and 1.8 m wide, though other plot sizes are sometimes used.[10]

One of the best uses for field plots is demonstration; examples are to demonstrate to farmers that serious erosion is taking place or to show that erosion is much less from a plot that has a good vegetative cover than from a bare plot. Another valid use is in comparative studies, for example, to test or get an approximate indication of the effect on runoff or erosion of a simple comparison such as with or without a surface mulch, or the amount of runoff at the top and at the bottom of a slope. A third possible use is to obtain data that are to be used to construct or to validate a model or equation to predict runoff or soil loss.[18] Data from experimental plots have revealed some precise mathematical relationships between erosion factors and erosion losses and have led to setting up of equations that enable calculations of precipitation interrill erosion to be made, and which maintain their validity.[19] The most thorough analysis of these relationships is the Universal Soil Loss Equation (USLE)[20] based on a database of approximately 10,000 plot-years of field experiments under natural rainfall in the United States, supplemented by data collected using rainfall simulators.

However, it is clear that using standard experimental plots will not give estimates of what is happening in the landscape as a whole as regards erosion rates.[6]

FIGURE 1 Rotating rainfall simulator.

Sediment Transport in Watersheds

River sediments present a variable grain size ranging from small particles, such as clays <0.002 mm to larger particles such as very coarse gravel (32–64 mm diameter) and boulder (2048–4096 mm). Depending on the size of these particles and the hydrodynamic conditions of flow (especially flow velocity), sediment is transported in suspension or by bedload. Fine particles, such as clay, silt, and medium sand fractions (<0.250 mm), are transported in suspension by the process of advection and diffusion, while larger particles, such as coarse sands and gravel (>0.250 mm), are transported preferentially by bedload over the bed.

Sediment transport in rivers (suspension and bedload) presents great spatial–temporal variability. In a river cross section, the suspended sediment concentration (SSC) varies both in the longitudinal direction (section width) and in the vertical one (section depth). In general (but not necessarily in this way), the SSC in a cross section varies from the center to the banks so that the highest SSCs are found in the region close to the center of flow and the lowest are found close to the banks. This condition is a function of the current velocity that is usually greater in the center and lower close to the banks (due to the effect of hydraulic roughness of the banks and the bed that caused the reduction of flow velocity). Also, depending on velocity, concentration along a vertical tends to increase with depth because coarser and/or denser sediment particles may not be homogeneously distributed.

The sediment flux represents how much sediment is transported by a river. Sediment flux is mass in time and the unit is represented in grams per second or metric tons per day. In order to measure bedload flux, samplers are positioned on the river bed for a few minutes so that a mass of sediments is collected in a given time (Figure 2). On the other hand, the suspended load flux is measured indirectly using the following relation:

$$\text{Supended sediment flux}\left(\text{tons day}^{-1}\right)=\text{SSC}\left(\text{mg L}^{-1}\right)\times Q\left(\text{m}^{3}\ \text{sec}^{-1}\right)\times 0.0864 \tag{1}$$

where SSC is the suspended sediment concentration (g m^{-3}) and Q is the flow rate ($\text{m}^3\ \text{sec}^{-1}$). In this way, to measure suspended sediment flux, it is necessary to obtain two variables, which are the SSC and Q, taking into account the spatial–temporal variability of SSC.

There are two principles involved in the collection of representative SSC samples. The first is isokinetic sampling that uses equipment (Figure 3) where the velocity of the river is used to fill the sampler.

FIGURE 2 Equipment used to measure bedload rates.

FIGURE 3 Equipment used to collect the water and suspended sediment to determine SSC.

Isokinetic sampling means that during the flow sampling to determine SSC, the sampler should be able to collect the mixture of water and sediments through a nozzle without changing flow velocity. If there is a change in this velocity, the SSC collected will not be representative of the SSC of flow. The second principle is depth-and-width integrated sampling, which collects water/sediment mixtures from the entire cross section. Details about methodology to sampler bedload and SSC can be found in the work by Edwards and Glysson.[21]

Automatic sampling equipment (Figure 4) does not collect isokinetically because the sample is pumped into the container, and it does not collect depth-and-width-integrated samples because it collects the sample from a single point in the cross section. However, it is possible to adjust the data generated from automatic samples using a so-called box equation. This equation is site specific and is developed by collecting concurrent samples (simultaneously collecting a manual isokinetic depth-and-width-integrated sample while pumping through the auto-sampler) over the typical range of flows at the site.[21]

FIGURE 4 Auto-sampler used to collect the water and suspended sediment to determine SSC.

The total amount of sediment that exits a drainage basin over a given period of time, usually a year, is called *sediment yield*.

Sediment yield can be measured using techniques that have been explained or estimated using the sediment delivery ratio (SDR) concept. The proportion of eroded sediment that exits the drainage basin is called SDR,[14] which, in other words, is the ratio of the primary erosion rate on hillslopes to the sediment yield at the basin outlet. Primary erosion hillslope rate is normally estimated using mathematical models and SDR is estimated using empirical relation based on drainage basin area.

Fingerprinting techniques[22] such as mineral magnetics and 137C can offer powerful but time-consuming approaches to establishing the source of the sediment.[6] In essence, the fingerprinting approach involves comparison of the geochemical properties of suspended sediment transported by the river with those of potential sources, in order to establish their relative importance.[23] At a relatively small scale of a few square kilometers, assessment of erosion can incorporate sediment fingerprinting to determine the source of deposits, e.g., in dams.[6]

Models

Mathematical models have been proven to be a cost-effective tool for improving our understanding of erosion processes and evaluating possible effects of land-use changes on soil erosion and water quality.1] Several water erosion and sediment transport models at hillslope and watershed scales can be found in the literature.[2,14,24–26] The mathematical models can be classified in various ways, but the most useful distinction is between empirical, conceptual, and physically based models.

The USLE[20] is an empirical model developed to estimate soil losses and to be used as a decision-making tool in soil conservation planning in cropping lands on a site basis.[27]

The USLE is often given as

$$A = R \cdot K \cdot L \cdot S \cdot C \cdot P \tag{2}$$

where A is the average annual soil loss, R is the rainfall erosivity factor, K is the soil erodibilty factor, L is the slope length factor, S is the slope gradient factor, C is the crop factor, and P is the conservation practice factor.

The USLE was originally applied to the prediction of soil losses from agriculture in the United States in order to preserve soil resources but has been extended for use in numerous countries.[28] In the way in which the USLE has generally been used (or misused), it provides an average rate of erosion over a long period of time—how that average is arrived at, or what events contribute to it, is not the issue. This simple point is often ignored or glossed over: erosion occurs when there is inadequate vegetation cover to offer protection, and sufficient runoff; both conditions must be satisfied. The USLE does not address this issue—it deals with average conditions.[6] Its modified version (MUSLE[29]) has been an attempt to compute soil loss for a single storm event. The USLE was also revised (RUSLE) and revisited[30] for improvement.

The Areal Nonpoint Source Watershed Response Simulation (ANSWERS[31]) includes a conceptual hydrological process and a physically based erosion process. The Agricultural NonPoint Source model (AGNPS[32]) simulates runoff, sediment, and nutrient transport from agricultural watersheds. The Water Erosion Prediction Project (WEPP[33]) is a model to predict soil erosion and sediment delivery from fields, farms, forests, rangelands, construction sites, and urban areas. The Griffith University Erosion System Template (GUEST[34]) was developed to interpret temporal fluctuations in sediment concentration from bare soil in single erosion events. The Limburg Soil Erosion Model (LISEM[35]) is a physically based runoff and erosion model that simulates the spatial effects of rainfall events on small watersheds. The European Soil Erosion Model (EU-ROSEM[36]) is a model for predicting soil erosion by water from fields and small catchments. The Soil and Water Assessment Tool (SWAT[37]) is a watershed scale model developed to predict the impact of land management practices on water, sediment, and agricultural chemical yields in complex watersheds with varying soils, land use, and management conditions over long periods of time.

Indicators

Visual Indicators

Monitoring soil erosion is costly, and the use of soil erosion models requires massive data input. Almost all soil erosion models, including USLE, are empirical and require careful calibration between actual soil erosion measurements and predictors prior to each application.[38] To improve the models, addition of an intermediate step, i.e., use of observed, site-specific soil erosion indicators, could bypass the massive data requirements of soil erosion models.

Examples of soil erosion indicators are defined as follows:[38]

- Eroding clods: located above flow surfaces, having predominantly convex forms, shaped by splash and disintegration
- Flow surfaces: almost flat areas with a smoothed micro-relief with (often parallel) linear flow marks or sediments, partly eroded by shallow non-concentrated flows
- Pre-rills: shallow channels (3–5 cm deep) cut by concentrated flows, slightly concave and not part of the micro-drainage system of the area
- Rills: deeper channels (5–30 cm) cut by concentrated surface flows, with clear lateral micro-scarps on the sides, usually part of the micro-drainage system of the area
- Soil accumulation: areas with smoothed micro-relief, caused by deposition of eroded materials

Quantitative Indicators

How much erosion can be tolerated? In order to answer this question, quantitative indicators that relate the rate of erosion and its effect should be determined.

For agricultural areas,[20] define the soil loss tolerance or allowable soil loss as the maximum level of soil erosion that will permit a high level of crop productivity to be maintained economically and indefinitely. Based on long-term average annual soil losses estimated by the USLE, values of soil loss tolerance were determined and a maximum value of 11 t/ha was chosen with lower values based primarily on the depth of soil favorable for plant root growth.[39] Nevertheless, these values are not applicable to construction or other nonfarm land use.[40] Although a soil tolerance value of 11 t/ha may maintain productivity, a value as low as 2 t/ha may be inadequate to control the offsite effects of erosion.[13] A modified definition of tolerable soil erosion is proposed by Verheijen et al.[41] as “any actual soil erosion rate at which a deterioration or loss of one or more soil functions does not occur,” actual soil erosion being “the total amount of soil lost by all recognized erosion types.”

Water Erosion Control

Soil erosion can be reduced by controlling either soil detachment or soil sediment transport or both.[12] The approach must be dynamic and must include the use of environmental technology, ecotechnology, and cleaner technology, as well as environmental policies.

$$\text{Environmental Technology} \times \text{Cleaner Technology}$$

The necessity of cleaner technology is an issue. Although no agricultural and engineering activity is totally clean, some practices of crop management and soil conservation can contribute to control soil water erosion. The use of environmental technology and ecotechnology includes mechanical methods such as contouring, terraces, contour ridges and stone terrace, waterways, stabilization structure, and geotextiles. Despite the decrease in soil erosion, these methods can cause some environmental impacts because of their mechanic nature, for instance, due to land movement and fuel consumption. On the other hand, some agricultural practices, such as no-tillage, not only can reduce soil erosion but also benefit the environment through C sequestration, energy conservation, and decreased N loss.

Soil Conservation Practices

Leaving vegetation and crop residue on the surface rather than burying it, applying mulches, and using soil-conservation cropping systems increase infiltration and reduce runoff.[42] A hypothetical example of how soil management affects soil erosion and water quality is shown in Figure 5.[43] The adoption of a farming system involving intense tillage for annual crops created favorable conditions for the occurrence of erosion, which generates a large amount of sediment. Moreover, the intense soil mobilization affects the water balance since the absence of soil cover decreases the infiltration of water. When the soil infiltration is reduced, the surface runoff volume increases and thereby reduces the amount of water for groundwater recharge. On the other hand, when the fields are cultivated with soil conservation practices, the coverage allowed above the soil surface reduces erosion and promotes water infiltration into the soil.

Soil-conservation practices often provide long-term benefits in exchange for immediate costs. The value of each ton of eroded soil varies according to its clay, organic-matter, and nutrient contents. A ton of eroded soil is usually more fertile, and therefore more valuable, than a ton of average soil because of textural sorting combined with the effects of organic-matter accumulation, fertilization, and liming that are concentrated in the upper part of the soil. Sedimentation damage occurs both in fields near the source of the sediment and in downstream areas. Some damage is unavoidable, but hundreds of millions of dollars per year could be saved through flood-prevention efforts.[43]

Contouring

Contouring consists of performing all field practices such as plowing, disking, planting, and cultivation on the contour (Figure 6). It is effective for low slopes and short slope length and for rainstorms of low intensity. The effectiveness of this practice is about 50%[44] depending upon slope grade and length, and this effectiveness can be increased by establishing a series of depressions or pits (Figure 7) that fill with water and sediment during rain.

Terraces

Terraces are mechanical structures constructed across a slope and consist of a channel and an earth or stone bank to intercept surface runoff, allow it to infiltrate and evaporate, or divert the excess to a stable outlet at a nonerosive velocity. Depending upon their function or type of construction, terraces are

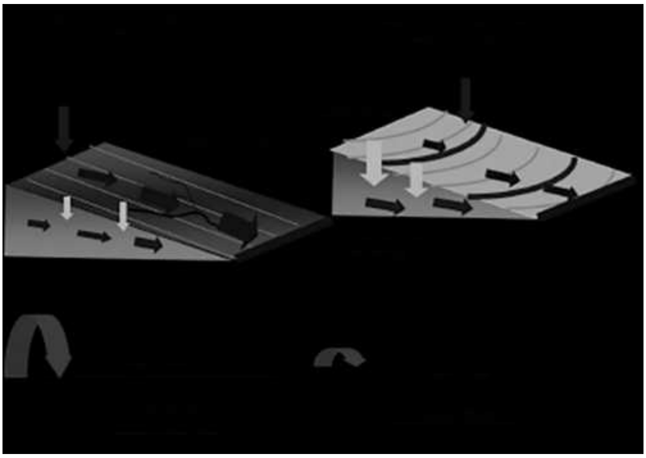

FIGURE 5 Comparative of hydrological effects and water quality impacts that occur in the watershed when subjected to a cultivated field with and without soil conservation practices.

FIGURE 6 Contouring in an agricultural field in southern Brazil.
Source: Reichert and Cassol.[43]

FIGURE 7 Sedimentation pits in a horticultural field in Costa Rica.
Source: Reichert and Cassol.[43]

classified as retention or absorption, diversion or graded, and bench terraces. Retention or absorption terraces are used when water is to be stored on the hillside of slopes less than 4.5°, having level channels able to accumulate runoff volume generated by a 10 years return period rainfall (Figure 8). Diversion or graded terraces aim at intercepting runoff and conducting it to a proper outlet through a channel of a slight grade, usually 1:250 (Figure 9) on slopes less than 7°. Bench terraces are used on steep slopes, up to 30°, alternating a series of shelves (cuts) and raises (fills) (Figure 10). Research data from several

FIGURE 8 Retention or absorption terraces in southern Brazil, accumulating runoff in a level channel.

FIGURE 10 Bench terraces on high-grade hillslope in Guatemala.
Source: Reichert and Cassol.[43]

authors[10] indicate effectiveness in soil loss control of bench terraces up to 93%. Terraces must be properly designed to avoid even greater soil erosion damage[44] and should be planned considering the whole farm, a group of neighboring farms, or even a small hydrographic catchment,[45] to ensure optimization of land use.

Contour Ridges and Stone Terraces

Contour ridges are earth banks, similar to narrow-based terraces, constructed across the slope using hand tools, animal traction implements, and sometimes motorized farm machinery. These structures are frequently used on small-scale farms and hilly regions. Their effectiveness in reducing soil loss varies, but research data from several authors indicate values up to 80% and even 100% control.[10] Contour stone bunds (Figure 11) are an alternative technique on stony lands, where stone walls are set up in shallow trenches. These allow slow retention of sediment and are permeable to water. With time, upslope sedimentation will generate a gradual development into bench terraces. The construction of stone barriers requires considerable labor and time, but it is more permanent and easier to maintain than earth barriers. Spacing and construction details are presented in Manual on Integrated Soil Management and Conservation Practices, IITA and FAO.[46]

Waterways

A system of graded terraces requires waterways to receive the excess drained runoff and safely conduct at a nonerosive velocity to lower parts of the landscape. Waterways must be carefully established (considering location, construction, and stabilization) and maintained (managing grass species and controlling incipient erosion) to avoid serious erosion problems, even causing gully formation. On grass waterways, tile drains, or steep slopes, concrete structures (Figure 12) are located in natural depressions or, if needed, reshaped channels. The grass waterways reduce water-flow velocity because of the retardance effects of vegetation and increased soil resistance to erosion due to soil coverage and aggressive rooting system holding soil particles together. To work properly, waterway design follows defined principles from channel hydraulics[10,46] and the flow ways must be maintained and cared for.[45]

FIGURE 11 Contour stone barriers in an agricultural field in Cape Verde.

FIGURE 12 Grass waterway draining to a concrete drop inlet structure in southern Brazil.
Source: Reichert and Cassol.[43]

Conservation Structures

In certain situations, the only feasible way to convey safely large amounts of runoff water from a higher elevation to a lower one is through the use of conservation structures that are made of some type of nonerodible material, such as concrete or large rocks. Examples of these structures include chute drop inlets (Figure 12), flumes and drop spillways (Figure 13), and pipe spillways, which must follow standard functional requirements to maintain channel stabilization.[45] Selection and design of these structures are based upon existing or anticipated erosion problem, slope steepness, estimated maximum water flow discharge, and cost of alternative systems. Conservation structures are usually used in conjunction with other erosion-control techniques such as grass waterways (Figure 12).

Source: Reichert and Cassol.[43]

FIGURE 14 Gully development on sandy soil in southern Brazil.
Source: Reichert and Cassol.[43]

Gully Stabilization Structures

Gullies represent an advanced stage of rill erosion (Figure 14) and are most important as a source of sediment in streams. If the gully is small, recovery might be suitable by filling it with soil, but in many cases, recovery is technically and economically not viable. In such cases, gully stabilization is recommended by constructing small dams using diverse materials depending on availability. These materials may include stones, wood planks or branches, earth, etc., to trap sediment, thus reducing gully depth and slope. Along with these stabilization structures, plants must be established to reclaim the affected areas (Figure 15). Sometimes, to control the overfall of water on the headwall on large gullies, more permanent structures are required.[9,44]

Geotextiles

Erosion on road banks or urban areas is best controlled by vegetation, but establishment on these highly erodible and usually infertile soil surfaces is difficult. Thus, other materials, including straw and hay, are used to help establish vegetation, but these do not hold tight to the soil and are washed away easily.[44] Alternative materials include geotextiles that are permeable textiles for erosion control interacting with soil and vegetation. The geotechnical material is in the form of a mat, sheet, grid, or web of natural or synthetic fiber.[10] The first type is biodegradable while the second type gives a more permanent protection to a slope, interacting with roots to improve soil cohesion and slope stability.

Environmental Legislation

Since the 1960s, Green Revolution technologies have been introduced in many countries actively supported by irrigation development, subsidized credit, and fertilizer programs.[4] Erosion is currently not regarded as simply due to water; there is a growing political awareness of the value of soil.[16] Both environmental legislation and economic instruments have the potential to improve the performance of soil erosion control.

FIGURE 15 Gully stabilization with used tires, stones, and vegetation in Costa Rica.
Source: Reichert and Cassol.[43]

Environmental legislation such as banning cultivation in hilly land and riparian zones is very important not only for erosion control but also for stream channel maintenance, flood control, and water quality. For instance, in Brazil, two major advances in legislation were made: the concepts of mandatory reservation areas, a portion of the properties left without any intervention, and the special preservation areas, such as those along river banks and around reservoirs and lakes.

In the European Community, different policies contribute to soil protection, particularly environment (e.g., air and water) and agricultural (agri-environmental and cross-compliance) policy. Nine member states have specific legislation on soil protection. However, these laws often cover only one specific threat, such as soil contamination, and do not always provide a coherent framework.[47]

Many developing country governments provided direct assistance to farmers to adopt soil conservation measures.[4] Direct payment programs to encourage sustainability in agriculture due its benefits to society are still incipient in developing countries. One example is the Program for Water Quality and Quantity Improvement in Rural Catchments proposed by The Brazilian Agency for Water Resources.[48] It provides financial compensation for farmers, known as Water Productor Program, which “buys” the benefits (products) generated by the participant (concept of “provider-recipient”) where the payments are proportional to erosion abetment. The parameter of erosion abatement performance consists of the ratio of soil loss in the present condition to the worst-case condition (bare soil).

Policies to facilitate the development of an efficient marketing system may encourage switch from low-value crops to high-value crops and improve returns on investment to soil conservation measures. There is a need to have more market-based policies so that resources will be allocated more efficiently. On the other hand, policies such as import controls and high prices can also enhance soil erosion; for instance, global food policies such as food subsidies in the United States and the European Union and food aid lower international food prices. The extent to which these are transmitted into domestic food prices and international policies can have an impact on soil erosion.[4]

Integrated Environmental Management

How can we reach a sustainable strategy to control soil erosion? What are the roles of scientists, farmers, constructors, and managers? These questions stray from the strictly scientific arena (certainly from the physical sciences) into areas of social science and management. The more difficult issues are those of the proper relationship between science and managers (e.g., farmers and policy makers).[6]

Scientists played an important role in the development of problem perception and control. It was mainly the results from scientific studies that revealed the magnitude and severity of soil loss and sediment delivery to people working in the administration, and later to policy makers as well. One of the most important roles that the soil erosion research community has played is to contribute to monitoring the problem. Whereas the administration recently recognized the problem and even started with some control measures, they almost completely neglected the monitoring part. In the framework of the erosion control program, scientists also provided more information on the various soil conservation measures and sediment delivery control techniques that are available and the locations in the landscape where these measures need to be taken to be most effective.[49]

In the past, farmers were little concerned about soil erosion on their fields. Farmers were also not concerned about downstream consequences of soil erosion, like muddy floods in the villages.[49] The expansion and concentration of cultivated acreage led to extensive land-use change and increased concern about soil erosion impacts. In response to increasing soil erosion hazards, especially from agricultural land, interest groups and policy-driving organizations worldwide fostered the development and use of techniques for soil and water conservation.[43]

Conservation prioritization is an important consideration for planning natural resources management, allowing decision makers to implement management strategies that are more sustainable in the long term.[50] Soil and water protection have to be considered together; the connection of land at risk of soil erosion to rivers has to be taken into account as a potential source of water pollution.[47]

Conclusions

The analysis of soil water erosion reveals that a holistic view of the problem is necessary to ensure that the causes and factors affecting the problem are understood for any control measures to be undertaken. In order to assess the problem, it is important to have a strong database especially from field monitoring of soil losses and sediment transport at hillslope and watershed scales. These data can be used in mathematical models to simulate the impacts of land uses and climate changes. As monitoring is costly and most of the models required massive input database, visual indicators can be used to improve the models. In order to relate the rate of erosion and its effect, quantitative indicators such as soil loss tolerance have been used; however, it is important to consider not only productivity but also the off-site environmental impacts. Environmental legislation and public policies must induct farmers and constructors to use the soil in their properties bearing in mind the need to have environmental and social practices in their economical enterprises. Erosion control practices need to be part of an integrated environmental management that includes farmers, constructors, scientists, and managers to ensure soil and water preservation to the present and future generations.

Erosion by Water: Empirical Methods

John M. Laflen

Introduction

Assessment of soil erosion requires some estimate of mass, volume, depth, and/or location of the source and/or deposition of eroded soil material and the frequency with which it occurs. Assessment may also require an estimate of the physical, chemical, and/or biological characteristics of eroded materials. Moreover, assessment usually includes some estimate of the impact of management and treatment on soil erosion. Usually, these estimates are made using a model. In this entry, the focus will be on empirical models to estimate the mass of soil erosion by water.

Why use models? Erosion is highly variable in time and space. Figure 1 shows annual sediment yields from a small western Iowa watershed cropped continuously to corn over a 24 years period. The coefficient of variation [CV (standard deviation/mean)] of annual values is 135%, while the CV for annual runoff is 85% and the CV for annual precipitation is only 20%. While annual values are shown in Figure 1, at Columbia, Missouri, USA, over an 11 yr period for continuous corn or continuous soybeans, 50% of the erosion occurred in a single storm, and 80% occurred in only seven storms.[1] Others have also shown that a major portion of sediment yield occurs in only a few storms.[2] This extreme variability in soil erosion makes it virtually impossible to make meaningful measurements of erosion for assessment purposes in a feasible period of time. Hence, the use of models for such purposes is required.

An empirical model is a representation of data.[3] The empirical models described here include variables generally based on our understandings of erosion processes, with the coefficients and relationships based on data. Generally, because they are based on data, empirical models give reliable answers for situations encountered in the data used for development. However, answers for other situations or outside the range of the experimental data are less reliable and, in fact, could be contrary to that expected.

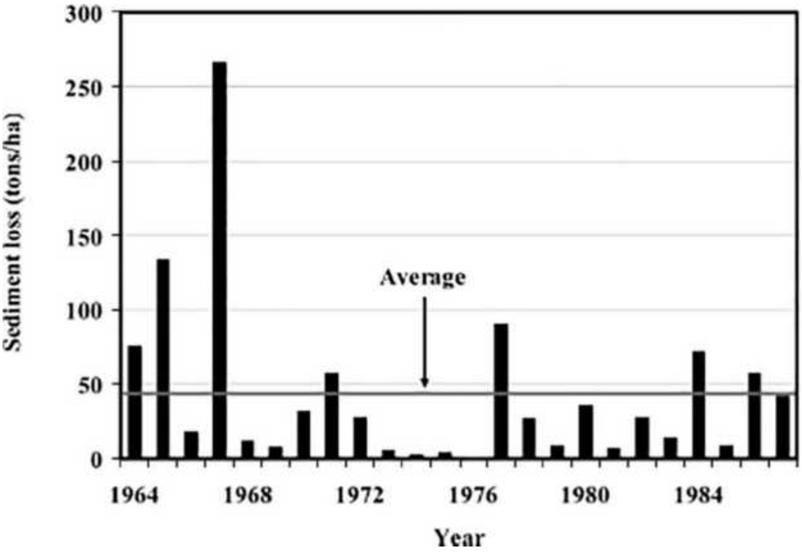

FIGURE 1 Annual sediment loss from a small watershed near Treynor, Iowa, USA, for 1964–1987 (unpublished data). The CV for annual sediment loss values was 135%, while the CV for the annual runoff was 85% and the CV for annual precipitation was 20%.

Empirical models can be easy to use and parameterize, an important factor in model selection. Equally important is that users may find them easier to understand than more sophisticated models. However, sophisticated models that are process based may find a wider range of use, a particularly important factor as needs for erosion assessment and other associated environmental assessments become more complex.

Models described here are "field scale" models for the most part. Models for large watersheds are not included, although some empirical models are components of some watershed models.

Empirical Erosion Model Development

Empirical model development began with experiments to understand the effect of various factors—climate, topography, soil, management, and conservation practices—on soil erosion. Early models considered a limited set of factors; these were expanded as the number of workers in the field increased the amount of information available on which to expand the models. As the science progressed, the complexity increased, with relationships of factor values to factor characteristics being developed based on experimental data.

The major factor in the development of empirical models was establishment of erosion plots at numerous locations in the United States.[4] These plots provided an immense data set that is still used today for evaluating soil erosion and hydrologic models. More than 10,000 plot years of data were collected on these plots.[5] Additionally, many plots were located on experimental farms that contained small watersheds on which conservation practices were installed, monitored, and evaluated. These experimental areas provided the necessary data for developing the relationships in water erosion empirical models.

Erosion plots were also established in other regions of the world.[6] Erosion plots can be found on every continent except Antarctica. They are frequently used to evaluate the applicability of empirical and non-empirical erosion models to specific regions, and to develop appropriate factor values for practices common to those regions.

TABLE 1 Evolution of U.S. Empirical Water Erosion Models

	Soil Loss	Coefficient or Rainfall Factor	Soil Erodibility Factor	Length–Slope Factor	Cropping and Management Factor	Conservation Practice Factor
Zingg 1940[31]	A	C'		$L^{0.6}\ S^{1.4}$		
Smith 1941[32]	A	C''		$L^{0.6}\ S^{1.4}$		P
Browning 1947[33]	A	*Cò*	K'	$L^{0.6}\ S^{1.4}$		P
Musgrave 1947[34]	A'	$P_{30}{}^{1.75}$	K''	$L^{0.35}\ S^{1.35}$	C^*	P
USLE 1961[9]	A	EI_{30}	K	$(L/72.6)^{0.5}(0.065+0.045\ S+0.0065\ S^2)$	C	P
USLE 1978[10]	A	EI_{30}	K	$(L/72.6)^{0.5}(65.4\ \sin^2\Theta+4.56\ \sin\ \Theta+0.065)$	C	P
MUSLE 1975[14]	A^*	$95(Qq_p)^{0.56}$	K	$(\mathrm{L}/72.6)^{0.5}(65.4\ \sin^2\Theta+4.56\ \sin\Theta+0.065)$	C	P
RUSLE 1997[25]	A	EI_{30}	K	$(\mathrm{L}/72.6)^{\mathrm{m}}(a\ \sin\Theta+b)$	C	P

A—soil loss (tons/acre). A'—soil loss (inches/year). A^*—sediment delivery (tons/year).
P30—maximum precipitation amount (inches) falling in 30 min in a storm.
Q—storm runoff volume (acre-feet). qp—peak runoff rate (cubic feet per second).
Qo—storm runoff volume (inches). qo—peak runoff rate (inches per hour).
E—storm rainfall energy (hundreds of foot-tons per acre).
I30—maximum rainfall intensity in a 30 min period within a storm (inches per hour).
K', K'', K—soil erodibility factors.
L—slope length (feet). S—slope (%). Θ—slope angle (degrees).
m—exponent on length term (values depend on slope or slope and rill/inter-rill ratio).
a, b—coefficients in function making up slope term (values depend on slope).
C', C'', *Cò*—coefficients. C^*—vegetal cover factor. C—cropping and management factor (before 1978) and cover and management factor (after 1978).
P—conservation practice factor.

The development of empirical models has been a classic example of the operation of science and its application to solving real-world problems. The steady progression of science is illustrated in Table 1, where the steps in the development of U.S. empirical erosion modeling are given chronologically. The work initiated in 1940 in the United States continues today, each step built on top of earlier work.[4,7]

Empirical Models

Universal Soil Loss Equation

The Universal Soil Loss Equation (USLE) is written as

$$\mathrm{A} = \mathrm{RKLSCP},$$

where A is soil loss per unit area (units depend on units used for R and K); R is the rainfall and runoff factor, the number of rainfall erosion index units, plus factors for runoff from snowmelt or applied water; K is the soil erodibility factor, the soil loss rate per rainfall erosion index unit on a plot 72.6 ft long of uniform 9% slope maintained in a clean tilled fallow; L is the slope-length factor, the ratio of soil loss for a given slope length to a 72.6 ft long slope; S is the slope-steepness factor, the ratio of soil loss for a given slope to soil loss from a 9% slope; C is the cover and management factor, the ratio of soil loss for a given land use and management to soil loss from a continuous clean tilled fallow; and P is the support practice factor, the ratio of soil loss with a support practice, such as contouring, terracing, or stripcropping, to soil loss for up and down the slope. Much more detail on factor values and assistance in computing these values is available elsewhere.[5]

The USLE was the culmination of more than two decades of work in developing a national model of soil erosion by water.[4] As shown in Table 1, the form and factors were long identified before the USLE was developed. The defining scientific finding in the development of the USLE was that a single rainfall variable was selected that could be used over the United States to model soil erosion from rainstorms.[8] This allowed the application of factor values in one region to be used in another region. Climatic databases were developed for the entire United States, and tables and charts were published to allow use of the USLE for most U.S. conditions.[5,9,10] It is being replaced by the Revised Universal Soil Loss Equation (RUSLE)[11] in the United States.

The USLE technology was the water erosion model of choice over much of the world through the last century, with major efforts in developing *R* values for the areas to which it would be applied. It served as the platform from which a number of other empirical technologies evolved.

Although the USLE is a good predictor of average annual erosion, it is a poor predictor of individual storm soil erosion. It does not contain variables associated with the hydrologic condition of the soil at the time the storm occurs. Additionally, the USLE does not consider deposition on a field and does not predict sediment yield, a needed estimate for many applications. The USLE's area of application is from the top of a hillslope (or divide) to where deposition begins, or runoff enters a channel.

Modified Universal Soil Loss Equation

The Modified Universal Soil Loss Equation (MUSLE) is written as

$$A^{*} = 95\left(Qq_{p}\right)^{0.56} KLSCP,$$

where A* is sediment delivery; *Q* is the total volume of runoff; q_p is the peak rate of surface runoff; and *K, L, S, C*, and *P* are the same as for the USLE.

MUSLE was developed to predict individual storm sediment yield, something that the USLE did not do. For individual storms, sediment concentration for five small watersheds near Riesel, Texas was highly correlated with the ratio of peak runoff rate per square mile to total volume of runoff.[12] The USLE was used to predict average annual sediment yield for the same five small watersheds, using a delivery ratio based on watershed characteristics.[13] The various factors in the USLE (except for the rainfall factor) were weighted based on drainage area of the various factor values, channel lengths, channel slopes, and cultivated area.

Data from 18 watersheds were used to examine three forms of a runoff factor.[14] The runoff factor $95(Qq_p)^{0.56}$ (Q—volume of runoff in acre-feet, q_p—peak flow rate in cubic feet per second) was the best form for estimating individual storm sediment yield from small watersheds. The 18 watersheds ranged in size from 2.7 to 4380 acres. Two watersheds were located at Hastings, Nebraska, the remainder were located at Riesel, Texas, and included the five small watersheds used in earlier analyses.

MUSLE requires inputs, storm volume of runoff, and peak rate of runoff, not used in the USLE. Simulation models can generate this information or it can be estimated for design storms.

MUSLE continues to be heavily used in various modeling activities. It is an option in the EPIC (Erosion Productivity Impact Calculator) model[15] for computing sediment yield. While MUSLE is widely used, there are few publications that detail the accuracy of MUSLE, outside of the original work in its development.

Soil Loss Estimation Model for Southern Africa

The Soil Loss Estimation Model for Southern Africa (SLEMSA) was introduced as a reliable management tool developed from limited resources.[16] The development team evaluated the USLE for adoption in Southern Africa but was concerned about adopting factor values developed in America.[17] Additionally, there was considerable concern about differences in farming practices. They felt that they did not have the resources to implement the USLE, and a simpler approach was needed.

SLEMSA is written as

$$Z = KCX,$$

where Z is the mean annual soil loss, K is the mean annual soil loss from a standard field plot 30 m × 10 m at 4.5% slope for a soil of known erodibility under a weedfree bare fallow, C is the ratio of soil lost from a cropped plot to that lost from bare fallow land, and X is the ratio of soil lost from a plot length L and slope percent S to that lost from the standard plot.

K values are computed as

$$\mathrm{Ln}\, K = b \ln E + a,$$

where E is seasonal rainfall energy, and a and b are given by

$$a = 2.884 - 8.1209F$$

$$b = 0.4681 - 0.7663F,$$

where F is soil erodibility. Based on soil texture, F is assigned a value between 4 (light textured, or sandy soil) and 6 (heavy textured, or clay soil). Additional adjustments are made based on hydrologic characteristics of the soil, tillage, soil structure, and crusting, giving a range of F values from 1 to 9.

C is computed as $C = e^{(-0.06i}$) when $\mathrm{i} < 50\%$ and as $\mathrm{C} = (2.3 - 0.01\mathrm{i})/30$ when $\mathrm{i} \geq 50\%$, where i is the percentage rainfall energy intercepted by the crop (used crop cover %).

X is computed as

$$X = (l)^{1/2}\left(0.76 + 0.53_S + 0.076s^2\right)/25.65$$

This is derived from the USLE LS factor in use in the 1970s. The equation above converted the USLE LS factor to the metric system and adjusted it to a 4.5%, 30 m long slope. The variables l and s are length (m) and slope (%), respectively.

The USLE and SLEMSA are very similar in many respects. The major differences are in the climate variables and the cropping-management approaches. The USLE climate factor contains both rainfall energy and rainfall intensity where SLEMSA contains only rainfall energy. The USLE C value incorporates both tillage and cropping while the C value for SLEMSA is a function of the interception of rainfall energy by crops. However, SLEMSA does capture some of the tillage component in the F value.

ABAG (German USLE)

The USLE was applied almost intact for German conditions.[18] Experimentally, most of the USLE factors were validated, and few modifications were needed to apply it under German conditions. One modification was that soils highly enriched in potassium were found to be more erodible than expected, based on the soil erodibility nomograph of Wischmeier et al.[19]

While no modification of the USLE was found necessary, ABAG factors were necessary for German conditions, specifically the R and C factors. A book detailing the use of the USLE for extension workers in Germany has been published.[20]

Soiloss

A computer program (SOILOSS), which used the USLE approach to estimate average annual soil losses and gave recommendations on ways to reduce soil loss through changes in land and crop management practices, was developed.[21] SOILOSS was developed for use in New South Wales, Australia. It used a slightly different equation for computing rainfall energy than that used in the USLE. It also used both the USLE nomograph[19] for soil erodibility, plus experimentally derived values for New South Wales. In a later revision,[22] equations to compute *LS* values were adopted from RUSLE.[11] From the earliest version of SOILOSS, the subfactor approach of Laflen et al.[23] that was implemented in RUSLE[11] was used to estimate the *C* value in SOILOSS. It contained *P* value estimates similar to those in the USLE,[5] but some *P* value estimates were from experimental work in New South Wales. SOILOSS also included a benefit from sediment deposited in bank (terrace) channels.

A SOILOSS user guide [24] was developed for high school students. It included the program, an introduction to the USLE, complete parameterization for most Australian conditions, and worksheets and examples.

In a number of ways, SOILOSS could be considered an early RUSLE, using much of the science and approaches that were eventually used in RUSLE. It was also developed in the time frame where RUSLE was developed.

Revised Universal Soil Loss Equation

RUSLE[25] maintains the form of the USLE in terms of the factors, but since it is operated on a computer, many improvements in computations, particularly those including interactions, have been incorporated. Major improvements in the RUSLE include an improved *R* value map for the United States, time variation in soil erodibility, an improved *LS* factor that incorporates recent science, a subfactor approach for computing the cover and management factor, and *P* values based on modeling analyses that include storm severity, ridge height, drainage, and off-grade contouring.

Development of RUSLE has continued. The latest version is named RUSLE2 and it is used by the Natural Resource Conservation Service of the United States Department of Agriculture (USDA) for estimating soil erosion on U.S. land.[26] RUSLE improvements include those in science, ease of use, supporting databases, and applications related to sediment deposition and delivery.

Accuracy of Erosion Predictions

A knowledge of the accuracy expected in an assessment of soil erosion is critical in many applications. For soil erosion runoff plots, the CV for replicated plots was found to be a function of the value of the measured soil erosion (M),[27–29] and the relationship could be expressed as

$$\mathrm{CV} = 0.73M^{-0.306} \tag{1}$$

where M is expressed in tons per hectare. The relationship held for erosion for all time periods.

Eq. 1 was used to derive a relationship between measured erosion and confidence intervals (CIs) for measured erosion. This relationship is

$$\mathrm{CI}(tons\,/\,ha) = t_{(\alpha+1)/2} M\mathrm{CV}, \tag{2}$$

where t is the cumulative t distribution value for $(\alpha+1)/2$ for an infinite number of points, and α is the probability level selected. For a 95% CI, and substituting Eq. 1 for CV in Eq. 2, CI can be written as

$$\mathrm{CI}_{95} = 1.43\, M^{0.694}, \tag{3}$$

and lower and upper bounds (LB and UB) for the 95% CI (Figure 2) are given by

$$\mathrm{LB}(\mathrm{tons/ha}) = M - \mathrm{CI}_{95} \tag{4}$$

$$\mathrm{UB}(\mathrm{tons/ha}) = M + \mathrm{CI}_{95} \tag{5}$$

Table 2 shows measured and USLE-predicted soil loss from erosion plots at 20 locations in the United States.[30] These data had been used in the development of the USLE. There were multiple plots and treatments at most locations. The same data are shown in Figure 2, plus the 95% CIs computed using Eqs. 3, 4, and 5. On the average, soil erosion was overpredicted by 22%, and 6 of the 20 soil erosion values predicted fell outside the 95% CI.

The UB and LB on the CI shown in Figure 2 are based on variability in measured data. It would be unrealistic to expect better estimates from any model of soil erosion—empirical or otherwise.[35]

TABLE 2 Comparison of Average Annual Measured and Predicted Soil Loss from Erosion Plots at 20 U.S. Locations

Site	Record Length Plot Years	Measured Soil Loss (tons/ha)	Predicted Soil Loss (tons/ha)*
Hays, Kansas	88	3.1	6.7
Tifton, Georgia	64	3.6	7.6
Ithaca, New York	79	6.5	9.1
Raleigh, North Carolina	10	7.1	25

HollySprings, Mississippi	24	88.8	109.7
Average	79.7	34.1	41.7

Predictions were made by the USLE.

Source: Tiwari et al.[30]

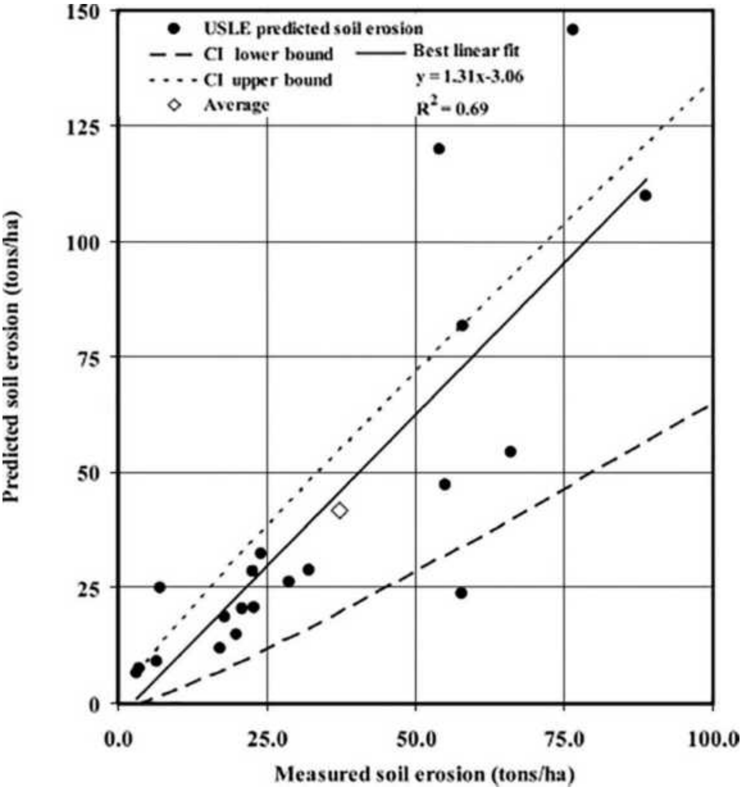

FIGURE 2 Measured versus predicted soil erosion from runoff plots. Also shown are CIs and the mean measured and predicted soil erosion. CIs (95%) for measured erosion, based on the work of Nearing and others[27–29] and of measured and predicted data from Tiwari et al.[30]

Conclusion

Soil erosion is highly variable with a large proportion of soil erosion occurring in only a few storms.

The USLE technology has been adapted to apply to most of the earth's land surface. Nearly all empirical technology for erosion prediction is based in large part on the USLE technology, and the development of the USLE was clearly an evolutionary process.

Soil erosion is highly variable. Measured erosion on replicated plots has high CV; it should be expected that erosion assessments based upon models (or measurements) will have similar levels of predictability.

Erosion by Water: Process-Based Modeling

Mark A. Nearing

Introduction

Historically models of soil erosion by water have been primarily either empirically based or process-based (sometime referred to as physically based). The first models of soil erosion were empirically based. The prime example of the empirically based model is the Universal Soil Loss Equation (USLE).[1–2] More recent models have been based on equations which describe the physical, biological, and/or chemical processes which cause or affect soil erosion. It is important to understand that both the process-based and the empirically based models possess a major empirical component, in the sense that the constitutive equations use parameters based on experimental data.

Process-Based Models

Process-based erosion models address soil erosion on a relatively fundamental level using mass balance differential equations for describing sediment continuity on a land surface. The fundamental equation for mass balance of sediment in a single direction on a hillslope profile is given as:

$$\partial(cq)/\partial x + \partial(ch)/\partial t + S = 0 \tag{1}$$

where c (kg/m^3) is sediment concentration, q (m^{2}s) is unit discharge of runoff, h (m) is depth of flow, x (m) is distance in the direction of flow, t (s) is time, and S [kg/(m^{2}s)] is the source/sink term for sediment generation. Eq. 1 is an exact one-dimensional equation. It is the starting point for development of all existing process-based models. The differences in various erosion models are primarily: a) whether the partial differential with respect to time is included; and b) differing representations of the source/sink term, S. If the partial differential term with respect to time is dropped then the equation is solved for the steady state, whereas the representation of the full partial equation represents a fully dynamic model. The source/sink term for sediment, S, is generally the greatest source of differences in soil erosion models. It is this term that may contain elements for soil detachment, transport capacity terms, and sediment deposition functions. It is through the source/sink term of the equation that empirical relationships and parameters are introduced.

One of the earliest process-based erosion models was presented by Meyer and Wischmeier.[3] This model considered soil detachment by rain and by runoff, and then compared the sediment load generated from this detachment to the sediment transport capacity of the flow. If sediment load exceeded sediment transport capacity, then deposition was calculated. The ideas from this early work were expanded and revised by Foster and Meyer,[4] and ultimately were worked into the Chemicals, Runoff, and Erosion from Agricultural Systems (CREAMS) model,[5] which is a hybrid model in the sense that it uses process-based equations with parameters from the USLE. Experience from developing CREAMS then led to the development of the fully process-based Water Erosion Prediction Project (WEPP) model.[6]

Continuous Simulation Models

Process-based models for soil erosion by water may be either continuous simulation or event models. Continuous simulation models predict soil erosion for series of individual storms, and have auxiliary components for updating system parameters between storms. Event models simply predict erosion for individual storm events, but require the user to provide system information for each event. As such, the continuous simulation model is useful for analyzing the effects of crop management systems on erosion, whereas the event model is relatively limited in that regard.

The Water Erosion Prediction Project (WEPP) model is an example of a continuous simulation model. WEPP includes nine major components: climate, infiltration, water balance, winter process and snowmelt erosion, plant growth and residue decomposition, irrigation, surface runoff, rainfall erosion, and channel routing for watersheds.[6] System parameters that are updated on a daily basis within the continuous simulation include soil moisture, soil density, soil resistance to erosion, plant canopy, surface residue, soil surface roughness, soil surface sealing and crusting, buried residue amounts, frozen soil layers, snow cover, and roots. All of these system parameters define the antecedent conditions for each erosion event.

The WEPP climate model has been tested for erosion and well parameterized for the United States.[7] The infiltration component of the hillslope model is based on the Green and Ampt equation as modified by Mein and Larson,[8] with the ponding time calculation for an unsteady rainfall.[9] The water balance and percolation component of the profile model is based on the water balance component of SWRRB (Simulator for Water Resources in Rural Basins),[10,11] with some modifications for improving estimation of percolation and soil evaporation parameters. The plant growth component of the model simulates plant growth and residue decomposition for cropland and rangeland conditions. The residue and root decomposition model simulates decomposition of surface residue (both standing and flat), buried residue, and roots for the annual crops specified in the WEPP User Requirements[12] plus perennial crops of alfalfa and grasses. Surface runoff is calculated using a kinematic wave equation. Flow is partitioned into broad sheet flow for interrill erosion calculations and concentrated flow for rill erosion calculations. The erosion component of the model uses a steady-state sediment continuity equation that calculates net values of detachment or deposition rates along the hillslope profile.[13] The erosion process is divided into rill and interrill components where the interrill areas act as sediment feeds to the rills, or small channel flows. The model is applicable to hillslopes and small watersheds.

Because the model is based on all of the processes described above, and more, it is possible with a continuous simulation, process-based model to have an enormous array of possible system interactions represented in the simulations. Just to name a very few examples, slope length and steepness effects are functions of soil consolidation, surface sealing, ground residue cover, canopy cover, soil water content, crop type and many other factors. Ground residue cover is a function of biomass production rates, tillage implement types, residue type, soil moisture, temperature and solar radiation, previous rainfall, and many other factors. Rill erosion rates are a function of soil surface roughness, ground cover, consolidation of the soil, soil physical and chemical properties, organic matter, roots, interrill erosion rates, slope, and runoff rates, among other factors. The lists continue ad infinitum. These are interactions which are simply not possible to represent with an empirical model. The continuous simulation, process-based model is quite complex in this sense.

The disadvantage of the process-based model is also the complexity of the model. Data requirements are huge, and with every new datum element comes the opportunity to introduce uncertainty, as a first order error analysis would clearly indicate. Model structure interactions are also enormous in number, and with every structural interaction comes the opportunity for error, as well. In a sense, the goal in using the process-based model is to capture the advantages of the complexity of model interactions, while gaining the accuracy and dependability associated with the simpler empirically based model. This can be done, and was done with the WEPP model, using a combination of detailed sensitivity analyses and calibration of the model to the large database of natural runoff plot information used to develop the USLE. Without the tie between model and database, and without knowledge of the sensitive input variables so as to know where to focus efforts, turning a complex model such as WEPP into a useful conservation tool would not be possible. Thus in a sense, even though WEPP routines are process-based descriptors of various components of the erosional system, ultimately the model must be empirically based on the same type of data as was used to develop the USLE, along with additional experimental data collected specifically for WEPP.

Examples of process-based event models of soil erosion by water include EUROSEM,[14] the Hairsine and Rose model,[15,16] and GUEST.[17] EUROSEM is a fully dynamic model that simulates the erosion, transport and deposition of sediment over the land surface by interrill and rill processes. The model requires break-point rainfall data, ideally of one-minute resolution, as input along with a detailed description of the soils, slopes and land cover of the watershed. The model computes the interception of rainfall by the plant cover, the generation of runoff as infiltration-excess, soil detachment by raindrop impact and runoff, the transport capacity of runoff and the deposition of sediment. EUROSEM uses the runoff generator and the water and sediment routing routines of KINEROS.[18] The model of Hairsine and Rose[15,16] develops the ideas presented earlier by Rose and colleagues,[19,20] where erosion is calculated as a net balance of instantaneous processes of sediment entrainment, deposition, and re-entrainment. The GUEST model[17] is a practical conservation tool developed from these same concepts.

Erosion by Wind: Source, Measurement, Prediction, and Control

Brenton S. Sharratt and R. Scott Van Pelt

Introduction

Wind erosion is the loss of soil caused by wind. Wind velocity in excess of that required to initiate movement of sand or soil particles results in particles rolling or creeping along the surface, bouncing or saltating on the soil surface, or being ejected from the surface directly into the atmosphere. Soil in motion is thus displaced from its original position; although displacement can be on the order of millimeters or kilometers, a net loss of soil may occur from the source area such as a field or dune. Wind erosion not only affects the productivity of the soil resource that supports plant growth but also can impact other natural resources. For example, soil eroded from a landscape and transported in the atmosphere can be deposited downwind into lakes or streams affecting water quality or linger over communities affecting air quality. On a larger scale, suspended sediment in the atmosphere can affect the radiation balance and therefore the earth's climate. Likewise, wind erosion of dunes can cause encroachment of sand onto roads or into communities.

This entry identifies causes of wind erosion as well as the implications to humans and ecosystems around the world. Discussion then focuses on a wide array of techniques and sensors used to monitor wind erosion. Indeed, measurements of wind erosion are integral to developing forecasting tools and conservation practices to protect our natural resources. This entry concludes with the authors' perspective on preventing wind erosion, recognizing that wind erosion continues today despite the availability of best management practices.

Causes

Wind erosion occurs as a result of displacement or movement of particles by wind at the earth's surface. Movement can occur as a result of rolling or creeping along the surface, bouncing or saltating on the surface, or suspension. The latter described a process whereby particles, once ejected from the surface, remain suspended and are transported off-site in the atmosphere. Creep is generally limited to particles 500 to 2000 μm in diameter, saltation to particles 100 to 500 μm in diameter, and suspension to particles smaller than 100 μm in diameter. Movement is governed by the shape, size, and density of the particle and occurs when the aerodynamic forces of wind overcome the gravitational and attraction forces imposed upon the particle at the surface. Aerodynamic forces result from wind shear at the surface; drag exerted by the surface on wind flow causes wind shear or a change in wind velocity with height above the surface. The wind velocity profile within the surface boundary or constant flux layer can be expressed as:

$$u_z = \left(\frac{u^*}{k}\right)\ln\left(\frac{z}{z_o}\right), \tag{1}$$

where u_z is wind velocity (m s^{-1}) at height z (m), u^* is friction velocity (m s^{-1}), z_o is aerodynamic roughness (m), and k is von Karman's constant (0.4). Friction velocity is proportional to the shear stress exerted by wind on the surface and is typically obtained from the wind velocity profile under conditions of neutral atmospheric stability. Particle movement occurs when u^* exceeds the threshold friction velocity of the particle (u^*_{tp}). The threshold velocity of a dry sand particle was originally described by Bagnold[1] as:

$$u^*_{\mathrm{tp}} = A\sqrt{\frac{\sigma - \rho}{\rho} gd} \tag{2}$$

where σ and ρ are the respective particle and air density (Mg m^{-3}), g is acceleration due to gravity (m s^{-2}), d is mean particle diameter (m), and A is an empirical coefficient of turbulence. As mentioned previously, the shape and size of a particle are important characteristics that affect movement. For example, flat particles are more easily entrained by wind than spherical particles due to greater lift forces at the surface of flat particles.[2] Thus, efforts have been made by scientists[3] to account for differences in particle shape and size using an equivalent particle size in estimating u^*_{tp}.

The cause of wind erosion is associated with factors that influence u^* and threshold friction velocity of the soil surface (u^*ts) since erosion can only occur when u^* exceeds u^*_{ts}. In fact, the streamwise sand transport rate and vertical dust flux from an eroding field are typically expressed as a function of the difference in u^* and u^*_{ts}.[4,5] Dust is used in this entry to describe the component of eroded soil, usually particles <100 μm in diameter, transported by suspension processes. Note that u^*_{ts} is not the same as u^*_{tp} since soil physical and chemical properties and protection afforded particles by nonerodible elements on the soil surface affect the threshold velocity. The principle factor affecting u^* is wind, and according to Eq. 1, u^* increases with wind velocity. Surface roughness also affects u^*. Roughness elements such as vegetation, stubble, ridges, and aggregates on the soil surface cause drag on the wind flow and an increase in u^*. Factors that influence u^*_{ts} include soil wetness, soil crusting, soil surface roughness, coverage of the soil surface with nonerodible aggregates and prostrate biomass, and frontal area of standing stubble or vegetation protruding above the soil surface. Shao[6] formulated an expression for u^*_{ts} based upon these soil and surface characteristics as follows:

$$u^*_{\mathrm{ts}} = u^*_{\mathrm{tp}} f_\theta(\theta) f_c(c) f_r(r) f_n(n) f_b(b) \tag{3}$$

where θ is soil moisture content, c is crust cover, r is roughness, n is nonerodible element surface cover, b is biomass frontal area, and f_θ, f_c, f_r, f_n, and f_b are respective corrective functions for soil moisture, crust cover, surface roughness, nonerodible element cover, and biomasss frontal cover. The corrective functions account for shear stress partitioning at the soil surface caused by soil wetness, crusting, roughness, nonerodible elements, and biomass. These functions are described as the ratio of $u*_t$ for a wet, crusted, rough, cloddy, or vegetative surface to $u*_t$ for a dry, loose, smooth, fine, or denuded surface. Therefore, the value of each function is ≥1. This mathematical portrayal of factors affecting $u*_{ts}$ indicates that roughening or wetting the surface or increasing coverage of crust or nonerodible elements on the surface will increase $u*_{ts}$ and therefore decrease erosion. Similarly, smoothing or drying the surface or decreasing coverage of crust or nonerodible elements on the surface will decrease $u*_{ts}$ and therefore increase erosion.

Wind erosion generally occurs in dry and windy environments. This would include the arid and semiarid regions of the world (see the section on "Source Regions") where precipitation deficits restrict or limit vegetative growth, thus allowing greater exposure of the soil surface to the forces of wind. Desertification and wildfires in these and other regions escalate wind erosion since removal of vegetation only enhances exposure of the soil surface. Thus, land use and management have a strong impact on the susceptibility of the soil to erode. Management practices that bury vegetation or biomass, destroy soil crusts or aggregates, smooth the soil surface, and aid soil drying will enhance the erodibility of the soil surface. Cultivation of land typically buries biomass on the soil surface, and although the soil surface may be rough after cultivation, crop residue generally provides greater protection than roughness to a smooth surface.[7] The type of tillage equipment and frequency of tillage operations can also affect the erodibility of the soil. Crop rotations are integral to processes that determine soil quality (e.g., biological activity, density, aggregation, water-holding capacity, crusting) and thus can influence the susceptibility of the soil to wind erosion. Intensifying the use of crops through annual cropping in drier regions or double cropping in wetter regions may enhance vegetative or crop residue cover on the soil surface throughout the year. However, rotations proven to be successful in drier regions have employed fallow in the rotation to conserve soil water for the subsequent crop. While fallow is beneficial to the subsequent crop, controlling weeds in fallow through tillage often reduces residue cover and destroys aggregates.

Climate change has a profound influence on wind erosion. Over a period of years to decades, drought will reduce vegetative growth and cover and thus enhance wind erosion. On a geologic time scale, wind erosion was thought to be enhanced during the Pleistocene as a result of modifications in wind pattern, hydrologic cycle, and the size of source areas. These factors contributed to the vast loessial deposits evident in Asia, Europe, North America, and South America.[8]

Implications

Wind erosion defines a process of moving soil particles across the landscape by wind. Wind erosion is a selective process whereby the uppermost layer of soil (topsoil) is removed from the soil profile. In regions where soils support crop production, the removal of topsoil represents an invaluable resource. In some regions of the world, loss of topsoil is an irreplaceable resource since loss of topsoil may exceed the rate of soil formation. Topsoil represents the most fertile and biologically active part of the soil profile. Eroded soil is generally enriched in carbon and nutrients[9] as well as soil microorganisms that are an important source of carbon, nitrogen, and macronutrients in desert regions.[10] Erosion of topsoil can also negatively affect the inherent physical properties of the soil such as waterholding capacity and density.[11] Thus, loss of topsoil will diminish the soil resource and the ability of the soil to support plant growth over time. Our ability to feed the world therefore deteriorates with the loss of the soil resource unless other means are used to offset the loss of nutrients and organic matter that are found in topsoil.

Wind erosion can cause immediate economic hardship to the agricultural and transportation industry. Damage to plants caused by saltation (sand blasting leaves and stems) can result in a reduction in yield or complete crop failure. Deposition of windblown soil can bury emerging seedlings and thus jeopardize plant establishment. Removal of topsoil by wind can expose newly sown seed or seedlings (Figure 1) and thus necessitate reseeding, hilling, or some other mechanical operation to reestablish the crop. Windblown sediment can also carry pesticides, weeds, and diseases harmful not only to sensitive crops and lands but also to humans. Windblown soil deposited in ditches or roads necessitates the removal of soil from these repositories. Transportation can also be impacted by failure of engines when exposed to high atmospheric dust concentrations, a particular concern in the aviation industry.

Wind erosion also contributes to poor air quality. Air quality refers to chemical constituents of the atmosphere that affects not only our health but also our visual assessment. Chemical constituents such as pesticides carried by windblown sediment can impair health or cause off-site damage to sensitive crops. In addition, inhalable particulate matter can be removed from soils by wind and travel for great distances in the atmosphere affecting communities downwind (Figure 2). Elevated PM10 [particulate

FIGURE 1 Etiolated stem and roots of potato plants exposed by wind erosion in southcentral Washington, USA. About 50 mm of topsoil was eroded during a high wind event in May 2010.

FIGURE 2 View looking to the west over Pullman, Washington, USA, as obstructed by windblown dust (top image) on October 28, 2003. Windblown dust emanated from sources 50 to 200 km west of the community and resulted in a PM10 concentration of 500 μg m^{-3} at the time of the photo. The bottom image was taken on a clear day after the dust storm.

matter ≤10 µm in diameter regulated by government entities such as the Chinese State Environmental Protection Administration, the European Commission, and the United States Environmental Protection Agency (USEPA)] concentrations downwind of eroding agricultural fields have been a concern in the Columbia Plateau region of the United States for the past two decades.[12] Wind erosion also contributes to poor visibility as a result of enhanced dust concentrations near the earth's surface. Regional haze caused by elevated dust concentrations can impair the value of natural and historic objects such as wilderness areas, national parks, and national monuments. Elevated dust concentration can also impair visibility along roadways, causing vehicular damage and loss of life.

Fine dust particulates suspended in the atmosphere as a result of wind erosion can impact regional and global climates. Atmospheric dust contributes to the scattering and absorbing of solar radiation and is a source of cloud condensation nuclei.[13] The efficiency with which dust particles affect these processes is complex and dependent on the chemical and physical properties of particles.

Deposition of windblown soil into water bodies can also impair the quality of water. Deterioration of water quality results from nutrients and pesticides being carried to water sources by airborne soil particles. In particular, phosphates bound to windblown soil trigger algae blooms that can impair both human and marine life. Recent evidence of windblown soil affecting water quality was reported in 2009 when a dust storm originating in South Australia on September 22 moved eastward, depositing suspended sediment into Sydney Harbor. The nitrogen and phosphorus bound to this sediment resulted in an explosion of plant life in the harbor, an event previously observed in Australian waters.[14]

Source Regions

Wind erosion occurs primarily in arid and semiarid regions of the world. This does not negate, however, the occurrence of wind erosion in humid regions. Nanney et al.,[15] for example, reported an annual erosion rate of 193 mt ha^{-1} in Indiana where the annual precipitation is 900 mm. Robinson[16] also reported 50 mm of topsoil eroded during a 5-day windstorm in Lincolnshire, England, where annual precipitation is nearly 600 mm. Wind erosion can also occur from roads and construction sites, but these sources are localized. Salt-affected soils are a major source of dust and are usually associated with ephemeral or dry lakes. Sparse vegetative growth and cover, characteristic of saline and sodic soils, and dispersion of aggregates in sodic soils enhance the vulnerability of salt-affected soils to wind erosion.

Wind erosion occurs on every continent of earth, even in Antarctica where rates of sand movement in McMurdo Dry Valleys rival those in many other desert regions of the world.[17] Wind erosion in Australia escalated over the past two centuries as a result of clearing lands for agricultural production. Dust storms occur with the greatest frequency in Western and South Australia. The Lake Eyre Basin located in South Australia is one of the largest sources of dust in the world.[18] Wind erosion in Africa occurs with the greatest frequency in the Saharan Desert. Chad, which lies at the southern boundary of the Sahara Desert, is the largest source of dust in the world. Warren et al.[19] suggested that the Bodele Depression in northern Chad is the dustiest place on earth. Dust storms in the Bodele Depression occur about 100 days per year. Wind erosion in Asia is prevalent in the Middle East and central Asia. Dust storms in the Middle East can occur on more than 35 days per year in Iran and Kuwait near the Persian Gulf,[20] whereas dust storms in central Asia can occur on more than 60 days per year in Turkmenistan[21] and in northwestern China.[22] The annual frequency of dust storms in Asia may seem of little consequence, but dust originating from sources such as the Taklamakan Desert in China and Gobi Desert in northern China and southern Mongolia was integral to the formation of the Loess Plateau. Wind erosion in Europe is of particular concern in the southeast region of Romania, Ukraine, and Russia.[23] Soils in these regions are generally sands. Wind erosion is not widespread in northern Europe, but degradation of agricultural land by wind is of concern from sands and silts in northern Germany, western Denmark, eastern England, southern Sweden, and the Netherlands.[24] Wind erosion in North America occurs most extensively within the Great Plains that extend from Texas, USA, into the provinces of Alberta, Manitoba, and Saskatchewan in Canada. The southern Great Plains was

known as the "Dust Bowl" in the 1930s when wind erosion created one of the most severe environmental catastrophes in U.S. history. Wind erosion continues to be problematic in other regions such as the Great Basin and Columbia Plateau of the United States. Wind erosion in South America is of particular concern in Argentina due to the extent of arid and semiarid lands and desertification. One of the major sources of dust in the world is the Salar de Uyuni in Bolivia.[18]

Source regions of wind erosion that contribute to the atmospheric load of dust around the world were simulated by Tegen et al.[25] The major sources of dust emanating from natural (desert, shrubland, and forest) and cultivated soils (rangeland and cropland) are from Africa, Asia, and Australia. Europe, North America, and South America also contribute as sources of dust emanating from natural and cultivated soils (Figure 3).

Tools for Monitoring

Although the redistribution of soil by wind is often quite visible, erosion and deposition can be difficult to quantify. Spatial and temporal variability of factors controlling erosion make simple measurements unreliable if not impossible.[26,27] For example, differences in topography and soil texture often create conditions where one location in the field or landscape erodes more easily than another location. Soil surface conditions such as soil roughness and crusting vary as a result of mechanical disturbance and weather. Drought reduces vegetative growth and cover and limits the ability of the land manager to protect the surface with tillage or longer lasting effects of cover crops. Wind speed and direction fluctuate on scales of seconds, and the number of erosive high wind events often varies between months and years. Stroos-nijder[28] points out that sediment cannot be collected at a single location in a field because of variations in wind direction, discharge with height above the soil surface, and distance across the field. Despite these obstacles, research over the past eight decades has resulted in numerous methodologies to assess and predict the redistribution of soil by wind.

Direct Measurement

The direct measurement of soil redistribution by wind is rarely found in the literature. Early in the history of wind erosion research, soil erosion pins or stakes were the only available devices to measure soil redistribution. The concept behind the use of soil pins is simple—anchor the pin in the soil to avoid heave or change in elevation of the pin from normal soil processes such as freezing and thawing, initially measure the distance between the top of the pin and soil surface, and return at some future date for a repeated measurement. If the distance between the top of the pin and soil surface has increased, net erosion has occurred and if the distance has decreased, net deposition has occurred at the location of

FIGURE 4 Pin frame with pins conforming to the soil surface. Dark pins on both outside edges of the frame are resting on erosion pins.

the pin. In a study in southern New Mexico, erosion pins installed in 1933 have been measured multiple times since, revealing interdecadal changes in patterns and rates of soil redistribution.[29] Selkirk and Saffigna also used erosion pins to document deflation of 43 mm yr^{-1} at the north end and accretion of 28 mm yr^{-1} at the south end of a mixed sand and peat field in Australia.[30]

Since an erosion pin measures localized erosion or deposition, a large number of spatially distributed pins are needed to obtain a spatial estimate of soil redistribution. Using the pin as a reference point and taking multiple measurements of the soil surface reduces the number of pins needed and increases the accuracy of the estimate. This technique necessitates using a pin frame such as shown in Figure 4. These measurements can be time-consuming and the frame pins may sink into unconsolidated soil, reducing measurement accuracy. Advances in technologies using lasers and photoreceptors have allowed very precise and spatially intensive measurement of surface elevations.[31] Recently, photoelectronic pins with built-in photoreceptors have been used to investigate the short-term fluctuations in erosion.[32] Direct measurement of soil erosion has also been made from observations of exposed crop roots[33] and native vegetation such as shown in Figure 5. Direct measurement of deposition is often possible along field margins where fences and vegetation trap the sediment, resulting in buried fences.

Horizontal Mass Flux

The concept of mass balance is often used to measure wind erosion. In practice, soil erosion or deposition is determined by the difference in sediment discharge between a windward and leeward location in the field. Sediment discharge is typically assessed by measuring the horizontal mass flux (HMF), or the mass of sediment moving across a small vertical plane, at several heights above the surface.[34] An increase in HMF between the windward and leeward locations represents a net loss of sediment between the two locations. There is a limit to the amount of sediment that may be entrained by the wind as the entrained particles exert a drag on the wind and reduce its erosivity.[35] The upper limit of sediment that wind may carry is termed *transport capacity*; this concept is used to describe the variation in HMF as a function of distance across an eroding field using the relationship:

$$f_x = f_{mx}\left(1 - e^{-x/b}\right), \tag{4}$$

FIGURE 5 Root of a shrub used to measure depth of soil excavated by wind erosion in southern Kansas. the distance to a protected surface (m), and *b* is the characteristic horizontal length scale or the distance at which $fx = 0.632\, fmx$.[36]

where f_x is the HMF in the windward direction (g $m^{-2}day^{-1}$), f_{mx} is the maximum value of HMF at a given height (g $m^{-2}day^{-1}$), x is the horizontal coordinate usually taken to be The HMF typically diminishes with height above the soil surface. A theoretical expression describing the vertical distribution of sediment in saltation is:[37]

$$f = f_o\left(1+\frac{y}{\sigma}\right)^{\beta}, \tag{5}$$

where f is the suspended soil mass flux (g m^{-2}), f_o is the soil mass flux moving in the interval of 0–3 mm above the surface (g m^{-2}), y is the height above the soil surface (m), $\boldsymbol{\sigma}$ is the height below which 50% of total HMF occurs for $\boldsymbol{\beta} = -2$ (m), and $\boldsymbol{\beta}$ is a dimensionless power term describing the slope of the height as a log transformed function of the measured HMF. Other investigators[38] reported that suspended sediment, which is above the layer of creep and saltation, conforms to the power function:

$$w = ay^{-b}, \tag{6}$$

where w is the mass of sediment per unit area of sampler opening (g m^{-2}) collected at height y (m) and a and b are regression coefficients. Sediment transported by creep and saltation were described by the relationship:

$$w = ce^{dy}, \tag{7}$$

where w and y are the same as Eq. 6 and c and d are regression coefficients. Eqs. 6 and 7 may be combined to describe the vertical distribution of creep, saltation, and suspension using the expression:

$$w = ay^{-b} + ce^{dy}. \tag{8}$$

Integrating either Eq. 5 or Eq. 8 throughout the height of vertical flux and entering these integrated vertical sediment fluxes into Eq. 4 results in the field-wise estimate of soil loss.[37]

HMF Samplers

Reliable measurements of HMF at several heights above the surface must be made to estimate sediment discharge at various locations within a field. Specialized samplers have been designed and utilized for measuring HMF. Among the first attempts to measure HMF was the vertical slot sampler of Bagnold.[1] Chepil improved on this design by adding a wind vane and mounting the sampler so that it could pivot into the wind.[39] Many designs have been tested over the years, but few have been truly accepted by the aeolian research community. Use of active samplers, those relying on a motive force to move air through the sampling orifice and sedimentation chamber or filter, is rare in the scientific literature. Passive samplers include the Modified Wilson and Cooke (MWAC),[40] the Big Spring Number Eight (BSNE),[41] and the Wedge Dust Flux Gauge (WDFG).[42] These samplers require frequent inspection to reinitialize and manually collect sediment prior to or after a high wind event. The SUSpended Sediment TRAp (SUSTRA) is a pivoting passive sampler that weighs the collected sediment, allowing for automated real-time HMF measurements.[43]

Among passive HMF samplers most widely used include the MWAC (Figure 6) and the BSNE (Figure 7) samplers. HMF samplers vary in sampling efficiency. The MWAC sampler has an 80%–102% efficiency while the BSNE sampler has a 35%–45% efficiency in trapping particles with a diameter ≤63 μm at wind speeds of 2 to 5 m s^{-1}.[44] In a similar investigation, the MWAC sampler was found to be 90%–120% efficient and the BSNE sampler was found to be 70%–130% efficient in trapping particles with diameters between 132 and 287 μm at wind speeds ranging from 6 to 14 m s^{-1}.[45] While the efficiency of the MWAC sampler was relatively independent of wind speed, the efficiency of the BSNE sampler tended to decrease with increased wind speed.

FIGURE 6 A profile of MWAC samplers used to measure the vertical distribution of airborne sediment. Inlet tubes (to the left of the bottles) are oriented into the wind by the sail (to the right of the image) and trap airborne sediment as the mast rotates in the soil mount (at the bottom of the image).

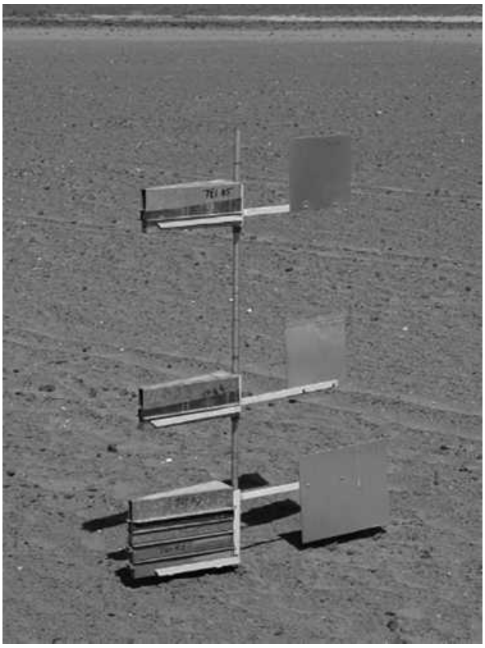

FIGURE 7 Field installation of BSNE samplers. The two uppermost samplers are single samplers while the bottom sampler is specially designed to sample HMF at three heights in the saltation layer (below a height of 0.25 m).

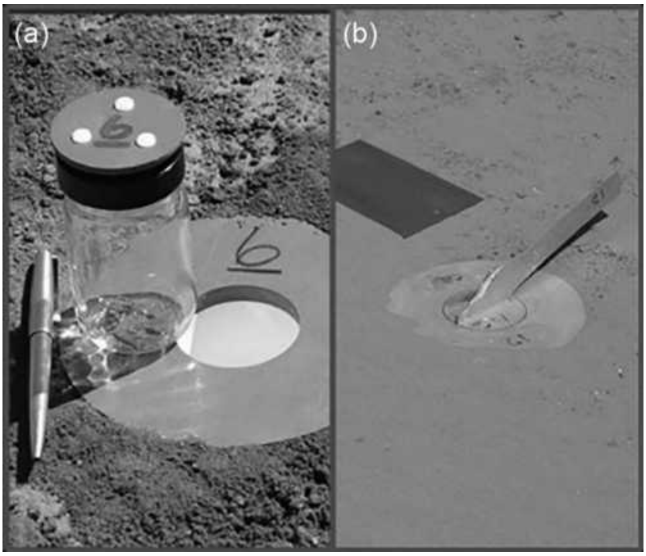

FIGURE 8 Two types of creep samplers include an omnidirectional sampler consisting of a jar with holes in the raised metallic lid (a) and a pivoting sampler that traps creep and saltation at a height of 0 to 0.02 m above the soil surface (b).

Movement of the creep component of HMF is measured by specialized samplers. The simplest design utilizes a jar with a small hole in the lid that collects particles passing over the hole. A more sophisticated design is a wind vane oriented sampler that is installed flush with the soil surface and samples particles moving along and very close to the soil surface.[46] An example of both these designs is shown in Figure 8.

Temporal resolution of saltation in the field is often measured using piezoelectric or acoustical impact sensors such as the Sensit[47] shown in Figure 9 or the saltiphone[48] shown in Figure 10. These sensors develop an electrical pulse when struck by a saltating particle. A temporal resolution of less than 1 sec allows these impact sensors to be used to estimate the threshold wind velocity of erodible surfaces.[49] A recent study found that the sensitivity varies among individual sensors of the same type and with wind speed and particle diameter. The authors concluded that impact sensors should only be used to

FIGURE 9 A Sensit omnidirectional saltation impact sensor with blue piezo sensing element. The Sensit is mounted vertically by burying the massive base or by inverting the Sensit and supporting the base above the soil surface as shown in the image.

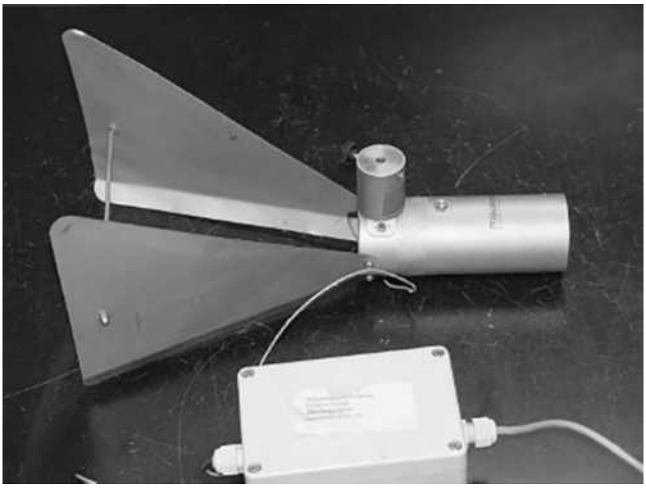

FIGURE 10 A saltiphone pivoting saltation impact sensor. The saltiphone is an acoustical sensor with a microphone diaphragm in the tubular body. The fins orient the saltiphone tube and microphone into the wind.

investigate temporal and spatial patterns of wind erosion unless carefully calibrated to the specific conditions expected in the field.[50] Recent advances in optical sensors promise more quantitative time-resolved measurements of saltation.[51]

Fugitive dust in suspension is often the most visible evidence of active wind erosion. Passive HMF samplers can be used to trap particles in suspension, but these samplers are inefficient at trapping dust due to resuspension of small particles within the sampling chamber. The suspension component of HMF is most often measured with aspirated sampling devices. Optical sensors such as the DustTrak (Figure 11), E-sampler, or Grimm particle sampler aspirate the sediment-laden air past a light source that measures the optical occlusion caused by the suspended sediment. Optical sensors have been used with saltation impact sensors to examine the linkage between saltation and fine dust emissions.[52] The Tapered Element Oscillating Microbalance (TEOM), as shown in Figure 12, aspirates the sedimentladen air, filters the particulates, and periodically weighs the collected dust. The TEOM is a USEPA-approved device for measuring real-time PM10. Filter-based samplers, such as the low-volume or high-volume sampler, are also used to measure dust in suspension. These samplers aspirate air at a known rate through a preweighed hydrophobic filter, thus providing a time-integrated measure of dust in suspension.

Radioisotopic Techniques

Radioisotopes, especially the anthropogenic isotopes such as ^{137}Cs, provide ideal soil tracers for studying long-term (50 years) soil redistribution rates. These radioisotopes were formed as a result of nuclear bomb detonations and distributed globally in the stratosphere. From 1954 to 1970, these isotopes were deposited on the earth's surface by wet and dry deposition processes, collectively termed fallout. The peak of radioisotopic fallout was in 1963 and 1964 as nations rushed to use test warheads prior to the nuclear test ban treaty of 1963.[53] Certain anthropogenic radioisotopes, especially ^{137}Cs and $^{239+240}$Pu are bound very tightly to the exchange surface of soil particles and only move in the environment with movement of the soil particle to which they are bound.[53]

Radioisotopes have been widely used to study the rates and patterns of soil redistribution by water,[54] but studies of aeolian soil redistribution using radioisotopes are limited. One of the first studies to look at redistribution of ^{137}Cs on the landscape as an indicator of aeolian soil movement assumed that the erosion on a field knoll might be due to wind.[55] Subsequent to this study, the ^{137}Cs technique has been used to study rates and patterns of soil redistribution by wind in North America,[56,57] Europe,[58]

FIGURE 12 A TEOM dust sampler. Air is aspirated through the inlet located above the white enclosure in the field (a) and into a tube before passing through a filter (in the tan base of b). The weight of the filter is periodically recorded by the controller unit (gray panel in upper left of b).

Africa,[59] Australia,[60] and Asia.[61] Models developed for estimating aeolian redistribution rates based upon loss of ^{137}Cs from the soil agree well with observations taken at field sites with documented erosion and deposition histories.[62] Future work will hopefully develop the use of the longer-lived $^{239+240}$Pu for estimating wind erosion and allow for calibration of wind erosion models based on 50 years average erosion rates.

Wind Erosion Models

The measurement of wind erosion during high wind events has allowed the development of a wide variety of models to predict sediment entrainment and transport at field to global scales.[34] The models range from early empirical models, such as the Wind Erosion Equation (WEQ) released in 1965, to more process-based models, such as the Wind Erosion Prediction System (WEPS). References and

TABLE 1 Commonly Used Wind Erosion Models along with Citations and Climatic and Soil Surface Input Variables[34]

Model	Citation	Climate Variables	Roughness	Aggregation	Crust	Soil
WEQ	[65–67]	Precipitation; potential evapotranspiration; monthly wind direction, preponderance, and % erosive energy; irrigation dates	Ridge height, ridge spacing, standing, and flat biomass	Fraction <0.84 µm	Presence or absence	Percent sand, silt clay, organic matter, and calcium carbonate

input parameters for selected wind erosion models are presented in Table 1. Although other wind erosion models such as the Wind Erosion on European Light Soils model[63] and Dust Production Model[64] can be found in the literature, discussion hereafter is limited to the WEQ and WEPS. These two models represent the oldest and one of the newest technologies available to predict wind erosion. The WEPS also dynamically simulates changes in soil properties and surface characteristics that govern wind erosion.

Wind Erosion Equation

In the United States, the WEQ has been used extensively over the past several decades to assess the effect of crop and management on wind erosion.[65,66] The WEQ was designed to predict long-term average annual wind erosion based on a specific set of climatic and field conditions; the model can be used to predict wind erosion for specific time periods in which the soil and climate factors do not change. Annual soil loss is then obtained by summing soil loss for all individual time periods in a year. Details for using WEQ are found in the U.S. Department of Agriculture-Natural Resources Conservation Service (USDA-NRCS) National Agronomy Manual.[66] The WEQ is defined by the following function:

$$E = f\left(IKCLV\right), \tag{9}$$

where E is the estimated annual soil loss (Mg ha^{-1}), f indicates a non-linear functional relationship among the variables, I is the soil erodibility index (Mg ha^{-1}), K is the soil surface roughness factor, C is the climatic factor, L is the unsheltered distance, and V is the vegetative cover factor.

In practice, I is determined by the surface soil texture and assigned a value determined by a predetermined effect of soil texture on the aggregate formation and stability of the soil. The absolute value of I is defined as the potential wind erosion for an unsheltered, bare, level, smooth, and loose soil at a location where C is 100. The other factors are then multiplied with I using nomographs in the USDANRCS National Agronomy Manual[66] to determine appropriate values.

Being an empirical model, WEQ tends to perform well within the range of original data used to develop the model. In a Global Change and Terrestrial Ecosystem/Soil Erosion Network (GCTE/SEN) exercise comparing the performance of wind erosion models during 46 high wind events across six states in the United States, WEQ was found to accurately estimate erosion in the central Great Plains but overestimate erosion in the northern Great Plains and underestimate erosion in the southern Great Plains.[67] The WEQ is very sensitive to soil texture, surface roughness, and residue. The high sensitivity of WEQ to soil texture necessitates adjusting the I factor to local conditions.[67]
