Exergy: Analysis

Marc A. Rosen

Introduction

Energy analysis is based on the first law of thermodynamics, which embodies the principle of conservation of energy and is the traditional method used to assess the performance and efficiency of energy systems and processes.

Exergy analysis is a thermodynamic analysis technique for systems and processes that is based on the second law of thermodynamics. Exergy analysis has been increasingly applied over the last several decades, in large part because of its advantages over energy analysis:

- More meaningful efficiencies are evaluated with exergy analysis because exergy efficiencies are always a measure of the approach to the ideal.
- Inefficiencies in a process are better pinpointed with exergy analysis because the types, causes, and locations of the losses are identified and quantified.

In this entry, the role of exergy analysis in the assessment and improvement of energy systems is examined. First, exergy and its use as an analysis technique are briefly described. Second, the ranges of energy systems that have been assessed with exergy analysis are surveyed. Third, several example applications of exergy analysis are presented, ranging from simple devices to large and complex systems.

Exergy

Exergy can be regarded as a measure of the usefulness or quality of energy. Technically, exergy is defined as the maximum amount of work that can be produced by a stream of energy or matter, or from a system, as it is brought into equilibrium with a reference environment. Unlike energy, exergy is consumed during real processes due to irreversibilities and conserved during ideal processes. Exergy and related concepts have been recognized for more than a century.[1]

Exergy analysis is a methodology that uses the first and second laws of thermodynamics for the analysis, design, and improvement of energy and other systems.[2–14] The exergy method is useful for improving the efficiency of energy-resource use, for it quantifies the locations, types, and magnitudes of wastes and losses. In general, more meaningful efficiencies are evaluated with exergy analysis rather than energy analysis because exergy efficiencies are always a measure of the approach to the ideal. Therefore, exergy analysis accurately identifies the margin available to design more efficient energy systems by reducing inefficiencies.

In evaluating exergy, the characteristics of the reference environment must be specified,[2–15] usually by specifying the temperature, pressure, and chemical composition of the reference environment. The results of exergy analyses, consequently, are relative to the specified reference environment, which in most applications is modeled after the actual local environment. The exergy of a system is zero when it is in equilibrium with the reference environment. The tie between exergy and the environment has implications regarding environmental impact.[7,8,16,17]

The theory and the applications of exergy have been described in specialized books, e.g.,[2–8] general thermodynamics texts, e.g.,[9,10], and journal entries, e.g.,[11–14]. Many applications of exergy analysis have been reported in fields ranging from power generation,[18] hydrogen energy,[18] and cogeneration[9,19] to district energy,[19] thermal processes,[20,21] and thermal energy storage[21–23] and on to systems as large as countries[24] and the world.[25]

Exergy and the Reference Environment

Exergy quantities are evaluated with respect to a reference environment. The intensive properties of the reference environment in part determine the exergy of a stream or system. The reference environment is in stable equilibrium, with all parts at rest relative to one another and with no chemical reactions occurring between the environmental components. The reference environment acts as an infinite system and is a sink and source for heat and materials. It experiences only internally reversible processes in which its intensive state remains unaltered (i.e., its temperature T_0, pressure P_0, and the chemical potentials μ_{i00} for each of the i components present remain constant). The exergy of the reference environment is zero. More information on reference-environment models can be found in this encyclopedia in an entry by the present author entitled “Exergy: Environmental Impact Assessment.”

Exergy Balances

Energy and exergy balances can be written for a general process or system.

Since energy is conserved, an energy balance for a system may be written as

$$\text{Energy input} - \text{Energy output} = \text{Energy accumulation} \tag{1}$$

Energy input and output refer, respectively, to energy entering and exiting through system boundaries. Energy accumulation refers to build-up (either positive or negative) of the quantity within the system.

By contrast, an exergy balance can be written as

$$\text{Exergy input} - \text{Exergy output} - \text{Exergy accumulation} = \text{Exergy accumulation} \tag{2}$$

This expression can be obtained by combining the principles of energy conservation and entropy non-conservation, the latter of which states that entropy is created during a process due to irreversibilities. Exergy is consumed due to irreversibilities, with exergy consumption proportional to entropy creation.

Equations 1 and 2 demonstrate an important difference between energy and exergy—energy is conserved while exergy, a measure of energy quality or work potential, can be consumed.

Definitions

It is helpful to define some terms related to exergy for readers. The following are exergy quantities:

Exergy: A general term for the maximum work potential of a system, a stream of matter, or a heat interaction in relation to the reference environment (see definition below) as the datum state; or the maximum amount of shaft work obtainable when a steady stream of matter is brought from its initial state to the dead state (see definition below) by means of processes involving interactions only with the reference environment.

Physical exergy: The maximum amount of shaft work obtainable from a substance when it is brought from its initial state to the environmental state (see definition below) by means of physical processes involving interaction only with the environment.

Chemical exergy: The maximum work obtainable from a substance when it is brought from the environmental state to the dead state by means of processes involving interaction only with the environment.

Thermal exergy: The maximum amount of shaft work obtainable from a given heat interaction using the environment as a thermal energy reservoir.

Exergy consumption: The exergy consumed during a process due to irreversibilities within the system boundaries.

The following terms relate to the reference environment and its state:

Reference environment: An idealization of the natural environment, which is characterized by a perfect state of equilibrium, i.e., absence of any gradients or differences involving pressure, temperature, chemical potential, kinetic energy, and potential energy. The reference environment constitutes a natural reference medium with respect to which the exergy of different systems is evaluated.

Dead state: The state of a system when it is in thermal, mechanical, and chemical equilibrium with a conceptual reference environment, which is characterized by a fixed pressure, temperature, and chemical potential for each of the reference substances in their respective dead states.

Environmental state: The state of a system when it is in thermal and mechanical equilibrium with the reference environment, i.e., at the pressure and temperature of the reference environment.

Reference state: A state with respect to which values of exergy are evaluated. Several reference states are used, including environmental state, dead state, standard environmental state, and standard dead state.

Exergy Analysis

Exergy analysis involves the application of exergy concepts, balances, and efficiencies to evaluate and improve energy and other systems. Many engineers and scientists suggest that devices are best evaluated and improved upon using exergy analysis in addition to or in place of energy analysis.

A journal devoted to exergy matters entitled *The International Journal of Exergy* was established by Inderscience. Some extensive bibliographies have been compiled, including one by Goran Wall (see the website http://exergy.se).

A simple procedure for performing energy and exergy analyses involves the following steps:

- Subdivide the process under consideration into as many sections as desired, depending on the depth of detail and the understanding desired from the analysis.
- Perform conventional mass and energy balances on the process, and determine all basic quantities (e.g., work, heat) and properties (e.g., temperature, pressure).
- Based on the nature of the process, the acceptable degree of analysis complexity and accuracy, and the questions for which answers are sought, select a reference-environment model.

- Evaluate energy and exergy values relative to the selected reference-environment model.
- Perform exergy balances, including the determination of exergy consumptions.
- Select efficiency definitions depending on the measures of merit desired, and evaluate the efficiencies.
- Interpret the results and draw appropriate conclusions and recommendations relating to such issues as design changes and retrofit plant modifications.

Exergy Analysis and Efficiency

Increases in efficiency are subject to two constraints, which are often poorly understood:

- Theoretical limitations, which establish the maximum efficiency theoretically attainable for a process by virtue of the laws of thermodynamics
- Practical limitations, which further limit increases in efficiency.

First, consider practical limitations on efficiency. In practice, the goal when selecting energy sources and utilization processes is not to achieve maximum efficiency, but rather to achieve an optimal tradeoff between efficiency and such factors as economics, sustainability, environmental impact, safety, and societal and political acceptability. This optimum is dependent on many factors controllable by society. Furthermore, these factors can be altered to favor increased efficiency (e.g., governments can offer financial incentives that render high-efficiency technologies economically attractive or provide disincentives for low-efficiency alternatives through special taxes and regulations).

Next, consider theoretical limitations on efficiency, which must be clearly understood to assess the potential for increased efficiency. Lack of clarity on this issue in the past has often led to confusion, in part because energy efficiencies generally are not measures of how nearly the performance of a process or device approaches the theoretical ideal. The consequences of such confusion can be significant. For example, extensive resources have at times been directed towards increasing the energy efficiencies of devices that in reality were efficient and had little potential for improvement. Conversely, devices at other times have not been targeted for improved efficiency even though the difference between the actual and maximum theoretical efficiencies, which represents the potential for improvement, has been large.

The difficulties inherent in energy analysis are also attributed to the fact that it only considers quantities of energy and ignores energy quality, which is continually degraded during real processes. Exergy analysis overcomes many of the problems associated with energy analysis.

Overview of Exergy Analysis Applications

Exergy analysis has been applied to a wide range of processes and systems, including those that are mechanical, thermal, electrical, and chemical. The types of applications of exergy methods that have been reported over the last several decades include

- Electricity generation using both conventional devices such as fossil and nuclear power plants as well as alternative devices such as fuel cells and solar energy systems
- Energy storage systems such as batteries, pumped storages, and thermal energy storages
- Combustion technologies and systems and engines of various types
- Transportation systems for land, air, and water transport
- Heating and cooling systems for building systems and industrial applications
- Cogeneration systems for producing heating and electrical needs simultaneously
- Chemical processes such as sulfuric acid production, distillation, and water desalination, as well as petrochemical processing and synthetic fuels production
- Metallurgical processes such as lead smelting.

Examples of Exergy Analysis Applications

Three examples of differing complexity of applications of exergy analysis are presented:

- An electrical resistance space heater (a simple component)
- A thermal energy storage system (a simple system containing a number of components)
- A coal-fired electrical generating station (a complex system).

Electrical Resistance Space Heater

An electrical resistance space heater converts electricity to heat at a temperature suitable for room comfort and is illustrated in Figure 1a.

The energy efficiency of electric resistance space heating often exceeds 99%, implying that the maximum possible energy efficiency for electric resistance heating is 100%, corresponding to the most efficient device possible.

This understanding is erroneous; however, energy analysis ignores the fact that in this process, high-quality energy (electricity) is used to produce a relatively low-quality product (warm air). Exergy analysis recognizes this difference in energy qualities and indicates the exergy of the heat delivered to the room to be about 5% of the exergy entering the heater. Thus, the exergy efficiency of electric resistance space heating is about 5%.

The exergy results are useful. Since thermodynamically ideal space heating has an exergy efficiency of 100%, the same space heating can in theory be achieved using as little as 5% of the electricity used in conventional electric resistance space heating. In practical terms, one can achieve space heating with a greatly reduced electricity input using an electric heat pump (see Figure 1b), using 15% of the electricity that electric resistance heating would require, for a heat pump with a "coefficient of performance" of 7.

Thermal Storage System

A thermal energy storage system receives thermal energy and holds it until it is required. Thermal storages can store energy at temperatures above or below the environment temperature, and they come in many types (e.g., tanks, aquifers, ponds, caverns).

The evaluation of a thermal energy storage system requires a measure of performance which is rational, meaningful, and practical. The conventional energy storage efficiency is inadequate. A more perceptive basis is needed if the true usefulness of thermal storages is to be assessed and their economic benefit optimized, and exergy efficiencies provide such performance measures.

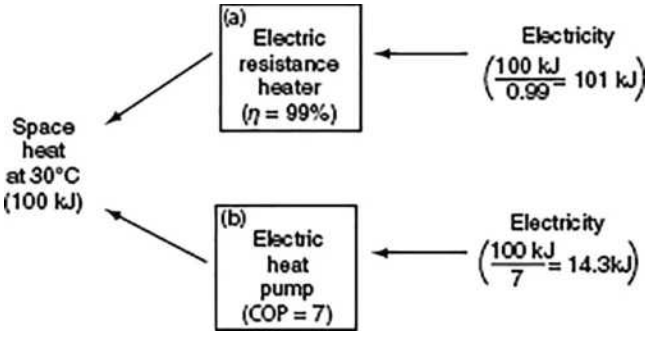

FIGURE 1 Comparison of the quantity of electricity required to provide 100 kJ of space heat using two different heating devices: (a) an electric resistance heater and (b) an electric heat pump. Here, η denotes the energy efficiency and COP the coefficient of performance.

The notion that energy efficiency is an inappropriate measure of thermal storage performance can be illustrated. Consider a perfectly insulated thermal storage containing 1,000 kg of water, initially at 40°C. The ambient temperature is 20°C, and the specific heat of water is taken to be constant at 4.2 kJ/kg K. A quantity of 4,200 kJ of heat is transferred to the storage through a heat exchanger from an external body of 100 kg of water cooling from 100°C to 90°C. This heat addition raises the storage temperature 1.0°C to a value of 41°C. After a period of storage, 4200 kJ of heat is recovered from the storage through a heat exchanger, which delivers it to an external body of 100 kg of water, raising the temperature of that water from 20°C to 30°C. The storage is returned to its initial state at 40°C.

For this storage cycle, the energy efficiency—the ratio of heat recovered from the storage to heat injected—is 4,200kJ/4,200 kJ = 1, or 100%. But the recovered heat is at only 30°C and is of little use, having been degraded even though the storage energy efficiency was 100%. The exergy recovered in this example is 70 kJ and the exergy supplied 856 kJ. Thus, the exergy efficiency, the ratio of the thermal exergy recovered from storage to that injected, is 70/856 = 0.082 or 8.2%, a much more meaningful expression of the achieved performance.

Consequently, a device which appears to be ideal on an energy basis is correctly shown to be far from ideal on an exergy basis, clearly demonstrating the benefits of using exergy analysis for evaluating thermal storage.

Coal-Fired Electrical Generating Station

Energy and exergy analyses are applied to the former Nanticoke coal-fired electrical generating station in Ontario, Canada, which has a net unit electrical output of approximately 500 MWe and is operated by the provincial electrical utility, Ontario Power Generation (formerly Ontario Hydro). This example illustrates how exergy analysis allows process inefficiencies to be better pinpointed than an energy analysis does and how efficiencies are to be more rationally evaluated.

A detailed flow diagram for a single unit of the station is shown in Figure 2. The symbols identifying the streams are described in a–c for material, thermal, and electrical flows, respectively, with corresponding data. Figure 2 has four main sections:

- *Steam Generation.* Eight pulverized-coal-fired natural circulation steam generators each produce 453.6 kg/s steam at 16.89 MPa and 538°C and 411.3 kg/s of reheat steam at 4.00 MPa and 538°C. Air is supplied to the furnace by two 1,080 kW 600-rpm motor-driven forced draft fans. Regenerative air preheaters are used. The flue gas passes through an electrostatic precipitator rated at 99.5% collection efficiency and exits the plant through two multiflued, 198 m high chimneys.
- *Power Production:* The steam passes through a series of turbine generators linked to a transformer. Extraction steam from several points on the turbines preheats feedwater in several low- and high-pressure heat exchangers and one spray-type open deaerating heat exchanger. The low-pressure turbines exhaust to the condenser at 5 kPa. Each station unit has a 3,600-rpm, tandem-compound, impulse-reaction turbine generator containing one single-flow high-pressure cylinder, one double-flow intermediate-pressure cylinder, and two double-flow low-pressure cylinders. Steam exhausted from the high-pressure cylinder is reheated in the combustor.
- *Condensation:* Cooling water from Lake Erie condenses the steam exhausted from the turbines. The cooling-water flow rate is adjusted to achieve a specified cooling-water temperature rise across the condenser.
- *Preheating:* The temperature and pressure of the feedwater are increased in a series of pumps and feedwater-heater heat exchangers.

The reference-environment model used here has a temperature of 15°C (the approximate mean temperature of the lake cooling water), a pressure of 1 atm, and a chemical composition consisting of air saturated with water vapor, and the following condensed phases at 15°C and 1 atm: water (H_2O),

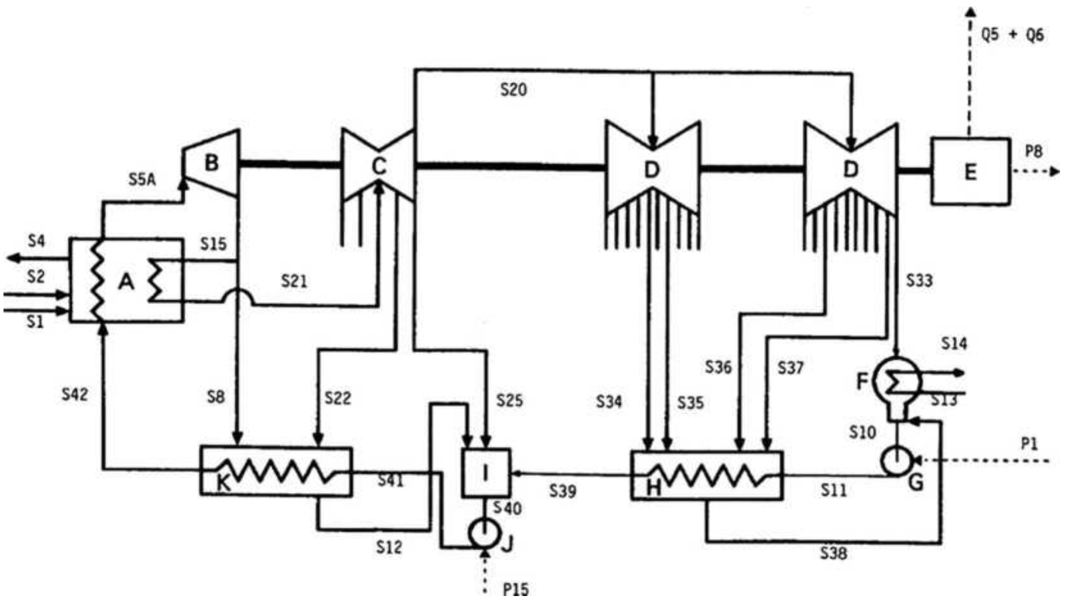

FIGURE 2 A unit of the coal-fired electrical generating station. Lines exiting the turbines represent extraction steam. The station has four main sections: *Steam Generation* (Device A), *Power Production* (B–E), *Condensation* (F), and *Preheating* (G–K). The external inputs for Device A are coal and air, and the output is stack gas and solid waste. The external outputs for Device E are electricity and waste heat. Electricity is input to Device G and Device J, and cooling water enters and exits Device F. A: steam generator and reheater, B: high- pressure turbine, C: intermediate-pressure turbine, D: low-pressure turbines, E: generator and transformer, F: condenser, G: hot well pump, H: low-pressure heat exchangers, I: open deaerating heat exchanger, J: boiler feed pump, and K: high-pressure heat exchangers.

gypsum ($CaSO_4 \bullet 2H_2O$), and limestone ($CaCO_3$). For simplicity, heat losses from external surfaces are assumed to occur at the reference-environment temperature of 15°C.

Energy and exergy values for the streams identified in Figure 2 are summarized in Tables 1a–1c. Exergy-consumption values for the devices are listed, according to process section, in Table 2. Figure 3a and b illustrates the net energy and exergy flows and exergy consumptions for the four main process sections.

Overall energy and exergy efficiencies are evaluated as

$$\text{Energy Efficiency} = (\text{Net energy output with electricity})/(\text{Energy input}) \tag{3}$$

and

$$\text{Exergy Efficiency} = (\text{Net exergy output with electricity})/(\text{Exergy input}) \tag{4}$$

Coal is the only input source of energy or exergy, and the energy and exergy efficiencies are 37% and 36%, respectively. The small difference in the efficiencies is due to the fact that the specific chemical exergy of coal is slightly greater than its energy. Although the station energy and exergy efficiencies are similar, these efficiencies differ markedly for many station sections.

In the *Steam Generation* section, exergy consumptions are substantial, accounting for 659 MW (or 72%) of the 916 MW station exergy loss. Of this 659, 444 MW is consumed with combustion and 215 MW with heat transfer. The energy and exergy efficiencies for the *Steam Generation* section, considering the increase in energy or exergy of the water as the product, are 95% and 49%, respectively.

TABLE 1A Data for Material Flows for a Unit of the Coal-Fired Electrical Generating Station

Stream	Mass Flow Rate (kg/s)[a]	Temperature (°C)	Pressure (N/m^2)	Vapor Frac.[b]	Energy Flow Rate (MW)	Exergy Flow Rate (MW)

High-pressure heat exchangers	6.4	
Hot well pumps	0.1	
Boiler feed pumps	1.1	
		23.4
Total		844.0

The *Steam Generation* section thus appears significantly more efficient on an energy basis than on an exergy basis. Physically, this discrepancy implies that although 95% of the input energy is transferred to the preheated water, the energy is degraded as it is transferred. Exergy analysis highlights this degradation.

In the condensers, a large quantity of energy enters (775 MW for each unit), of which close to 100% is rejected, while a small quantity of exergy enters (54 MW for each unit), of which about 25% is rejected and 75% is internally consumed. Thus, energy analysis leads to the erroneous conclusion that almost all losses in electricity-generation potential for the station are associated with the heat rejected by the condensers, while exergy analysis demonstrates quantitatively and directly that the condensers are responsible for little of these losses (see Figure 3b). This discrepancy arises because heat is rejected by the condensers at a temperature very near that of the environment.

In the *Power Production* and *Preheating* sections, energy losses are small (less than 10 MW) and exergy losses moderately small (118 MW in *Power Production* and 23 MW in *Preheating*). The exergy losses are almost completely associated with internal consumptions.

In assessing the thermodynamic characteristics of a coal-fired electrical generating station, several illuminating insights into performance are acquired:

- Although energy and exergy efficiencies are similar for the station, energy analysis does not identify the location and cause of process inefficiencies, while exergy analysis does. Energy losses are associated with emissions (mainly heat rejected by condensers), and exergy losses are primarily associated with consumptions (mainly in the combustors).
- Because devices with the largest thermodynamic losses have the largest margins for efficiency improvement, efforts to increase the efficiencies of coal-fired electrical generating stations should focus on the combustors. For instance, technologies capable of producing electricity without

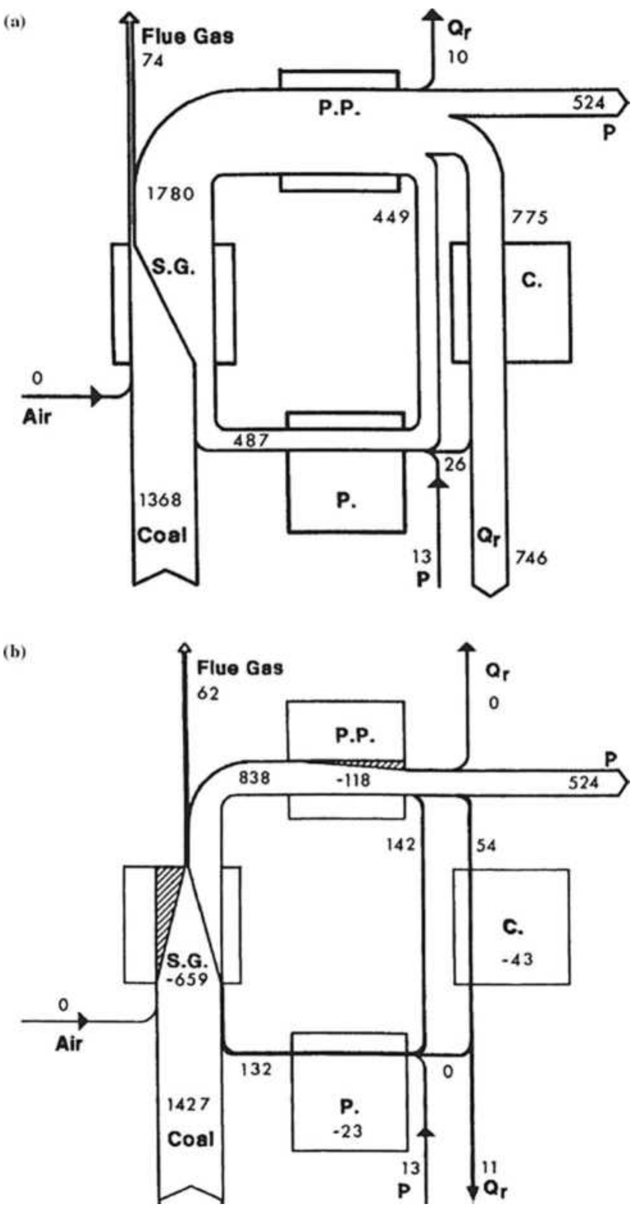

FIGURE 3 (a) Diagram for a coal-fired electrical generating station unit indicating net energy flow rates (MW) for streams. Stream widths are proportional to energy flow rates. Station sections shown are *Steam Generation* (S.G.), *Power Production* (P.P.), *Condensation* (C.), and *Preheating* (P.). Streams shown are electrical power (P), heat input (Q), and heat rejected (Q_r). (b) Diagram for a coal-fired electrical generating station unit indicating net exergy flow rates for streams and consumption rates (negative values) for devices (in MW). Stream widths are proportional to exergy flow rates and shaded regions to exergy consumption rates. Other details are as in (a).

combustion (e.g., fuel cells) or utilizing heat at high temperatures could increase efficiencies significantly. This suggestion is, of course, overly simplistic, as such decisions must also account for other technical and economic factors.

- The use of heat rejected by condensers only increases the exergy efficiencies by a few percent.

Applications beyond Thermodynamics

Exergy concepts can be applied beyond thermodynamics in such fields as environmental impact assessment,[7,8,16,17] economics,[5,17,20,26] and policy.[27,28]

Exergy and Environment

Many suggest that the impact of energy utilization on the environment is best addressed by considering exergy. Although the exergy of an energy form or a substance is a measure of its usefulness, exergy is also a measure of its potential to cause change. The latter point suggests that exergy may be or may provide the basis for an effective measure of the potential of a substance or energy form to impact the environment. The relation between exergy and the environment is discussed in this encyclopedia in an entry entitled "Exergy: Environmental Impact Assessment."

Exergy and Economics

Another area in which applications of exergy are increasing is that of economics. In the analysis and design of energy systems, techniques are often used that combine scientific disciplines like thermodynamics with economics to achieve optimum designs. For energy systems, costs are conventionally based on energy. Many researchers, however, have recommended that costs are better distributed among outputs based on exergy. Methods of performing exergy-based economic analyses have evolved (e.g., thermoeconomics, second-law costing, and exergoeconomics). These analysis techniques recognize that exergy, not energy, is the commodity of value in a system, and assign costs and prices to exergy-related variables. These techniques usually help in appropriately allocating economic resources so as to optimize the design and operation of a system and its economic feasibility and profitability (by obtaining actual costs of products and their appropriate prices).

Conclusion

Exergy analysis provides information that influences design, improvement, and application decisions, and it is likely to be increasingly applied. Exergy also provides insights into the "best" directions for research, where "best" is loosely considered most promising for significant efficiency gains. There are two main reasons for this conclusion:

- Unlike energy losses, exergy losses represent true losses of the potential to generate the desired product from the given driving input. Focusing on exergy losses permits research to aim at reducing the losses that degrade efficiency.
- Unlike energy efficiencies, exergy efficiencies always provide a measure of how closely the operation of a system approaches the ideal. By focusing research on plant sections or processes with the lowest exergy efficiencies, effort is directed to those areas that inherently have the largest margins for efficiency improvement. By focusing on energy efficiencies, on the other hand, research can inadvertently be expended on areas for which little margins for improvement exist, even theoretically.

Exergy analysis results typically suggest that improvement efforts should concentrate more on internal rather than external exergy losses based on thermodynamic considerations, with a higher priority for the processes that have larger exergy losses. Of course, effort should still be devoted to processes having low exergy losses when cost- effective ways to increase efficiency can be identified.

Energy-related decisions should not be based exclusively on the results of energy and exergy analyses even though these results provide useful information to assist in such decision-making. Other factors must also be considered, such as economics, environmental impact, safety, and social and political implications.

Glossary

COP	coefficient of performance
i	component
P	pressure
$\mathbf{P_0}$	reference-environment pressure
T	temperature
$\mathbf{T_0}$	reference-environment temperature
$\boldsymbol{\eta}$	energy efficiency
$\boldsymbol{\mu}$	chemical potential
μ00	reference-environment chemical potential

Air Pollution: Monitoring

Waldemar Wardencki

Introduction

Concern about air quality is not new. The first reports of air pollution problems appear to have been made by writers in ancient Rome who were aware of its adverse effects on human health. Air pollution and its consequences had originally been considered to be relatively local phenomena associated with urban and industrial centers. Complaints were recorded in the 13th century when coal was first used in London. Now, it has become apparent that pollutants may be transported long distances in the air, causing adverse effects in environments far removed from the source emission. Scientific research, conducted over 200 years, has evidently shown that polluted air has a negative influence on health and, in some cases, may lead to death. The World Health Organization (WHO) appraises that air pollution causes approximately 2 million premature deaths worldwide per year. The levels of pollutants, which have a negative influence on life, are nowadays well defined. Because current thresholds set by national or global air quality guideline values are frequently exceeded, further reductions of emissions are necessary.

The first essential step in controlling and mitigating air pollution is to quantify the emissions of air pollutants. Most countries entail controlling a range of key pollutants at their point of discharge. The most important tool in environmental protection is monitoring. Environmental monitoring is the general term for systematic observations of what is going on in the environment. In the broadest context, environmental monitoring is defined as a system of measurements, evaluations, and forecasts of environmental states, and the collecting, processing, and spreading of information on the environment.

Air pollution and its control are a global issue demanding international cooperation. Monitoring of air pollution is a very important source of data. However, measurement of air pollutant concentrations, in comparison to monitoring of other elements of the environment, is the most difficult. This is related to the dynamics of the atmosphere, making it the main route of pollutant transport between the remaining environmental compartments. Unlike the case of water and soil pollution, environmental pollution is not geographically restricted, as a result of which large human populations can be exposed to it. Another problem is low concentration of air pollutants and their interaction with other gases.

This entry reviews the issues in the field of air pollution monitoring. At the beginning, the general objectives of air monitoring, ambient air quality standards for so-called criteria pollutants, and their sources are presented. In the next part, both analytical methods and instruments for monitoring of ambient air and stack gases are briefly presented. Additionally, other approaches applied in air pollution monitoring, such as biomonitoring, geographical information system (GIS), or remote monitoring, are also briefly characterized.

Objectives of Air Monitoring

Collecting information on the presence and concentration of pollutants in the environment, both naturally occurring or from anthropogenic sources, may be achieved by measurements of such substances or phenomenon of interest. For realistic assessment, temporal and spatial variations of concentrations in the particular environmental compartment, repeated measurements rather than single ones, are made.

The general aim of monitoring is to provide information about the actual levels of harmful or potentially harmful pollutants to indicate areas in which the quality of air does not fulfill proper standards. The main objectives of air monitoring are as follows:

- To measure pollutant mixing ratios and their interactions, patterns, and fate in the environment.
- To carry out ecotoxicological studies and assessment of the effects of pollution on man and the environment, to identify possible cause-and-effect relationship between pollutant concentration and health effects.
- To assess emission sources and the need for legislative controls on emissions of pollutants and to ensure compliance with emission standards.
- To activate emergency procedures in areas prone to acute pollution episodes.
- To obtain a historical record of air quality to provide a database for future use.

The area of applications of air monitoring data is presented in Figure 1.

When the objectives of monitoring are clearly defined, several decisions should be made to generate suitable data for the intended use. Decisions on what to monitor, when and where to monitor, and how to monitor are usually undertaken at the beginning. More difficult are next decisions, e.g., establishing the number and location of sampling sites, the duration of the survey, and the time resolution of sampling. All the steps in the design of a monitoring program are presented in Figure 2.

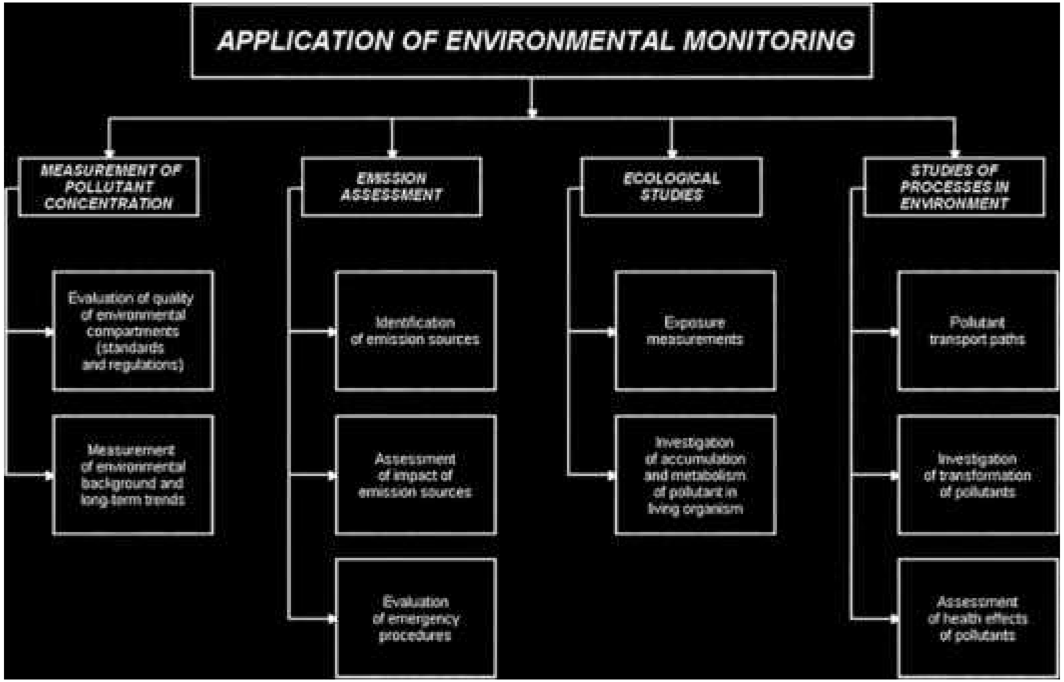

FIGURE 1 The detailed goals of activities in air monitoring.

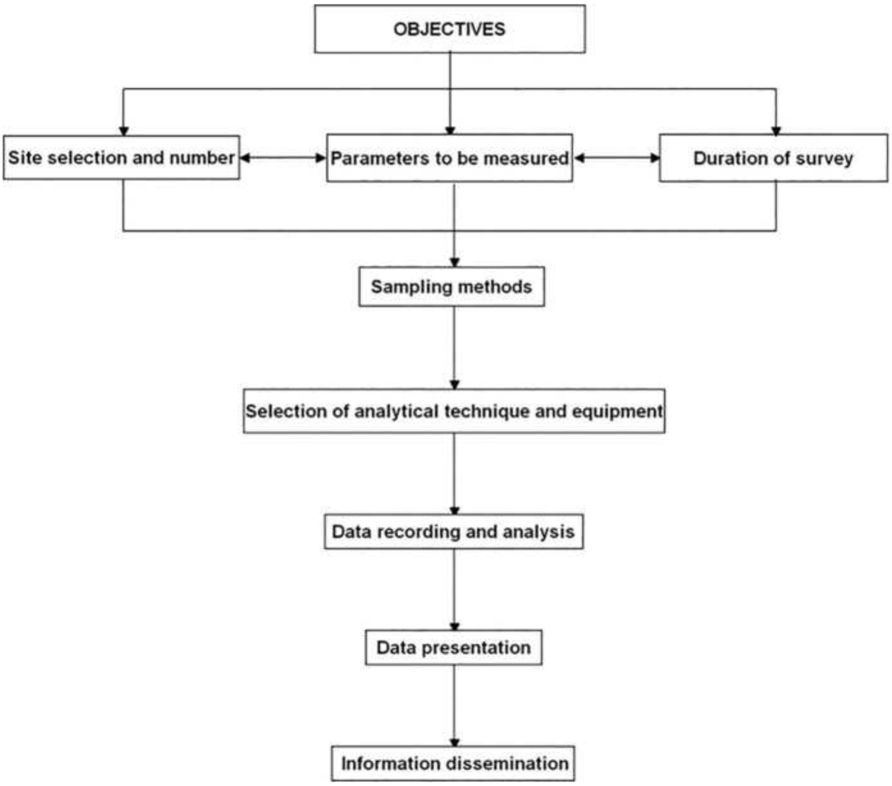

FIGURE 2 Steps in the design of a monitoring program.

History of Air Pollution Legislation

A growing concern over the influence of different air pollutants on human health was the main driving force to develop and implement air quality criteria and standards. Impetus was given to the development of air quality standards in 1958 when it was realized that photochemical problems could not be resolved without control of motor vehicle emission.

Air Quality Standards

Efforts to regulate air quality by law were discussed and undertaken in the 1960s. One of the first proposition was presented by Atkisson and Gaines[1] in 1970. The initial regulations were set in California in response to concerns over human health.[2] After that, similar air quality programs were soon adopted nationally. In 1967, the U.S. Congress enacted the Air Quality Acts, the first modern environmental law.

The Clean Air Act,[3] which was last amended in 1990, requires the United States Environmental Protection Agency (US EPA) to set National Ambient Air Quality Standards (NAAQS) for pollutants considered harmful to public health and the environment. The Clean Air Act established two types of national air quality standards. *Primary standards* set limits to protect public health, including the health of "sensitive" populations such as asthmatics, children, and the elderly. *Secondary standards* set limits to protect public welfare, including protection against decreased visibility and damage to animals, crops, vegetation, and buildings. EPA has established NAAQS for six principal pollutants, which are called criteria pollutants: sulfur dioxide, particulate matter (PM), nitrogen oxide, carbon monoxide, ozone, and lead. These standards are threshold concentrations based on a detailed review of scientific information related to effects.

In Europe, the first international air quality standards were introduced by the European Commission in 1980 for SO_2 and suspended particulates, mainly aimed at protecting human health. A few years later, the WHO, recognizing ecological damage as being relevant to human health, introduced air quality guidelines for Europe, which include the former as well as the latter revision in 2000.[4] The newest directive on ambient air quality and cleaner air of the European Union (EU) entered into force in June 2008.[5] It merges four earlier directives and one Council decision into a single directive on air quality. The new directive of the EU on air quality takes into account concerns from latest WHO air quality guidelines[6] on fine particles. Reflecting the latest WHO air quality guidelines that identify fine particles (PM2.5) as one of the most dangerous pollutants for human health, the new EU directive sets objectives and target dates for reducing population exposure to PM2.5. It also maintains limits for concentration of coarser particles known as PM10 and other main pollutants already subject to legislation.

Table 1 presents examples of air quality standards issued by the EPA, the WHO, and some states.

Air Quality Index

The Air Quality Index (AQI), also known as the Air Pollution Index (API) or Pollutant Standard Index (PSI), is a number used by different government agencies to characterize the quality of the air at a given location. The index aims to help the public easily understand air quality level and protect the health of people from air pollution. As the AQI increases, an increasingly large percentage of the population is likely to experience increasingly severe adverse health effects. Computing the AQI requires an air pollutant concentration from a monitor or model. The function used to convert air pollutant concentration to AQI varies by pollutant and is different among countries. AQI values expressed in different values (most frequently from 0 or 1 to 10, 100, or to 500) are divided into ranges (from 4 to 10), and each range is assigned a descriptor and a color code. Standardized public health advisories are associated with each AQI range. An agency might also encourage members of the public to take public transportation or work from home when AQI levels are high.

Not all air pollutants are characterized by AQI. Many countries monitor only some pollutants, e.g., ground-level ozone, sulfur dioxide, carbon monoxide, and nitrogen dioxide, and calculate AQIs for these pollutants.[7]

The EPA in the United States measures air quality in all parts of the country and publishes a daily AQI based on the data obtained. The following six priority pollutants are measured regularly in order to generate the AQI: carbon monoxide, nitrogen dioxide, particulates, sulfur dioxide, ozone, and lead. EPA has assigned a specific color to each AQI category to make it easier for people to understand quickly whether air pollution is reaching unhealthy levels in their communities. For example, the color orange means that conditions are "unhealthy for sensitive groups," while red means that conditions may be "unhealthy for everyone," and so on.

In Canada, API has values of 0 up to 100+ and is divided into four categories (from good to very poor).

CITEAIR (Common Information to European Air) has developed the first AQIs in Europe.[8] An important feature of the indices is that they differentiate between traffic and city background conditions. The Common Air Quality Index (CAQI) is designed to present and compare air quality in near real time on an hourly or daily basis. The CAQI has five levels, using a scale from 0 (very low) to >100 (very high) and the matching colors range from light green to dark red. The Year Average Common Air Quality Index (YACAQI) uses a different approach adopting the difference to target's principle. If the index is higher than 1.0, it means that for one or more pollutants, the limit values are not met. If the index is below 1, it means that on average the limit values are met. Both indices are practically implemented on a Common Operational Webpage (COW).[9] The project CITEAIR II will further develop the AQIs.[10]

The EU's Sixth Environment Action Programme (EAP), "Environment 2010: Our Future, Our Choice," includes Environment and Health as one of the four main target areas requiring greater effort—air pollution is one of the issues highlighted in this area. The Sixth EAP aims to achieve levels of air quality that do not result in unacceptable impacts on, and risks to, human health and the environment.

The EU is acting at many levels to reduce exposure to air pollution: through EC legislation, through work at the international level to reduce cross-border pollution, through cooperation with sectors responsible for air pollution, through national and regional authorities and NGOs, and through research. The Clean Air for Europe (CAFE) initiative has led to a thematic strategy setting out the objectives and measures for the next phase of European air quality policy.[11]

Regulated Air Pollutants

The contaminants in ambient air that are of concern are basically categorized as criteria and non-criteria pollutants.[12]

Criteria air pollutants are those air contaminants for which numerical concentration limits have been set as the dividing line between acceptable air quality and poor or unhealthy air quality. Criteria pollutants include five gases/vapors and two solids: nitrogen oxides (NO_x), sulfur dioxide (SO_2), carbon monoxide (CO), ozone (O_3), benzene, PM10, and lead (Pb). Non-criteria pollutants are those contaminants designated as toxic or hazardous by legislation or regulation. They fall in two further subcategories, depending on the legislation that defines them. In general, hazardous air pollutants may pose a variety of health effects, whereas toxic ones focus on one physiological response.

Main Sources of Air Pollutants

Air pollution may be defined as a situation in which substances change the qualitative composition of air in relation to average composition of troposphere sufficiently high above their normal ambient air levels to produce a measurable effect on humans, animals, vegetation, or material.[13–17]

Pollutants (both organic and inorganic) may be present in different forms such as gases, aerosols (liquid, solid), and sorbates and have a very broad range of concentration.

The concentrations of ambient air pollutants are expressed in terms of either a mass per unit volume ratio, such as $\mu g/m^3$, or a volumetric ratio (i.e., volumes of contaminant per million or billion volumes of air). The conversion between mass units and volumetric ratios at standard temperature or pressure is:[12]

$$\mu g / m^3 = \text{ppm} \times \text{MW}/0.02445 = \text{ppb} \times \text{MW}/24.45,$$

where:
$\mu g/m^3$—micrograms per cubic meter
ppm—parts per million by volume ($1{:}10^6$)
ppb—parts per billion by volume ($1{:}10^9$).
MW—molecular weight of the contaminant

Some of the most important atmospheric pollutants, their sources, and impacts on the environment and human health are presented in Table 2.

TABLE 2 Atmospheric Pollutants and Their Sources and Effects

Pollutant	Sources	Impact
Sulfur dioxide (SO_2)	Power generation, industry	Acid deposition, smog formation, threat to human health, smog formation
Nitrogen oxides (NO, N_2O, NO_2)	Transport, power generation, industry	Acid deposition, smog formation, O_3 precursor, threat to human health
Carbon dioxide (CO_2)	Combustion processes, power generation, transport, landfills	Global warming
Carbon monoxide (CO)	Combustion processes, power generation	Toxic to humans
Particulate matter (PM)	Power generation, industry, transport	Threat to human health, reduced visibility
Volatile organic compounds (VOCs)	Transport, industry	Photochemical smog, O_3 precursor, global warming
Ozone (O_3)	Photochemical reactions between VOCs and NO_x	Photochemical smogs, respiratory irritant, crop damage
Methane (CH_4)	Landfills, agriculture, gas industry	Global warming
Benzene, 1,3-butadiene	Transport industry	Carcinogenic
Ammonia (NH_3)	Industry, farming, refrigeration, power plant	Toxic to humans and wildlife
Heavy metals	Industry, transport	Toxic to humans and wildlife
Dioxins and furans	Incineration, electrical equipment	Toxic to humans

Source: Bogue.[18]

Urban traffic has become the most important cause of air pollution in the cities.[15] Road traffic is responsible for emission of several air pollutants; the most important of which are nitrogen oxides (NO and NO_2), sulfur dioxide (SO_2), PM, carbon monoxide (CO), and volatile organic compounds (VOCs), all of which can pose a health hazard.

Characteristics of Criteria Air Pollutants

Air pollutants arise from a wide variety of sources although they are mainly a result of the combustion process.[15] The largest sources include power generation, motor vehicles, and industries. The emissions of pollutants to the atmosphere badly influence vegetation, human and animal life, agriculture, and climate. Emissions of carbon monoxide (CO), nitrogen oxides (NO_x), and hydrocarbons are controlled by catalytic converters on new gasoline-driven cars. Emissions of sulfur oxides are being reduced through a lower sulfur content in gasoline. However, emissions of PM are not decreasing. Any successful strategies for controlling or countering these problems must be based on reliable air quality monitoring data for management, to make informed decisions on air pollution control.

Volatile organic compounds is a collective name for a very large number of different chemical species, including hydrocarbons, halocarbons, and oxygenates that have different physicochemical properties and are directly emitted from both anthropogenic and natural sources, and which can contribute to the formation of secondary pollutants with different efficiencies. For vehicular emissions, the list of compounds is long and variable depending on fuel, type of engine, and operating conditions. Hydrocarbons such as ethane, ethyne, higher aliphatic hydrocarbons, benzene, toluene, and xylenes are typical emissions in most cases. Each of these compounds can be released unreacted or can undergo oxidation reactions. One of them, benzene, is found in highest concentrations. Ambient concentrations are typically between 1 and 50 ppb, but close to major emissions can be as high as several hundred parts per billion. In the unreacted state, it has undesirable ecotoxicological properties. Besides causing annoying physiological reactions such as dizziness and membrane irritation, it is known to be a human carcinogen.

The two nitrogen oxides, NO and NO_2 (together called NO_x), from anthropogenic sources are present as a consequence of various combustion processes from both stationary sources, i.e., power generation (21%), and mobile sources, i.e., transport (44%). These species have very short atmospheric lifetimes, around 5 days, and have been ultimately converted to nitric acid and removed in rainfall. However, nitrogen oxide is important because it is a precursor to tropospheric ozone. Whereas NO does not affect climate, ozone does. A typical sea-level mixing ratio of NO is 5 ppt (parts per trillion, $1{:}10^{12}$), but in urban regions, NO mixing ratios reach 0.1 ppm in the early morning, but it decreases to zero by midmorning due to reaction with ozone. A major source of NO_2 is oxidation of NO, with NO_2 being intermediary between NO emission and O_3 formation. Nitrogen dioxide is one of the six criteria air pollutants for which ambient standards are set by the US EPA under CAAA70 (Clean Air Act Amendments of 1970). In the urban regions, the mixing ratio of NO_2 ranges from 0.1 to 0.25 ppm. It is more prevalent during midmorning than during midday or afternoon because sunlight breaks down most NO_2 past midmorning. Exposure to high concentrations of NO_2 harms the lungs and increases respiratory infections. It may trigger asthma by damaging or irritating and sensitizing the lungs, making people more susceptible to allergens. At higher concentrations, it can result in acute bronchitis or death.

Sulfur dioxide (SO_2) is a strong-smelling, colorless gas that is formed by the combustion of fossil fuels, smelting, manufacture of sulfuric acid, conversion of wood pulp to paper, incineration of refuse, and production of elemental sulfur. Power plants, which may use coal or oil high in sulfur content, can be major sources of SO_2, accounting for about 50% of annual global emissions. SO_2 and other sulfur oxides contribute to the problem of acid deposition and can be major contributors to smog. Natural background levels of SO_2 are about 2 ppb. Hourly peak values can reach 750 ppb on infrequent occasions. Sulfur dioxide can lead to lung diseases. SO_2 is a criteria air pollutant.

Ozone (O_3) is not directly emitted from both anthropogenic and natural sources. Its only source into air is chemical reaction. In the urban air, ozone mixing ratios range from less than 0.01 ppm at night to 0.5 ppm (during afternoons in the most polluted cities worldwide), with typical values of 0.15 ppm during moderately polluted afternoons. Ozone causes headaches at concentrations greater than 0.15 ppmv, chest pains at mixing ratios greater than 0.25 ppm, and sore throat and cough at mixing ratios greater than 0.30 ppm. Exceeding the level 0.30 ppm, it decreases lung functions. Symptoms of a respiratory condition include coughing and breathing discomfort. Ozone can also accelerate the aging of lung tissue. It also interferes with the growth of plants and deteriorates organic materials, such as rubber, textiles, and some paints and coatings. Furthermore, ozone increases plant and tree stress and their susceptibility to disease, infestation, and death.

PM, frequently described simply as particle pollution, in the atmosphere arise from natural sources, such as wind-borne dust, sea spray, and volcanoes, and from anthropogenic activities, such as combustion of fuels. Particle pollution in the air includes a mixture of solids and liquid droplets and come in a wide range of sizes. Those less than 10 micrometers (μm) in diameter (PM10) are so small that they can get into the lungs, potentially causing serious health problems. Particles less than 2.5 pm in diameter are called fine particles. These particles are so small that they can be detected only with an electron microscope. Sources of fine particles include all types of combustion, including motor vehicles, power plants, residential wood burning, forest fires, agricultural burning, and some industrial processes. Particles between 2.5 and 10 μm in diameter are referred to as coarse. Sources of coarse particles include crushing or grinding operations and dust stirred up by vehicles traveling on roads. After releasing into air, particles can change their size and composition by condensation of vapor species or by evaporation, by coagulating with other particles, or by chemical reaction. Particles with a diameter smaller than 1 pm generally have atmospheric concentrations in the range from around 10 to several thousands per cubic meter; those exceeding 1 pm diameter are usually found at concentration less than 1 cm^{-3}.

Carbon monoxide (CO) is a colorless, odorless gas that is produced by the incomplete burning of carbon-based fuels including petrol, diesel, and wood. It is also produced from the combustion of natural and synthetic products such as cigarettes. Natural background levels of CO fall in the range of 10–200 ppb. Levels in urban areas are highly variable, depending upon weather conditions and traffic density. Eight-hour mean values are generally less than 10 ppm, but sometimes, they can be as high as 500 ppm. Carbon monoxide lowers the amount of oxygen that enters the blood. It can slow human reflexes and make people confused and sleepy.

Air Quality Monitoring

Design of Monitoring Networks for Air Pollution

For the purpose of monitoring and reporting air pollution, most industrialized countries have been divided into regions or zones and urban areas or agglomeration, e.g., in Europe, in accordance with EC Directive 96/62/EC.[19] This Directive sets a framework for ways how to monitor and report ambient levels of air pollutants. Other directives set ambient air limit values for particular pollutants:

- Directive 99/30/EC for nitrogen dioxide and oxides of nitrogen, sulfur dioxide, lead, and PM.
- Directive 2000/69/EC for benzene and carbon monoxide.
- Directive 2002/3/EC for ozone.

The monitoring sites are organized into automatic and non-automatic networks (regional and national) that gather a particular kind of information using a particular method. For example, across the U.K., there are more than 1500 monitoring sites that monitor air quality, and these are organized into networks (automatic and non-automatic) that gather a particular kind of information, using a particular method. The pollutants measured and method used by each network depend on the reason for setting

FIGURE 3 Stationary monitoring station of the ARMAAG network.

FIGURE 4 General view of an interior of a monitoring station.

up the network, and what the data are to be used for. In Poland, monitoring of air quality has been performed systematically since 1992, mainly by using automatic air monitoring stations. Air quality monitoring data are used at national, voivodship (provincial), and local scale. An exemplary air automated monitoring station, together with a general view of analyzers situated in them, is shown in Figures 3 and 4. This station belongs to the Agency of Regional Air Monitoring of the Gdansk Agglomeration (ARMAAG), which is Poland's first local government-owned air monitoring network. Foundation ARMAAG provides information of air condition in Gdansk agglomeration in real time from the automatic measurement network.

The obtained data from air monitoring are used in air quality inventories and bulletins.

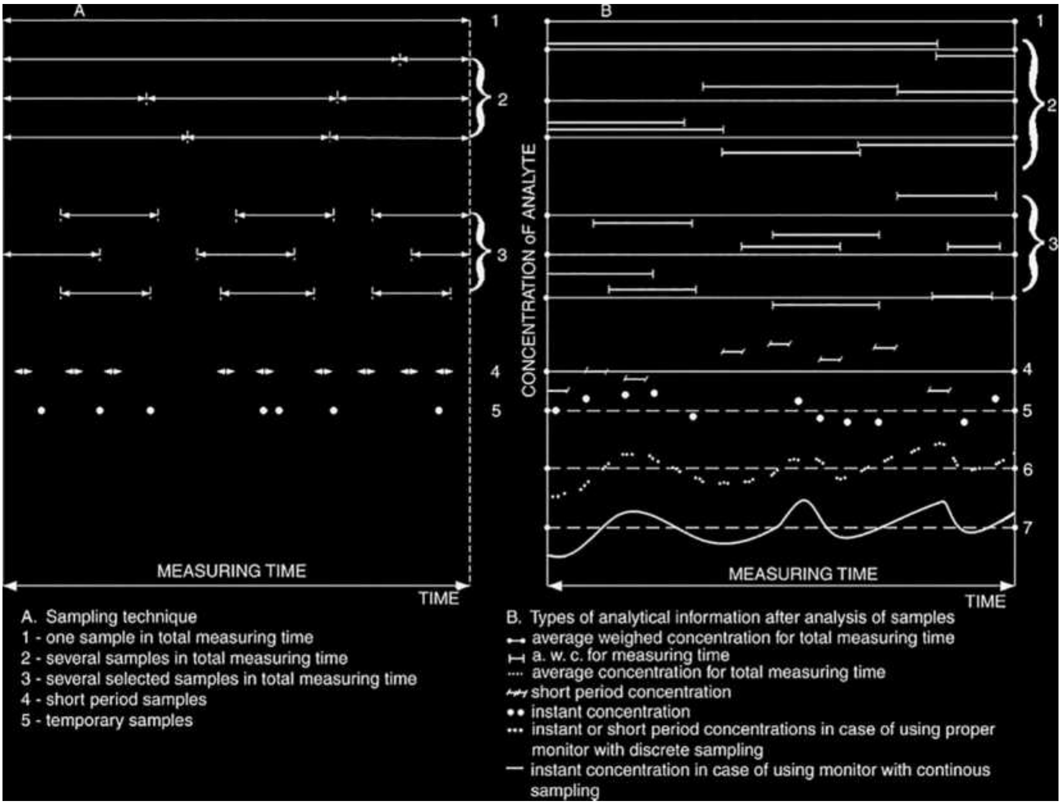

FIGURE 5 Schematic diagram of different sampling techniques used for getting information on concentration of pollutants in determined measuring time.

Types of Information Obtained from Air Monitoring

The obtained information concerns different types of concentration of investigated pollutants depending on applied sampling techniques and measuring period. The results of measurements may be referred to real time (instantaneous concentrations) or to a selected period of time (e.g., 1 hr, 8 hr, 24 hr, 1month, 1year). Final measurements represent averaged concentrations.

Figure 5 presents schematically different forms of concentration obtained as a function of sampling time.[20]

Considering the frequency of sampling, discrete, periodic, and instantaneous measurements are distinguished. Taking into account space, parameter measurements are divided to a point, averaged along a defined part of space, and averaged on the selected area. Point monitoring is inadequate to measure poorly mixed gases such as fugitive emissions over large areas. If the point instrument is wrongly placed, measurement results are not representative. Final measurements enable determination of weighted average concentrations over the sampling period.

General Requirements of the Instruments Used in Monitoring

Monitoring of air pollution is a prerequisite of air quality control and is carried out by a wide variety of analytical methods employing different measuring instruments (analyzers) that have different sensitivities and specificities.[21]

The basic requirement of the analyzers for air monitoring is high measurement sensitivity, i.e., the low limit of detection (LOD) and the low limit of quantitation (LOQ). It gives a chance to detect the pollutants at required levels. The instruments that should acquire analytical data in real time or only with a small time delay have to possess the following additional capabilities:

- Providing high data resolution (characterized by low response time).
- Providing automatic calibration and zeroing.
- Long functioning without service.

The last demand means that they should be equipped with an independent power supply and be able to automatically regenerate or exchange worn-out filters and, depending on the type of detector used (sensor), fulfill special demands, e.g., for electrochemical sensors, exchange or supplement the working solution and reagents, and in devices with Flame Ionisation Detector (FID) or Flame Photometric Detector (FPD) detection, protect against flame extinguishing.

Depending on the number of analytes that an instrument can determine in a single sample, they can be single-parameter (single gas) or multiparameter (multigas) instruments.

Based on sampling frequency, analyzers can be discrete (for single measurement), periodic (for measurements at preset intervals), or continuous (for permanent monitoring).

Classification of the Instruments Used for the Detection and Monitoring of Air Pollutants

The analytical instruments currently used for the detection and determination of atmospheric pollutants can be classified according to various criteria.

Recently, measuring techniques based on a physical (or physicochemical) principle are more frequently used in the assessment of air quality. Such methods involve direct determination of a physical property of a pollutant, sometimes after its interaction with another compound. In this approach, better stability, sensitivity, and reliability may be easily achieved. Furthermore, the practical application requires less maintenance. Instruments based on this principle can be easily automated, which enables their use in providing continuous measurements needed for up-to-date assessments of air quality. It is especially relevant to environmental monitoring because many existing standards refer to specified period of time, i.e., 1 hr, 24 hr, or 1 year.

According to the location where measurements are taken, instruments can be stationary or *on-site*. In the first case, analysis is performed in the laboratory and sophisticated instruments are applied, such as mass, electron mobility, or x-ray fluorescence spectrometers. *On-site* systems enable measuring of pollution levels in the field. Since access to a sophisticated laboratory is not required, the devices (usually uncomplicated, relatively cheap, and portable) hold great promise for use in remote locations. The main advantage of on-site analysis is the potential for rapid assessment and response to a particular problem.

All monitoring systems can be classified as mobile or stationary. Most existing systems monitoring gaseous pollutants of atmospheric air and ambient aerosols, both automatic and manual, usually perform stationary measurements; i.e., they are directly linked to a specific point or space in the vicinity of that point. Basing on the data obtained from single monitoring sites, it is not possible to assess spatial and temporal variations of air pollutants.

Mobile refers to a continuous-monitoring instrument that is portable or transportable. They are usually designed to perform analytical measurements without preliminary operations. Portable refers to self-contained, battery-operated, or worn or carried by the person using it, or may require the use of special vehicles for placement in a specific area to be monitored. Transportable gas monitors can be mounted on a vehicle such as a car, plane, balloon, ship, or space shuttle, but not to a mining machine or industrial truck.

For mobile systems, the registered values of pollutants have to be correlated with information about the geographical site and actual meteorological conditions (temperature and humidity).

Portable systems for field measurements should meet the following requirements:

- Compactness and robustness
- Ease of handling
- Adaptability to on-site measurements
- Automated operation with a long-lasting power supply
- Stability under aggressive environmental conditions

Several contributions published during the last decade have proven the advantages of mobile systems in getting information concerning the spatial and temporal distribution of atmospheric trace gases, without the need of a dense network of stationary stations. Most of the proposed systems are based on application of mobile laboratories,[21–23] equipped with appropriate monitors. There are also systems that allow to measure pollutants in a stream of vehicles but the measuring unit is installed on any vehicle[24–27] rather than attached to a dedicated van.[28,29]

The general trend in the field of creating instruments for air quality assessment is combining several instruments into one system and forming so-called hybrid multisensor systems, controlled by a microprocessor capable of transferring the obtained data to a central station, frequently using a wireless system. In the central station, the data are collected both from single objects (houses, plants) and from large areas. Many systems are equipped with devices for testing the sensors and for providing diagnosis of the whole instrument. Frequently, they have alarms that warn the user of any dangerous situation due to the breaching of some value limit. Such systems are battery powered and able to work continuously for several days or months.

The environments in which analyzers are used differ from the relative calm of the laboratory. Analyzers have to withstand wide ambient temperatures, fluctuations, and vibrations. Due to this, many systems are completely sealed so as to operate independent of outside conditions and be able to withstand the onslaught of monkey-wrench mechanics.

General Characteristics of the Methods and Analytical Instruments for Air Monitoring

Due to the complexity of environmental problems and the variety of pollutants and their different concentrations (typically parts per million or percentage levels in stack gases and parts per billion in air), there is a wide range of methods and instruments used in measuring ambient air quality.

Based on physicochemical principles, the monitoring instruments involve direct determination of the different physical properties of the pollutant or following its interaction with another compound. These methods allow determination of air pollutants in a continuous and automatic way. Such approach requires extremely sensitive instrumentation. Therefore, the most advanced techniques, comprising chemistry, physics, and microelectronics, should be used. As a result, the instruments are combinations of many different devices giving one measuring system. In developing such a system, it should be remembered that it will be exposed to environmental impact, such as changes in temperature, dustiness, humidity of air, aggressive components of air, vibrations, and transportation stress.

The typical instruments used for atmospheric ambient monitoring are based on optical, electrochemical, and semiconductor principles. Among spectroscopic techniques, chemiluminescence, infrared (IR), and fluorescence are the most frequently applied.

The range of typical measuring methods and techniques used in air monitoring is shown in Table 3.

Among the many different optical spectroscopic methods, differential optical absorption spectroscopy (DOAS) has found wide use in atmospheric research and air quality monitoring. The technique is based on the measurements of absorption features of gas molecules along a path of known length in the open atmosphere. The DOAS systems, due to the calibration-free absolute measurements and the unequivocal identification of many trace pollutants, such as CO, SO, NO, and VOCs, and highly

TABLE 3 Air Quality Monitoring Techniques Used in Air Monitoring

Pollutant	Emissions	Ambient Air
CO_2	FTIR, NDIR, TDLAS	NDIR, DOAS
CO	FTIR, NDIR, TDLAS, DOAS	NDIR (gas filter correlation variant)
SO_2		UV fluorescence
NO_x		Chemiluminescence
PM	Triboelectric, opacity, beta ray attenuation	Beta ray attenuation, oscillating microbalance, gravimetric
VOCs	FID, GC	FID, GC
CH_4	NDIR, FTIR,TDLAS, FID	FID, GC
O_3		UV absorption spectroscopy, DOAS, electrochemical sensors
NH_3	FTIR,TDLAS, chemiluminescence GC	Chemiluminescence, DOAS GC
Benzene, 1,3-butadiene	In situ GC-MS with continuous sampling	MS, GC-MS
Dioxins and furans	XRF, LIBS, cold vapor AFS, atomic	Sampling plus MS or GC-MS
Metals	Emission spectrometry	Sampling plus ICP-MS, DOAS (for Hg)

FTIR, Fourier transform infrared absorption spectroscopy; NDIR, non-dispersive infrared absorption; TDLAS, tunable laser diode absorption spectroscopy; DOAS, differential optical absorption spectroscopy; FID, flame ionization detector; GC, gas chromatography; MS, mass spectrometry; XRF, x-ray fluorescence; LIBS, laser-induced breakdown spectroscopy; ICP, inductively coupled plasma; AES, atomic emission spectrometry; AFS, atomic fluorescence spectrometry.

reactive radicals, e.g., OH, NO, and halogen oxide radicals, are exploited by air quality monitoring agencies around Europe and in the United States. The physical and chemical principles, the current state of this measurement method, and details for users are broadly presented in a recently published book.[30]

In Europe, standard/reference methods (EN) are provided by the European standardization body (CEN). The standard methods use the following principles:

Chemiluminescence for NO EN 14211

Nitrogen oxide reacts with ozone, generated within the instrument, produces an excited molecule of nitrogen dioxide, which emits light returning to its original state. A photomultiplier tube measures the emitted light that, if the volumes of sample gas and excess ozone are carefully controlled, is proportional to the concentration of NO in the gas sample.[31]

The chemiluminescent method used for nitrogen oxides is based on the following reactions:

$$NO + O_3 \rightarrow NO_2^* + O_3$$

$$NO_2^* \rightarrow NO_2 + h\nu$$

The chemiluminescence technique may be used to measure total oxides of nitrogen (NO_x) by passing the sample over a heated catalyst to reduce all oxides of nitrogen to NO. This is done within the instrument, just prior to the reaction chamber. Some instruments can perform the automatic switching of the catalyst in and out of the sample path so that the resulting signals may be compared to indirectly measure NO_2.

Ultraviolet Fluorescence for SO_2 EN 14212

Sulfur dioxide is measured without chemical pretreatment by gas-phase fluorescence spectrometry in the UV region. Molecules of SO_2 are excited by UV radiation (200–220 nm) into unstable forms, which return to a basic state, emitting radiation in the range of 240–420 nm according to following reactions:[32]

$$SO_2 + h\nu \rightarrow SO_2^*$$

$$SO_2^* \rightarrow SO_2 + (UV)$$

The intensity of fluorescence radiation is proportional to sulfur dioxide in the sample.

Non-Dispersive Infrared for CO EN 14626

The analytical principle is based on absorption of IR light by the CO molecule. NDIR-GFC (non-dispersive infrared-gas filter correlation) analyzers operate on the principle that CO has a sufficiently characteristic IR absorption spectrum such that the absorption of IR by the CO molecule can be used as a measure of CO concentration in the presence of other gases. CO absorbs IR maximally at 2.3 and 4.6 pm. Because many other molecules also absorb IR radiation in practice, different technical designs are proposed. The following approaches are typically applied:[33]

- Measurement of IR absorption at specific wave for CO (2.3 or 4.6 pm)
- Analyzers with two cells, one of which is filled with pure air (compensation of drift)
- Analyzers with turning circle (GFC)

Ultraviolet Photometry for O_3 EN 14625

Upon exposure to UV light, ozone absorbs some of the light and the intensity difference is directly proportional to the concentration of ozone. Frequently, the UV light source is a 254 nm emission line from a mercury discharge lamp.[34]

Online Gas Chromatography for Benzene EN 14662-Part 3

A measured volume of sample air is drawn or forced through a sorbent tube. Provided suitable sorbents are chosen, benzene is retained by the sorbent tube and thus is removed from the flowing air stream. The collected benzene (on each tube) is desorbed by heat and is transferred by inert carrier gas into a gas chromatograph equipped with a capillary column and a flame ionization detector or another suitable detector, where it is analyzed. Prior to entering the column, the sample is concentrated either on a cryo trap, which is heated to release the sample into the column, or on a pre-column, where higher boiling hydrocarbons are removed from the pre-column by back flush. Two general types of instruments are used. One is equipped with a single sampling trap and the other is equipped with two or more traps. The single-trap instrument samples for only part of the time in each cycle, whereas the multitrap instrument samples continuously. Typical cycling times are between 15 min and 1 hr.[35]

PM is usually determined using active filter method by gravimetry as the reference method.[36] In this method, the air is passed through a filter that stops particles above 10 pm (PM10) or 2.5 pm (PM2.5). Measurements are made over a period of 24 hr or longer. The filters are collected and the adsorbed particles are measured in the laboratory. Other methods use beta ray absorption or tapered element oscillating microbalance (TEOM) of PM. In beta gauge instruments, which are used for real-time measurements of particulate emissions from stationary sources, the mass of the sample deposited on the filter tape is automatically measured by beta ray attenuation. The measurement is made first on a blank, then on the particulate-laden filter. The range is 2–4000 mg/m^3 without interference or effect from color, size, or atomic mass of the dust.

An interesting review on *online* analyzers for monitoring of VOCs was recently published.[37]

Other Monitoring Approaches

Biomonitoring Using Plants

Modern air instruments cannot measure the effects air pollution has on living cells and are limited to measuring the present conditions. Biological materials can be an excellent basis for establishing a biomonitoring network on large areas for a long time. Biomonitoring, as a continuous observation of an area with the help of bioindicators, can allow a qualitative survey and quantitative estimation of the pollutants in the environment. Since the 19th century, biological monitoring as a rather simple observation has turned into a serious alternative if not a useful complement to the traditional methods of assessing contamination, from both natural and anthropogenic sources. In the case of airborne pollution, its heyday really began after World War II. The expensive growth of biomonitoring research works has gained momentum mainly from lower organisms such as lichens, bryophytes, and, to a lesser degree, fungi. The use of cosmopolite organisms for assessing pollution has developed notably during the last two decades.

Bioindicators are organisms or organs of such organisms that respond to a certain level of pollution by the change in their life cycle or accumulation of the particular pollutant. Bioindicators, in contrast to direct analysis, reflect complex effects of harmful substances, as such organisms show not only the synergistic effects of a sum of parameters but also a time-integrated picture of the history of their life span. Another advantage is the selective uptake of such substances, as an organism exposed to an environmental pollutant, either through air or via direct uptake, absorbs the bioavailability fraction only. They readily reflect the proportion of the pollutants, which may be dangerous to human beings as well.

In air monitoring, two organisms, i.e., lichens and mosses, have become the most popular bioindicators.

Lichens are unusual organisms because they consist of fungal threads and microscopic green alga living together and functioning as a single organism. Lichens grow on rocks, soil, trees, or artificial structures in unpolluted habitats. Lichens act like sponges, taking in everything that is dissolved in the rainwater and retaining it. Different species of lichens vary in sensitivity to air pollution. Lichens are commonly used as air quality indicators since some species are more pollution tolerant than others. The most sensitive lichens are shrubby and leafy, whereas the most tolerant lichens are crustose. In city centers, lichens may be entirely absent. If the air is clean, shrubby, hairy, and leafy lichens colonize every available surface.

Lichens may be used as bioindicators in two different ways:

- By mapping all species present in a specific area.
- Through the individual sampling of lichen species and measurement of the accumulated pollutants or by transplanting lichens from a clean environment to a contaminated one.

Lichens are used as biomonitors in the examination of the level of pollutants such as sulfur, nitrogen, and phosphorus compounds, as well as ozone, fluorides, chlorides, and heavy metals. Several biomonitoring methods using lichens have been described since the 1970s when Hawksworth and Rose[38,39] proposed a method based on the determination of zones (from 0—strong pollution to 10—clear air) with selected epiphytic lichens (on two different kinds of tree bark) that relate to levels of sulfur dioxide pollution. This method was widely adopted (both in the original scale and in relation to the real concentrations of sulfur dioxide) in many countries mainly due to its simplicity. Over the last decade, new techniques like the European method for mapping lichen diversity (LDV), as an indicator of environmental stress/quality, have been proposed. The procedure is based on the fact that epiphytic lichen diversity is impaired by air pollution and environmental stress. It provides a rapid, low-cost method to define zones of different environmental quality. In addition to information on the long-term effects of air pollutants, data on eutrophication, anthropization, and climatic change on sensitive organisms may likewise be obtained. Data quality depends on the uniformity of growth conditions, and usually standardization in sampling procedure is necessary.

The relative ease of sampling, the absence of any need for complicated and expensive equipment, and the accumulative and time-integrative behavior of the monitor organisms that make biomonitoring of atmospheric pollutants possible could be continued for the foreseeable future, especially in large-scale surveys.[40–45]

GIS in Air Quality Monitoring

Reliable information on air quality is needed not only on temporal trends in air pollution (as, for example, provided by data from fixed-site monitoring stations) but also on geographical variations. Maps are needed, for example, to identify so-called hot spots, to define at-risk groups, to show changes in spatial patterns of pollution, and to provide improved estimates of exposure for epidemiological studies. The development of GIS techniques offers considerable potential to mapping air pollution. GIS technology enables obtaining statistical and spatial data on air quality by estimation of environmental levels of regulated contaminants.[46]

Remote Monitoring Techniques

Remote monitoring techniques enable the measurement of atmospheric pollutants in remote, poorly accessible, and dangerous regions.[47–49] Remote sensing is especially recommended for the detection of diffuse emissions that are hard to quantify with typical ground-point measurements, but its use is restricted to specialized monitoring demands due to very considerable cost of the equipment.

The cheapest and most widely used methods are those of aerial photography, including IR sensing and optical spectroscopy. Different spectrometers, whether they are ground based in a mobile laboratory or airborne, are the most common instruments used in air pollution for determination of SO_2 and NO_2 concentrations in plumes from tall stacks. The results provide reliable data for studying the transport and dispersion of a plume.

Typical gaseous pollutants such as NO_x, SO_2, CO, and O_3 may be monitored using different types of lasers, which, due to long-path absorption measurements, enable the determination of pollutants at very low concentrations. In laser absorption methods, a detector is used to monitor absorption of specific wavelengths in light paths. Lidar (light detection and ranging) transmits light out to a target and part of this light is reflected/scattered back to the instrument where it is analyzed. The time for the light to travel out to the target and back to the lidar is used to determine the range to the target, allowing spatial resolution of pollutant concentration data within the light path; by monitoring back-scatter intensity at two close wavelengths, the species concentration as well as its spatial distribution may be inferred. This method has been successfully used for measurements of SO_2 up to a range of 2 km.

There are three basic generic types of lidars: range finder lidars, differential absorption lidars (dial), and Doppler lidars.

Range finder lidars are used to measure the distance from the lidar instrument to a solid or hard target. Dial is used to measure pollutant concentration in the atmosphere on the basis of the difference of the two return signals having two different wavelengths (one is absorbed by the molecule of interest while the other is not absorbed). The Doppler lidar is used to measure the velocity of a target. The target can be either a hard target or an atmospheric target.

Another type of device used for remote monitoring is sodar (sound detection and ranging). The Doppler sodar sends out sound pulses of several frequencies in slightly different directions. The acoustic signals are back-scattered by inhomogeneities in the atmosphere.

Further significant developments of laser techniques use the Raman back-scatter, which is highly characteristic of the scattering molecule.

Monitoring of Flue and Exhaust Gas Emissions

Different industrial branches, e.g., coal-fired power plants, chemical plants, petrochemical plants, oil refineries, PVC factories, heavy industries, and incinerators, are principal stationary pollution sources emitting, usually by chimneys, stack (flue) gases, containing different pollutants. Monitoring of such emission sources needs continuous, automatically acting systems that are usually a multielement, integrated, and cooperative set of measuring devices, auxiliary equipment, and calibration appliance.[50,51]

Systems for Continuous Monitoring of Stack Gases

The monitoring systems for continuous monitoring can be classified on the basis of different criteria. Depending on the way in which measurement is made, and especially on the applied sampling mode, extractive and in situ systems are distinguished.[52]

In extractive systems, as the name implies, the sample is extracted continuously from a duct or stack from a representative volume of stack gases and transported by transfer line to analyzers (one or more single-component analyzers or one multicomponent analyzer). However, in most cases, some conditioning of the sample is required to remove water vapor and PM. The two main types of extractive systems are fully extractive (sometimes called simply "extractive") and dilution extractive (also known as "dilution").

A typical extractive system (Figure 6) has a stainless steel probe, with a filter to remove coarse particulates. After filtration, a heated, unchanged sample is transferred to a sample conditioner located in the system enclosure. Calibration gas is delivered from the enclosure to the probe and back through the sample tubing to calibrate the system. The simplest sampling conditioning method is cooling the sample and allowing the moisture to condense and drain out of the system.

Instruments based on spectroscopic techniques (mainly UV and IR), paramagnetic properties, and solid electrolytes (zirconium dioxide) for oxygen determination are frequently used to monitor CO, CO_2, NO_x, and SO_2. For low concentrations of NO_x and SO_2, a chemiluminescent method can be applied. Fully extractive systems can be sometimes used without moisture removal, especially when the sample contains components that are easily soluble in water.

Fully extractive systems are recommended for monitoring of pollutants in stack gases with different physicochemical parameters of compounds. Another advantage of such systems is the possibility of monitoring several locations using one analyzer (time-share systems).

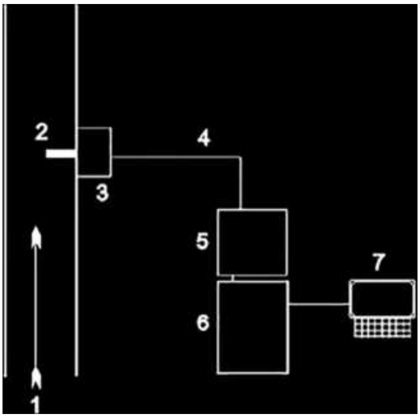

FIGURE 6 Schematic diagram of a fully extractive system for continuous emission monitoring of stack gases: 1, stack gases; 2, probe; 3, filter; 4, heated sampling line; 5, moisture removal; 6, analyzers; 7, storage unit.

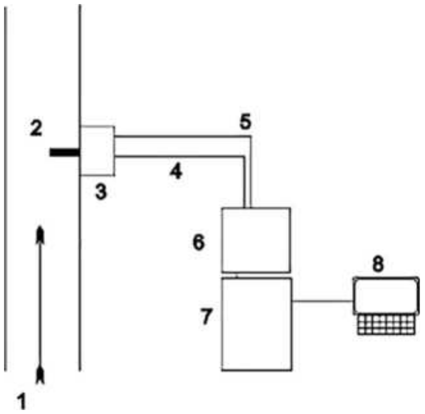

FIGURE 7 Schematic diagram of a dilution-extractive system for continuous emission monitoring of stack gases: 1, stack gases; 2, probe; 3, filter; 4, clean and dry dilution air; 5, diluted sample to analyzers; 6, dilution control unit; 7, analyzers; 8, storage unit.

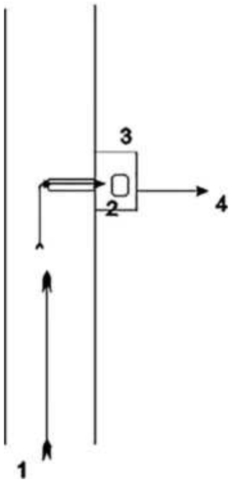

FIGURE 8 Schematic diagram for a point-type in situ system for continuous emission monitoring of stack gases (sensor mounted in the box with the sensor electronics): 1, stack gases; 2, sensor; 3, electronics in enclosure; 4, signal.

Dilution of the sample gas (Figure 7) with clean, dry air to the sample (usually from 50:1 to 250:1) considerably facilitates sample handling and reduces the dew point of the sample gas so that the sampling line can be unheated. Furthermore, the diluted sample is similar in respect of pollutant concentration to ambient air, enabling the use of ambient analyzers. Relatively small amounts of sampled gases increase the time between cleaning the filters. Because most dilution-extractive systems are affected by changes in temperature and barometric pressure, it is recommended that temperature and pressure sensors be installed at the sampling location to compensate these effects. The dilution systems are recommended for plants fueled with carbons when high levels of particulates are present in stack gases (0.1 g/m^3) and corrosive substances (e.g., HCl or SO_3).

In in situ systems (Figure 8), a gas probe is inserted into the wall. It allows monitoring the sample without removing it from the source and does not require sample conditioning or transport of the sample gas, thus minimizing the measurement errors during sampling, transferring, and conditioning

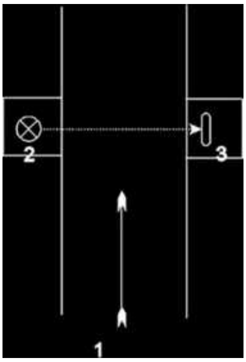

FIGURE 9 Schematic diagram of a single-path-type in situ system for continuous emission monitoring of stack gases: 1, stack gases; 2, light source; 3, receiver.

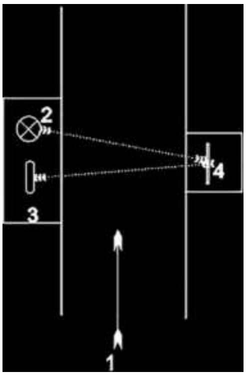

FIGURE 10 Schematic diagram of a dual-path-type in situ system for continuous emission monitoring of stack gases: 1, stack gases; 2, light source; 3, receiver; 4, reflector.

the sample. An optical beam is contained within the probe. This optical beam represents the absorption path that enables the analysis. The sample is drawn into the probe but remains under the conditions found in the stack. The sample is never removed or extracted from the stack.

In practice, two types of in situ systems are used: point and path monitoring systems (Figures 9 and 10). In point monitoring systems, a sample probe and analyzer are installed inside the stack. They are also called in-stack monitors and measure gas at a single point. Therefore, it is important to choose a location that is representative in terms of the components of interest. As analyzers in such systems, spectroscopic instruments are used (based on absorption of UV and IR radiation) as well as electrochemical devices. In situ monitoring systems are recommended for locations with easy stack access and for measuring SO_2 and O_2 in combustion sources because point monitors are very cost-effective for measuring only one or two components.

Path monitoring systems minimize errors that can arise when the location of a measuring point is not representative and due to the disturbances in the flow of stack gases. They measure gas concentration along a path, usually across the diameter of the stack or duct. A light source is mounted on one side of the stack and a beam is passed through to the other side. A single-pass system measures the light that reaches the other side of the stack, whereas a double-pass system uses a reflector and passes the light back across the stack before performing the measurements. Two parameters are limited in these systems: the length of the measuring path (no less than 0.5 m, no more than 8–10 m) and the temperature of stack gases (no more than 300°C).

In situ systems are usually mounted in the ducts after electrostatic precipitators or in chimney ducts.

The systems for stack sampling can be easily adapted to process monitoring or even ambient (closed or open path) monitoring.

Conclusions

Air quality has unquestionably adverse effects on human health. For example, air pollution is increasingly being cited as the main cause of lung conditions such as asthma—twice as many people suffer from asthma today compared to 20 years ago.

This is the main reason that the issue of air quality is now a major concern for many countries that have been working to improve air quality by controlling emissions of harmful substances into the atmosphere, improving fuel quality, and integrating environmental protection requirements into the transport and energy sectors. Despite these improvements in air quality over the last few years, the problem of air pollution still remains. Therefore, more needs to be done at the local, national, and international level. For example, a wide interest is observed to establish common criteria (e.g. AQIs-Air Quality Criteria (AQC)) to compare the state of the air for different countries that follow different directives.

During the last decade, different types of AQC were proposed in literature[53,54] and/or adopted by governments. An interesting review on AQI published recently online by the Italian Group of Environmental Statistics (GRASPA) (http://www.graspa.org) shows the lack of a common strategy to compare the state of the air for cities that follow different directives.[55] The major differences between the indices in the literature are found in the number of index classes (and their associated color) and relative descriptive terms (e.g., considered pollutants, averaging time, frequency). Also, the guidelines themselves are sometimes consistently different from state to state, not only in indicating the pollutants to be monitored but also in setting the threshold values and the number of exceedances per year. Furthermore, the way air quality is interpreted on the basis of a country-or city-specific AQI differs considerably.

Monitoring of air pollution is a prerequisite of air quality control and is carried out by a wide variety of analytical methods employing different measuring instruments that have different sensitivities and specificities. Monitoring plays a critical role in protecting the environment and is a key element of all actions related with management and protection of ambient air.

Every developed country has legislation to control or limit emissions of atmospheric pollution. The air quality standards that could be regulated by law and achieved were established. Concentrations of selected pollutants would have to be determined, and reliable analytical methods would be required to measure the levels of the pollutants. Monitoring actions are based on using stationary networks of measuring stations and/ or mobile laboratories equipped with proper instruments.

Air Pollution: Technology

Sven Erik Jørgensen

Sources of Particulate Pollution

When considering particulate pollution, the source should be categorized with regard to the contaminant type. Inert particulates are distinctly different from active solids in the nature and type of their potentially harmful human health effects. Inert particulates comprise solid airborne material, which does not react readily with the environment and does not exhibit any morphological changes as a result of combustion or any other process. Active solid matter is defined as particulate material that can be further oxidized or react chemically with the environment or the receptor. Any solid material in this category can, depending on its composition and size, be considerably more harmful than inert matter of similar size.

A closely related group of emissions come from aerosols of liquid droplets, generally below 5 μm. They can be oil or other liquid pollutants (e.g., freon) or may be formed by condensation in the atmosphere. Fumes are condensed metals, metal oxides, or metal halides, formed by industrial activities, predominantly as a result of pyro-metallurgical processes: melting, casting, or extruding operations. Products of incomplete combustion are often emitted in the form of particulate matter. The most harmful components in this group are particulate polycyclic organic matter (PPOM), which are mainly derivatives of benz[a]pyrene.

Natural sources of particulate pollution are sandstorms, forest fires, and volcanic activity. The major sources in towns are vehicles, combustion of fossil fuel for heating and electricity production, and industrial activity.

The total global emission of particulate matter is in the order of 10^7 t per year. Deposition of particles may occur by three processes:

1. Sedimentation (Stokes law may be applied, particles >20 μm)
2. Impaction (determined by differences in concentrations by use of Fick's law, particles between 5 and 20 μm)
3. Diffusion (particles <5μm)

Particles <20 μm are identified as suspended particulate matter. Particles >20 μm may be denoted dust, which will be deposited close to the source due to the high sedimentation rate. Dry deposition consists of gases or dry particles. Wet deposition is raindrops containing gases and particles. Particles may consist of minor concentrations of dissolved salts in water drops, crystals, or a combination of the two.

Particulate Pollution Problem

Particulate pollution is an important health factor, most crucially the toxicity and size distribution. Many particles are highly toxic, such as asbestos and those of metals such as beryllium, lead, chromium, mercury, nickel, and manganese. In addition, particulate matter is able to absorb gases, which enhances the effects of these components. In this context, the particle size distribution is of particular importance, as particles greater than 10 μm are trapped in the human upper respiratory passage and the specific surface (expressed as square meter per gram of particulate matter) increases with l/d, where d is the particle size. The adsorption capacity of particulate matter, expressed as grams adsorbed per gram of particulate matter, will generally be proportional to the surface area. Table 1 lists some typical particle size ranges. However, size as well as shape and density must be considered. Furthermore, particle size is determined by two parameters: the mass median diameter, which is the size that divides the particulate sample into two groups of equal mass, i.e., the 50% point on a cumulative frequency versus particle size plot, and the geometric standard deviation.

Control Methods Applied to Particulate Pollution

Particulate pollutants have the ability to adsorb gases including sulfur dioxide, nitrogen oxides, carbon monoxide, and so on. The inhalation of these toxic gases is frequently associated with this adsorption, as the gases otherwise would be dissolved in mouthwash and spittle before entering the lungs. Particulate pollution may be controlled by modifying the distribution pattern. This method is described in detail below. In principle, it represents an obsolete philosophy of pollution abatement, dilution, but it is still widely used to reduce the concentration of pollutants at ground level and thereby minimizes the effect of air pollution. Particulate control technology can offer a wide range of methods aimed at the removal of particulate matter from gas. These methods are settling chambers, cyclones, filters, electrostatic precipitators, wet scrubbers, and the modification of particulate characteristics.

Modifying the Distribution Patterns

Although emissions, gaseous or particulate, may be controlled by various sorption processes or mechanical collection, the effluent from the control device must still be dispersed into the atmosphere. Atmospheric dispersion depends primarily on horizontal and vertical transport. The horizontal transport depends on the turbulent structure of the wind field. As the wind velocity increases, so does the degree of dispersion and there is a corresponding decrease in the ground-level concentration of the contaminant at the receptor site.

TABLE 1 Typical Practical Size Ranges

	µm
Tobacco smoke	0.01–1
Oil smoke	0.05–1
Ash	1–500
Ammonium chloride smoke	0.1–4
Powdered activated carbon	3–700
Sulfuric acid aerosols	0.5–5

Source: Jørgensen[10]

The emissions are mixed into larger volume of air, and the diluted emission is carried out into essentially unoccupied terrain away from any receptors. Depending on the wind direction, the diluted effluent may be funneled down a river valley or between mountain ranges. Horizontal transport is sometimes prevented by surrounding hills that form a natural pocket for locally generated pollutants. This particular topographical situation occurs for instance in the Los Angeles area, which suffers heavily from air pollution.

The vertical transport depends on the rate of change of ambient temperature with altitude. The dry adiabatic lapse rate is defined as a decrease in air temperature of 1°C per 100 m. This is the rate at which, under natural conditions, a rising parcel of unpolluted air will decrease in temperature with elevation into the troposphere up to approximately10,000 m. Under so-called isothermal conditions, the temperature does not change with elevation. Vertical transport can be hindered under stable atmospheric conditions, which occur when the actual environmental lapse rate is less than the dry adiabatic lapse rate. A negative lapse rate is an increase in air temperature with latitude. This effectively prevents vertical mixing and is known as inversion.

The dispersion from a point source (a chimney for instance) may be calculated from the Gaussian plume model (see, for instance, Reible.[1])

These different atmospheric conditions are illustrated in Figure 1 where stack gas behavior under the various conditions is shown. Further explanations are given in Table 2. The distribution of particulate material is more effective the higher the stack. The maximum concentration, $C_{\max}$, at ground level can be shown to be approximately proportional to the emission and to follow approximately this expression:

$$C_{\max} = kQ/H^2 \tag{1}$$

where Q is the emission (expressed as grams per particulate matter per unit of time), H is the effective stack height, and k is a constant. The effective height is slightly higher than the physical height and can be calculated from information about the temperature, the stack exit velocity, and the stack inside diameter.

These equations explain why a lower ground-level concentration is obtained when many small stacks are replaced by one very high stack. In addition to this effect, it is always easier to reduce and control one large emission than many small emissions, and it is more feasible to install and apply the necessary environmental technology in one big installation.

Particulate Pollution Control Equipment

Environmental technology offers several solutions to the problem of particulate matter removal. The methods and their optimum particle size and efficiency are compared in Table 3. The cost of the various installations varies of course from country to country and is dependent on several factors (material applied, standard size or not standard size, automatized, and so on). Generally, electrostatic precipitators are the most expensive solution and are mainly applied for large quantities of air. Wet scrubbers also belong among the more expensive installations, while settling chamber and centrifuges are the most cost-effective solutions.

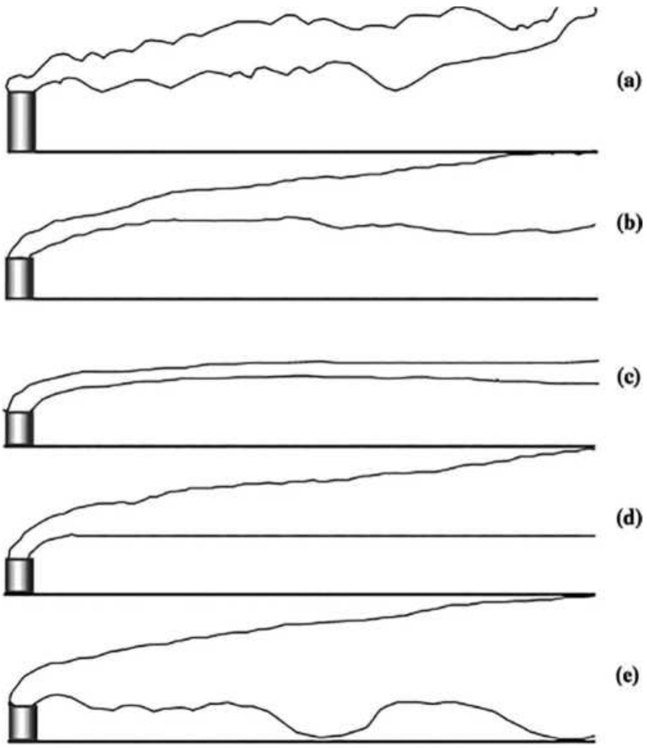

FIGURE 1 Stack gas behavior under various conditions. (a) Strong lapse (looping); (b) weak lapse (coning); (c) inversion (fanning); (d) inversion below, lapse aloft (lofting); (e) lapse below, inversion aloft (fumigation).

TABLE 2 Various Atmospheric Conditions

Strong lapse (looping)	Environmental lapse rate > adiabatic lapse rate
Weak lapse (coning)	Environmental lapse rate < adiabatic lapse rate

Electrostatic precipitators	>0.3	>3	–30 to 500	<20	<99
Wet scrubbers	>2–10	>3–30	0 to 350	>5–25	<95–99

Source: Jørgensen.[10]

Settling Chambers

Simple gravity settling chambers depend on gravity or inertia for the collection of particles. Both forces increase in direct proportion to the square of the particle diameter, and the performance limit of these devices is strictly governed by the particle settling velocity. The pressure drop in mechanical collectors is low to moderate, 1–25 cm water in most cases. Most of these systems operate dry, but if water is added, it performs the secondary function of keeping the surface of the collector clean and washed free of particles.

The settling or terminal velocity can be described by the following expression, which has general applicability:

$$V_t = \left(\partial_p - \partial\right) g \frac{d_p^2}{17\mu} \tag{2}$$

where V_t is terminal velocity, ∂_p is particle density, ∂ is gas density, d_p is particle diameter, and μ is gas viscosity.

This is the Stokes' law and is applicable to $N_{Re} < 1.9$,

Where

$$N_{Re} = d_p^* V_t^* \frac{\partial}{\mu} \tag{3}$$

The intermediate equation for settling can be expressed as:

$$V_t = \frac{0.153 * g^{0.71} * d_p^{1.14} \left(\partial_p - \partial\right)^{0.71}}{\partial^{0.29} * \mu^{0.43}} \tag{4}$$

This equation is valid for Reynolds numbers between 1.9 and 500, while the following equation can be applied for $N_{Re} > 500$ and up to 200,000:

$$V_t = 1.74 \left(d_p^* g \frac{\left(\partial_p - \partial\right)^{1/2}}{\partial} \right) \tag{5}$$

The settling velocity in these chambers is often in the range 0.3–3 m/sec. This implies that for large volumes of emission, the settling velocity chamber must be very large in order to provide an adequate residence time for the particles to settle. Therefore, the gravity settling chambers are not generally used to remove particles smaller than 100 µm (= 0.1 mm). For particles measuring 2–5 µm, the collection efficiency will most probably be as low as 1% –2%. A variation of the simple gravity chamber is the baffled separation chamber. The baffles produce a shorter settling distance, which means a shorter retention time. The shown equations can be used to design a settling chamber.

Cyclones

Cyclones separate particulate matter from a gas stream by transforming the inlet gas stream into a confined vortex. The mechanism involved in cyclones is the continuous use of inertia to produce a tangential motion of the particles towards the collector walls. The particles enter the boundary layer close to the cyclone wall and lose kinetic energy by mechanical friction. The forces involved are the centrifugal force imparted by the rotation of the gas stream and a drag force, which is dependent on the particle density, diameter, shape, etc. A hopper is built at the bottom. If the cyclone is too short, the maximum force will not be exerted on some of the particles, depending on their size and the corresponding drag forces.[2] If, however, the cyclone is too long, the gas stream might reverse its direction and spiral up the center.

It is therefore important to design the cyclone properly. The hopper must be deep enough to keep the dust level low. The efficiency of a cyclone is described by a graph similar to Figure 2, which shows the efficiency versus the relative particle diameter, i.e., the actual particle diameter divided by D_{50}, which is defined as the diameter corresponding to 50% efficiency. D_{50} can be found from the following equation:

$$D_{50} = K * \left(\frac{\mu Dc}{V_c * \partial_p} \right)^{1/2} \tag{6}$$

where D_c is the diameter of cyclone, V_c is inlet velocity, ∂p is the density of particles, μ is gas viscosity, and K is a constant dependent on cyclone performance.

If the distribution of the particle diameter is known, it is possible to calculate the total efficiency from a graph such as Figure 2:

$$\text{eff} = \sum \text{m}_i^* \text{eff}_i \tag{7}$$

where m_i is the weight fraction in the ith particle size range and eff_i is the corresponding efficiency.

The pressure drop for cyclones can be found from:

$$\Delta p = N^* \frac{V_c^2}{2_g} \tag{8}$$

From these equations, it can be concluded that higher efficiency is obtained without increased pressure drop if D_c can be decreased while velocity V_c is maintained. This implies that a battery of parallel coupled small cyclones will work more effectively than one big cyclone. Such cyclone batteries are available as blocks and are known as multiple cyclones. Compared with settling chambers, cyclones offer higher removal efficiency for particles below 50 µm and above 2–10 µm, but involve a greater pressure drop.

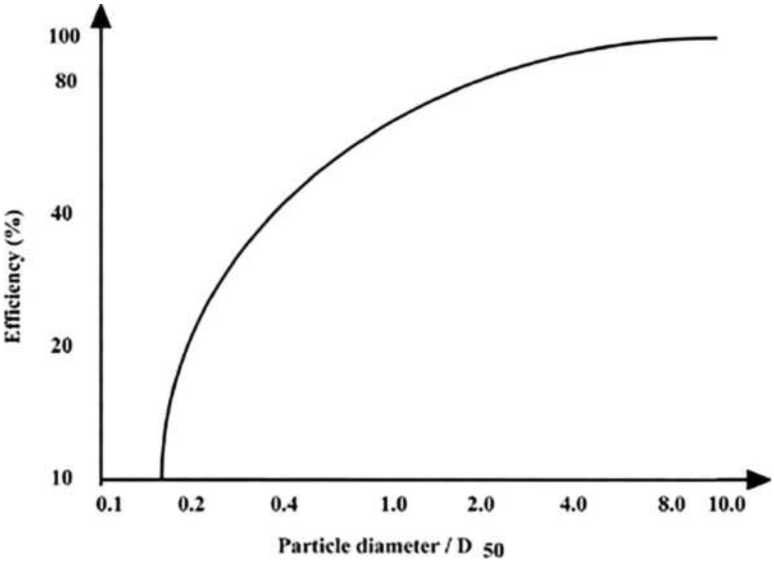

FIGURE 2 Efficiency plotted against relative particle diameter. Notice that it is a log–log plot.

Filters

Particulate materials are collected by filters by the following three mechanisms:

Impaction, where the particles have so much inertia that they cannot follow the streamline around the fiber and thus impact on its surface.

Direct interception, where the particles have less inertia and can barely follow the streamlines around the obstruction.

Diffusion, where the particles are so small (below 1 µm) that their individual motion is affected by collisions on a molecular or atomic level. This implies that the collection of these fine particles is a result of random motion.

Different flow patterns can be used, as demonstrated in Figure 3. The types of fibers used in fabric filters range from natural fibers, such as cotton and wool, to synthetics (mainly polyesters and nylon), glass, and stainless steel.

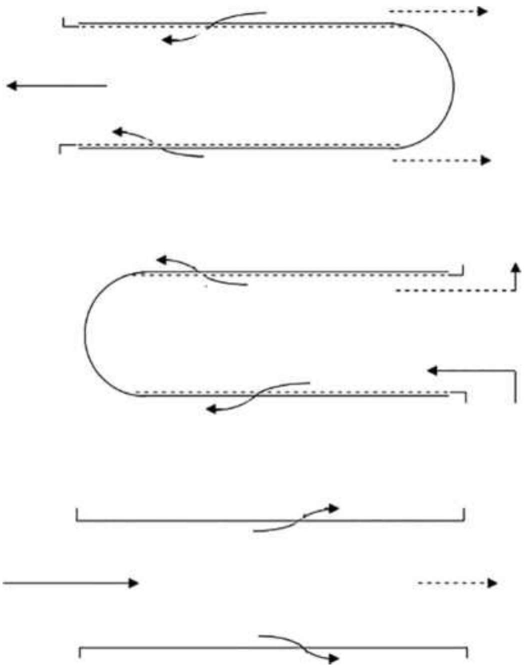

FIGURE 3 Flow pattern of filters.

TABLE 4 Properties of Fibers

Fabric	Acid Resistance	Alkali	Fluoride Strength	Tensile	Abrasion Resistance
Cotton	Poor	Good	Poor	Medium	Very good
Wool	Good	Poor	Poor	Poor	Fair
Nylon	Poor	Good	Poor	Good	Excellent
Acrylic	Good	Fair	Poor	Medium	Good
Polypropylene	Good	Fair	Poor	Very good	Good
Orlon	Good	Good	Fair	Medium	Good
Dacron	Good	Good	Fair	Good	Very good
Teflon	Excellent	Excellent	Good	Good	Fair

Some properties of common fibers are summarized in Table 4. As can be seen, cotton and wool have a low temperature limit and poor alkali and acid resistance, but they are relatively inexpensive. The selection of filter medium must be based on the answer to several questions:[3,4]

What is the expected operating temperature?

Is there a humidity problem that necessitates the use of a hydrophobic material, such as, e.g., nylon?

How much tensile strength and fabric permeability are required?

How much abrasion resistance is required?

Permeability is defined as the volume of air that can pass through 1 m^2 of the filter medium with a pressure drop of no more than 1 cm of water.

The filter capacity is usually expressed as cubic meter of air per square meter of filter per minute. A typical capacity ranges between 1 and 5 $m^3/m^2/min$.

The pressure drop is generally larger than for cyclones and will in most cases be 10–30 cm of water, depending on the nature of the dust, the cleaning frequency, and the type of cloth.

There are several specific methods of filter cleaning. The simplest is backwash, where dust is removed from the bags merely by allowing them to collapse. This is done by reverting the airflow through the entire compartment. The method is remarkable for its low consumption of energy. Shaking is another low-energy filter-cleaning process, but it cannot be used for sticky dust. The top of the bag is held still and the entire tube sheath at the bottom is shaken. The application of blow rings involves reversing the airflow without bag collapse. A ring surrounds the bag; it is hollow and supplied with compressed air to direct a constant stream of air into the bag from the outside.

The pulse and improved jet cleaning mechanism involves the use of a high-velocity, high-pressure air jet to create a low pressure inside the bag and induce an outward airflow, cleaning the bag by sudden expansion and reversal of flow.

In some cases, as a result of electrostatic forces, moisture on the surface of the bag, and a slight degree of hygroscopicity of the dust itself, the material forms cakes that adhere tightly to the bag. In this case, the material must be kept drier, and a higher temperature on the incoming dirty airstream is required. Filters are highly efficient even for smaller particles (0.1–2 m), which explains their wide use as particle collection devices.

Electrostatic Precipitators

The electrostatic precipitator consists of four major components:

1. *A gas-tight shell with hoppers* to receive the collected dust, inlet and outlet, and an inlet gas distributor
2. *Discharge electrodes*
3. *Collecting electrodes*
4. *Insulators*

The principles of electrostatic precipitators are illustrated in Figure 4. The dirty airstream enters a filter, where a high, 20–70 kV, usually negative voltage exists between discharge electrodes. The particles accept a negative charge and migrate towards the collecting electrode. The efficiency is usually expressed by use of Deutsch's equation (see the discussion including correction of this equation in the work of Gooch and Francis[5]). This equation entails that the relationship between migration velocity and particle diameter has a minimum between 0.1 and 1.0 μm.

The operation of an electrostatic precipitator can be divided into three steps:

1. The particles *accept a negative charge.*
2. The charged particles *migrate towards the collecting electrode* due to the electrostatic field.
3. The collected dust *is removed from the collecting electrode* by shaking or vibration, and is collected in the hopper.

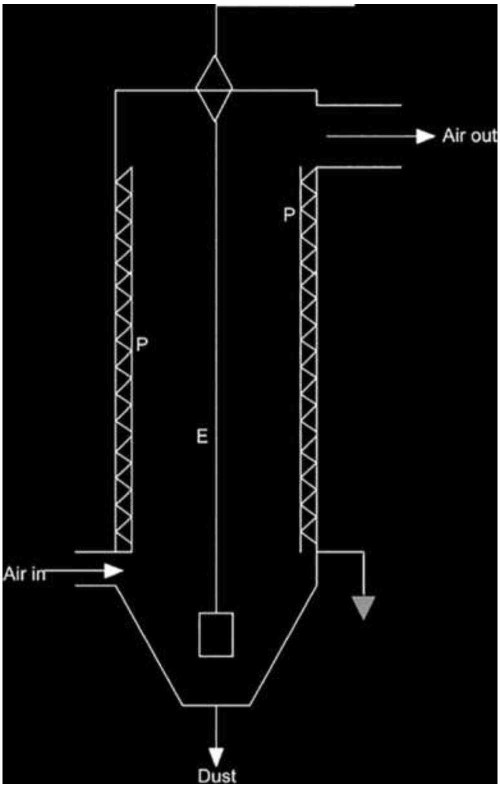

FIGURE 4 The dust is precipitated on the electrode P. E has a high, usually negative voltage and emits a great number of electrons that give the dust particles a negative charge. The dust particles will therefore be attracted to P.

r, the specific electrical resistance, measured in ohm meter, determines the ability of a particle to accept a charge. The practical specific resistance can cover a wide range of about four orders of magnitude, in which varying degrees of collection efficiencies exist for different types of particles. The specific resistance depends on the chemical nature of the dust, the temperature, and the humidity.

Electrostatic precipitators have found wide application in industry. As the cost is relatively high, the airflow should be at least 20,000 m^3/hr; volumes as large as 1,500,000 m^3/hr have been treated in one electrostatic precipitator.

Very high efficiencies are generally achieved in electrostatic precipitators and emissions as low as 25 mg/m^3 are quite common. The pressure drop is usually low compared with other devices—25 mm water at the most. The energy consumption is generally 0.15–0.45 Wh/m^3/hr.

Wet Scrubbers

A scrubbing liquid, usually water, is used to assist separation of particles, or a liquid aerosol from the gas phase. The operational range for particle removal includes material less than 0.2 μm in diameter up to the largest particles that can be suspended in air. Gases soluble in water are also removed by this process. Four major steps are involved in the collection of particles by wet scrubbing. First, the particles are moved to the vicinity of the water droplets, which are 10–1000 times larger. Then, the particles must collide with the droplets. In this step, the relative velocity of the gas and the liquid phases is very important: If the particles have an excessively high velocity in relation to liquid, they cannot be retained by the droplets unless they can be wetted and thus incorporated into the droplets. The last step is the removal of the droplets containing dust particles from the bulk gas phase. Scrubbers are generally very flexible. They are able to operate under peak loads or reduced volumes and within a wide temperature range.[6] They are smaller and less expensive than dry particulate removal devices, but the operating costs are higher. Another disadvantage is that the pollutants are not collected but transferred into water, which means that the related water pollution problem must also be solved.[7]

Several types of wet scrubbers are available and their principles are outlined below:

1. *Chamber scrubbers* are spray towers and spray chambers that can be either round or rectangular. Water is injected under pressure through nozzles into the gas phase.
2. *Baffle scrubbers* are similar to a spray chamber but have internal baffles that provide additional impingement surfaces. The dirty gas is forced to make many turns to prevent the particles from following the airstream.
3. *Cyclonic scrubbers* are a cross between a spray chamber and a cyclone. The dirty gas enters tangentially to wet the particles by forcing its way through a swirling water film onto the walls. There, the particles are captured by impaction and are washed down the walls to the sump. The saturated gas rises through directional vanes, which are used solely to impart rotational motion to the gas phase. As a result of this motion, the gas goes out through a demister for the removal of any included droplets.
4. *Submerged orifice scrubbers* are also called gas induced scrubbers. The dirty gas is accelerated over anaerodynamic foil to a high velocity and directed into a pool of liquid. The high velocity impact causes the large particles to be removed into the pool and creates a tremendous number of spray droplets with a high amount of turbulence. These effects provide intensive mixing of gas and liquid and thereby a very high interfacial area. As a result, reactive gas absorption can be combined with particle removal.
5. The *ejector scrubber* is a water jet pump (see Figure 5). The water is pumped through a uniform nozzle and the dirty gas is accelerated by the action of the jet gas. The result is aspiration of the gas into the water by the Bernoulli principle and, accordingly, a lowered pressure. The ejector scrubber can be used to collect soluble gases as well as particulates.
6. The *venturi scrubber* involves the acceleration of the dirty gas to 75–300 m/min through a mechanical constriction. This high velocity causes any water injected just upstream of or in the venturi throat to be sheared off the walls or nozzles and atomized. The droplets are usually 5–20 µm in size and form

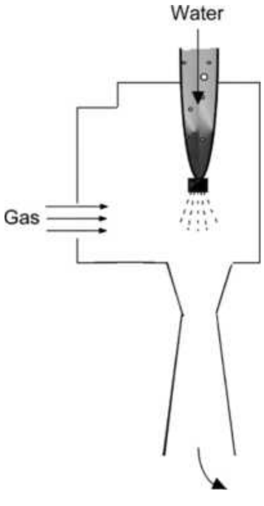

FIGURE 5 Principle of ejector scrubber.

into clouds from 150 to 300 μm in diameter, depending on the gas velocity. The scrubber construction is similar to that of the ejector scrubber, but the jet pump is replaced by a venturi constriction.

7. *Mechanical scrubbers* have internal rotating that which break up the scrubbing liquid into small droplets and simultaneously create turbulence.
8. *Charged-droplet scrubbers* have a high voltage ionization section where the corona discharge produces air ions (as in electrostatic precipitators). Water droplets are introduced into the chamber by the use of spray nozzles or similar devices. The additional collection mechanism provided by the induction of water droplets increases the collection efficiency.
9. *Packed-bed scrubbers* have a bottom support grid, and a top retaining grid (see Figure 6). The fluid (often water or a solution of alkali or acid) is distributed as shown in the figure over the top of the packed section, while the gas enters below the packing.

The flow is normally counter current. Packed-bed scrubbers offer the possibility of combining gas absorption with the removal of particulate material. The pressure drop is often in the order of 3 cm water per meter of packing. If the packing consists of expanded fiber, the bed scrubber is known as a fiber-bed scrubber. The packed-bed scrubber has a tendency to clog under high particulate loading, which is its major disadvantage.

Common packing includes saddles, rings, etc., like those used in absorption towers. Some important parameters for various scrubbers are plotted in Figure 7, which demonstrates the relationship between pressure drop, energy consumption, and D_{50} (the diameter of the particles removed at 50% efficiency).

Air Pollution Problems of Carbon Hydrides and Carbon Monoxide: Sources of Pollutants

All types of fossil fuel will produce carbon dioxide on combustion, which is used in the photosynthetic production of carbohydrates. As such, carbon dioxide is harmless and has no toxic effect, whatever the concentration levels, but see the entries about the greenhouse effect of carbon dioxide. An increased carbon dioxide concentration in the atmosphere will increase absorption of infrared radiation and the heat balance of the earth will be changed.

Carbon hydrides are the major components of oil and gas, and incomplete combustion will always involve their emission. Partly oxidized carbon hydrides, such as aldehydes and organic acids, might also be present.

The major source of carbon hydrides pollution is motor vehicles.

In reaction with nitrogen oxides and ozone, they form so-called photochemical smog, which consists of several rather oxidative compounds, such as peroxyacyl nitrates and aldehydes. In areas where solar radiation is strong and the atmospheric circulation is weak, the possibility of smog formation increases as the processes are initiated by ultraviolet radiation.

Incomplete combustion produces carbon monoxide. By regulation of the ratio of oxygen to fuel, more complete combustion can be obtained, but the emission of carbon monoxide cannot be totally avoided.

Motor vehicles are also a major source of carbon monoxide pollution. On average, 1 L of gasoline (petrol) will produce 200 L of carbon monoxide, while it is possible to minimize the production of this pollutant by using diesel instead of gasoline.

The annual production of carbon monoxide is more than 200 million tons, of which 50% is produced by the United States alone.

In most industrial countries, more than 75% of this pollutant originates from motor vehicles.

Pollution Problem of Carbon Hydrides and Carbon Monoxide

Carbon hydrides, partly oxidized carbon hydrides, and the compounds of photochemical smog are all more or less toxic to man, animals, and plants. Photochemical smog reduces visibility, irritates the eyes, and causes damage to plants, with immense economic consequences, for example, for fruit and tobacco plantations. It is also able to decompose rubber and textiles.

Carbon monoxide is strongly toxic as it reacts with hemoglobin and thereby reduces the blood's capacity to take up and transport oxygen. Ten percent of the hemoglobin occupied by carbon monoxide will produce symptoms such as headache and vomiting. It should be mentioned here that smoking also causes a higher carboxyhemoglobin concentration. An examination of policemen in Stockholm has shown that non-smokers had 1.2% carboxyhemoglobin, while smokers had 3.5%.

Control Methods Applied to Carbon Dioxide, Carbon Hydrides, and Carbon Monoxide Pollution

Carbon dioxide pollution is inevitable with the use of fossil fuels. Therefore, it can only be solved by the use of other sources of energy.

Legislation plays a major role in controlling the emission of carbon hydrides and carbon monoxide. As motor vehicles are the major source of these pollutants, control methods should obviously focus on the possibilities of reducing vehicle emission. The methods available today are as follows:

1. Motor technical methods
2. Afterburners
3. Alternative energy sources

The first method is based upon a motor adjustment according to the relationship between the composition of the exhaust gas and the air/fuel ratio. A higher air/fuel ratio results in a decrease in the carbon hydrides and carbon monoxide concentrations, but to achieve this, a better distribution of the fuel in the cylinder is required, which is only possible through the construction of another gasification system. This method may be considered cleaner technology.

At present, two types of afterburners are in use—*thermal* and *catalytic afterburners*. In the former type, the combustible material is raised above its autoignition temperature and held there long enough for complete oxidation of carbon hydrides and carbon monoxide to occur. This method is used on an industrial scale[8,9] when low-cost purchased or diverted fuel is available; in vehicles, a manifold air injection system is used.

Catalytic oxidation occurs when the contaminant-laden gas stream is passed through a catalyst bed, which initiates and promotes oxidation of the combustible matter at a lower temperature than would be possible in thermal oxidation. The method is used on an industrial scale for the destruction of trace solvents in the chemical coating industry. Vegetable and animal oils can be oxidized at 250–370°C by catalytic oxidation. The exhaust fumes from chemical processes, such as ethylene oxide, methyl methacrylate, propylene, formaldehyde, and carbon monoxide can easily be catalytically incinerated at even lower temperatures. The application of catalytic afterburners in motor vehicles presents some difficulties due to poisoning of the catalyst with lead. With the decreasing lead concentration in gasoline, it is becoming easier to solve that problem, and the so-called double catalyst system is now finding wide application. This system is able to reduce nitrogen oxides and oxidize carbon monoxide and carbon hydrides simultaneously. New catalysts are currently coming on the market and offer a higher efficiency.

Lead in gasoline has been replaced by various organic compounds to increase the octane number. Benzene has been applied, but it is toxic and causes air pollution problems because of its high vapor pressure. MTBE (methyl tertiary butyl ether) is another possible compound for increasing the octane number. It is, however, very soluble and has been found as a groundwater contaminant close to gasoline stations.

Application of alternative energy sources is still at a preliminary stage. The so-called Sterling motor is one alternative, as it gives more complete combustion of the fuel, but there have been several improvements of the efficiency of the motor during the last years due to the increasing cost of fossil fuel. Much interest has, however, been devoted to electric and hybrid vehicles.

Air Pollution of Sulfur Dioxide: Sources, Problems, and Solutions

Fossil fuel contains approximately 2%–5% sulfur, which is oxidized by combustion to sulfur dioxide. Although fossil fuel is the major source, several industrial processes produce emissions containing sulfur dioxide, for example, mining, the treatment of sulfur containing ores, and the production of paper from pulp. The total global emission of sulfur dioxide has been decreasing during the last 25 years due to the installation of pollution abatement equipment, particularly in North America, the European Union, and Japan. The concentration of sulfur dioxide in the air is relatively easy to measure, and sulfur dioxide has been used as an indicator component. High values recorded by inversion are typical.

Sulfur dioxide is oxidized in the atmosphere to sulfur trioxide, which forms sulfuric acid in water. Since sulfuric acid is a strong acid, it is easy to understand that sulfur dioxide pollution indirectly causes the corrosion of iron and other metals and is able to acidify aquatic ecosystems.[10]

The health aspects of sulfur dioxide pollution are closely related to those of particulate pollution. The gas is strongly adsorbed onto particulate matter, which transports the pollutant to the bronchi and lungs. There is a clear relationship between concentration, effect, and exposure time, which is reflected in the emission standards for sulfur dioxide (see Table 5).

Clean Air Acts were introduced in all industrialized countries during the 1970s and 1980s. Table 5 illustrates some typical sulfur dioxide emission standards, although these may vary slightly from country to country.

The approaches used to meet the requirements of the acts as embodied in the standards can be summarized as follows:

1. Fuel switching from high to low sulfur fuels.
2. Modification of the distribution pattern—use of tall stacks.
3. Abandonment of very old power plants that have a particular high emission.
4. Flue gas cleaning.

Desulfurization of liquid and gaseous fuel is a well-known chemical engineering operation. In gaseous and liquid fuels, sulfur either occurs as hydrogen sulfide or reacts with hydrogen to form hydrogen sulfide. The hydrogen sulfide is usually removed by absorption in a solution of alkanol- amine and then converted to elemental sulfur. The process in general use for this conversion is the so-called Claus process. The hydrogen sulfide gas is fired in a combustion chamber in such a manner that one-third of the volume of hydrogen sulfide is converted to sulfur dioxide. The products of combustion are cooled and then passed through a catalyst-packed converter, in which the following reaction occurs:

$$2H_2S + SO_2 = 3S + 2H_2O \tag{9}$$

TABLE 5 SO_2 Emission Standards

Duration	Concentration (ppm)	Comments
Month	0.05	
24 hr	0.10	Might be exceeded once a month
30 min	0.25	Might be exceeded 15 times/month

Source: Jorgensen.[10]

The elemental sulfur has commercial value and is mainly used for the production of sulfuric acid.

Sulfur occurs in coal both as pyritic sulfur and organic sulfur. Pyritic sulfur is found in small discrete particles within the coal and can be removed by mechanical means, e.g., gravity separation methods. However, 20%–70% of the sulfur content of coal is present as organic sulfur, which can hardly be removed today on an economical basis. Since sulfur recovery from gaseous and liquid fuels is much easier than that from solid fuel (which has other disadvantages as well), much research has been and is being devoted to *the gasification or liquefaction of coal.* It is expected that this research will lead to an alternative technology that will solve most of the problems related to the application of coal, including sulfur dioxide emission. Approach (2) listed above has been mentioned earlier in this entry, while approach (3) needs no further discussion. The next subsection is devoted to (4) flue gas cleaning.

Flue Gas Cleaning of Sulfur Dioxide

When sulfur is not or cannot be economically removed from fuel oil or coal prior to combustion, removal of sulfur oxides from combustion gases will become necessary for compliance with the stricter air pollution control laws.

The chemistry of sulfur dioxide recovery presents a variety of choices and five methods should be considered:

1. Adsorption of sulfur dioxide on active metal oxides with regeneration to produce sulfur.
2. Catalytic oxidation of sulfur dioxide to produce sulfuric acid.
3. Adsorption of sulfur dioxide on charcoal with regeneration to produce concentrated sulfur dioxide.
4. Reaction of dolomite or limestone with sulfur dioxide by direct injection into the combustion chamber. A lime slurry is injected into the flue gas beyond the boilers.
5. Fluidized bed combustion of granular coal in a bed of finely divided limestone or dolomite maintained in a fluid-like condition by air injection. Calcium sulfite is formed as a result of these processes.

In particular, the two latter methods have found wide application, particularly to large industrial installations. It is possible to recover the sulfur dioxide or elemental sulfur from these processes, making it possible to recycle the spent sorbing material.

Air Pollution Problems of Nitrogenous Gases: Sources, Problems, and Control

Seven different compounds of oxygen and nitrogen are known: N_2O, NO, NO_2, NO_3, N_2O_3, N_2O_4, and N_2O_5— often summarized as NO_x. From the point of view of air pollution, it is mainly NO (nitrogen oxide) and NO_2 (nitrogen dioxide) that are of interest. Nitrogen oxide is colorless and is formed from the elements at high temperatures. It can react further with oxygen to form nitrogen dioxide, which is a brown gas. The major sources of the two gases are combustion of gasoline and oil (nitrogen oxide) and combustion of oil, including diesel oil (nitrogen dioxide). The production of NO is favored by high temperature. In addition, a relatively small emission of nitrogenous gases originates from the chemical industry. The total global emission is approximately 10 million tons per year. This pollution has only local or regional interest, as the natural global formation of nitrogenous gases in the upper atmosphere by the influence of solar radiation is far more significant than the man-controlled emission.

As mentioned above, nitrogen oxide is oxidized to nitrogen dioxide, although the reaction rate is slow—in the order of 0.007/hr. However, it can be accelerated by solar radiation. Nitrogenous gases take part in the formation of smog, as the nitrogen in peroxyacyl nitrate originates from nitrogen oxides. They are highly toxic but as their contribution to global pollution is insignificant, local and regional problems can partially be solved by changing the distribution pattern (see the section on *Control Methods Applied to Particulate Pollution).*

The emission from motor vehicles can be reduced by the same methods as mentioned for carbon hydrides and carbon monoxide. The air/fuel ratio determines the concentration of pollutants in exhaust gas. An increase in the ratio will reduce the emission of carbon hydrides and carbon monoxide, but unfortunately will increase the concentration of nitrogenous gases. Consequently, the selected air/ fuel ratio will be a compromise. A double catalytic afterburner is applied today, and it is able to reduce nitrogenous gases and simultaneously oxidize carbon hydrides and carbon monoxide. The application of alternative energy sources will, as for carbon hydrides and carbon monoxide, be a very useful control method for nitrogenous gases at a later stage.

Between 0.1 and 1.5 ppm of nitrogenous gases, of which 10%–15% consists of nitrogen dioxide, are measured in urban areas with heavy traffic. On average, the emission of nitrogenous gases is approximately 15 g per liter of gasoline and 25 g per liter of diesel oil.

Nitrogenous gases in reaction with water form nitrates that are washed away by rainwater. In some cases, this can be a significant source of eutrophication. For a shallow lake, for example, the increase in nitrogen concentration due to the nitrogen input from rainwater will be rather significant. In a lake with a depth of 1.7 m and an annual precipitation of 600 mm, which is normal in many temperate regions, the annual input will be as much as 0.3 mg/L.

The methods used for control of industrial emission of nitrogenous gases, including ammonia, will be discussed in the next section that discusses industrial air pollution, but as pointed out above, industrial emission is of less importance, even though it might play a significant role locally. The emission of nitrogenous gases by combustion of oil for heating and the production of electricity can hardly be reduced.

Industrial Air Pollution, Overview, and Control Methods

The rapid growth in industrial production during recent decades has exacerbated the industrial air pollution problem, but due to increased application of continuous processes, recovery methods, air pollution control, use of closed systems, and other technological developments, industrial air pollution has, in general, not increased in proportion to production.

Industry displays a wide range of air pollution problems related to a large number of chemical compounds in a wide range of concentrations.

It is not possible in this context to discuss all industrial air pollution problems; instead, we shall touch on the most important problems and give an overview of the control methods applied today. Only the problems related to the environment will be dealt with in this context.

A distinction should be made between air quality standards, which indicate that the concentration of a pollutant in the atmosphere at the point of measurement should not be greater than a given amount, and emission standards, which require that the amount of pollutant emitted from a specific source should not be greater than a specifically indicated amount.

The standards reflect, to a certain extent, not only the toxicity of the particular component but also the possibility for its uptake.

Here, the distribution coefficient for air/water (blood) plays a role. The more soluble the component is in water, the greater the possibility for uptake. For example, the air quality standard for acetic acid, which is very soluble in water, is relatively lower than the toxicity of aniline, which is almost insoluble in water.

Since industrial air pollution covers a wide range of problems, it is not surprising that all three classes of pollution control methods mentioned previously have found application: modification of the distribution pattern, alternative (cleaner) production methods, and particulate and gas/vapor control technology.

All the methods mentioned in the section on *Control Methods Applied to Particulate Pollution* also apply for industrial air pollution control.

In gas and vapor technology, a distinction has to be made between condensable and non-condensable gaseous pollutants. The latter must usually be destroyed by incineration, while the condensable gases can be removed from industrial effluents by absorption, adsorption, condensation, or combustion.

Recovery is feasible by the first three methods.

Gas Absorption

Absorption is a diffusion process that involves the mass transfer of molecules from the gas state to the liquid state along a concentration gradient between the two phases. Absorption is a unit operation that is enhanced by all the factors generally affecting mass transfer, i.e., high interfacial area, high solubility, high diffusion coefficient, low liquid viscosity, increased residence time, turbulent contact between the two phases, and possibilities for reaction of the gas in the liquid phase. This last factor is often very significant and almost 100% removal of the contaminant is the result of such a reaction. Acidic components can easily be removed from gaseous effluents by absorption in alkaline solutions, and, correspondingly, alkaline gases can easily be removed from effluent by absorption in acidic solutions (Table 6).

Carbon dioxide, phenol, and hydrogen sulfide are readily absorbed in alkaline solutions in accordance with the following processes:

$$+CO_2 + 2N_aOH \rightarrow 2N_a^+ + CO_3^{2-} \tag{10}$$

$$H_2S + 2NaOH \rightarrow 2N_a^+ + S_{2-} + 2H_2O \tag{11}$$

$$C_6H_5OH + NaOH \rightarrow C_6H_5O^- + N_a^+ + H_2O \tag{12}$$

Ammonia is readily absorbed in acidic solutions:

$$NH_3 + H_2SO_4 \rightarrow 2NH_4 + SO_4^{2-} \tag{13}$$

Gas Adsorption

Adsorption is the capture and retention of a component (adsorbate) from the gas phase by the total surface of the adsorbing solid (adsorbent). In principle, the process is the same as when dealing with wastewater treatment; the theory is equally valid for gas adsorption.

Adsorption is used to concentrate (often 20 to 100 times) or store contaminants until they can be recovered or destroyed in the most economical way. Figure 8 illustrates some adsorption isotherms applicable to practical gas adsorption problems. These are often described as either Langmuir's or Freundlich's adsorption isotherms. Adsorption is dependent on temperature: increased temperature

TABLE 6 Absorber Reagents

Reagents	Applications
$KMnO_4$	Rendering, polycyclic organic matter

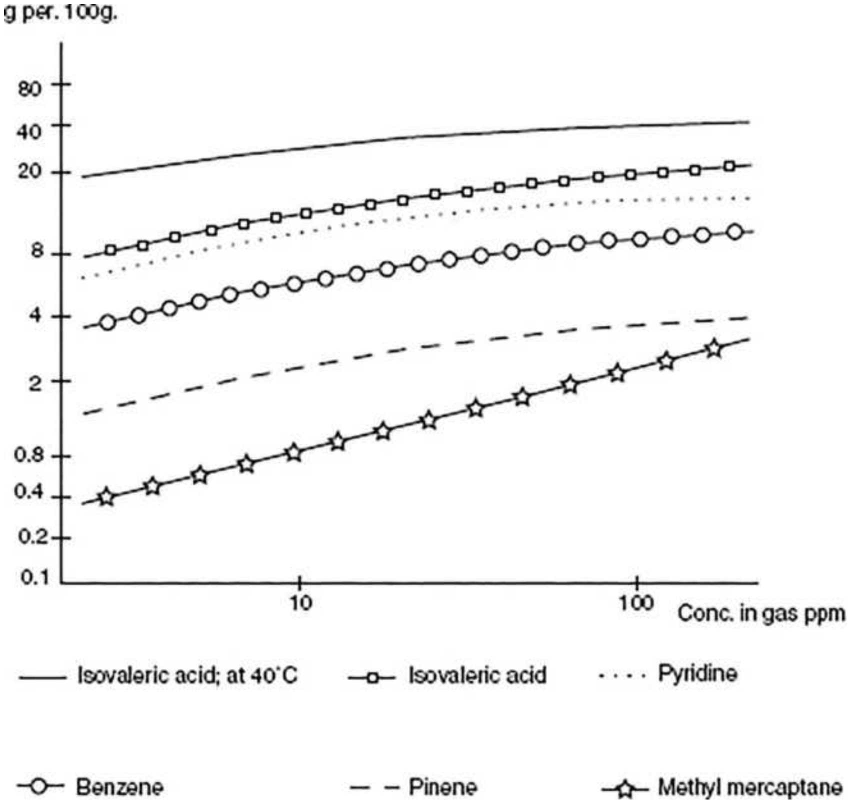

FIGURE 8 Adsorption isotherms, at 20°C.

means that the molecules move faster and therefore it is more difficult to adsorb them. There are four major types of gas adsorbents, the most important of which is activated carbon, but aluminum oxide (activated aluminum), silica gel, and zeolites are used as well.

The selection of adsorbent is made according to the following criteria:

1. High selectivity for the component of interest.
2. Easy and economical to regenerate.
3. Availability of the necessary quantity at a reasonable price.
4. High capacity for the particular application so that the unit size will be economical. Factors affecting capacity include total surface area involved, molecular weight, polarity activity, size, shape, and concentration.
5. Pressure drop, which is dependent on the superficial velocity.
6. Mechanical stability in the resistance of the adsorbent particles to attrition. Any wear and abrasion during use or regeneration will lead to an increase in bed pressure drop.
7. Microstructure of the adsorbent should, if at all possible, be matched to the pollutant that has to be collected.
8. The temperature, which has a profound influence on the adsorption process, as already mentioned.

Regeneration of the adsorbents is an important part of the total process. A few procedures are available for regeneration:

1. *Stripping* by use of steam or hot air.
2. *Thermal desorption* by raising the temperature high enough to boil off all the adsorbed material.

3. *Vacuum desorption* by reducing the pressure enough to boil off all the adsorbed material.
4. *Purge gas stripping* by using a non-adsorbed gas to reverse the concentration gradient. The purge gas may be condensable or non-condensable. In the latter case, it might be recycled, while the use of a condensable gas has the advantage that it can be removed in a liquid state.
5. *In situ oxidation* based on the oxidation of the adsorbate on the surface of the adsorbent.
6. *Displacement* by use of a preferentially adsorbed gas for the desorption of the adsorbate. The component now adsorbed must, of course, also be removed from the adsorbent, but its removal might be easier than that of the originally adsorbed gas, for instance, because it has a lower boiling point.

Although the regeneration is 100%, the capacity of the adsorbent may be reduced 10%–25% after several regeneration cycles, due to the presence of fine particulates and/or high molecular weight substances that cannot be removed in the regeneration step. A flowchart of solvent recovery using activated carbon as an adsorbent is shown in Figure 9 as an illustration of a plant design.

Combustion

Combustion is defined as rapid, high-temperature gas-phase oxidation. The goal is the complete oxidation of the contaminants to carbon dioxide and water, sulfur dioxide, and nitrogen dioxide.

The process is often applied to control odors in rendering plants, paint and varnish factories, rubber tire curing, and petrochemical factories. It is also used to reduce or prevent an explosion hazard by burning any highly flammable gases for which no ultimate use is feasible. The efficiency of the process is highly dependent not only on temperature and reaction time but also on turbulence or the mechanically induced mixing of oxygen and combustible material. The relationship between the reaction rate, *r,* and the temperature can be expressed by Arrhenius' equation:

$$r = A^*e - \frac{E}{RT} \tag{14}$$

where A is a constant, E is the activation energy, R is the gas constant, and T is the absolute temperature. A distinction is made between combustion, thermal oxidation, and catalytic oxidation, the latter two being the same in principle as the vehicle afterburners.

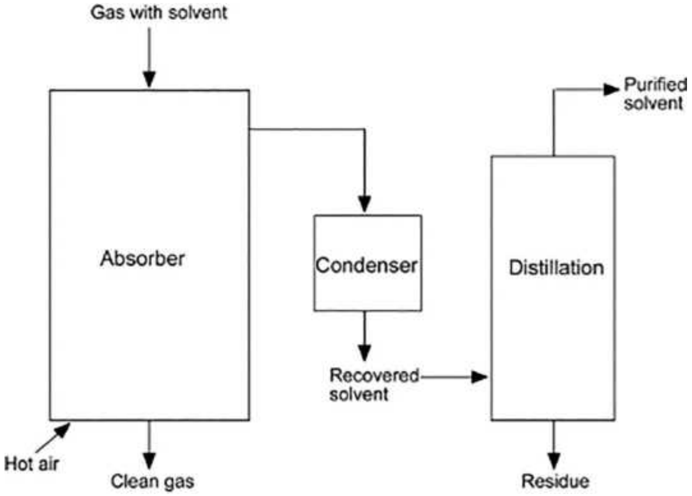

FIGURE 9 Flow chart of solvent recovery by the use of activated carbon.

Heavy Metals as Air Pollutants

Heavy metals, which may be defined as the metals with a specific gravity >5.00 kg/L, comprise 70 elements. Most of them are, however, only rarely found as pollutants. The heavy metals of environmental interest form very heavy soluble compounds with sulfide and phosphate and form very stable complexes with many ligands present in the environment. It means, fortunately, that most of the heavy metals are not very bioavailable in most environments (see also *Bioremediation,* p. 408).

A number of enzymes activated by metal ions and metalloenzymes are known. Members of the first mentioned group, comprising iron, cobalt, chromium, vanadium, selenium, copper, zinc, iron, cobalt, and molybdenum, are able with a stronger bond to form metalloenzymes: metalloproteins, metalloporphyrins, and metalloflavins.

Heavy metals are emitted to the atmosphere by energy production and a number of technological processes (see Table 7). It makes the atmospheric deposition of heavy metals originating from human activities the dominant pollution source for the vegetation of natural ecosystems— forests, wetlands, peat lands, and so on. The heavy metal content in sludge and fertilizers plays a more important role for agricultural land where also the inputs of heavy metals by irrigation, natural fertilizers, and application of chemicals including pesticides may add to the overall pollution level. The atmosphere and hydrosphere both have a well- developed ability for "self-purification"—for heavy metals by removal processes, for instance, sedimentation. The lithosphere has a high buffer capacity toward the effects of most pollutants and also has an ability to self-purify, for instance, by runoff and uptake by plants, although the rates usually are much lower than in the two other spheres. Table 8 illustrates the removal rates.

Heavy metals are bound to clay particles due to their ion-exchange capacity and to hydratized metal oxides, such as iron sesquioxide (As, Cr, Mo, P, Se, and V) and manganese sesquioxides (Co, Ba, Ni, and lanthanides). Calcium phosphate is further better able to bind As, Ba, Cd, and Pb in alkaline soil. Fulvic acids (molecular weight about 1000) and humic acid (molecular weight about 150,000) are able to form complexes with a number of heavy metals, Hg(II), Cu(II), Pb(II), and Sn(II). The mobility of heavy metals is dependent on a number of factors. The soil pore water contains soluble organic compounds (acetic acid, citric acid, oxalic acid, and other organic acids), partly excreted by the roots. These small

organic molecules form chelated, soluble compounds with metal ions such as Al, Fe, and Cu. Activity of living organisms in soil may also enhance the mobility of heavy metal ions. Fungi and bacteria may utilize phosphate and thereby release cations. Formation of insoluble metal sulfide under anaerobic conditions from sulfate implies a reduced mobility. The lower oxidation stages of heavy metals are generally more soluble than the higher oxidation stages, implying increased mobility.

The many possibilities of binding heavy metals in soil explain the long residence time. Cadmium, calcium, magnesium, and sodium have the most mobile metal ions with a residence time of about 100 years. Mercury has a residence time of about 750 years, while copper, lead, nickel, arsenic, selenium, and zinc have residence times of more than 2000 years under temperate conditions. Tropic residence times are typically lower (for all heavy metals, about 40 years).

The biological effect of heavy metal pollution occurs in accordance with Sections 4.4 and 4.5 on two levels: on an organism level and on the higher level—the ecosystem level.

Plant toxicity is very dependent on the presence of other metal ions. For instance, Rb and Sr are very toxic to many plants, but the presence of the biochemically more useful K and Ca is able to reduce or eliminate toxicity. The toxicity of arsenate and selenate can be reduced in the same manner by sulfate and phosphate.

Formation of complexes by reaction with organic ligands also reduces toxicity due to reduced bioavailability. The plant toxicity of heavy metals in soil is consequently also correlated with the concentration of heavy metal ions in the soil solution.

The heavy metals that are most toxic to plants are silver, beryllium, copper, mercury, tin, cobalt, nickel, lead, and chromium. With the exception of silver and chromium, the divalent form is most toxic. For silver, it is Ag^+, and for chromium, it is chromate and dichromate that are most toxic. Silver and mercury ions are very toxic to fungus spores, and copper and tin ions are very toxic to green algae; lethal concentrations may be as low as 0.002–0.01 mg/L.

One of the key processes on ecosystem level is the mineralization process, because it determines the cycling of nutrients. Heavy metals can inhibit the mineralization due to the blocking of enzymes. The effect is known not only for the enzymes produced in the organisms but also for extracellular enzymes—exoenzymes—originated from dead cells or excreted from roots and living microorganisms. As the various processes forming the cycling of nutrients are coupled, the entire mineralization cycle is disturbed if only one process is reduced. It is therefore possible to determine the change of the mineralization cycle by measuring the respiration, the transformation of nitrogen, and the release of phosphorus. As low a concentration of copper as 3–4 times the background concentration may imply a reduced soil respiration. A few hundred milligrams of copper per kilogram of soil is furthermore able to diminish the nitrogen release rate by one half.

The most sensitive mineralization process is phosphorus cycling. Biological material binds phosphorus as esters of phosphoric acid. The phosphate is released by the hydrolysis of the ester bond, a process catalyzed by phosphatase. This process is inhibited by the presence of heavy metals. The inhibition is decreasing in the following sequence: molybdenum (VI) > wolframate (VI) > vanadate (V) > nickel (II) > cadmium > mercury (II) > copper (II) > chromate (VI) > arsenate (V) > lead (II) > chromium (III).

The inhibition of exo-enzymes by heavy metals does not form a clear pattern. It is therefore difficult to generalize. Most experiments, however, give a clear picture of the influence of heavy metals on mineralization: the rate of mineralization may be reduced significantly with a consequent reduction of the productivity of the entire ecosystem.

In Denmark (a country with relatively little heavy industry and good pollution control), atmospheric deposition causes an average annual increase of the total content of heavy metal in soil between 0.4% and 0.6%, but it varies very much from location to location. In accordance with the many possibilities for side reactions of heavy metals in soil, including adsorption to the soil particles, the amount of heavy metal ions that are available to plants is only a fraction of the total content. If only the bioavailable heavy metals are used as the basis, the annual percentage increase in the soil concentration due to atmospheric deposition is probably higher.

Most lead in soil is not mobile and cannot be transported via the root system to the leaves and stems. This is in contrast to cadmium, which is very mobile. About 50% of the cadmium in soil will be found in the plants after the growth season, although the concentration may be very different in different parts of the plants. The cadmium in grains for instance has not increased parallel to the increased atmospheric deposition of cadmium.

The heavy metal pollution of soil is one of the major challenges in environmental management in industrialized countries. Due to the many diffuse sources of heavy metal pollution, the solution of the problem requires a wide spectrum of methods, the first of which is application of cleaner technology (see the section on *Industrial Air Pollution, Overview, and Control Methods*). It is in other words necessary to reduce the total emission of heavy metals. Dilution (for instance, higher chimneys) is not an applicable solution. Moreover, as pollution, particularly air pollution, has no borders, it is necessary to take international initiatives and agree on international standards, particularly for the most problematic heavy metals, i.e., cadmium, mercury, nickel, chromium, and vanadium. A three-point program must be adopted:

- A nationally and internationally accepted environmental strategy.
- Agreed international standards and long-term goals.
- A monitoring program to assess the pollution level and compare the measured concentrations with standards.

Alternative Energy: Hydropower

Andrea Micangeli,
Sara Evangelisti, and
Danilo Sbordone

Introduction

Approximately 70% of the earth's surface is covered with water, a resource that has been exploited for many centuries. Hydropower is currently the most common and the most important renewable energy source: throughout the world, it produces 3288 TWh, just over 17% of global production and the 84% of energy produced by renewable energy sources[1] from an installed capacity of about 850 GW.[2]

The International Energy Agency (IEA) has developed a number of scenarios that describe the efforts needed to reduce carbon dioxide emissions. The "business-as-usual" baseline scenario foreshadows the situation in the absence of policy change and major supply constraints leading to increases in oil demand and CO_2 emissions. The "**BLUE**" scenario is the most ambitious, bringing emissions at 50% of the 2005 level by 2050. This implies of course higher investment costs, as well as greater needs in technological and policy developments. In *Energy Technology Perspectives 2010*, it states that hydro could produce up to 6000 TWh in 2050.

The main characteristics that make hydropower a successful energy source are its plant storage capacity and fast responses to meet sudden fluctuations in electricity demand. Global hydropower generation has increased by 50% since 1990, with the highest absolute growth in China, as shown in Figure 1.

IEA estimates the *global technically exploitable hydropower potential* (the *technically exploitable potential* is the annual energy potential of all natural water flows that can be exploited within the limits of current technologies[3]) at more than 16,400 TWh per year.[1] However, hydroelectric plants of big dimensions, with million cubic meter water basins, have negatively affected the natural and social environment of the territories. Small plants are characterized by a different management, distributed on the territory, managed in small communities, integrated in the multiple and balanced use of the water resources.

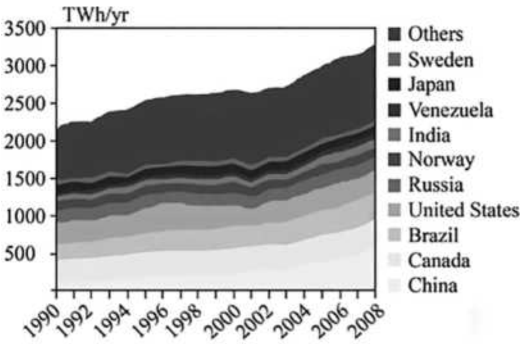

FIGURE 1 Evolution of global hydropower generation, 1990–2008.
Source: International Energy Agency.[1]

The contribution of *small hydropower* (*SHP*) *plants*, defined as those with installed capacity of up to 10 MW, to the worldwide electrical supply is about 1%–2% of the total one, amounting to about 61 GW.[2] Europe with about 13 GW installed capacity has the second biggest contribution to the world's installed capacity, just behind Asia. Moreover, the SHP potential is estimated in 180,000 MW.

SHP has a key role to play in the development of renewable energy resources and an even greater role in developing countries. In the face of increasing electricity demand, international agreements to reduce greenhouse gases, environmental degradation from fossil fuel extraction and use, and the fact that, in many countries, large hydropower sites have been mostly exploited, there is an increasing interest in developing SHP. Indeed, SHP has a huge, as yet largely untapped potential, which will enable it to make a significant contribution to future energy needs, offering a very good alternative to conventional sources of electricity, not only in the developed world but also in developing countries.

A hydropower sector technological maturity has already been reached during the last century, but only big plants have received all the benefits from technological development, while those of smaller dimension have been neglected. Nowadays the economy of scale, social and environmental implications, suggest this solution due to their economical feasibility and environmental respectful, allowing sustainable distributed production with an easy installation and great applicability in developing countries.

This entry is organized as follows: first, a classification of the hydropower plants is given. Then, the basics of the technology of mini and micro-hydro plants are illustrated, together with a description of the main civil works that occurred in a hydropower scheme. Finally, a conclusion on the potential and shortcomings of the hydropower technology is drawn.

Classification of the Hydroelectrical Plants

Hydropower plants can be generally classified in terms of power outputs:

Micro-hydro plant, with a nominal power lower than 100 kW, subdivided into *low-head plants,* when the vertical drop is lower than 50 m, and *low-flow rate plants,* when the water flow is lower than 10 m^3/sec.

Mini-hydro plant, with a nominal power between 100 kW and 1000 kW, subdivided into *mini-head plants*, when the vertical drop is between 50 and 250 m, and *mini-flow rate plants*, if the water flow is between 10 and 100 m^3/sec.

Small hydro plants, with a nominal power between 100 kW and 10 MW, subdivided into *medium-head plants,* when the drop is between 250 and 1000 m, and *medium flow-rate plants*, when the water flow is between 100 and 1000 m^3/sec.

Big hydro plants, as shown in Figure 2, with a nominal power of more than 10 MW, defined as *high-head plants* if the drop is higher than 1000 m and as *high-flow rate plants* with a water flow of more than 1000 m^3/sec.

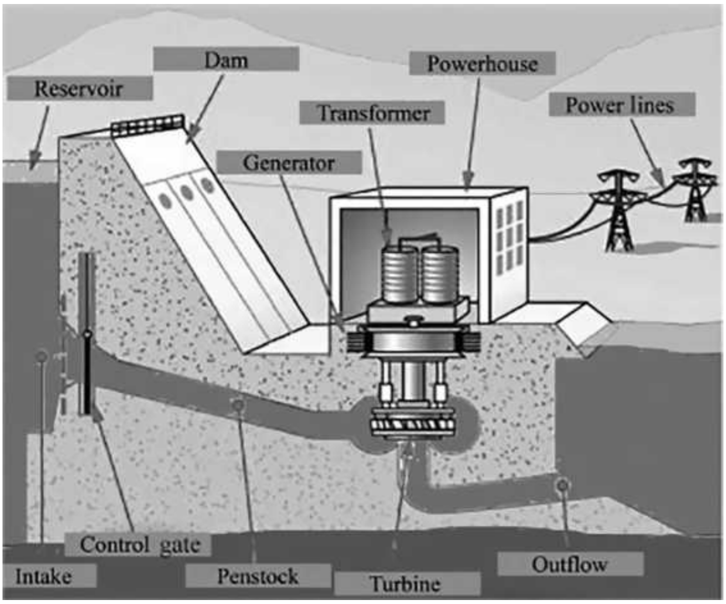

FIGURE 2 Big hydro storage scheme.

Another important way to classify hydroelectric plants is on the basis of their typology. In particular, they can be classified as follows:

Run-of-river scheme: or fluent water plants, they take a portion of a river through a canal or penstock. They do not require the use of a dam or catch basin. Because of that, they aim to affect upstream water levels and downstream stream flow less than any other power plants. Electricity generation from these plants could change in the amount of water flowing in the river.

Storage scheme: an impound water behind a dam, as a reservoir. Water is released through turbine generators to produce electricity. The water storage and release cycles can be relatively short, for instance, storing water at night for daytime power generation, or the cycles can be long, storing spring runoff for generation in the summer, when air conditioner use increases power demand. Some projects operate on multiyear cycles carrying over water in a wet year to offset the effects of dry years.

Pumped-storage scheme: these plants use off-peak electricity to pump water from a lower reservoir to an upper reservoir. During periods of high electrical demand, the water is released back to the lower reservoir to generate electricity.

The following sections focus on mini and micro-hydropower plants and run-of river scheme.

Mini-Hydro Plants

Mini-hydropower (MHP) plants have an installed power lower than 1 MW actually in Europe is 3 MW but in many country (in particular USA 5 MW) it may be more. Generally, these plants need less civil works, consistently reducing the costs connected to the realization of the plant and justifying their realization also under an economic point of view. If the plants are well planned and placed, their environmental impact is reduced for their limited dimensions. The simplicity of construction allows them to be introduced in contexts where the technology of the sector is not yet developed and there is a strong need for mechanical or electrical power. Also in those cases, MHP plants can be operated and maintained locally, even with less-specialized technicians. Changing hydropower plant size or typology, many things are the same, such as a turbine installation. This entry focuses on mini-hydro due to its low environmental impact and its opportunities of developing in the future.

Water Resource

Hydraulic energy, as almost every forms of energy on the earth, comes from the sun, which is the "engine" of the hydrological cycle. The sun, irradiating and warming up the atmosphere, makes seas and lakes evaporate; the water vapor rises up and thickens the clouds that move because of the wind, also generated by the sun; the clouds then produce precipitations in the form of snow, hail, and rain. When the rainfall ends up in the natural basin situated at a higher level, energy is transformed to *potential energy*. This energy is naturally stocked in rivers and in creeks that flow into the sea, closing in this way the hydrological cycle (see Figure 3).

The amount of available energy, which the water basin can produce at a given height, comes from the water level reached at the end of the cycle. In other words, to know the potential energy of a basin, it is necessary to evaluate the available rise, depending on the orography of the territory and on specific water works such as dams or small barriers.

The amount of water available is defined as the mass of water flowing per time unit (*flow rate*). In general, the potential power from a reservoir can be calculated by the following equation:

$$P_0 = \rho \cdot g \cdot Q \cdot H_0 \tag{1}$$

where

P_0 = theoretical power (W)
ρ = water density (1000 kg/m^3)
g = gravitational acceleration (9.8 m/sec^2)
Q = flow rate (m^3/sec)
H_0 = net head (m)

The output power of the plant is a percentage of it, due to mechanical, electrical, and friction losses.

Hydrology and Rain Measurements

In order to exploit the energy of water for power purposes, a *hydro geological analysis* of the territory is needed, particularly for catch basins. The analysis is based on the evaluation of the supply of the basin and its outflow. To obtain a balanced catch basin, it has to take into consideration the *meteoric flow rate,*

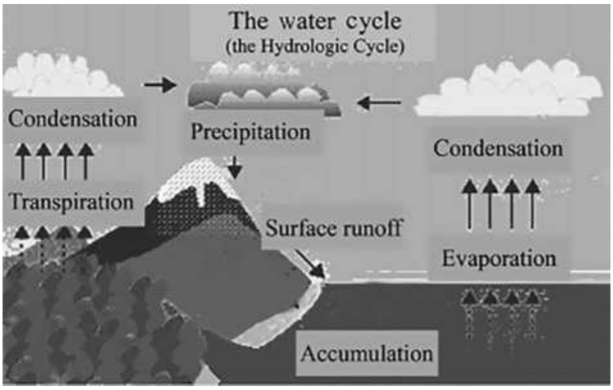

FIGURE 3 Hydrological cycle. (Source: Harvey et al.[4])

evaporation, and both *superficial* and *underground circulation*. The quantity of water from the rainfall to the basin, the *meteoric supply*, must be evaluated not only on the water surface of the basin itself but also on the whole area in which the rainfall is collected as well as the streams towards the basin (see Equation 2). The flows, which depend on soil permeability, are essentially of two types: *superficial* and *underground*, i.e., when the water filters through the soil and supplies underground basins and water-bearing stratum.

It is possible to evaluate the *meteoric supply*—superficial flow, as:

$$P = E + D + (I - C) \tag{2}$$

where P is the *meteoric supply* to the basin, E is the contribution given to the evaporation, D is the outflows, and I and C are the increase and decrease of the basins, respectively.

The term E is the amount of the following different contributions:

- Evaporation of water from the soil
- Transpiration of plants
- Evaporation of water intercepted by vegetation
- Evaporation of internal basins

Similarly, the term in relation to draining—underground flow—can be subdivided into the following:

- Natural water draining underground toward the external (*groundwater*)
- Artificial draining water toward the external (*inversion*)
- Natural superficial water inflow from the external (*water flows*)
- Underground natural water inflow (*water-bearing stratum*)
- Artificial inflow from the external (*adduction*)

Joining of different rivers has to be considered as well. The evaluation of the meteoric intake is usually performed through specialized devices, such as *rain gauges,* very common all over the world (see Figure 4).

The intensity of the rainfall flow rate is not constant through time and it has to be referred to different periods of the year (usually a multiyear). Not all the water from the rainfall ends up in the catch basin as

FIGURE 4 Example of a rain gauge.

shown before. Generally, the phenomenon is estimated by introducing a *coefficient of draining,* depending on the waterfall and the water collected into the catch basin, as shown in Equation 3:

$$C = \frac{V}{V_0} \tag{3}$$

where V is the real caught volume and V_0 is the waterfall.

Once V is determined, it is possible to calculate directly the energy exploitable from the plant in a given site:

$$E = 0.00273 \cdot \eta \cdot H_0 \cdot V \tag{4}$$

where H_0 indicates the *net drop*, in other words, the available drop minus the losses in the work of adduction with η output efficiency of the turbine.

Within a natural *hydrological basin,* it is necessary to analyze the head and the flow rate available along the whole river bed, through the *hydrodynamic curve* (see Figure 5). It shows the surfaces of the catch basin on the horizontal axes and the height of the water flow on the vertical one. Through the hydrodynamic curve, it is possible to optimize the entire use of a catch basin, while for the realization of a single plant, without having the intention to optimize the use of the resource along the whole river bed, it is enough to measure the flow rate of the river and the consequent evaluation of the quantity of water that can be taken from the basin or from the available drop.

Measure of the Water Flow

The determination of the water flow of a catch basin can be done by using specific devices, but it has to be undertaken only in absence of historical data of the course along the years. Different methods exist.[4] However, for each of them, it would be necessary to repeat the measures along a period of time to obtain the variation that occur throughout the year.

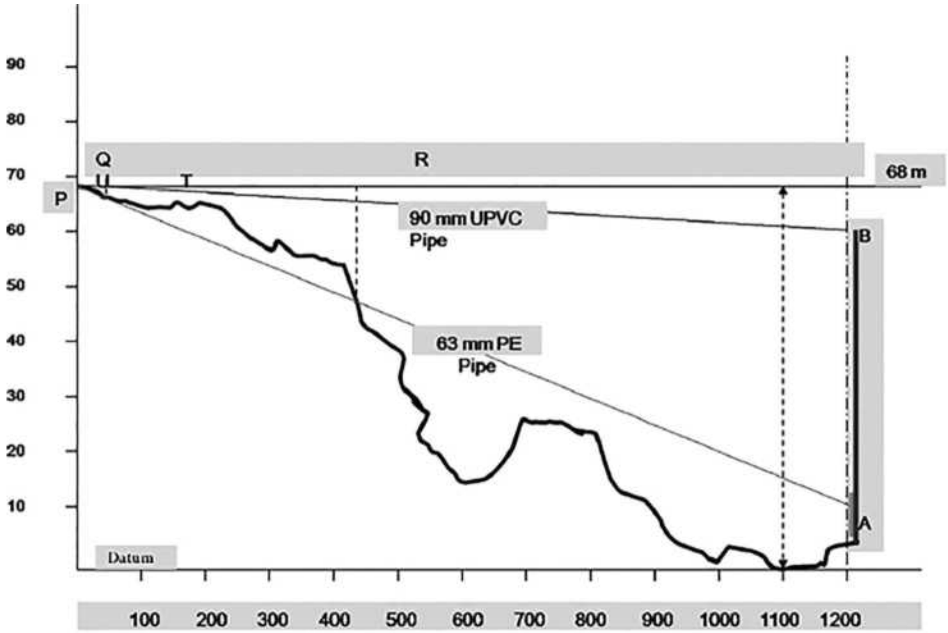

FIGURE 5 Example of a hydrodynamic curve.

One of the simplest methods that can be used is to force the flow to get into a container of known dimensions, measuring the necessary time to fill it up. This method is known for its simplicity; however, it is limited in that it can be applied only in rivers with small water flows.

A second method (Figure 6) consists of the realization of a weir of known dimensions, in which the river is forced to get into—the *weir method*. This method can be used to bring up to around 1 m^3/sec. To measure how much is carried, the second level reached by the water is taken into consideration as illustrated in Figure 7.

The water flow Q can be calculated using:

$$Q = 0.41 \cdot B \cdot H \cdot \sqrt{2 \cdot g \cdot H} \tag{5}$$

In this formula, H can be calculated as the difference between H_2 and H_1 (see Figure 7), B is the width of the weir, and g is the gravitational acceleration.

Another method of measuring water flow involves the evaluation of water velocity on the cross-sectional area. Velocity measurements can be made through a very simple method: with a floating, not too light in order to avoid the friction with the air, in a place where the river is pretty regular and flat, measuring the time that the floating takes to cover a specific distance. The measurement must be repeated more than once and the sought value taken into consideration must be the average between the distance covered and the time spent to cover it. The final velocity must be corrected with a factor between 0.75 and 0.85, given by the losses due to the friction with the sides of the canal.

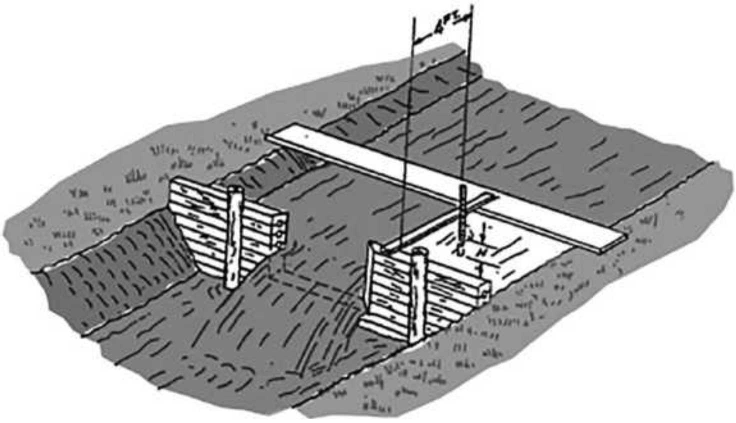

FIGURE 6 Weir method.

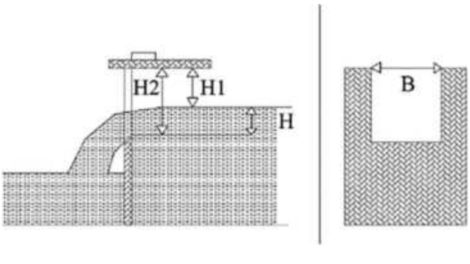

FIGURE 7 Weir realization.

TABLE 1 Value of the *Factor of Manning* (n) for Different River Bed Typologies

River Bed Typology	n
Regular river bed with a minimum annual flow	0.030
Stable flow condition	0.035
River with stagnant water, aquatic vegetation, and meanders	0.045
River with stones and shrubs with shallow pools and lush vegetation	0.060

The velocity can be obtained also through different methods, such as the use of "titled solutions," taking into account the variations on the electricity conductivity of the river when it flows with a known quantity of salt inside.

Once the cross section is evaluated, the water flow can be then calculated through the *formula of Manning*:[5]

$$Q = \frac{A \cdot R^{\frac{2}{3}} \cdot S^{\frac{1}{2}}}{n} \tag{6}$$

where A represents the cross section, R is the hydraulic radius, and S is the slope of the water surface. The value of n can be obtained from Table 1.

Flow Duration Curve

Water flow measurements are always referred to a specific period, as the water of the river changes during the year, passing several times from huge quantities of water to smaller ones. In general, the curve is uneven as it reports the water flow rate throughout the year as shown in Figure 8.

To organize the collected measurement data, it is possible to use another graphic that puts them all together. Indeed, in Figure 8, it is possible to note that there are two evident points of absolute maximum and absolute minimum, corresponding to the maximum quantity of water that occurs for a very short period and the minimum quantity of water that is the quantity available all year. Moreover, Figure 9 shows a *flow duration curve*, which presents the duration of each amount of the flow rate.

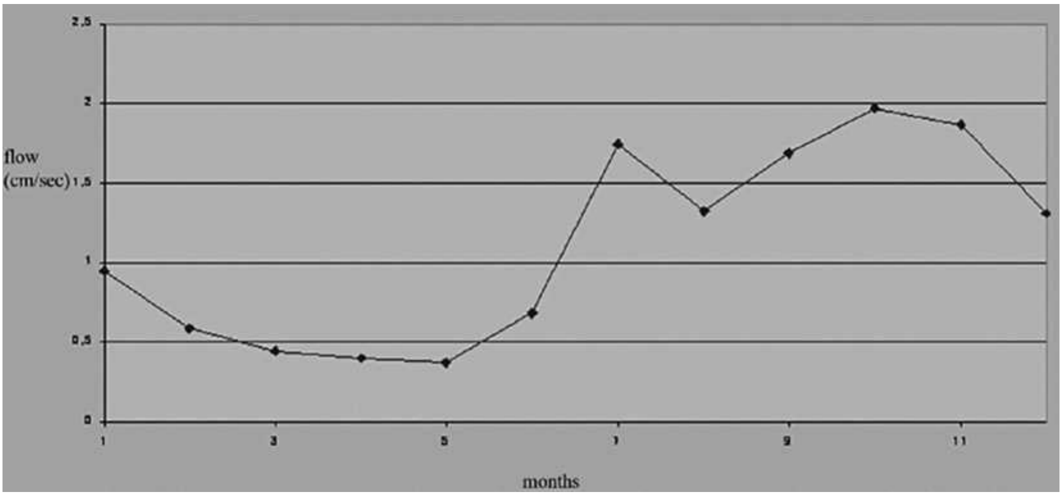

FIGURE 8 Example of a daily flow curve.

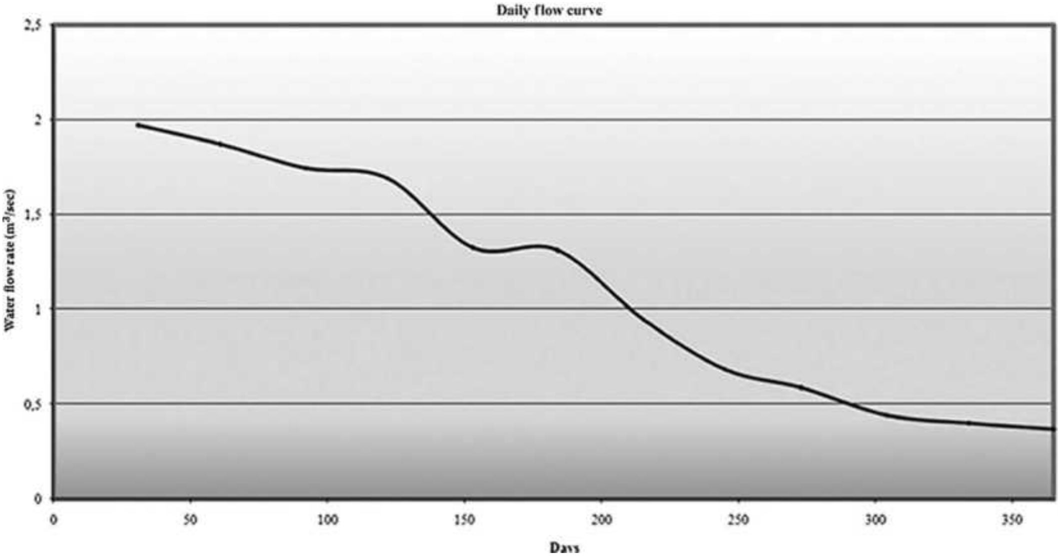

FIGURE 9 Example of a flow duration curve.

Measurements of the Gross Head

To measure the height difference between two points, it is necessary to utilize a level and to follow the scheme in Figure 10. The operator must simply read the values of each ruler to come out with the height by computing the difference between the two values. This procedure can be repeated until the final point is reached. If a level is not available, it is possible to use a table with a carpenter level—even if it requires a lot of patience—or to proceed with a plastic transparent pipe filled up with water, which fulfills the same characteristics of a level. While measuring from the available head, it is wise to also calculate the length of the *forced penstock* as distance from the hold point to the arrival of the penstock itself. This is essential both for the choice of the material of the penstock and for the evaluation of the pressure drop.

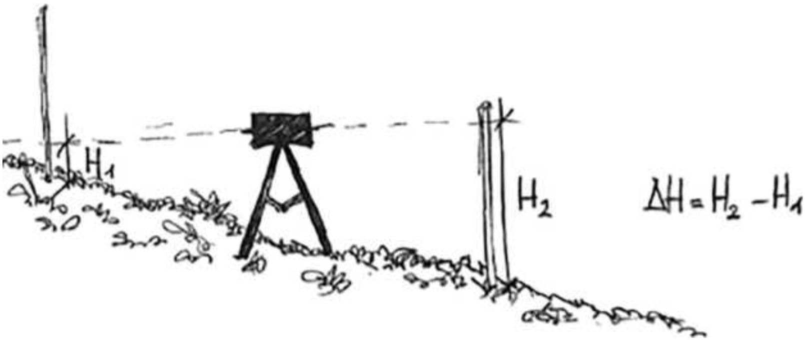

FIGURE 10 Example of measurement of the gross head.

Instream Flow and Environmental Impact

The balance of any catch basin is connected not only to the water balance but also to the real possibility of exploitation, characterized by other aspects:

Rivers can be used not only for power purposes. Before proceeding to the derivation of the outflow, it is necessary to be sure that it will not have a negative impact on further communities. It is necessary to verify all the aspects connected with the multiple uses of the water resource.
The subsistence of the natural balances involved in the river and in the catch basin itself. An example, to adduce water to a riverbed of a catch basin, can be useful for the fish fauna, although the flow rate is high and it comes from nearby.

The use of the water resource of a catch basin refers to a wider issue that generally is approached letting a minimum natural course of the river, generally indicated as *minimum instream flow* (*IF*), defined as "the minimum height of water needed to maintain the values of the basin at an acceptable level." The calculation of the IF is essential: in fact, if the minimum flow rate is lower than the IF during the planning stage, the no-working periods of the plant can be estimated.

To guarantee a minimum flow means to preserve the biological balance and the need of the use of a civil work as a caption downriver. The derivation established on the basis of this context must be lower than the limit beyond which it may influence the river ecosystem and may cause the entering in crisis however the natural water regime must be guaranteed.

The river regime model must therefore take into account the following aspects:

Biological species that would suffer from the uncontrolled derivation of water.
Hydrologic characterization for the protection of water balance (equilibrium) and the defense of soil.
The use of the water resource represented by the social and economic wardship of needs.

Two different relations are commonly used for the calculation of the minimum IF:

$$Q_{\mathrm{IF}} = \frac{15 \cdot \alpha \cdot Q_{\mathrm{media}}}{\left[\ln\left(\alpha \cdot Q_{\mathrm{media}}\right)\right]^2} \tag{7}$$

where α is the *coefficient of perpetuity* given by the relation between low intake and the medium IF values, expressed in liters per second:

$$\mathrm{IF}_{\mathrm{hydrol.}} = 6.\mathrm{IF}_{\mathrm{microhabitat}} \tag{8}$$

The equation shows that conserving the IF from a hydrological point of view also means, with a big margin, that the conservation of IF from a biological point of view is connected with the microhabitat. If the value of the low intake is unknown and only the average is known, it is possible to assume that the coefficient of perpetuity α is equal to 0.24, showing the outflow of hydropower plant that guarantees the preservation of the fish fauna and hydrology. Figure 11 shows a typical example of the realization of a canal to guarantee the conservation of hydrology and of the fish fauna in a hydropower plant.

Civil Works in MHP Plants

The *civil works* for *hydropower facilities* have the functions to capture, to exploit, and to return the water downriver. In small rivers, the realization of those works is done by deflecting the water flow for a short period of time, to operate in dry conditions. To deflect the river, a provisional river bed has to be built or the plant must be realized during the dry season, if feasible.

FIGURE 11 Example of a system to conserve fish fauna.

Dams and Weirs

The choice of the typology of the dam must be made taking into consideration the orography of the territory and the water resource to exploit.[6] Generally, hydraulic works must create a good drop between mountain and valley, to have the possibility to exploit the potential energy from the mass of water. The structure can be *dams* (Figure 12) or *catch basins* (Figure 13).

A *dam* is a "lung" of water available that is able to compensate, partially and totally depending on the volume created, the variation of the flow rate of the river during the year. Although the creation of a dam needs a big investment, this makes it practically not usable in MHP.[7]

A type of barrier—often installed in small plants—is the *derivation weir*. The derivation weir is smaller and more cost-effective than a traditional dam and generally the water overflows the traverse, reversing in the natural path of the river. If the plant is big enough, the derivation weir turns into a small dam that basically does not function like a water accumulator, but it aims at raising the level of the water flow.

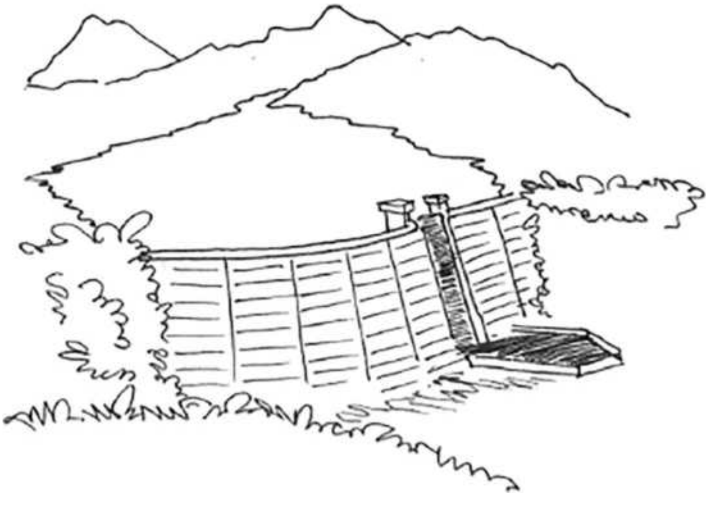

FIGURE 12 Example of a dam.

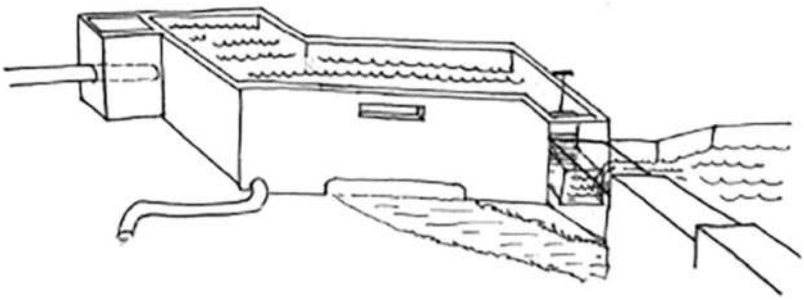

FIGURE 13 Example of a catch basin.

The derivation weir can be realized with several different materials and, when possible, it is suggested that locally available material, such as rocky materials, be used. Otherwise, it is possible to use blocks of flat rocks and soil kept altogether by metal nets to constitute the *barrage.*

It is important that the barrage is realized with a central waterproof nucleus, made with clay, and supported with soil or minerals. If there sand or gravel is available, a barrier made of concrete can be also taken into consideration.

If the regimes of full flow are huge, it is necessary that the intake must be drained through ad hoc dischargers not easy to realize when the barrage has been made in the river. Instead, in places with much seismic activities or in very cold climates, it is better to avoid rigid structures, so floor barriers are preferred.

Stability of the Dam

In small plants, the stability of the dam generally depends on the weight of the dam itself. The strains that the dam applies to the ground through its own weight can be higher than those that the ground can take. It is necessary to minimize the infiltration of water underneath the dam with the use of spillway drain and erosion or diaphragms.

Also, the stability to the overturning of the dam must be guaranteed in all the conditions of charge concerning the hydrostatic push related to the dragging of solid material or to seismic waves. In order to guarantee that, it is enough to ensure that all the strains against the ground are not negative, in order to avoid dangerous situations that can bring the structure to overturn. This entails designing a dam where all the horizontal and vertical strains fall internally in the central part of its own basement (see Figure 14).

As the hydrostatic strains generally go from upstream to downstream, the side of the dam facing downstream is more sloping as compared to the perpendicular of the basement; thus, the profile of the dam upstream has to be more vertical than the downstream.

System of Elevating the Free Water Surface

To control the water flow, *floodgates* are generally used. Given that most of these devices are used to control the free water surface elevation being stored or routed, they are also known as *crest gates.*

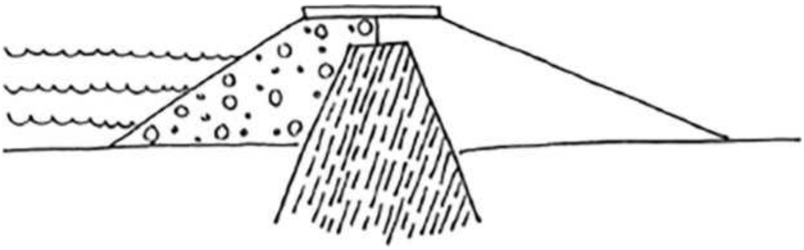

FIGURE 14 Stability of the dam.

A removable type of *floodgates* is *flashbooks gates*— wooden panels usually installed on the cap of the barrier that allow the increase of the water surface and that can be removed during floods, avoiding the inundation of the upstream fields.[8]

Generally, to avoid the manual intervention and to check upstream flooding, it is possible to install a gate that can be opened progressively during full intakes. Another solution is to install *fusegates*, concrete crates that flip over when the water level is reached (Figure 15). Finally, another type is the *dinghy*, anchored to the cap of the barrier that blows up during full intakes of water, only to deflate again during the rest of the year.

Spillway

If the flow rate varies during the year, it could be that the floodgates systems are not enough to guarantee the integrity of the plant. In this case, it is necessary to foresee a system that takes the surplus flow rate to downstream— the *spillway*. Except during flood periods, water does not normally flow over a spillway. The surplus water usually flows at a high velocity and often it is necessary to insert a system to reduce its kinetic energy. In small plants, the introduction of a drainage, which allows emptying the loading tank to help in the maintenance of the plant, is always considered.

The spillway is also used in times of emergency, i.e., shutting down the plant.

Intake

The *water intake* (see Figure 16) is a structure in which water is adduced in order to bring it to the *forebay tank*. It must be able to address in the penstock or in the drainage canal the amount of water estimated in the project. It is pleonastic to underline how the civil work has to be studied and realized in a way to minimize friction losses and the impact on the environment. It must also be designed to minimize maintenance and to reduce the costs. Practical aspects of the project related to civil work therefore must follow the following criterion: Hydraulics and structural works have to guarantee the resistance of the pipes to minimize the waste of energy and to be cost-effective, to avoid transportation of solid material inside the pipes to the powerhouse and for easier maintenance, and to reduce the passage of fishes and to not compromise the ecosystem of the area in which it has been realized.

FIGURE 15 Example of fusegates: “Sant’Antonio 1” IdroPower Station (Italy).

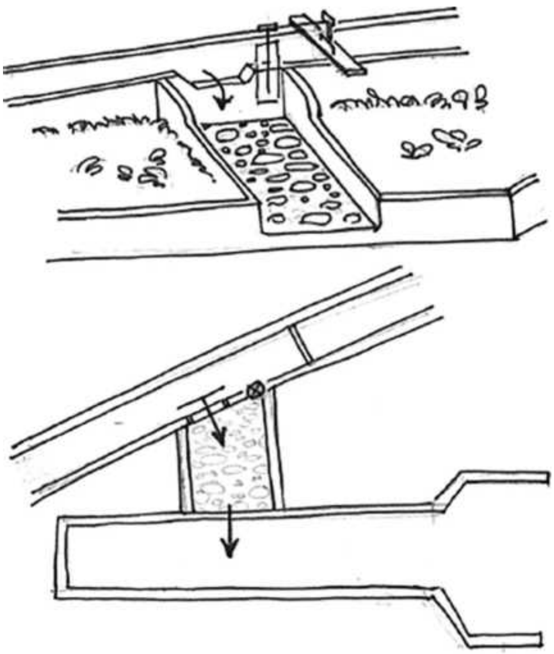

FIGURE 16 Example of intake works.

The water intake works can be realized in different ways, depending on the peculiarity of the orography of the territory. Often it is a channel that brings the water to the point where the forced pipe is. In this case, the channel is realized in a way that the water flows slowly with a contained slope of the pipe in order to contain the losses and the erosion of the walls and to preserve the jump.

The choice of the dimension of the intake channel and the water velocity are results of a compromise to avoid frequent maintenance due to the deposits of sand and slime, to avoid losses and erosion against the wall. Generally, the water flows along the channel with a velocity between 0.1 and 0.4 m/sec. If the quantity of solid materials to be transported is huge, then a bigger tank, where the deposits end up due to the reduction of the speed of the water as a result of a bigger section, is needed, based on the fundamental hypothesis of the continuity of the intake.

The *sedimentation tank* is necessary if the channel has not an open surface, due to the costs connected to the maintenance of the closed channel. In small plants, the drainage tank usually works as a sedimentation tank as well; however it must be cleaned more frequently and it will have a bigger dimension due to the sedimentation process. The transportation of solid material is very deleterious not only for turbine performance but also for the life of the device itself.[5]

The *orientation* of the *intake* is crucial when choosing a project, as it can reduce the accumulation of material over the grid itself and the frequency of the intervention of maintenance. The best position is parallel to the flow letting the full flows the task of removing the material stuck in front of the grid. Anyway, it does not have to be located in areas of stagnant water as the whirlpool and the parasite flows tend to accumulate solid material in front of the grill. If there is a discharger, it is good to place the grill next to it to simplify maintenance as the deposits can be pushed to the discharger as well.

Forebay Tank

At the end of the channel or coincident with the intake, replacing the channel of charge, a little tank, known as *forebay tank* or *basin of charge,* has to be realized. Its function is to guarantee the presence of upstream water in the penstock, in order to avoid the entrance of air along the pipe and the formation of whirlpools.

Channel

If the plant needs it, the sampling of the flow to adduce in the central, is done by using a channel. The channel can be realized both as open channel and as under pressure pipe. In the small plant, the technical solution is oriented towards an open surface channel, the sizing of which is done considering first the intake to derive. The intake is the function of the section of the channel as well as of the slope and the roughness that depends on the material used and on the degree of finishing of the wall. The channel can be made from different materials such as soil, wood, and concrete.

Generally, for small plants where the banks have an inclination of 45° with the base, if the width is L, the width of water surface is $2L$ and the height is $L/2$. Concerning concrete structures, using one that is rectangular shaped, which helps in the cleaning of the channel, is usually preferred.

Penstock and Pressure Drop

The *penstock* (see Figure 17) takes the water from the load tank and pushes it to the turbine. It can be realized with the use of different materials. One should take into account the cost, weight, type of joints, and the conditions of the ground when choosing the type of material to be used. The *penstock* is also characterized by the diameter of the conduit itself that must contain the loss of load.

The choice of the pipe diameter has to be made as a compromise between three needs:

1. Keeping the costs down and therefore realizing a small-diameter pipe.
2. Containing load losses.
3. Realizing a bigger pipe to increase the energy.

The first head measure can be seen as a gross head, keeping into consideration the losses inside the conduits and all the other works of adduction.

The real *head* exploited by the turbine is lower than the first value above. Indeed, the definition of drop goes together with the *net head* that identifies the usable jump by the turbine; thus, the gross head minus the losses of the adduction works. Such a definition allows dividing the losses of the hydraulic parts from those related to the turbine. The value of the net head obviously depends on the pressure

FIGURE 17 Example of a penstock.

drops occurring inside the penstock. Through the definition of *net head*, it is also possible to define the output of the section of the hydraulics work simply as:

$$\eta_{\mathrm{idr}} = \frac{H_{\mathrm{n}}}{H_0} \tag{9}$$

where n and 0 refer to the net head and the gross head, respectively. The bigger is the hydraulic output of the plant, the better will be the exploitation of the water resource as higher power can be obtained with the same load or the same power can be obtained with less load. Moreover, if the entity of the load losses compared to the available drop is modest in high- and very-high-fall plants, in the low-fall plant with 6 m of available drop, a load loss of 1 m is almost 20% of the produced power. Thus, the hydraulic works of an adduction channel have to be realized with focus on MHP plants.

The penstock is the part of the plant in which the water flows faster. Considering that the losses are proportional to the square of the speed, the realization of the penstock is very important in terms of hydraulic performances of work of adduction.

The amount of water that flows inside the penstock is functional to the section of the pipe, its diameter and the water velocity. Once the flow is designed, a relation between speed flooding and penstock diameter is needed.

The problem can be solved with a dimensional analysis that puts into evidence how the *Fanning factor* is a function of the *Reynolds number* and *relative roughness,* known from fluid dynamic theory. The Fanning factor is connected to load losses and it represents their adimensionalization; the Reynolds number comes from the relation between inertia forces, viscosity, and velocity. Relative roughness is connected to the choice of material and the level of superficial finishing. Generally speaking, it is verified that, depending on the fluid regime, the Fanning factor tends to depend only on one of the variables.[8]

Walls

The thickness of the walls and veins are subject to the pressure of the impulse load, which also includes a water hammer. Nevertheless, in the case of a water hammer, plastic pipelines react better than iron ones, because the elasticity of the plastic tends to absorb overpressure better than other materials.

Once the ideal material is selected, the formula of the thickness can be found using the *Mariotte's formula*:[9]

$$t = \frac{P \cdot D}{2\sigma_{\mathrm{f}}} \tag{10}$$

where t is the thickness of the pipe, P stands for the hydrostatic pressure, D is the diameter, and σ is the allowable stress.

Equation 10 is only valid for stationary systems, where both capacity reductions and closure operations are not verified. Moreover, it does not take into account the problems that occur in iron pipes. Therefore, Equation 11 should be amended, and, taking into account the types of joints, it becomes:

$$t = \frac{P \cdot D}{2\sigma_{\mathrm{f}} \cdot k_{\mathrm{f}}} + t \cdot s \tag{11}$$

where k_{f} is the efficiency of the welding and $t \times s$ represents the overpressure due to corrosion. k_{f} can be derived using Table 2.

In general, the value obtained as the thickness is always corrected when it is too low to take into account other factors: the tube must have achieved a sufficient rigidity to be moved without deformation. If the plant has a high fall, then a conduct with variable thicknesses (based on the pressure) can

TABLE 2 Value of k_f for Different Types of Joints

Type of Joint	k_f
Without welding	1
Welding checked with x-ray	0.9
Welding checked with x-ray and subjected to a relaxation	1

be used in order to reduce the cost of the materials. In addition to resistance to pressure increases, a conduct has also to withstand internal depressions to avoid collapsing:

$$P_c = 882.500 \cdot \left(\frac{t}{D}\right)^3 \tag{12}$$

where P_c is the pressure of collapse.

The depressions can be avoided through an *aerophore* with a minimum diameter:

$$d = 7.47\sqrt{\frac{Q}{\sqrt{P_c}}} \tag{13}$$

where d is the diameter of the aerophore.

Finally, to conclude the calculation of the wall thickness, a water hammer has to be considered. The *Allievi-Michaud formula* can be modified if the pressure is expressed in water column, as:

$$\Delta P = c\frac{\Delta V}{g} \tag{14}$$

where c is the propagation speed in the middle of the pressure wave that depends on the water density and the elasticity of the material:

$$c = \sqrt{\frac{k}{\left(1 + \frac{kD}{Et}\right)}} \tag{15}$$

where k is the water cubic compression module (2.1×10^9 MPa); E is Young's modulus of the conducting material; t and D are the thickness and diameter of the tube, respectively; and ρ is the water density. By applying the relationships (Equations 14 and 15) to PVC and iron pipes, it is possible to calculate for an instant closure (d of 400 mm, PVC thickness of 14 mm, and iron thickness of 4 mm):

$$c_{\text{pvc}} = 305 \text{ m/sec}$$

$$c_{\text{acciaio}} = 1023 \text{ m/sec}$$

$$\Delta P_{\text{pvc}} = 123 \text{ m}$$

$$\Delta P_{\text{acciaio}} = 417 \text{ m}$$

This provides a quantitative demonstration of the previously described nature of the two materials. If the operating time increases, the pressure is drastically reduced. Indeed, the maneuvering speed plays a crucial role in the generation of the overpressure. In large systems, it is common not to install pipes that can withstand overpressure, or water hammer, but rather to install mechanisms for the exclusion of the load to prevent the turbine from going into "overspeed."

Another device that serves to absorb the pressure waves that can occur within the pipes is the *piezometric borehole.* To evaluate if its installation is needed, the following formula can be considered:

$$I = \frac{V \cdot L}{gH} \tag{17}$$

where I is the constant acceleration. If I is less than 3, it can be assumed that the piezometric borehole is not necessary.[5]

The penstocks are also anchored to the ground, or supported on special works such as anchor blocks or saddles. The distance between two saddles or between two anchor blocks has to be as much as to make the pipe's arrow acceptable when it is full.

Water Turbines

A turbine converts energy in the form of falling water into rotary shaft power. The selection of the best turbine depends on several factors: the net head of the plant, the nominal flow, the power rating, and the shape of the turbine. The most installed turbine models, mainly used in big hydro plants, are three different typologies: Pelton, Francis, and Kaplan. In MHP, the turbine choice is made on different considerations, not only economical. Indeed, its construction and operational simplicity become essential, especially in developing contexts. Often, it is possible to install simpler versions of big hydro plant turbines—not for the Pelton model, which is the simplest one yet, for example, changing the blade edges.

As stated before, the choice of the turbine depends on the net head and the flow rate, as well as on the available water resources and the plant typology. A good criterion to select the turbine is resumed in the following well-known diagram, where they have a range in head and flow (Figure 18).

It should be stressed that the fields of employment are not very narrow and are only suggestions for the best choice. In fact, a Pelton turbine could be installed in a low head-high flow rate plant, even if the turbine efficiency will be strongly penalized. This results in areas of the diagram where different typologies of turbines can be used at the same time. The final choice has to be taken considering also other factors, such as the operation of the plant.

Conclusion

Hydropower has been used as far back as the Roman empire and through history has been used to power water mills, textile machines, sawmills, and irrigation systems. In the early 1800s, however, people started to see that the use of water to power small factories and machines is but a minor application of its potential. As early as the 19th century, waterpower was being used as a source of electricity. Though primitive hydropower technology only consisted of wheels, buckets, and river flow, it was from this point on that waterpower's potential as one of the most efficient and abundant sources of renewable energy became apparent.

Mini-hydropower is probably the least common of the three readily used renewable energy sources (i.e., water, sun, and wind), but it has the potential to produce the most power, more reliably than solar or wind power if you have the right site. Small-scale hydro is in most cases run-of-river, without dam or water storage, and is one of the most cost-effective and environmentally benign energy technologies for developing countries and further hydro development in Europe.[17]

In this entry, a summary of the main advantages and shortcomings of small-scale hydropower has been presented. The hydro resource is a much more concentrated energy resource than either wind or solar power and the energy available is readily predictable. Moreover, no fuel and only limited maintenance

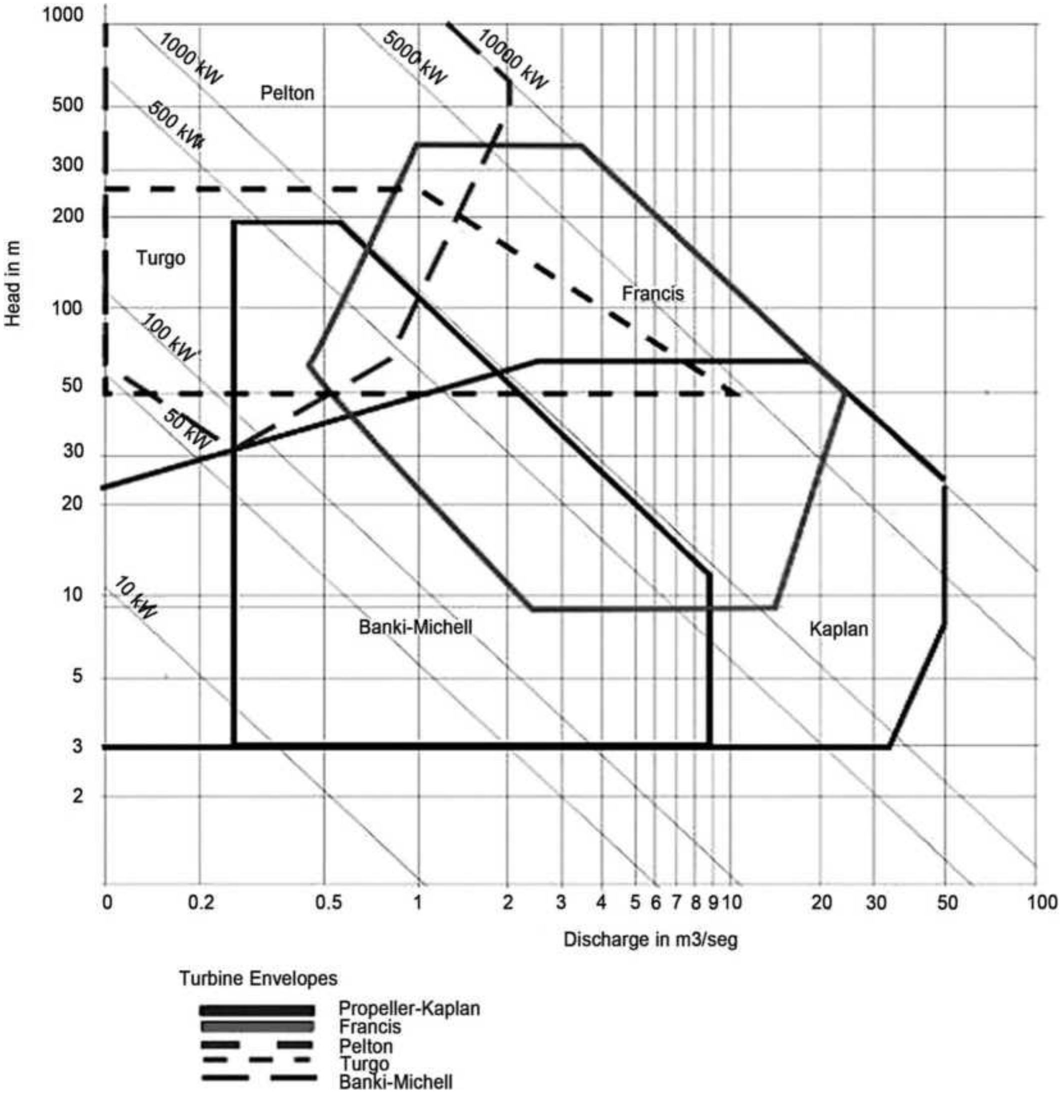

FIGURE 18 Values of flow and height for each field of application of different turbines.

are required and, if well designed, it has almost no environmental impact. On the other hand, it has to be considered that it is a site-specific technology and no general consideration has to be taken in the design of the plant; otherwise, environmental, social, or economical problems could occur, such as conflicts with fisheries interests on low-head plants and with irrigation needs on high-head plants. Furthermore, river flows often vary considerably with the seasons, especially where there are monsoon-type climates, and this can limit the firm power output to quite a small fraction of the possible peak output.

However, where a hydropower resource exists, experience has shown that there is no more cost-effective, reliable, and environmentally sound means of providing power than a hydropower system. Even with the various advantages of hydropower, it is still an underused alternative energy source. As of 2008, only 6% of the United States' electricity production came from hydropower, while nearly 50% came from the non-renewable source that is coal.[12] Due to a lack of economic speculation, a vast amount of potential for renewable hydropower remains untapped. Third world countries and underdeveloped areas have many areas that would be highly conducive to hydropower. The construction and use of hydropower facilities in these countries/areas, along with an increase in hydropower in the United States, could result in a great increase in renewable, affordable, and non-polluting energy.

However, if the prospected potential has to be realized, significant challenges have to be faced, in terms of *decision-making process,* establishing an equitable, credible, and effective environmental assessment procedure that takes into account both environmental and social concern and that takes into consideration the share of the benefits with local communities, both in the short term and in the long term. Finally, increasing efficiency, developing high-tech turbines, and reducing the costs of very low-head schemes, along with proper technology transfer of appropriate turbines to local manufacturers and technical support to the developers, will help realize our long-term objectives.

Alternative Energy: Photovoltaic Solar Cells

Ewa Klugmann-Radziemska

Introduction

Nowadays, fossil fuels are the main sources of energy from which electricity is obtained, but these sources will not last forever, so in due course renewable energies will have to replace them in this role. One of these new sources is solar energy. Each year, the Earth receives around 1×10^{18} kWh of solar energy, which is more than 1000 times the current global energy demand. This is therefore a vast source of energy that can be tapped to satisfy human energy requirements. To generate electricity from sunlight, solar cells (photovoltaic cells) are used. These devices are based on the photovoltaic effect, in which a p–n semiconductor is exposed to light, and photons are absorbed by electrons, providing an electric current. The electrons that are set free are pulled through the electric field and into the n-area. The holes produced move in the other direction, into the p-area.

The use of solar energy releases no CO_2, SO_2, or NO_2 gases and does not contribute to global warming. Photo-voltaics is now a proven technology that is inherently safe, as opposed to some dangerous electricity-generating technologies. Over its estimated life, a photovoltaic module will produce much more electricity than was used in its production. A 100 W module will prevent the emission of more than 2 tons of CO2. Photovoltaic systems make no noise and cause no pollution while in operation.

Photovoltaic Effect

The solar cells now in use are the practical application of fundamental physical phenomena observed already in the 19th century (see Table 1).

The absorption of light in semiconductors takes place when electrons are released from interatomic chemical bonds. In order to produce a free electron in a given semiconductor material, a certain quantity of energy must be supplied, equal at least to that of the energy band gap, which in the case of silicon at a temperature of 300 K is $E_g = 1.12\,\text{eV}$. The liberated electron leaves behind it a hole that can move about by diffusion or drift under the influence of an electrical field owing to its being positively charged (Figure 1).

The introduction of other atoms in place of the parent atoms (or at interstitial positions) of a pure intrinsic semiconductor considerably improves its electrical conductivity. Energy levels of elements with one valence electron more than the semiconductor atoms form donor levels in the neighborhood

TABLE 1 The Beginnings of Photovoltaics Worldwide

Year	Achievement
1839	Alexander Edmund Becquerel observed the photovoltaic effect in a circuit of two illuminated electrodes immersed in an electrolyte.
1843	Fritts produced the first tin–selenium solar cell.
1879	Adams and Day observed the photovoltaic effect at the interface between two solid bodies (selenium–platinum).
1930	The first copper/copper oxide solar cell.
1941	Ohl patented the silicon cell (monocrystalline silicon doped during its growth).
1954	At the Bell laboratory (United States), Chapin, Fuller, and Pearson developed a cell on monocrystalline silicon with a diffusion p–n junction of 6% efficiency, which was subsequently manufactured by two companies.
1954	Lindmayer and Allison obtained a cell with an efficiency of 16% (radiation intensity, 1000 w/m^2).
1954	Reynolds produced the first multiple-junction Cu_2S/ CdS cell.
1958	Monocrystalline solar cells were used for the first time in the Vanguard I satellite, where modules of six cells supplying 5 W of electrical power were installed; the traditional batteries ran out after a few months, but the photovoltaic panels powered the satellite's transmitter for another 6 years.
1962	The first thin-layer Cu_2S/CdS photocell was obtained.

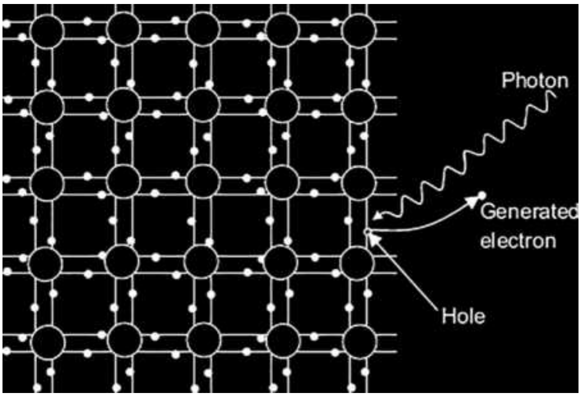

FIGURE 1 The generation of an electron–hole pair by a photon of energy $h\nu > E_g$.

of the conduction band (n-type). Energy levels of elements with one valence electron less than the semiconductor atoms form acceptor levels in the vicinity of the valence band (p-type).

If a p –n junction is formed from the p- and n-type areas of the semiconductor, then the charge carriers move around in such a way that the Fermi level will be identical throughout the crystal (Figure 2b). At room temperature (300 K), practically all donor and acceptor dopants are ionized; hence, the concentrations of majority carriers (electrons in the n-type area and holes in the p-type area) are approximately equal to the concentrations of the relevant dopants (Figure 2a).

At the instant these two areas are brought into intimate contact, a very large concentration gradient of electrons and holes across the boundary between them comes into existence. This gradient causes electrons to diffuse from the n-type area to the p-type area and the holes to move in the opposite direction. As a result of this diffusion, a space charge region comes into being near the junction: on the n-type side, this is positive, since electrons have left this area, while the uncompensated positive charges of immobile donor ions remain along with the holes newly arrived from the p-type area; on the p-type side, it is negative, because in the same way carrier diffusion has given rise to an area of negative charge consisting of immobile acceptor ions and electrons newly arrived from the n-type area. In this way, a dipole space charge layer is formed in the area around the p–n junction (Figure 3). A potential barrier and electric field are formed within this layer that counteract further diffusion and restrict the diffusion

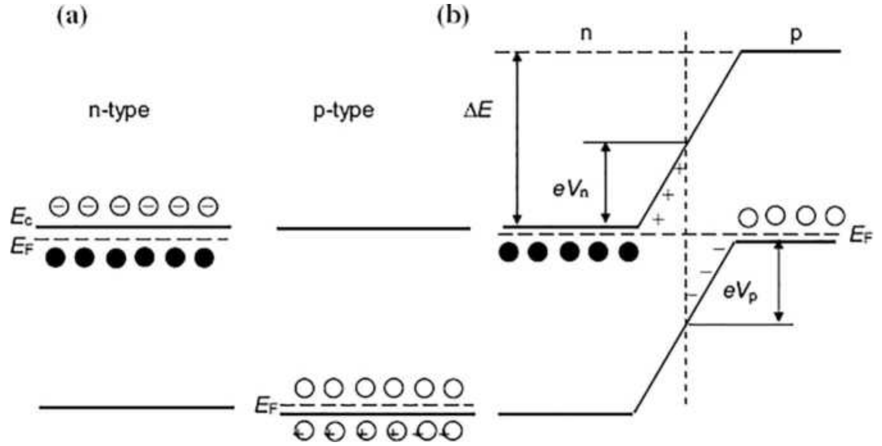

FIGURE 2 Formation of an abrupt p–n junction (b) as a result of the juxtaposition of n- and p-type areas (a), $\Delta E = e(V_n + V_p)$.

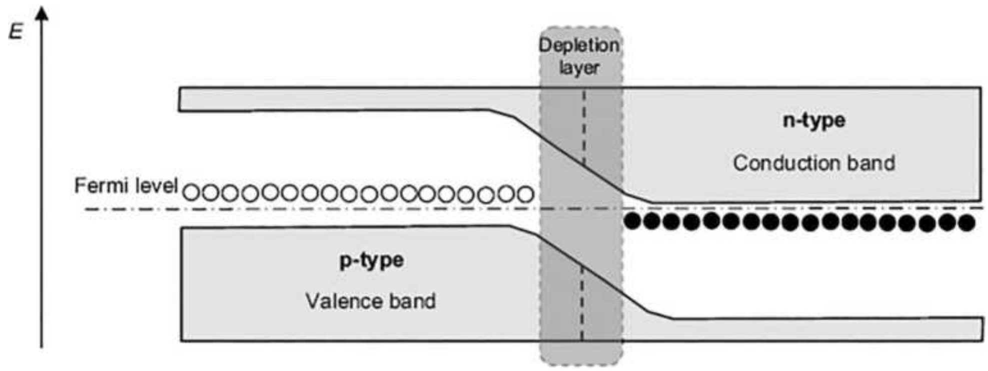

FIGURE 3 Equilibrium in the p–n junction region.

current. Apart from majority carriers, there are minority carriers in the two areas on either side of the junction, which come about as a result of the thermal generation of electron–hole pairs. The potential barrier formed as a result of majority carrier diffusion favors the outflow of minority carriers from both areas. The movement of these carriers creates a dark current, which flows in the opposite direction to that of the diffusion current.

If the p–n junction is illuminated by photons with an energy equal to or greater than the band gap width E_g ($h\nu \geq E_g$), then electron–hole pairs form on either side of the junction, as in the case of thermal generation (Figure 4).

Carriers forming no farther from the potential barrier than the diffusion length of minority carriers will diffuse towards the potential barrier and will be distributed there by the electric field due to the presence of the junction (the diffusion length is the mean distance that minority carriers have to move before they recombine with majority carriers). This field causes the carriers to move in opposite directions—electrons to the n-type area and holes to the p-type area. If an electron–hole pair forms on the p-type side of the junction, the electron reaches the junction before it has any chance of recombining with the hole (if recombination does occur, the resultant energy is emitted in the form of heat, and the effect is entirely useless as far as the photovoltaic effect is concerned), and the hole in this pair stays on the p-type side since it is repelled by the barrier in the junction. There is no danger of recombination here as there is an excess of holes in this region. The same thing happens when an electron–hole pair is generated by light on the n-type side of the junction. Then, the liberated electron remains on the n-type side, as it is repelled by the barrier. On the p-type side, however, we now have very few free electrons capable of recombining. This causes an increase in negative charge on the n-type side and of positive charge on the p-type side, which leads to a charge imbalance in the cell. This charge separation gives rise to a potential difference across the junction. As a result, a photoelectric current I_f comes into being in a closed circuit, regardless of the height of the potential barrier.

The generation of a photoelectric current I_f by a stream of photons in a solar cell can be demonstrated using the model of a current generator connected in parallel with a diode representing the p–n junction of the cell. As Figure 5 shows, the output current I flowing through the series resistance r_s of the cell and the load resistance is equal to the difference between the generated photoelectric current I_f and the diode current I_d.

$$I = I_f - I_d = I_f - I_s\left(\exp\frac{eU}{mkT} - 1\right),$$

where I_s is the saturation current and m is the diode ideality factor.

It emerges from the above equation that for cell operated at open circuit ($I = 0$):

$$I_d = I_f \text{ and } U = U_{oc} = \frac{mkT}{e}\text{In}\left(\frac{I_f}{I_s} + 1\right).$$

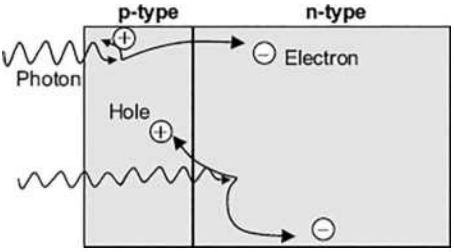

FIGURE 4 The potential barrier in a solar cell distributes the charge carriers generated by light.

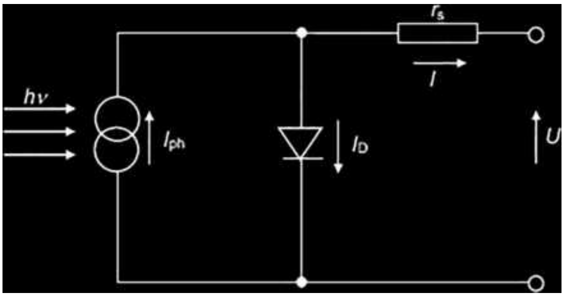

FIGURE 5 Electrical model of a solar cell.

From this last relationship, we obtain:

$$I_f = I_s\left(\exp\frac{eU_{oc}}{mkT}-1\right)\text{ and}$$

$$\text{finally}: I = I_s\left(\exp\frac{eU_{oc}}{mkT}-\exp\frac{eU}{mkT}\right).$$

For an exact description, however, we replace the single-diode electrical model with a two-diode equivalent circuit, which has two resistors: r_s is the series resistance of the cell, which consists of a number of components, and r_p is the effect of all defects in the crystal in the p–n junction area and is a shunt resistor (Figure 6).

In this model, the current generated is described as a function of the cell voltage as follows:[2]

$$I = I_{s1}\left(\exp\frac{e(U-Ir_s)}{m_1kT}-1\right)+I_{s2}\left(\exp\frac{e(U-Ir_s)}{m_2kT}-1\right)+\frac{U-Ir_s}{r_p}-I_{ph}$$

where I_{ph} is the photoelectric current, I_{s1} and I_{s2} are saturation currents, and m_1 and m_2 are non-ideality factors of the characteristics of the two diodes.

The parameters of the model are defined in such a way as to ensure that the above equation gives a good description of the real characteristic of a photovoltaic cell. The first exponential term in the characteristic equation represents the diffusion current, whereas the second one represents the recombination currents in the entire cell, particularly in the space charge region. The characteristics, which also enable the parameters of the two-diode model to be determined, are measured when the cell is polarized in the

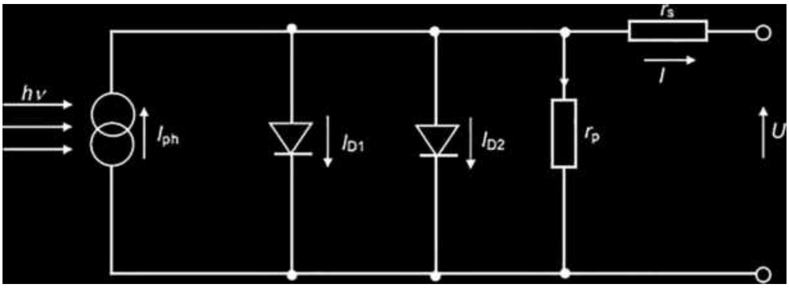

FIGURE 6 Equivalent circuit of a two-diode model of a solar cell.
Source: Stutenbaeumer and Masfin.[1]

forward direction and in the complete absence of any illumination, the dark current being measured as a function of the external voltage.

Solar Cell Characteristics

The usable voltage from solar cells depends on the semiconductor material. In silicon cells, it amounts to approximately 0.6 V.

Under illumination, the fourth quadrant of the light I–U is the region of interest (Figure 7), and the figures of merit for the device are the following:

1. The open-circuit voltage (U_{oc}) is the maximum voltage obtainable under open-circuit conditions (Figure 8).
2. The short-circuit current (I_{sc}) is the maximum current through the load under short-circuit conditions (Figure 8).
3. Fill factor (*FF*).

The output voltage of the photovoltaic cell is only slightly dependent on irradiance, while the current intensity increases with intensity of insolation. The working point of the solar cell therefore depends on load and insolation. In addition, the output voltage of a solar cell is temperature dependent. A higher cell working temperature leads to lower output and, hence, to lower efficiency (Figure 9)

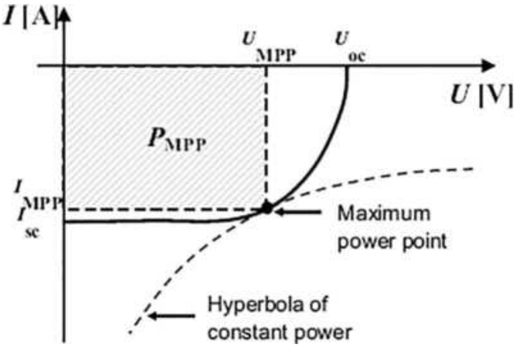

FIGURE 7 Current–voltage characteristic of illuminated photovoltaic solar cell.

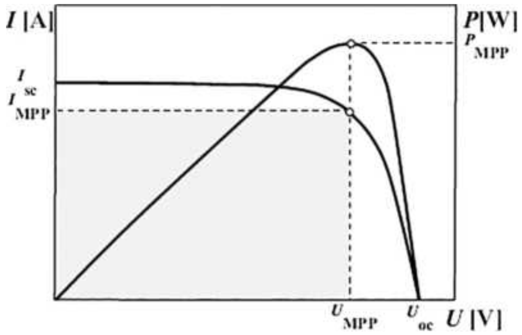

FIGURE 8 Current–voltage and power–voltage characteristics of the solar cell.

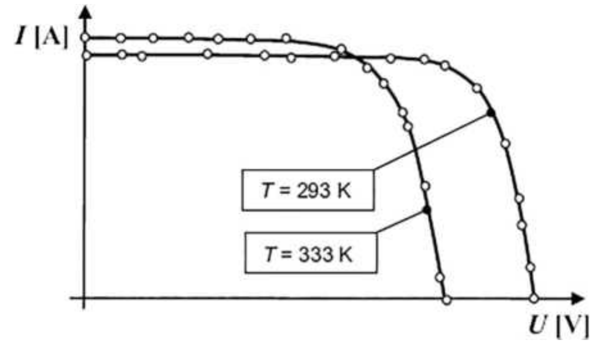

FIGURE 9 Temperature dependence of the solar cell characteristic.
Source: Radziemska and Klugmann.[3]

An important parameter as regards the application of a PV module in photovoltaics is the peak power obtainable from the module at the load resistance R_{opt}, where the rectangle under the characteristic $I(U)$ has the maximum area equal to the maximum power $P_{\text{mpp}} = I_{\text{MPP}}\, U_{\text{MPP}}$, and the point of intersection with the curve of $I(U)$ is in this case the maximum power point (MPP). The load resistance R in the cell circuit or PV module should be chosen such that the power it generates takes the maximum value, i.e., $P = \text{P}_{\text{Mpp}}$.

The MPP is the point at which the coordinates I_{MPP} and U_{MPP} form a rectangle with the largest possible area under the $I(U)$ curve.

The level of efficiency indicates how much of the radiated quantity of light is converted into usable electrical energy. The photovoltaic conversion efficiency of the cell η_{PV} is calculated from the maximum output power point (MPP) in the $I(U)$ curve:

$$\eta_{\text{pv}} = \frac{I_{\text{MPP}} I_{\text{MPP}}}{E.S_{\text{C}}}.100\%,$$

where S_{C} is the total surface of solar cell and E is the irradiance (W/m^2).

To describe solar cell quality, a special parameter—the fill factor (*FF*)—is used. It can be calculated from the following equation:

$$FF = \frac{I_{\text{MPP}} U_{\text{MPP}}}{I_{\text{sc}}.U_{\text{oc}}},$$

where I_{MPP} is the MPP current, U_{MPP} is the MPP voltage, I_{sc} is the short-circuit current, and U_{oc} is the open-circuit voltage.

For the ideal solar cell, the fill factor is a function of open-circuit parameters and can be calculated as follows:

$$FF \approx \frac{v_{\text{oc}-\ln(v_{\text{oc}}+0.72)}}{v_{\text{oc}}+1},$$

where v_{oc} is the voltage, calculated from the equation:

$$v_{\text{oc}} = U_{\text{oc}} \frac{e}{mkT},$$

where k is the Boltzmann constant = 1.38×10^{-23} J K^{-1}, T is the temperature (K), e is the charge on an electron = 1.6×10^{-19} C, and m is the diode ideality factor (–).

Solar Cell Materials: Production and Features

Silicon

The most important material for solar cell production is silicon. At the present time, it is almost the only material used for the mass production of solar cells. Being the most often used semiconductor material, it has some important advantages.

In nature, it is readily found in large quantities. Silicon dioxide forms one-third of the Earth's crust. It is environmentally friendly and not poisonous, and its waste does not cause any problems. It is easily melted and handled and it is fairly easy cast into its monocrystalline form. Its electrical properties, which remain unchanged up to temperatures of 125°C, allow the use of silicon semiconductor devices even in the harshest environments and applications.

In technology, pure silicon is the only widely used chemical element produced at such a high level of purity. The percentage of pure silicon in "pure silicon" is at least 99.9999999%. The concentration of silicon is 5×10^{22} atoms/cm^3, which means 5×10^{13} impure atoms/cm^3. Quantities of impure atoms are measured using sophisticated physical methods like mass spectrometry.

Pure silicon is produced from sand (silicon dioxide—SiO_2) by reduction at carbon electrodes at 1800°C in specially designed furnaces. The final material contains 98%–99% pure silicon. The complete reaction is:

$$\mathrm{SiO_2 + C \rightarrow Si + CO_2}.$$

Such silicon is the raw material for the production of pure silicon. It is also used in steel and aluminium production as a supplementary material. The most important producers of raw silicon are Canada, Norway, and Brazil. Fifteen to twenty-five kilowatt-hours of electrical energy is needed to produce 1kg of silicon. Silicon tetrachloride (tetrachlorosilane) gas is obtained by the chlorination of finely ground metallurgical-grade silicon in a special reactor. Additions or impurities are eliminated in the form of chlorine salt.

$$\mathrm{Si + 2CI \rightarrow SiCI_4}.$$

The following reaction produces trichlorosilane gas:

$$\mathrm{SiCI_2 + HCI \rightarrow SiHCI_3} \qquad .$$

This gas is then further purified with the removal of any remaining tetrachlorosilane and other silanes. The purification is followed by reduction in a hydrogen atmosphere at 950°C:

$$\mathrm{4SiHCl_3 + H_2 \rightarrow 2Si + SiCl_4 + SiCl_2 + 6HCl}.$$

Besides pure silicon, the procedure yields a number of gaseous by-products, which condense outside the reactor. Tetrachlorosilane is one of these by-products. At 1200°C, it can be converted into trichlorosilane using the following reaction:

$$\mathrm{SiCl_4 + H_2 \rightarrow SiHCl_3 + HCl}$$

This example illustrates one possible way of producing pure silicon. There are other procedures using different chemical reactions, but the end product is the same—pure silicon.

Crystalline Silicon Solar Cells

Polycrystalline as well as monocrystalline solar cells belong to this group. The basic form for crystalline solar cell production is the silicon ingot (see the description of the production procedure above). The ingot (block of silicon), cut with a diamond saw into thin wafers, is the basis of solar cell production. One-millimeter-thick wafers sawn accurate to 1/10 mm are placed between two plane-parallel metal plates rotating in opposite directions. This procedure enables the wafer thickness to be adjusted to within 1/1000 mm. The subsequent procedure for solar cell production consists of the following steps:

- Doped wafers are first etched some micrometers deep. The procedure removes crystal structure irregularities caused by sawing and cleans the wafer. During the extraction of pure silicon, the material is doped either as powdered polycrystalline silicon or by the addition of a suitable gas. This is then followed by diffusion. Phosphorus, supplied inside the material in gaseous form, diffuses at 800°C. The n-doped layer and the p-rich oxide layer form on top of the wafers as a result of reaction with oxygen.
- The wafers are then folded to form a cube and etched in oxygen plasma, which removes the n-doped layer from the edges. Wet chemical etching then removes the oxide layers from the top of the wafer.
- At the rear, the contact surface is produced from silver containing 1% aluminium. Special procedures enable silver to be printed over mask on cell surface. The pressed cells are then sintered at high temperatures. A similar procedure is used to print the contacts on the front cell surface, and the anti-reflex layer is applied likewise. In this case, titanium paste is used, which, on sintering, forms titanium dioxide (TiO_2) or silicon nitride (Si_3N_4).

Polycrystalline Silicon Production

The extraction of pure polycrystalline silicon from trichlorosilane can be carried out in special furnaces, such as those developed by Siemens. The furnaces are heated by electric current, which, in most cases, flows through silicon electrodes. These 2 m long electrodes are 8 mm in diameter. The current flowing through the electrodes can be as much as 6000 A. The furnace walls are cooled to prevent the formation of unwanted reactions producing gaseous by-products. The procedure yields pure polycrystalline silicon, which is used as a raw material for solar cell production. Polycrystalline silicon can be extracted from silicon by heating it up to 1500°C and then cooling it down to 1412°C, which is just above the melting point of the material. As material cools, a 40 × 40 × 30 cm ingot of fibrous polycrystalline silicon forms.

Monocrystalline Silicon Production

Two different technological procedures are used to produce monocrystalline silicon from pure silicon.

Czochralski's Method

In 1918, the Polish scientist Jan Czochralski discovered a method for producing monocrystalline silicon, from which monocrystalline solar cells could be manufactured. The first monocrystalline silicon solar cell was constructed in 1941. In Czochralski's method, silicon is extracted from the melt in a graphite-lined induction oven at a temperature of 1415°C. A silicon crystal with a set orientation is placed on a rod. Spinning the rod in the melt makes the crystal grow. The rod spins at 10 to 40 revolutions per minute and grows in length at a rate of between 1 μm and 1 mm per second. This allows the production of rods measuring 30 cm in diameter and several meters in length. The whole process takes place in an inert atmosphere. Possible impurities are burnt or eliminated in the melt.

Float Zone Method

With this method, monocrystalline silicon is produced from polycrystalline silicon. The main advantage of this procedure over the previous one is the better yield of pure silicon.

The silicon rods produced measure 1 m in length and 10 cm in diameter. This procedure, in which an induction heater travels along the rod melting the silicon, also takes place in an inert atmosphere. Monocrystalline silicon is produced during the cooling stage. Monocrystalline or polycrystalline silicon ingots are then sawn and the wafers are worked upon until they can serve as a foundation for solar cell production. Sawing causes approximately 50% of the material to be wasted.

Amorphous Solar Cells

Amorphous silicon is produced in high-frequency furnaces under partial vacuum. In the presence of a high-frequency electrical field, gases like silane, B_2H_6, or PH_3 are blown through the furnaces, supplying silicon with boron and phosphorus.

Amorphous solar cells are produced with technologies similar to those used in the manufacture of integrated circuits. Due to this procedure, these modules are also known as thin-film solar cells (thin-film modules). Here is a brief summary of amorphous solar cell production:

- The glass substrate is cleaned thoroughly.
- The lower contact layer is applied.
- The surface is then structured—it is divided into bands.
- The amorphous silicon layer is applied under vacuum and in the presence of a high-frequency electric field.
- The surface is rebanded.
- The upper metal electrodes are fixed.

Other Solar Cells

The less frequently used solar cell types include solar cells produced by the EFG (edge-defined film-fed growth) method, as well as Apex solar cells made from silicon, cadmium telluride (CdTe) solar cells, and copper-indium selenide (CIS) solar cells. EFG monocrystalline solar cells are produced directly from the silicon melt, which eliminates wafer sawing; production costs are thus lower and material is saved since there is no “sawdust.” In the EFG procedure, an octagonal tube of silicon, several meters long, is extruded from the silicon melt. The flat sides of this tube are then laser sawn into separate solar cells. Most solar cells are square in shape and 100 × 100 mm in size. Consequently, the module power is greater with a smaller surface compared to crystal modules of square cells with truncated sides. Contacts take the form of copper bands. The separate cells are then combined in the same way as other cell types.

EFG cells are produced by Schott Solar. In contrast to EFG cells, Apex cells are polycrystalline. Their production procedure is protected by patent. The production procedure was developed by Astropower Inc.

Cadmium Telluride

Thin-film material produced by deposition or by sputtering is a promising low-cost foundation for photovoltaic applications in the future. The disadvantage of this procedure, however, is that the materials used in production are toxic. The efficiency of solar cells in the laboratory is as high as 16%, but that of commercial types is only 8%.

Copper-Indium-Diselenide ($CuInSe_2$, or CIS)

$CuInSe_2$ is a thin-film material with an efficiency of up to 17%. The material is promising, but not yet widely used owing to production-specific problems. CdTe and CIS cells have so far been used mostly in laboratory research. Commercial modules made from these materials are still hard to find.

Gallium Arsenide (GaAs)

GaAs is used in the production of high-efficiency solar cells. It is often utilized in concentrated PV systems and space applications. Their efficiency is as good as 25%, and even 28% at concentrated solar radiation. Special types have an efficiency of more than 30%.

Structure and Manufacture of Photovoltaic Cells from Crystalline Silicon

In principle, a photovoltaic cell consists of the following elements (see Figure 10):

- A mono-or polycrystalline silicon wafer in which a p–n junction has been formed.
- Contacts, i.e., the front and rear electrodes; the front one should be shaped in such a way that the maximum amount of incident radiation can reach the junction region, the depth of which is limited by the permeability of silicon to radiation.
- An antireflective coating (ARC) on the front side of the cell.

The manufacture of a crystalline cell takes place in the following stages.

Surface Preparation

The surfaces of silicon wafers, cut from monocrystalline ingots, are degreased, cleaned, polished (mechanically or chemically), and etched in an aqueous solution of sodium hydroxide (40% NaOH) at a temperature of 383 K. A pyramidal surface structure is thereby obtained, which is then rinsed in hydrochloric or nitric acid. Dry (plasma) etching is also possible.

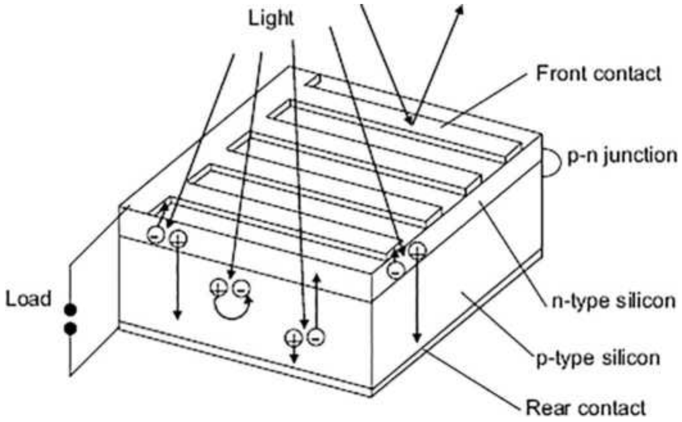

FIGURE 10 The structure and functioning of a photovoltaic cell (not to scale).

Diffusion Formation of a p–n Junction

A dopant, usually an acceptor, is added to the silicon base during crystal growth, whereas the n–p junction is produced by the diffusion of a dopant (usually a donor) to the p-type base wafer across one of its surfaces. If the donor concentration in the subsurface layer of the silicon (initially p-type) is greater than the acceptor concentration, this layer then becomes an n-type semiconductor.

The source of the dopant may be a solid or a gas. There are a number of techniques involving diffusion from the solid phase:

- Vacuum deposition of a thin layer of dopant
- Doping a vacuum-deposited layer of SiO_2
- Doping a mechanically deposited or screen-printed layer of SiO_2
- Coating the silicon wafer with a material containing phosphorus and silicon dioxide

If the diffusion of phosphorus to silicon is carried out at a temperature of 1220 K, 10 min are sufficient to obtain an n-type layer 0.25 μm in thickness.

Formation of an p–n Junction by Ion Implantation

Ion implantation is a technique for obtaining shallow, abrupt n–p junctions; it allows precise control of junction depth and dopant concentration. It is based on the implantation of dopant ions into silicon when its surface is bombarded with a beam of ions (of the order of 10^{16} ions/cm^2) of energy 5–300 keV.

The depth of the junction depends on the energy of the ions. A drawback of this method it that its gives rise to a large number of structural defects in the silicon; these can be removed after implantation by either heating the silicon wafer or irradiating it with an electron or laser beam. Ion implantation is quite a costly method—the necessary equipment (ion source, ion separator and accelerator, vacuum) is expensive.

Passivation of the Silicon Surface

Both the quantum efficiency for blue light and the open circuit voltage can be considerably enhanced if the front surface of the silicon is passivated. This is easily done with a layer of silicon dioxide, which forms on the surface when this oxidizes. Such a thin layer of SiO_2 of controlled thickness can be obtained by heating the silicon wafer in a stream of neutral gas like nitrogen containing a small quantity of dry oxygen. In the cells designed by Green, there is also a very thin layer of SiO_2 (ca. 2 nm thick) underneath the metal front electrode.

Metal Contacts

Since cells are an integral part of an electrical installation, metal contacts are made on either side of the cell. The front electrode is a fine grid, so as to reduce shading of the light-sensitive surface to a minimum. The “fingers” are ca. 0.1 mm wide, and the bus bar is from 1.5 to 2 mm wide. During the module’s construction, the bus bar is connected to the rear electrode of the adjacent cell by means of copper strips soldered to it.

The metallic layers in a cell should be in ohmic contact with the silicon and have a low contact resistance, good adhesion to the silicon surface, and good soldering properties. Various techniques are used worldwide for producing metal contacts fulfilling these requirements.

Unlike the front electrode, the rear one can cover the entire area of the wafer. To improve efficiency, the rear electrode is made from a layer of aluminium vacuum deposited on the silicon surface between silver contacts in the form of strips or squares 2.5–6 mm wide. When this electrode is heated at temperatures from 770 to 1070 K, aluminium diffuses to the silicon forming a thin p^+ layer. To obtain a $p–p^+$

junction, the p^+ layer must be far thicker (0.2 μm); this is achieved by heating the cell to a temperature of 970–1070 K.

A very much cheaper method of making the two electrodes is the chemical deposition of nickel, or screen printing using a paste containing silver, aluminium, copper, or some other metal. Screen printing is a method that was used to produce lettering with a stencil over a thousand years ago. In 1975, it was first used in silicon cell technology to deposit the front and rear electrodes, thus replacing the costly vacuum deposition technique.

Silver paste is used for producing the front electrode, while aluminium paste combined with a small quantity of silver is usually used for the rear one. The silver pastes used for screen printing metal contacts on a silicon surface consist of a conducting phase (powdered silver of grain size 1–3 pm), an auxiliary phase (assisting the sintering of solid-phase grains—an enamel formed from the melting of a mixture of inorganic oxides), and an organic carrier facilitating the screen-printing process, which is burnt off when the layer is fired. The silver layers are usually sintered at 850°C.

About 86% of the silicon cells produced in 2006 had screen-printed metal contacts. At present, standard silicon cells with screen-printed electrodes achieve an efficiency of around 15% if they are polycrystalline and ca. 18% if they are monocrystalline (produced by Czochralski's method). During the screen printing of metal contacts, the mesh must be placed at a constant distance from the front side of the wafer. Silver paste is applied to the mesh and then imprinted using two squeegees. To ensure that the paste properly fills all the openings in the mesh, one squeegee moves along it, spreading the paste down its whole length. The other squeegee then applies just enough pressure to force the paste out of the mesh openings onto the wafer surface. After drying at 120°C for ca. 60 min, the printed layer consists of an aggregation of loose grains 1–2 μm in size; this must now be fired in order to impart stability to the layer.[4]

Cells with Rear Contacts

In cells of this type, both the positive and negative contacts are made on the rear surface of the cell. In this way, the whole of the front light-sensitive surface can be used to harvest light and the space between the cells can be minimized. The SunPower company produces commercial cells and modules of this type from n-type monocrystalline silicon—the efficiency of the cells is 21.5%, and that of the modules is 18.6%. The p–n junction is produced in the lower layer in the form of bands. This means that the photogenerated charges have to cover quite a long distance to reach the junction region, so only high-quality silicon is suitable for this type of cell.

Deposition of *the ARC*

One of the most significant parameters affecting the efficiency of a cell is the coefficient of light reflection from its surface—in the case of silicon, this is 33%–54%. This can be minimized by applying a transparent ARC to the cell's active surface.

ARCs can be applied in various ways: chemical vapor deposition (CVD), spraying, spin-on, and screen printing. The spin-on technique is the simplest one, as it does not require expensive equipment and is very efficient, but it can only be usefully applied to silicon wafers with a smooth, polished surface. If the wafer surface is textured, the ARC obtained in this way will not be of uniform thickness. Plasma-enhanced chemical vapor deposition (PECVD) produces ARCs with very good refractive index, photonic band gap, homogeneity, chemical composition, and controlled thickness. The surfaces of silicon wafers are usually coated with one or two antireflective layers.

The presence of an ARC is responsible for the color of the cells: polycrystalline cells are blue and monocrystalline ones are dark blue to black. By optimizing the thickness of the ARC, it is now possible to produce cells that are green, gold, brown, and violet in color, but this is only at the expense of their efficiency. One can, of course, do without the ARC and apply the cells in their original silver (polycrystalline) or dark gray (monocrystalline) colors; depending on architectural requirements, solar panels without an ARC can be integrated, for example, into the façades of buildings.

Dye-Sensitized Solar Cells

Dye-sensitized cells (DSCs) imitate the way that plants and certain algae convert sunlight into energy. The cells are inexpensive, easy to produce, and can withstand long exposure to light and heat compared with traditional silicon-based solar cells. This is a relatively new class of low-cost solar cell. It is based on a semiconductor formed between a photosensitized anode and an electrolyte, a photoelectrochemical system.

The fruits, flowers, and leaves of plants are tiny factories in which sunlight converts carbon dioxide gas and water into carbohydrates and oxygen. Although not very efficient, they are very effective over a wide range of sunlight conditions. Despite the low efficiency and the fact that the leaves must be replaced, the process has worked for hundreds of millions of years and forms the primary energy source for all life on earth. On the basis of this principle, there were early attempts to cover crystals of semiconductor titanium dioxide with a layer of chlorophyll. Unfortunately, the efficiency of the first solar cells sensitized in this way was about 0.01%. In 1991, Michael Grätzel and Brian O'Regan at the École Polytechnique Fédérale de Lausanne (Switzerland) used a sponge of small particles, each about 20 nm in diameter, coated with an extremely thin layer of pigment to obtain the effective surface area available for absorbing light.[5] These dye-sensitized solar cells (DSSCs or DSCs) are also known as Grätzel cells. Following much academic research, the energy conversion efficiency of laboratory cells made on glass substrates with liquid electrolytes has steadily increased to around 10% at air mass 1.5, 1 Sun conditions (for testing, the cells, regardless of design and active material, are typically insolated at a constant density of roughly 1000 W/m^2, which is defined as the standard 1 Sun value).

Dye-sensitized photoelectrochemical solar cells differ from conventional photovoltaic solar cells in that they separate the function of light absorption from charge carrier transport. The cells are made up of a porous film of tiny (nanometer sized) white pigment particles of titanium dioxide. These are covered with a layer of dye that is in contact with an electrolyte solution. Photoexcitation of the dye results in the injection of an electron into the conduction band of the oxide. The original state of the dye is subsequently restored by electron donation from a redox system, such as the iodide/tri-iodide couple. This process results in the conversion of sunlight into electrical energy.

In the case of the original Grätzel design, the cell has three primary parts. On the top is a transparent anode made of fluorine-doped tin dioxide (SnO_2:F) deposited on the back of a (typically glass) plate. On the back of the conductive plate, a thin layer of titanium dioxide (TiO_2) is deposited, which forms into a highly porous structure with an extremely high surface area. The plate is then immersed in a mixture of a photosensitive ruthenium-polypyridine dye and a solvent. After the film has been soaked in the dye solution, a thin layer of the dye is left covalently bonded to the surface of the TiO_2. A separate backing is made with a thin layer of the iodide electrolyte spread over a conductive sheet, typically platinum metal. The front and back parts are then joined and sealed together to prevent the electrolyte from leaking. The construction is simple enough that there are hobby kits available for hand-constructing them. Although they use a number of advanced materials, these are inexpensive compared to the silicon needed for normal cells because they require no expensive manufacturing steps. TiO_2, for instance, is already widely used as a paint base.

Principles

DSSCs separate the two functions typical of a traditional silicon cell design. In the crystalline silicon solar cells, the silicon acts as the source of photoelectrons and provides the electric field to separate the charges and produce the current.

In the DSSC, the bulk of the semiconductor is used solely for charge transport, while the photoelectrons are provided from a separate photosensitive dye. Charge separation occurs at the semiconductor/dye/electrolyte interface.

Although photoelectrochemical cells can operate without an organic dye, the efficiency of such cells is very low due to the low light-harvesting ability of inorganic n-conductors, which normally absorb light only from the high-energy ultraviolet region of the solar spectrum. The introduction of an organic dye makes for a significant increase in the absorption ability of the cells that extends across almost the entire solar spectrum.

DSC Structure

The structure of currently produced DSSCs is similar to those produced by Grätzel and O'Regan: on the top, there is a transparent anode made of indium tin oxide (ITO), deposited on the back of a glass plate. ITO (or tin-doped indium oxide) is a solid solution of indium (III) oxide (In_2O_3) and tin (IV) oxide (SnO_2), typically 90% In_2O_3 + 10% SnO_2 by weight. In thin layers, it is transparent and colorless, but in bulk form, it is yellowish to gray. In the infrared region of the spectrum, it is a metal-like mirror. ITO's main feature is the combination of electrical conductivity and optical transparency. A compromise has to be reached during film deposition, as a high concentration of charge carriers will increase the material's conductivity but decrease its transparency. Thin films of ITO are most commonly deposited on surfaces by electron beam evaporation or a range of sputter deposition techniques.

The thin oxide coating on one side of the glass makes the glass surface electrically conducting. On the back of the conductive plate, a thin layer of titanium dioxide (TiO_2) is deposited, which forms into a highly porous structure with an extremely high surface area—a 10 μm layer of randomly stacked nanoparticles (ca. 20 nm in diameter) (Figure 11).

The plate is then immersed in a mixture of a photosensitive ruthenium–polypyridine dye and a solvent. After the film has been soaked in the dye solution, a thin layer of the dye is left covalently bonded to the surface of the TiO_2. A separate backing is made with a thin layer of the iodide electrolyte spread over a conductive sheet, typically platinum metal. The front and back parts are then joined and sealed together to prevent the electrolyte from leaking. Sunlight enters the cell through the transparent top contact, striking the dye on the surface of the TiO_2.

Titanium Dioxide

Titanium dioxide, also known as titanium(IV) oxide or titania, is the naturally occurring oxide of titanium TiO_2. When used as a pigment, it is called titanium white.

Titanium dioxide occurs in nature as the well-known, naturally occurring minerals rutile (the most common and stable form), anatase, and brookite. Crude titanium dioxide is purified via titanium tetrachloride in the chloride process. In this process, the crude ore (containing at least 90% TiO_2) is reduced with carbon, oxidized with chlorine to give titanium tetrachloride.

This titanium tetrachloride is distilled and then reoxidized with oxygen to give pure titanium dioxide. Another widely used process utilizes ilmenite as the titanium dioxide source, which is digested in sulfuric acid (as in Millennium Inorganic Chemicals). The by-product, iron(II) sulfate, is crystallized

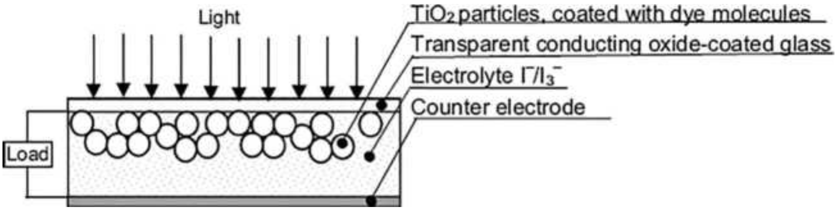

FIGURE 11 DSC structure.

and filtered off to yield only the titanium salt in the digestion solution, which is processed further to yield pure titanium dioxide.

The TiO_2 semiconductor has three functions in the DSSC:

1. It provides the surface for the dye adsorption.
2. It functions as electron acceptor for the excited dye.
3. It serves as electron conductor.

Colloid preparation and layer deposition have been developed to optimize the TiO_2 for these functions. Most important for the performance of desensitized solar cells was the development of a mesoporous semiconductor structure. This becomes evident considering the limited light capture of a dye monolayer on a flat surface.

The conductivity of nanophase TiO_2 films in a vacuum has been found to be very low, $\sim 10^{-9}$ $(\Omega \text{ cm})^{-1}$ at room temperature.[6] However, on exposure to UV light, the conductivity is much increased, indicating that the low conductivity in the dark is due to the low electron concentration in the conduction band rather than to poor electrical contacts between the particles.

Untreated TiO_2 is an insulator that becomes "photodoped" and therefore conductive following electron injection of the adsorbed dye. Electronic contact between the nanoparticles is established by sintering the nanoparticles together, which enables the entire surface-adsorbed molecular layer to be accessed electronically. The interconnection of the nanoparticles by the sintering process allows the deposition of a mechanically stable, transparent film, typically a few microns thick. It is not necessary to increase the free electron concentration in the dark; indeed, this may even be detrimental to the photoelectrochemical behavior of the TiO_2. Among several semiconductors studied for photoelectrochemical applications, TiO_2 is by far the most commonly used, because of its energetic properties, its stability, and the ability to attach dyes. It is, furthermore, a low-cost material that is widely available. TiO_2 is used in its low-temperature stable form anatase (pyramid-like crystals), as rutile shows non-negligible absorption in the near-UV region (350–400 nm). This excitation within the band gap leads to the generation of holes, which are strong oxidants and cause long-term instability issues in the solar cell.

Mechanism of Operation

Photons striking the dye with enough energy to be absorbed will create an excited state in the dye, from which an electron can be injected directly into the conduction band of the TiO_2, and from where it moves by diffusion (as a result of an electron concentration gradient) to the clear anode on top (Figure 12).

Meanwhile, the dye molecule has lost an electron and the molecule will decompose if another electron is not provided. The dye strips one from the iodide in the electrolyte below the TiO_2, oxidizing it to tri-iodide. This reaction occurs quite quickly compared to the time that it takes for the injected electron to recombine with the oxidized dye molecule, thus preventing the recombination reaction that would

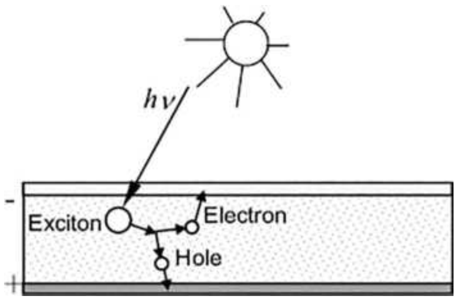

FIGURE 12 Photogeneration of charge carriers in DSC.

effectively short-circuit the solar cell. The tri-iodide then recovers its missing electron by mechanically diffusing to the bottom of the cell, where the counter electrode reintroduces the electrons flowing through the external circuit.

The dye-sensitized oxide is usually deposited on a highly doped transparent conducting oxide (TCO), which allows light transmission while providing sufficient conductivity for current collection. Recently, high-conductivity organic polymers deposited onto plastic foil have found increasing application as substrates for flexible devices. The conductivities of metal foils are superior to those of TCOs and polymers. Because of their opacity, the illumination of the cell has to be established through the counter electrode. The surface of TCO should make good mechanical and electrical contact with the porous TiO_2 film.

To reduce dark current losses due to the short-circuiting of electrons in the substrate with holes in the hole conductor, a thin underlayer of TiO_2 is introduced between the SnO_2 layer and the nanocrystalline TiO_2 layer. This thin compact layer improves the mechanical adhesion of the porous TiO_2 film to the substrates, especially to SnO_2 layers of low haze, i.e., layers with less surface roughness and thus less contact area. Figure 13 illustrates a model of charge carrier separation and charge transport in a nanocrystalline film.[7] The electrolyte is in contact with the individual nanocrystallites. Illumination produces an electron–hole pair in one crystallite. The hole transfers to the electrolyte and the electron traverses several crystallites before reaching the substrate.

The photogenerated hole always has a short distance (roughly equal to the particle radius) to cover before reaching the semiconductor–electrolyte interface whenever an electron–hole pair is created in the nanoporous film. However, the probability that the electron will recombine depends on the distance between the photoexcited particle and the back contact.

The mechanism for converting solar energy into electrical energy in a DSSC is a five-step process:

1. Solar energy (photons of light *hv*) causes electrons in the molecular orbitals within the adsorbed dye sensitizer (S) molecules to become photoexcited (S*):

   S (adsorbed on TiO_2) + $hv \rightarrow$ S* (adsorbed on TiO_2)

   The trapping of solar energy by a sensitizer molecule is analogous to the light-absorbing chlorophyll molecule found in nature, which converts carbon dioxide and water to glucose and oxygen.

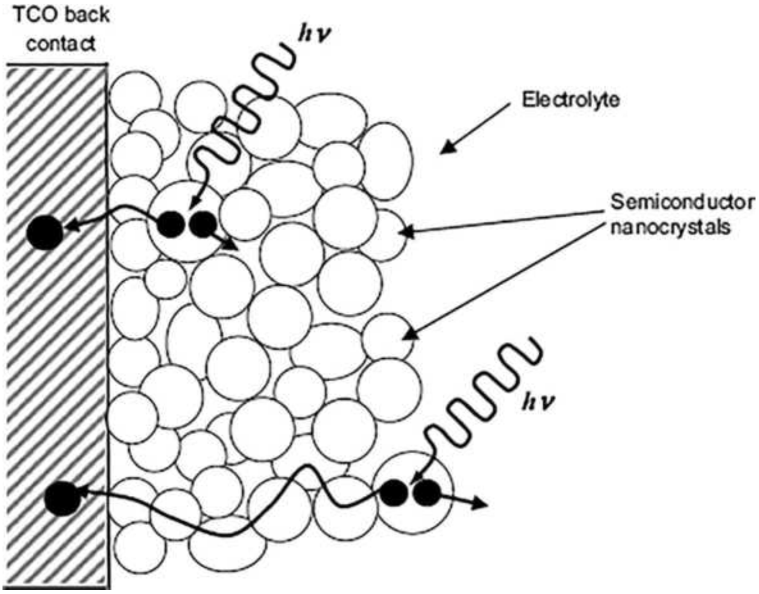

FIGURE 13 Qualitative model of photocurrent generation in nanocrystalline films.

2. The excited electrons escape from the dye molecules: S* (adsorbed on TiO_2) → S^+ (adsorbed on TiO_2) + e^-
3. The free electrons then move through the conduction band of TiO_2, gather at the anode (the dyed TiO_2 plate), and then start to flow as an electric current through the external load to the counter electrode.
4. The oxidized dye (S^+) is reduced to the original form (S) by regaining electrons from the organic electrolyte solution that contains the iodide/tri-iodide redox system, with the iodide ions being oxidized (loss of electrons) to tri-iodide ions:
   S^+ (adsorbed on TiO_2) + 3/2 I^- → S (adsorbed on TiO_2) + 1/2 I_3^-
5. To restore the iodide ions, free electrons at the counter (graphite) electrode (which have travelled around the circuit) reduce the tri-iodide molecules back to their iodide state. The dye molecules are then ready for the next excitation/oxidation/reduction cycle.

Initially, the solutions of iodine–iodide mixtures in volatile solvents, usually acetonitrile, were used as redox electrolytes:

Electrolyte:	I2 + I– ↔ I3–
Anode (Dye):	2 Dye+ + 3 I– → 2 Dye0 + I3–
Cathode:	I3– + 2e– → 3 I–

On the basis of different measurements, it is possible to indicate the orders of magnitude for the rate of the reaction steps. Upon illumination, the sensitizer is photoexcited in a few femtoseconds and electron injection is ultrafast from S* to TiO_2 on the subpicosecond time scale, where they are rapidly (less than 10 fs) thermalized by lattice collisions and phonon emissions. The nanosecond-ranged relaxation of S* is rather slow compared to injection, which ensures that the injection efficiency is unity. The ground state of the sensitizer is then recuperated by I^- in the microsecond domain, effectively annihilating S^+ and intercepting the recombination of electrons in TiO_2 with S^+, which happens in the millisecond time range. This is followed by the two most important processes—electron percolation across the nanocrystalline film and redox capture of the electron by the oxidized relay, I_3^-, within milliseconds or even seconds.[8]

Recently, solvent-free redox electrolytes, prepared from ionic liquids (liquid ionic organic compounds) or from ionically conducting polymer–nanocrystal blends were found to be very efficient. Figure 14 shows the processes taking place during the conversion of light into electrons in a DSSC.

Upon excitation, the dye injects electrons into the conduction band of the titanium oxide. The photo-induced electrons diffuse through the porous TiO_2 network and are extracted at the SnO_2 substrate. The dye itself is regenerated by the electrolyte containing the I^-/I_3^- redox pair. In the most efficient DSCs, the dye is regenerated by I^-, present in an external electrolyte at high (~0.45 M) concentrations.[10] The electronic circuit is closed by the reduction of the iodide couple at the platinized SnO_2 counter electrode.

Titania Solar Cells: Manufacturing Process

Manufacturing processes utilize the production methodologies and equipment already in use in the manufacture of electronic components. Production of cells needs a relatively low capital investment, the equipment does not rely on highly skilled operators, and—most importantly—the technology is environmentally friendly. A number of these manufacturing processes are protected by patents.

During production, a piece of glass is coated with fluorine-doped tin oxide and then sputtered onto a 500 nm thick layer of titanium. The layer is then anodized by placing it in an acidic bath with a mild electric current, and the titanium dioxide nanotube arrays grow to about 360 nm. The tubes are then

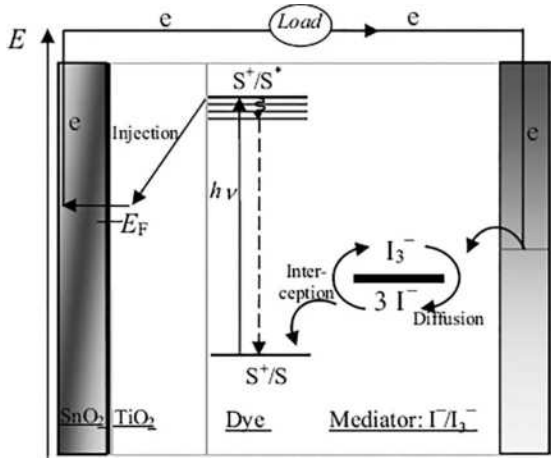

FIGURE 14 The electron processes taking place in an illuminated DSSC under open-circuit conditions.
Source: Anandan.[9]

heated in oxygen so that they crystallize. The process turns the opaque coating of titanium into a transparent coating of nanotubes.

In the next step, the nanotube array is coated with a commercially available dye—this becomes the negative electrode. The cell is sealed with a positive electrode, which contains an iodized electrolyte.

The most important advantages of the DSC manufacturing processes are as follows:

- The materials can be produced cheaply in large quantities.
- They use standard processing and assembly equipment.
- They are not very energy intensive (about 32 kWh/m^2).
- They can be automated.
- The equipment consists of a number of processing stations, each easily reprogrammable to adopt a wide range of DSC designs.

DSSCs can be connected in series or parallel and integrated into solar panels (modules). The tiles are normally ochre, but other colors such as gray, green, and blue are to be introduced shortly.

Advantages of DSC in Comparison with Other Solar Cells

The important features that distinguish a DSC from a conventional silicon crystalline solar cell are as follows:

- It is a photoelectrochemical cell: charge separation occurs at the interface between a wide band gap semiconductor and an electrolyte.
- It is a nanoparticulate titania cell: it is not a dense film like amorphous silicon, but a “light sponge.”
- In a DSC, the dye monolayer chemically absorbed on the semiconductor is a primary absorber of sunlight; free charge carriers are generated by electron injections from a dye molecule, excited by visible radiation.
- In a DSC, light absorption and charge carrier transport are separate, whereas in a conventional cell, both processes are performed by the semiconductor.
- An electric field is necessary for charge separation in the p–n junction cell. Nanoparticles in the DSC are too small to sustain a built-in field; accordingly, charge transport occurs mainly via diffusion.

- Inside a p–n junction, minority and majority charge carriers coexist in the same bulk volume. This makes conventional solar cells sensitive to bulk recombination and demands the absence of any recombination centres such as trace impurities. DSCs are majority charge carrier devices in which the electron transport occurs in the TiO_2 and the hole transport in the electrolyte. Recombination processes can therefore only occur in the form of surface recombination at the interface.
- The maximum voltage generated by DSC in theory is the difference between the Fermi level of the TiO_2 and the redox potential of the electrolyte, equal to about 0.7 V (V_{oc})—it is slightly higher than V_{oc} for silicon, which has an open cell voltage equal to 0.6 V. However, the most important differences are dominated by current production.
- Compared to other solar cells, the titania solar cell has the following advantages:
- It is much less sensitive to the angle of incidence of radiation—it can therefore utilize refracted and reflected light.
- It performs over a much wider range of light conditions owing to the high internal surface of the titania (light sponge)—it can thus be designed for operation under very poor light conditions.
- It can be designed to operate optimally over a wide range of temperatures; unlike silicon solar cells, whose performance declines with increasing temperature, DSSC devices are only negligibly influenced when the operating temperature increases from ambient to 60°C.
- There is an option for transparent modules—they can be used for daylighting, roof lighting, and displays.
- DSC production needs only commonly available (nonvacuum) processing equipment, making it appreciably cheaper to set up facilities.
- DSC has a significantly lower embodied energy than all other forms of solar cell.
- Crystalline silicon PV modules are suited to full sun applications, particularly sun tracking systems and roofs, and are best suited to cold climates and clear sky conditions.
- In contrast, the DSC is particularly suited to target markets in temperate and tropical climates, because of its good temperature stability and excellent performance under indirect radiation, during cloudy conditions, and when temporarily or permanently partially shaded.
- The DSC is 7also particularly suited to indoor applications that require stability of voltage and power output over a wide range of low-light conditions.

Comparison of Different Types of Solar Cell

Table 2 compares the different solar cell types.

Conclusion

In many countries, the decentralization of power production, the increasing proportion of energy generated from renewable sources, and the development of cogenerative systems for producing heat and electricity are viewed as the paths to be taken by energy production in the future. A secure, long-term plan for energy development that takes environmental conservation requirements into account should therefore fulfill two conditions:

- The supply of power from conventional sources should decrease.
- The proportion of energy generated from renewable sources should increase.

Electricity consumption is increasing by 1% per annum in developed countries and by ca. 5% per annum in developing countries.[11] This implies the necessity to look for sources of electrical energy other than the traditional ones. Photovoltaics is one such non-traditional source, which satisfies all the criteria now required of energy sources: solar energy is universally available, and photovoltaic cells and modules are some of the environmentally safest devices for energy conversion.

TABLE 2 Comparison of Different Types of Solar Cell (copyright: ©pvresources.com)

Material	Thickness	Efficiency (%)	Color	Features
Monocrystalline Si solar cells	0.3 mm	15–18	Dark blue, black with AR coating; gray, without AR coating	Lengthy production procedure, wafer sawing necessary. Best researched solar cell material—highest power/area ratio
Polycrystalline Si solar cells	0.3 mm	13–15	Blue, with AR coating; silver-gray, without AR coating	Wafer sawing necessary. Most important production procedure, at least for the next 10 years
Polycrystalline transparent Si solar cells	0.3 mm	10	Blue, with AR coating; silver-gray, without AR coating	Lower efficiency than monocrystalline solar cells. Attractive solar cells for different BIPV (Building Integrated Photovoltaics) applications
EFG	0.28 mm	14	Blue, with AR coating	Limited use of this production procedure. Very fast crystal growth; no wafer sawing necessary
Polycrystalline ribbon Si solar cells	0.3 mm	12	Blue, with AR coating; silver-gray, without AR coating	Limited use of this production procedure; no wafer sawing necessary. Decrease in production costs expected in the future
Apex (polycrystalline Si) solar cells	0.03 to 0.1 mm + ceramic substrate	9.5	Blue, with AR coating; silver-gray, without AR coating	Production procedure used only by one producer; no wafer sawing necessary; production in band form possible. Significant decrease in production costs expected in the future
Monocrystalline dendritic web Si solar cells	0.13 mm including contacts	13	Blue, with AR coating	Limited use of this production procedure; no wafer sawing necessary; production in band form possible
Amorphous silicon	0.0001 mm + 1 to 3 mm substrate	5–8	Red-blue, black	Lower efficiency; shorter life span. No sawing necessary; possible production in band form
CdTe	0.008 mm + 3 mm glass substrate	6 –9 (module)	Dark green, black	Toxic raw materials; significant decrease in production costs expected in the future
CIS	0.003 mm + 3 mm glass substrate	7.5 –9.5 (module)	Black	Limited supply of indium in nature. Significant decrease in production costs possible in the future
Hybrid silicon (HIT) solar cell	0.02 mm	18	Dark blue, black	Limited use of this production procedure; higher efficiency; better temperature coefficient and lower thickness

Alternative Energy: Solar Thermal Energy

Andrea Micangeli,
Sara Evangelisti, and
Danilo Sbordone

Introduction

The sun produces energy through nuclear fusion at its core, where tremendous amounts of energy are released by the fusion of nuclei into more massive nuclei under extreme conditions such as extreme pressures and temperatures. In this way, the conversion of hydrogen nuclei into the much heavier helium causes neutrinos and photons to be discharged. This energy travels through space by radiation that is a form of energy transmitted in electromagnetic waves. The energy is transferred from the core to the photosphere through the convection zone. The photosphere, or the radiating surface of the sun, is where the energy will be radiated into space. Electromagnetic radiation is mostly emitted here, though sometimes small amounts of microwave, radio, and x-ray emissions can also be emitted. A typical photon journey lasts about 100,000 years from the core of the sun to its surface, while a photon will take only 8 min from the sun's surface to reach the Earth.

Solar intensity can be measured by the Inverse Square Law, where the intensity of radiation hitting or striking objects in space, such as planets, asteroids, or dust, can be quantitatively assessed. The total energy given off by the sun is very high, owing through the tremendous energy released by nuclear fusion. Scientists estimate the energy output at 63,000,000 W/m^2 (watts per square meter).

Given the distance of the Earth from the sun, and due to the intercepting atmosphere, this figure is definitely much lower. Radiation in the outer atmosphere amounts to approximately 1367 W/m^2. Of these, only about 40% will reach the surface of the Earth as shown in Figure 1.

The solar energy that reaches the surface of the Earth can be used by a photovoltaic system to produce electricity or by a thermal system to produce heat. When the solar energy is used to produce heat, it is called *solar thermal energy* technology. In this case, the solar radiation is used to warm up a fluid (water, air, solutions appropriated to each system) that can circulate, mainly:

- In heat exchangers at the beginning of the circuit that will use the returned available heat.
- In pipes and radiant objects put in place to warm up.
- In the refrigeration cycles to evaporate the volatile substances that are used in the condensation phase.

Through the surface, rarely adjustable, the solar energy must be accumulated and transformed into thermal energy, so it is possible:

- To concentrate it through mirrors or lenses that reflect the radiation towards panels and a boiler to be able to use directly to warm water or to the production of vapor in the pipe and into a turbine.
- To collect it from applied panels or integrated panels in closure of buildings (walls, roofs, parapet, etc.)

The most important application that can be used by everyone is a *low-temperature solar thermal technology*. It consists of a system that uses a solar collector to warm up a liquid. The purpose is to capture and to transfer solar energy to produce *domestic hot water* (DHW) or to control the temperature inside a

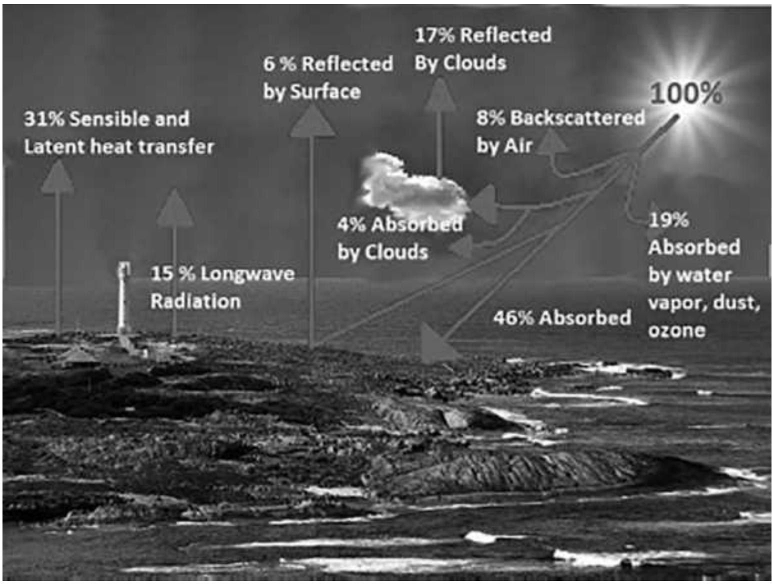

FIGURE 1 Earth's energy budget.

building. The term “low temperature” refers to the temperature that a working fluid can reach, generally up to 100–120°C.

This technology is ideal for application on a small scale, because it is cost-effective and it is simple to install and to manage. Low-temperature solar collectors can be classified as follows:

- *Flat plate collectors,* the most common type that consists of a dark flat-plate absorber of solar energy, a transparent cover that allows solar energy to pass through but reduces heat losses, a heat-transport fluid (air, antifreeze, or water) to remove heat from the absorber, and a heat-insulating backing.
- *Unglazed collectors* that are realized with tubes in plastic materials such as propylene, neoprene, synthetic rubber, and PVC. These are cheap because there is no insulation or transparent coverage. They have good performance only during summertime. They are recommended only if thermal energy for open swimming pools (and the like) is requested for.
- *Integrated collector storage,* recommended only for temperate climates, where the collector itself is the storage.
- *Evacuated tube panels*, where it is possible to eliminate the air between the capturing plate (reduced to a strip) and the evolved transparent sheet in a glass cylinder to resist the pressure difference.

The principal elements that are used by solar collectors are as follows:

- *The capturing plate*
- *The insulated material*
- *The transparent coverage*
- *The external casing*
- *The working fluid*

Solar Collector Technology

Flat-Plate Solar Collector

The *capturing plate* is realized with copper or steel and it is treated with satin and dark paint to reduce the reflection losses to bost the absorption capability to the wavelength of solar radiations with a low emissivity in the infrared radiations.

Normally, the canalizations on the plate are built to resist a pressure of about 6–7 bar; some collectors guarantee the resistance to a pressure of up to 10 bar.

The *insulated material* is a barrier against the conduction losses of the plate toward the external part of the collector. The materials used are always characterized by a porous or alveolar conformation in order to create microscopic motionless air spaces (that constitute a perfect barrier to the heat transmission). Polyurethane, polyester wool, glass wool, and rock wool are the most used materials. An enemy of the insulating material is humidity, which can appear for many reasons inside the collector (moisture, rain due to the gasket caused by little leakage in the pipes); often, the above-mentioned materials are covered with a thin aluminum layer that acts as a barrier to humidity and, at the same time, reflects towards the absorption plate.

The *transparent coverage* has the dual function of limiting the loss of energy towards the outside of the collector and facilitating the penetration of the radiation inside the collector. To satisfy this request, the coverage should be the most transparent as possible to the wavelength typical of the solar radiation (approximately between 0.2 and 2.5 mm) and at the same time it should be matt to the infrared radiation coming from the pipe-table while their temperature rises. The material that meets these qualifications is glass, above all if treated to acquire more transparency. Sometimes, due to some adverse elements, such as fragility and weight, plates made of plastic materials (polycarbonate) are preferred to glass plates.

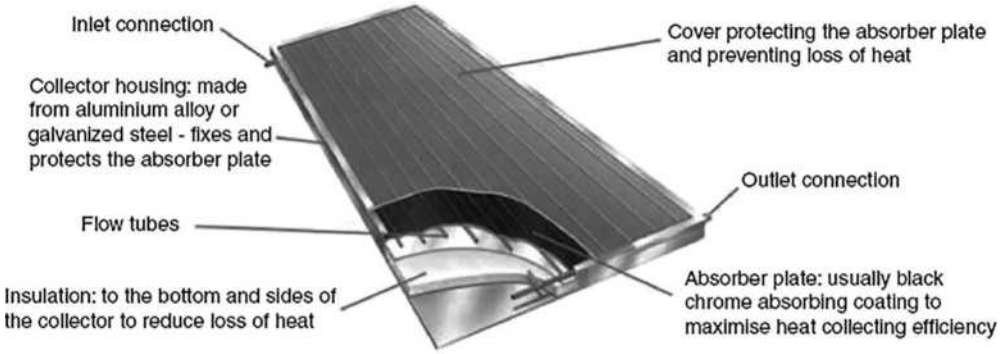

FIGURE 2 Flat plate solar collector scheme.

The *external casing* has the dual function of contributing consistency and mechanical solidity to the collector and protecting the internal elements from dirt and atmospheric agents. It can be made of stainless steel (zinced) or aluminium.

The *working fluid* that flows along the pipe system must take the largest quantity as much as possible. The fluid should also have a high density even at high temperature. It is important that it does not have a corrosive effect along the wall of the circuit; it must be inert and stable at temperatures below 100°C, and it should also have limited hardness to avoid limestone deposits. The hardness of the water refers to the quantity of magnesium and calcium salts in the water. The fluid should have a low freezing point. The option used among the producers of solar panels is a water solution of propylene glycol (not toxic and has a good anti-freezing action). In Figure 2, a section of a flat plate collector with all components is shown.

Unglazed or Open Collectors

An *unglazed collector* is a simple form of flat-plate collector without a transparent cover. Typically, polypropylene, Ethylene-Propylene Diene Monomer (EPDM) rubber, or silicone rubber is used as an absorber as shown in the left panel of Figure 3. Used for pool heating, they can work quite well when the desired output temperature is near the ambient temperature (i.e., when it is warm outside); moreover, they are cost-effective. As the ambient temperature gets cooler, these collectors become less effective. They can be used as preheat make-up ventilation air in commercial, industrial, and institutional buildings with a high ventilation load. They are called “transpired solar panels,” and they employ a painted perforated metal solar heat absorber that also serves as the exterior wall surface of the building. Heat conducts from the absorber surface to the 1mm thick thermal boundary layer of air on the outside of the absorber and to air that passes behind the absorber. The boundary layer of air is drawn into a nearby perforation before the heat can escape by convection to the outside air. The heated air is then drawn from behind the absorber plate into the building’s ventilation system (Figure 3, right panel).

Integrated Collector Storage

An *integrated collector* storage system is constituted by a unique element that assumes the role of capturing plate, absorber, and external accumulation. In this type of solar collector, the storage is located in the collector itself, and it is exposed to a slow heating process.

The water is placed inside the insulated tank and in this case the heat losses due to the exposure surface cannot be ignored. The integrated collector storage works without pumps or electrical devices: the panel absorbs the solar energy and the water inside the collector rises up for conduction, moving towards the outlet pipe and reaching the domestic network when hot water is required (see Figure 4).

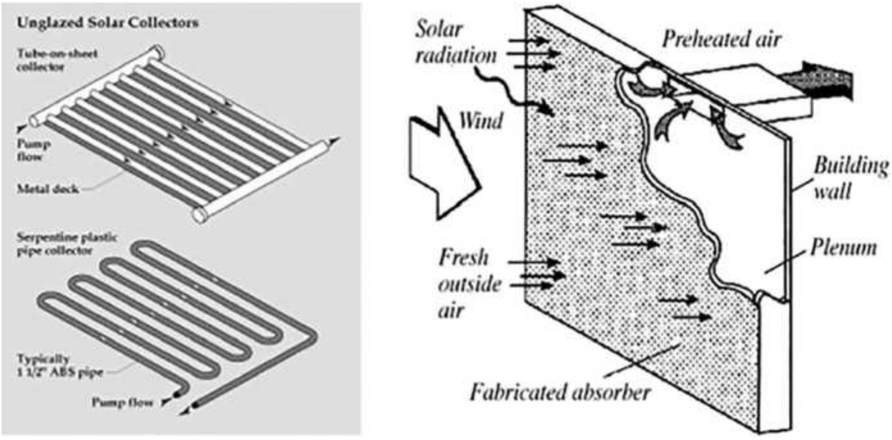

FIGURE 3 Unglazed solar collector scheme.

FIGURE 4 Example of an integrated collector storage system.

The performance of such equipment is not fully satisfactory, because during the discharge phase, the water temperature decreases rapidly, reducing the overall usability of the collector.

Evacuated Tube Collectors

The *evacuated tube collectors* are obtained, reducing the presence of air in the space between the plate and the transparent cover, thus avoiding losses caused by convective movements. In spite of their higher cost, these collectors are able to perform well even when the environment temperature is low. Among the possible technological solutions that can be used to build these collectors, the *heat pipe* technology does not limit the exchange of heat between liquids but in the case the fluid flows in thin tube pipes, also between vapor and liquid, taking advantage of the heat for the condensation along its way, resulting more efficient although more complex. Taking advantage of this type of heat exchange, the pipe system where the thermal vector liquid flows should be depressurized to decrease the evaporation temperature. A collector is built by the plate in long metal cylinders (copper) superficially covered with black and selected paint; this tube is in a second glass tube, in a way that surface of the first one is perfectly tallying with the internal of the second one; it is concentrically inserted in a second glass pipe. Figure 5 shows a section of the collector.

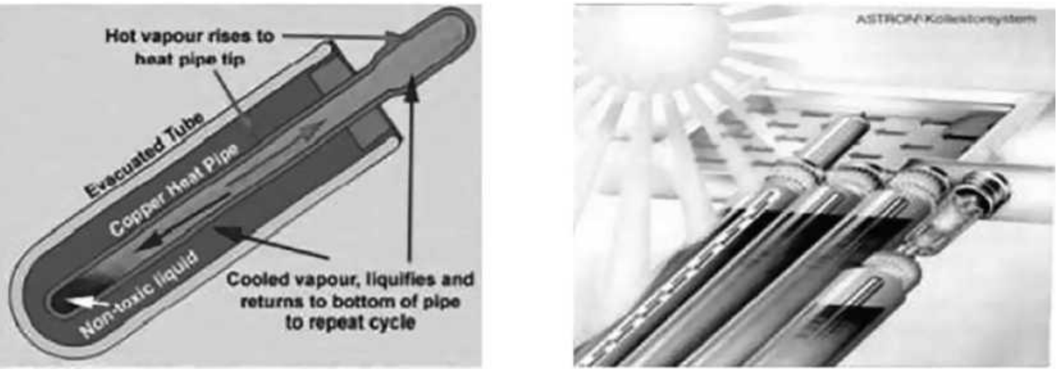

FIGURE 5 Section of an evacuated tube collector.

The air between the two tubes is vacuumed out, until a pressure of $P = 5 \times 10^{-3}$ *Pa* is reached. A small tube goes lengthwise through the copper cylinder following a U path, inside the thermal vector fluid flows reaching a temperature close to 100°C. In order to maximize the use of the heat pipe, a bigger pipe can be used in a concentric position; the heating of the fluid in the pipe will increase because the captured radiation increases. Heater exchangers are placed at the ends of the pipes, in order to transfer heat to the users. The evacuated tube collectors are divided into two main types:

1. *Evacuated pack collectors* with direct circulation of thermal vector fluid.
2. *Heat pipe evacuated pack collectors:* the fluid inside the pipe system evaporates along the way and give its heat, due to the condensation process.

In the first type, the plate is divided in long metal cylinders superficially treated with selected black paint, with each of these tubes inserted in a glass tube, which is also inserted in a larger glass tube, and then vacuum packed. A small tube goes through the copper cylinder following a U path.

In the heat pipe evacuated pack collectors, the little tube under pressure (heat pipe) receives heat from the capturing plate. The tube contains water or alcohol that evaporates at around 25°C under pressure. The vapor goes up until the head, where it exchanges heat through the condensation phase giving heat to another external fluid.

Energy Balance of a Collector

The phenomena that interact within a manifold are multiple and interconnected: the main energy exchanges between solar radiation and the various elements of the system are here described.

As shown in Figure 6, the solar radiation (E_0) hits the glass cover. A small amount of radiation (E_1) is reflected and absorbed by the transparent cover. The copper absorber does not absorb all the remaining radiation into useful heat and partly reflects and dissipates heat (E_2) by convection, conduction, and radiation to the outside. Treatment with selective coatings, as mentioned above, reduces leakages. On one side, the transparent cover prevents the reflection of the solar radiation from the plate to disperse outwards favoring the greenhouse effect inside the collector, and on the other side, it limits the heat convection dispersion (Q_1). If a good thermal insulation in the back and sides of the collector is designed, with standard insulating materials such as rock wool or polyurethane foam, the energy losses by thermal conduction are reduced to a minimum (Q_2).

Only a portion of the incident solar energy (E_0) is transferred to the fluid as useful heat (Q_3) due to the different energy losses (E_1, E_2, Q_1, and Q_2).

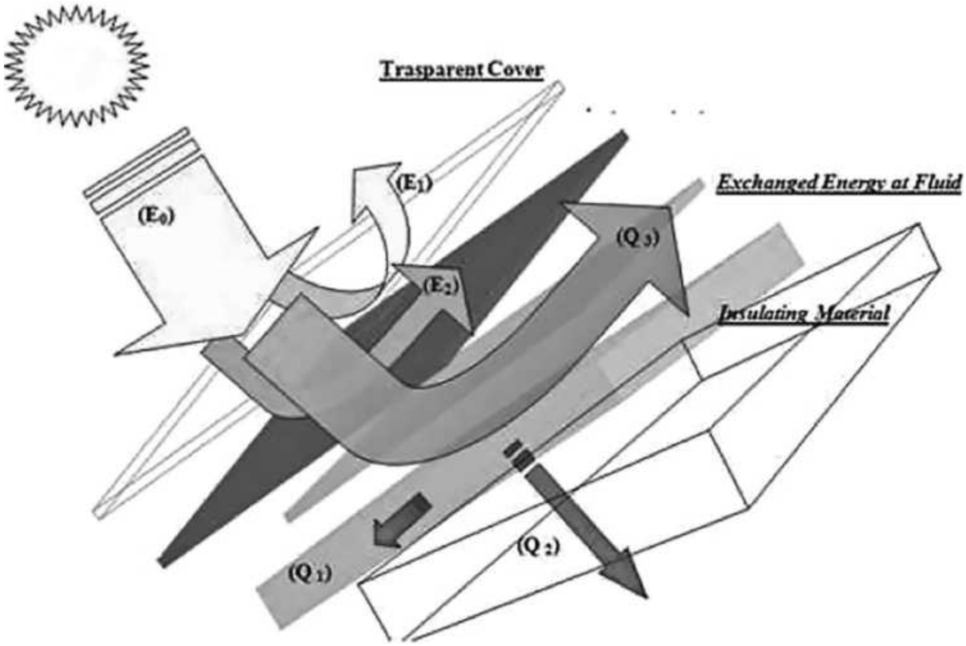

FIGURE 6 Energy balance of a solar thermal collector.

Collector Efficiency Curves

The thermal energy transferred to the fluid per time unit is calculated as the difference between solar radiation captured by the plate and converted into heat, and the heat losses by convection, conduction, and radiation.

$$\mathrm{Q_n} = E_c - \mathrm{Q_p} \tag{1}$$

E_c takes into account the absorbance and transmittance of the glass plate, and it is calculated as the product of the irradiance E, the transmittance τ, and absorbance of the plate α, as follows:

$$E_c = E^{*}\tau^{*}\alpha \tag{2}$$

The heat loss depends on the temperature difference between the plate and the environment. As a first approximation (for low temperatures of the plate), this relationship is linear and it can be described through the coefficient of total losses:

$$Q_p = k^{*}\Delta T \tag{3}$$

where $\Delta T = T_p - T_a$, T_p is the average temperature of the plate, and T_a is the ambient temperature.

By substituting these relations in the efficiency of the collector, the following are obtained:

$$\eta = \left(E^{*}\tau^{*}\alpha - k^{*}\Delta T\right)/E, \tag{4}$$

$$\eta = \left(E^{*}\tau^{*}\alpha / E\right) - \left(k^{*}\Delta T/E\right), \tag{5}$$

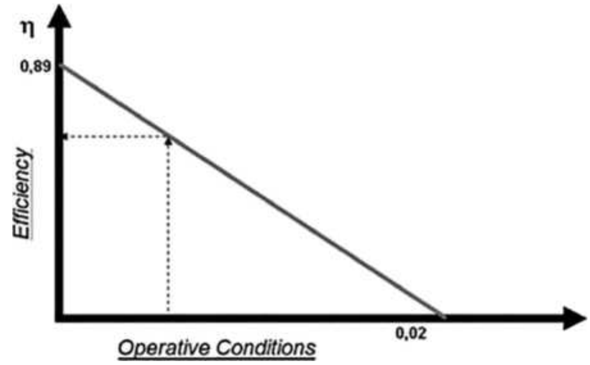

FIGURE 7 Efficiency of a solar thermal collector at different operative conditions.

and

$$\eta = \tau^{*}\alpha - \left(k^{*}\Delta T/E\right), \tag{6}$$

Whereas

$$\eta_0 = \tau^{*}\alpha. \tag{7}$$

It follows that the efficiency of the collector is equal to:

$$\eta = \eta_0 - \left(k^{*}\Delta T/E\right). \tag{8}$$

Conventionally, it is defined:

$$\Delta T^{*} = \left(T_{\mathrm{mf}} - T_a\right)/E. \tag{9}$$

Finally, the efficiency of a collector can be expressed as:

$$\eta = F'^{*}\eta_0 - K\Delta T^{*}. \tag{10}$$

In Figure 7, the efficiency curve of a collector is shown.

Instantaneous Efficiency of a Collector

The instantaneous efficiency depends on the optical losses (E_1 and E_2) and on the temperature (Q_1 and Q_2).

The overall losses of the total heat occurring in the collector by conduction, convection, and radiation can be expressed as the coefficient of total loss in K (W/m^2 * °C).

The graph shows that, with constant irradiance, the higher is the difference between the average temperature of the fluid and the ambient temperature, the heat losses also increase and, consequently, the efficiency of the collector decreases.

Comparison between Different Types of Collectors

By comparing the two efficiency curves, the principal characteristics of the collectors can be classified:

- *No glass collector* is the one with the best possibility to absorb the incidental radiations; its efficiency though decreases fast until zero in situations where the other collectors still have valid performances.
- *Flat-plate collector* with a selective plate has a better performance than the open one, practically in every working condition.
- *The evacuated collector* has a more stable efficiency curve, and it guarantees good performance even during bad weather conditions.

From Figure 8, which shows the efficiency curve of different collector types, it is possible to observe that the unglazed collectors have better optics than others. In fact, the absence of covering helps eliminate the untransparency losses and reflection that often occur with the glass covering.

Natural Circulation Systems

Once the differences between an open and a closed circuit have been examined, it is possible to analyze the circulation of the thermal vector fluid of the plant.

Natural circulation and closed circulation systems are based on the convective movements flown from the thermal vector fluid caused by a difference of temperature in the fluid itself. Indeed, the fluid warms up inside the serpentine of the capturing plate and it naturally goes up to the top of the collector. It will need an inclination compared to the floor to maximize the quantity of transferred energy.

Over the collector, a “storage tank” is placed with the heat exchanger inside. In the tank for the accumulation, there are two separate flows: the closed circuit of the collector with the thermal vector fluid and the water net of the running system designated to the final users.

The water, in contact with the heat flow, has a lower temperature, with higher heat absorption capacity, thanks to its stratification. While liberating heat to the running water, the fluid cools off moving to the lower part of the capturing plate; meanwhile, the part of the fluid that was at a colder temperature, being at this point at a higher temperature, tends to go up to the accumulation tank, cooling off while transferring heat to the running water. The quantity of fluid inside the solar collector remains constant and does not need any regulation pump for the circulation of the water, because a self-regulation natural mechanism works thanks to the trigger of the convective movement (see Figure 9).

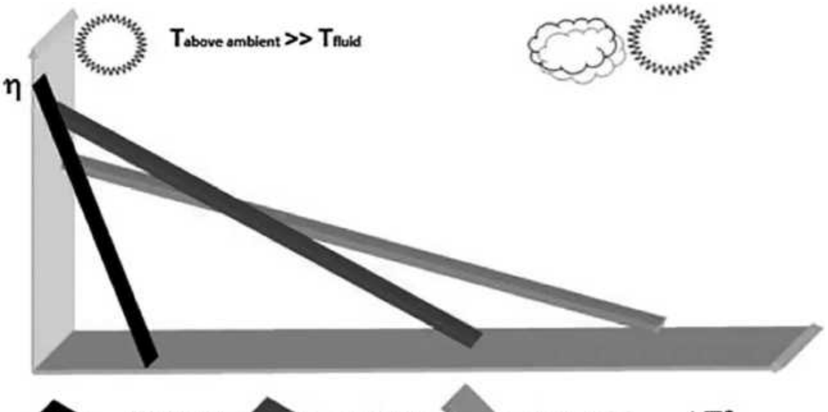

FIGURE 8 Efficiency curves of different collector systems.

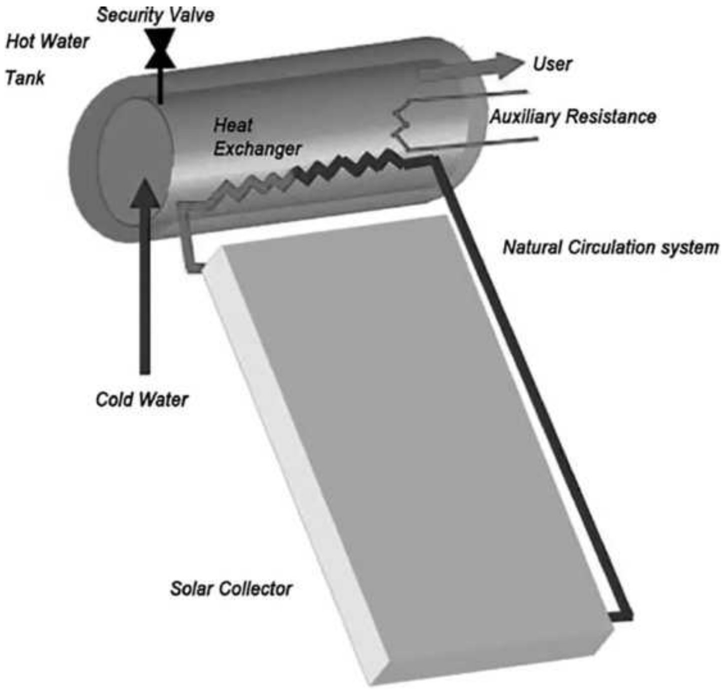

FIGURE 9 Natural circulation system.

Forced Circulation Systems

In the system where the circulation is forced, the presence of the circulation pump, driven by a differential thermostat, allows the fluid to circulate inside the pipes. After a selected difference between the water temperature and the fluid, it activates automatically. The tube in which the thermal vector fluid circulates represents a primary circuit. In the highest part of the accumulation tank, there is an exchange of heat coming from an auxiliary traditional circuit that starts functioning when the water temperature designated to the users does not arrive to the requested one. The fluid that liberates its heat inside the tank of accumulation cools off through a pump of circulation that is sent to the lower part of the collector usually sited on the roof. See Figure 10 for the scheme.

Open Circuit Systems

Open circuit systems have some advantages, such as the simplicity of the hydraulic circuit realization and the lowest thermal losses that always occur when heat goes from one fluid to another. There are two problems that put limitations to this type of plant: the possible freezing of the water in case the temperature reaches values below 0°C and the calcium deposits along the tube system of the collector. In both cases, the collectors could go out of service.

Closed Circuit Systems

The closed circuit is the most common solution. In this case, there are two different hydraulic systems: the main one, in which the thermal vector fluid circulates, and the secondary one, where the water coming from the hydro net is used (a third circuit is foreseen in the large-scale plans for the heat storage).

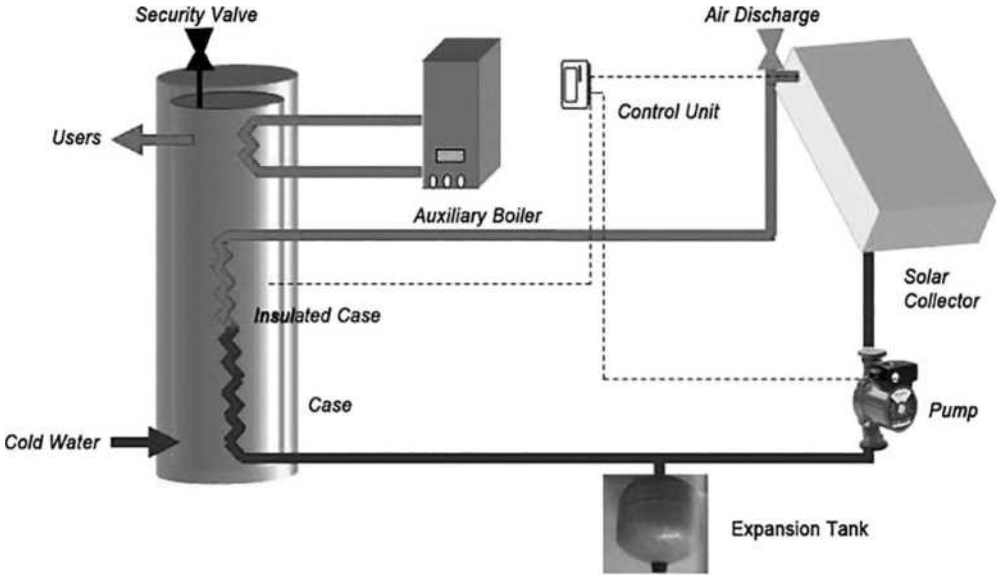

FIGURE 10 Forced circulation system.

The thermal vector fluid must respond to specific functions:

1. To increase density and specific heat capacity to be able to use the smaller pipe systems.
2. To avoid limestone deposits due to hardness of the water.
3. To reduce freezing points and viscosity.
4. To be not toxic (in the case of plant for sanitary warm water).
5. To be chemically inert, stable, and not corrosive.

The option adopted by most of the producers is a solution of water and polyethylene glycol (usually 25%–45% of glycol).

The purpose of the thermal vector fluid is to take thermal energy captured by plane and transfer it to the water to heat up. In this energy transfer, the fluid can give some heat to the cold water through the exchanger in a proportional measure depending on the difference of temperature between the two fluids. In Figure 11, the plate exchanger of heat is shown together with the tank with a double exchanger and a serpentine plunged. The larger the interface, the greater the amount of energy exchanged. The differences in temperature are of the utmost importance. To unify the need of big exchange surfaces with compact exchangers, the immersion serpentines are used.

Solar Cooling

The physical principle of generating solar cooling power is almost similar to the operating principle of conventional air-conditioning systems (condenser-compressor type) air-conditioning. Both systems rely on systems full vacuum single glass heat pipe collector picture liquid-to-vapor phase change energy of the refrigerant to attract heat (i.e., to produce cooling effect). The way the two systems achieve this is quite different because the condenser machine achieves a cooling effect by expanding compressed refrigerant into a low-pressure chamber, while the solar cooling machine relies on the absorbing action of the absorbent to create near-vacuum inside its chamber. In near-vacuum, the refrigerant will evaporate at a very low temperature, removing latent heat from the refrigerant (i.e., producing a cooling effect). This happens at a temperature significantly lower than the refrigerant's evaporation temperature

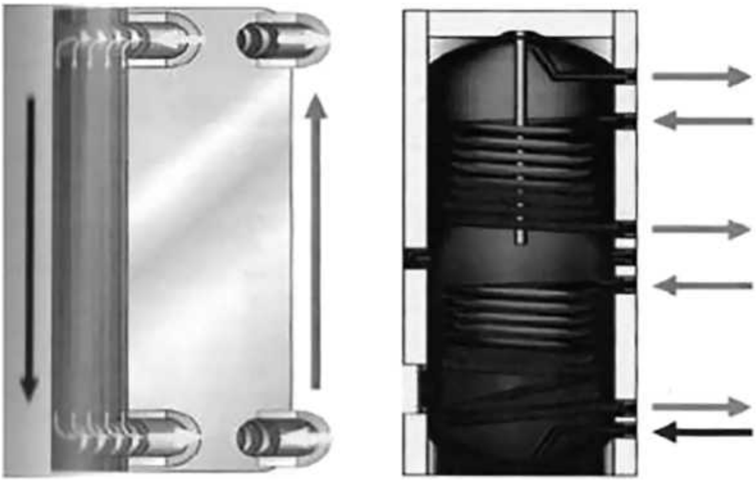

FIGURE 11 The plate exchanger of heat is shown together with a tank with a double exchanger and a serpentine plunged.

at atmospheric pressure. A cooling effect is thus achieved at usefully low refrigerant temperatures, making this principle practical for commercial use.

Heat supply from a field solar collector to the solar air-conditioning system is required not to directly provide the cooling action directly but to maintain the absorbent concentration. This ensures that low chamber pressure and low evaporation temperature of the refrigerant are maintained.

Preliminary Analysis and Solar Thermal Plant Design

Due to the abundance and benefits of solar energy, solar thermal plants can be very useful especially if there is a willingness to invest some capital into them, but the choice should be made taking into account the quality of the project and the devices.

The covered need can be high (60%–70% or more), for various reasons such as the randomness of the sunshine and the urban or market situations; it will not be able to meet the demand of the users. Most of the time, the plant will limit the use of fuel for heat production.

In the supply of DHW (domestic home water) through this type of plant, it must take into consideration that the weather conditions will not always be able to provide a sufficient quantity of energy to satisfy the demand and the complete comfort of the users. Demand and supply of heat will not be equal at the same time, and so to obtain independent plants in an annual scale, the capturing surface should be overestimated for summer (to supply the energy needed during winter).

Nowadays, investing in large seasonal storage is still in an experimental phase and involves very interesting cases. Figure 12 shows the offset of the thermal charge compared to the availability of the energetic source as the solar radiation incident. The latter is present in a solar thermal plant.

Matching Energy Availability and Thermal Energy Need

The way to estimate the energy needed to consume hot water is simple, but it is important to pay attention to the details involved.

Previously collected data can be used, but it is important to verify who collected them and what the original purpose was. If purposes are not reliable, it is necessary to go through monitoring to carry out data collection using a manual or digital device (calorie counter or a simple flow meter), gathering the data daily for at least 1 mo. In the sizing of the solar plants, the most important element is the energy

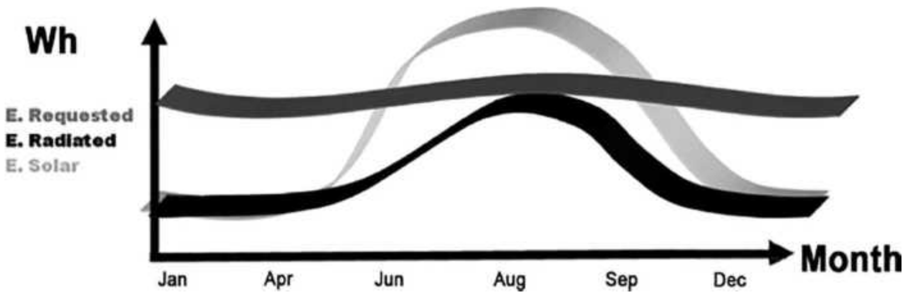

FIGURE 12 Offset of the thermal charge compared to the availability of the energetic source as the solar radiation incident.

need that will be accumulated and not the power need, which will be obtained at the right moment, from the mix of the solar heat storage and the auxiliary heater. Moreover, it is worth to invest on a thermal solar plant, as in all the renewable energies, only after a strong initiative to reduce the energy consumption, for example the aerator to be put at the final tap, can reduce up to 50% of the consume of hot water.

The Design Phase

The main design activities for a thermal solar system will be described here. The parameters and the different components that must be chosen for the plant and its dimensioning will be analyzed by the on-site procedure. It is important to note that in order to obtain the estimation of the costs of a solar plant, there is no need to proceed with detailed dimensioning, but it is sufficient to make an estimation of the following data:

- The surface of the collectors
- The volume of the tanks
- The thermal energy needs of the user

The phases of the project can be organized in the following way:

1. On-site investigation
2. Selection of the typology of plant and collectors
3. Dimensioning of the capturing surface
4. Dimensioning of the different components

On-Site Investigation

This is the first step in the design of thermal solar plants that includes three main targets:

- A detailed analysis of user energy consumption to estimate energy need (in joules, kilowatt-hours, or calories).
- A set of possible solutions to reduce the consumptions through energy saving.
- A check on possible solutions considering the logistic realization of the plant, with particular reference to the collectors' colocation.

Analysis of the Users' Consumptions

The first step toward a correct project is to estimate the exact heat consumptions; this allows the dimensioning of the solar system to satisfy the user energy needs through solar energy. There are two rapid assessment methods through which the evaluation of the users on thermal energy consumption is made:

1. The study of energy bills of the previous years
2. The study of the consumption habit of the users

Saving Energy Interventions

The dimensioning of a solar system cannot be based exclusively on the previous analysis; it needs to examine the opportunity to minimize each and every cost, to utilize clean energy after dispersion and waste reduction. Saving energy represents an objective of main importance, which can be realized in two ways:

1. Working on the demand level, boosting the users to modify their habits (this is called energy sacrifice), not always accepted but free of cost.
2. Working on the level of the offer, promoting the substitution of old and common devices with high efficiency products having the same performance but lower consumption.

The realization of a recovery intervention implies almost all the time an economic investment, the convenience of which must be analyzed before comparing the saved energy that would be obtained. It has to be found out *how much is saved*.

In the first case, the person who is taking care of the project must underline the waste, applying devices of energy saving. For example, in the case of DHW, both flow reducers and an air–water mixer limit the flow of hot water. In this way, users have the impression that the jet of water is the same although the quantity is much lower.

Logistic Aspects

The purpose of the on-site visit is to analyze some logistic aspects because it is very important to evaluate the feasibility of the solar plant. This phase is often ignored but very important. The first examination should verify if any historical constraint, related to the buildings or to the landscape in the area, exists. There could be situations where it is not possible at all to install a solar plant because it should be a waste of time to proceed. Under a technical point of view, it is necessary to find out a free area in which the solar panel could be installed, on the surface of which it is necessary to measure:

- Typology and material of the surface (characteristic of the roof, for instance)
- Gross area available
- Obstacles (antenna, chimney, others)
- Shade elements nearby or far away (buildings, trees, etc.)
- Accessibility for the installation and for the following maintenance operations
- Azimuth (orientation compared to the south) and inclination compared to the horizon

With reference to the specific problem of the shade, it can be useful in areas that are growing, to evaluate the local urbanization policies on the short and medium terms and to avoid that some years after the installation, the panels might fall in the shade of a new building.

Choice of Solar Plant Type

From an initial analysis, it is possible to distinguish the solar thermal plants on the basis of the hydraulic circuit. In an open circuit, the thermal vector fluid coincides with the thermal vector fluid used by the final users. A closed circuit consists of three hydraulic circuits divided into

1. Thermal vector fluid
2. Accumulation fluid
3. Water from the user

Analyzing the system circulation two categories of plants can be underlined: systems of natural circulation and systems of forced circulation. In most cases, the plant is designed with a closed circuit because there is the possibility of using a thermal vector fluid different from simple water.

The use of water as a fluid has some disadvantages like the presence of calcium and a low freezing point on one hand, and the open circuit is more economic and rapid to be installed on the other hand.

Estimation of the DHW Need

The production of DHW represents one optimum solution for the use of solar energy because it allows using solar radiation also when it is at its maximum power. A reason that has increased their new diffusion is the economic return in terms of capital investment due to the costs relatively contained for the installation and the good reliability of the plant. The evaluation of the theoretical thermal need in the systems of DHW can be quantified through the following expression:

$$Q_{\mathrm{ac}} = V^{*}\left(t_{\mathrm{ut}} - t_{\mathrm{al}}\right)^{*} C_{s} \tag{11}$$

where Q_{ac} is the needed daily thermal energy (kcal/g), V is the requested water volume (L/g), t_{al} is the temperature of water source (°C), t_{ut} is the temperature of water output (°C), and C_{s} is the specific heat (kcal/kg * °C).

The supplied temperature depends on the place of the plant installation and on the water net from which it is taken, as it is possible to have differences of temperature depending on the period of the year. The temperature of warm water supply depends on the user considering that the maximum temperature of the water to the thermal generation should be $t_{\mathrm{ut}} = 48 + 5$°C, where the second term indicates the maximum tolerance. To be able to guarantee this temperature until the water reaches the user, it is necessary that the distribution system must be suitably insulated. For the buildings that have no isolated distribution system, the temperature of supply would be higher than 50–55°C with peaks of 60°C.

The effective calculation takes into consideration the thermal losses that occur in the distribution network that brings the water from the production point to where it should be used. These losses make one think of the necessity of an effective thermal load higher than the theoretical one, to be able to satisfy the users' needs.

The total output of the distribution network depends on the grade of the insulation of the network itself. The average of the final output can have values in the following ranges:

- 0.85 to 0.90 in the case of recent constructions with insulated pipe system and with the recirculation.
- 0.75 to 0.85 for the constructions with plants without recirculation or with a cycle that works only during the day.
- 0.65 to 0.705 for the construction of plants with a working recycle during full time.

Sizing the Collector Field Surface

The first step to designing a solar plant system is to evaluate the surface needed for the plant as a compromise between the technical need and the economic need: unless a solar roof is used, it is necessary to think about the tilt angle and its right positioning. Basically, the exposure should not face north and the surface should be enough to have all the collectors needed. That surface of collectors must avoid getting over economic convenience, even only on log term. The dimension of the capturing also depends on the type of chosen collectors, particularly on their performance and on the orientation of the tilt in the roof.

The quantity of energy on the surface of the collectors varies in function of two angles: the azimuth angle θ and the tilt angle φ. The azimuth angle θ is the projection on the horizon plane surface and the tilt angle φ defines the inclination of the collector to the surface as shown in Figure 13.

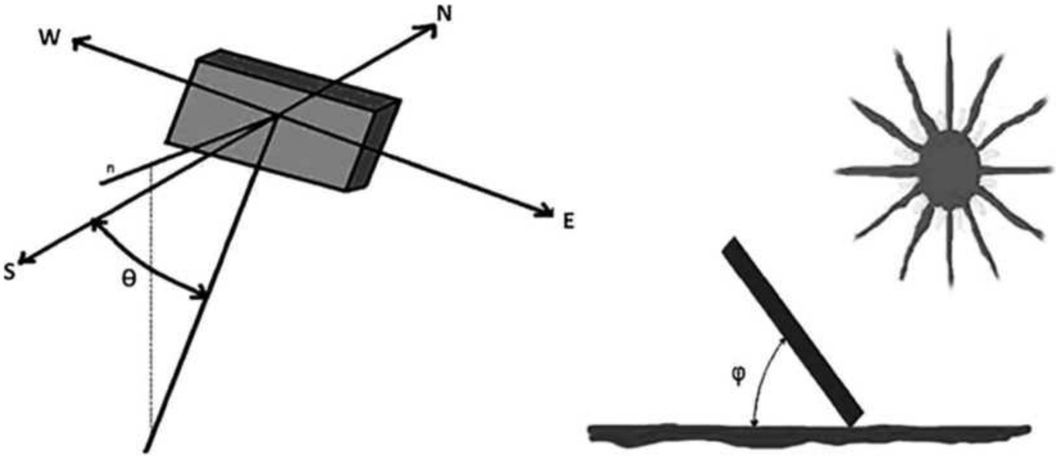

FIGURE 13 Azimuth and tilt angles.

TABLE 1 Increment of the Surface of the Collectors under Suboptimal Conditions

	Tilt Angle						
	0°	**15°**	**30°**	**45°**	**60°**	**75°**	**90°**
South	12%	3%	0%	1%	8%	20%	45%
South/East or South/West	12%	6%	3%	5%	11%	23%	43%
East and west	12%	14%	15%	20%	28%	41%	61%

The tilt angle depends on the building on which the plant is installed and on the orientation of the building itself as well. Since it is often not economically and aesthetically convenient, they are fixed directly on the top of the roof to create an ad hoc structure to hold the collectors.

About the typology of collectors, the choice depends on the conditions of the performance that will influence the output, and so from

- The internal temperature: the temperature to which the water is heated up.
- The external temperature: it depends on the period of the year in which it will be used.

The most important data (for the output) are the difference between the temperatures of the collector and the external environment because it characterizes the thermal losses. If data on consumptions are not yet available (for example, the building has just been built), an estimation on the energy needed (referring to average values) must be done. The corrections match the increases of the surface in bad orientation conditions, as seen in Table 1.

For combined plants, used for house heating and for the production of DHW would be appropriate to increase the value of the inclination to reduce the difference between the summer and winter production as underlined in Figure 14.

Heat Storage System

The energy needed for a large number of applications depends on the time, but often in a different way from solar energy. As a consequence, it is necessary that the accumulation of thermal energy produced with solar panels firstly in those cases in which the solar energy must cover an important fraction of consumes. The optimal skill of the heat storage system depends on

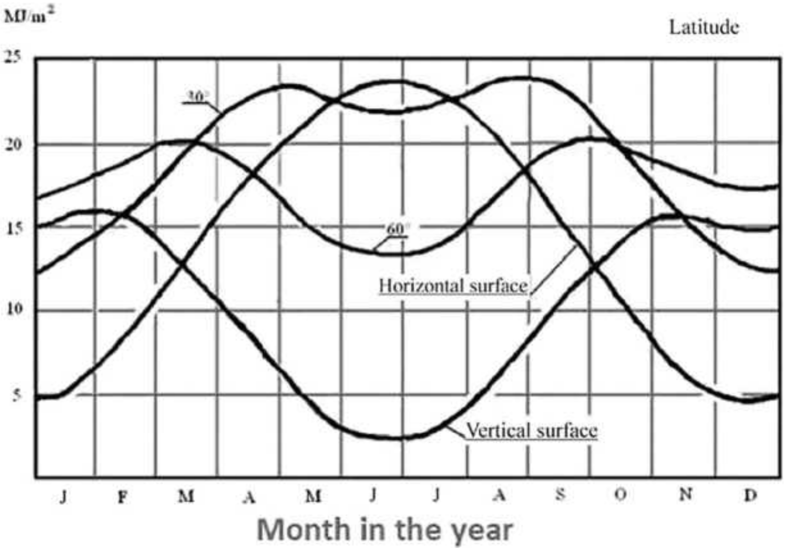

FIGURE 14 Monthly average solar radiation during a year at 40° latitude.

1. The availability of solar energy.
2. The nature of the loads.
3. The level of reliability needed in supply processes.
4. The economic analysis that sets the optimal percentage of traditional means.

Normally, a thermally isolated tank and a boiler are used. The boiler should store the solar energy when available and give it back when requested.

The most common energy discrepancy include alternation of day and night, sunny days as against cloudy days, and the summer season compared to the winter season. The latter is very important under a technical point of view because it reduces the technical problems connected to the summer overproduction as well.

A typical situation is a plant with accumulation. Paste Figs. 9 and 10:

Heat Storage Systems Dimensioning

Considering the time course of thermal loads and solar energy available:

- G_c represents the incident solar power.
- q_u represents the power delivered to the fluid.
- L is the power required by the loads that vary over time.

The areas above the red line and below the green one represent the time intervals that exceed the energy needs and must be accumulated. In contrast, the areas above the line in red and green show the time intervals in which the heat must be supplied to the loads from the storage system as in Figure 15.

The storage systems can be divided into two broad categories:

- Sensible heat storage systems
- Latent heat storage systems

In the sensitive system, energy is stored by raising the temperature of a suitable material. Latent heat storage systems take advantage of the latent energy at the phase change (usually the liquefaction) of a substance, and in this case, the process takes place at constant temperature.

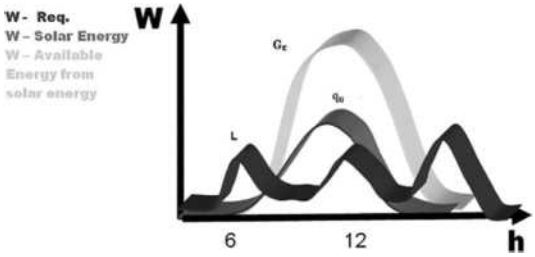

FIGURE 15 Energies during the day for a typical plant with storage.

In the first type, energy is taken by decreasing the temperature of the substance in storage while in the second type, stored energy is made available, causing a phase change.

In the build-sensitive systems, adopted in most cases, the energy is proportional to the temperature change of the substance contained in the batteries themselves:

$$Q_s = Mc_p\Delta T_s \tag{12}$$

where Q_s represents the accumulated energy, M is the mass storage, c_p is the specific heat of substance accumulation, and ΔT_s is the temperature variation.

Often a single temperature does not characterize the accumulation, because it cannot be considered perfectly mixed; it is actually layered. The top tank is the hottest part and the bottom is colder. The stratification is beneficial because of the collectors; reducing the average temperature of the absorber plate improves the efficiency to capture solar energy.

The best storage material in liquid systems is certainly water, since it has a low cost, has high specific heat, and is not toxic, and its boiling temperature at atmospheric pressure is high enough. The size of the storage system depends on the absorbing surface. Recommended values for solar systems for hot water are 100 L/m^2. The most important aspect to consider is, as already mentioned, the stratification of the water tank. As an index to assess the extent of the stratification of the water in a reservoir, the extraction efficiency is defined as:

$$\eta = \left(Qt^{*}\right)/V \tag{13}$$

where Q is the volumetric tank drain, V is the volume of accumulation, and t^* is the time required for starting from a completely mixed storage; the temperature difference of input-output has fallen to 90% of initial value.

Since the tank has a considerable cost, mainly due to heat insulation, sizing is necessary to make technical evaluations of economics. The storage tanks can be recharged in a sunny day or in an entire season. The first are those most commonly used and consist of an insulated tank to maintain hot water temperature. The degree of isolation of the accumulation should be as high as possible if the tank is installed outside, as often happens in systems with forced circulation. The storage tanks must also possess other important characteristics:

- They must be suitable for containment of potable water and must have had internal anticorrosion treatment.
- They must be resistant to high pressure (6 bar).
- They must be equipped with safety devices such as air vent, expansion vessel, and safety valve.
- They must be equipped with the following measuring devices: temperature gauge and pressure gauge for measuring pressure.

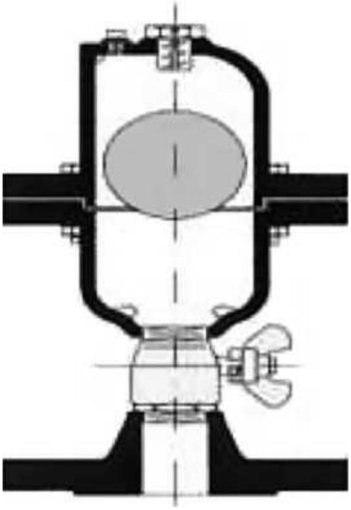

FIGURE 16 Example of an expansion tank.

When the heat demand is roughly constant during the day, usually about 20 L/m^2 of collector is sufficient, while this figure varies between 50 and 100 L/m^2 of collector daily batch loads such as residential use, where consumption of water for showers are concentrated at certain times of day (morning or evening).

An important phenomenon is the *stagnation* of the system. In summer, the energy produced is often greater than the amount of thermal energy users and, if the accumulation is too small or absent, the excess energy increases the temperature inside the collector to allow evaporation of the fluid heat transfer. This leads to the thermal gradients and overpressure under serious problem the hydraulic components of the system, and it can compromise the integrity of the plant. Also, bear in mind that the plant also has air release valves to eliminate the air that enters the piping system itself, inevitably compromising the thermal exchanges and thus the operation. If it is used, an automatic valve (Jolly) is strongly discouraged, due to the stagnation of the primary because the emptying of the liquid transfer medium such as air comes out unwanted in automatic air vents. The sizing of the accumulation is performed for the reasons outlined above, depending on the surface of the manifold: in practice, it takes an average of 50 to 90 L of storage per square meter of collector area (see Figure 16).

Size of the Auxiliary

The sizes of the auxiliary are dependent on the diameter pipes that are obviously related to flow values (Table 2).

Another very important element, which has a major impact on system performance, is the pressure drop. The volume flow can be calculated by the following equation:

TABLE 2 The Size of the Pipes according to the Scale

Flow (L/hr)	External Diameter per Thickness (mm)
<240	15 × 1
240–410	18 × 1
410–570	22 × 1
570–880	28 × 1.5
880–1450	35 × 1.5

$$P_v = Q/\left(c_g \Delta T\ m_v\right) \tag{14}$$

where Q is the thermal power made available by the solar collector (W/m^2); $c_g = 1.3$ Wh/(kg °C), the specific heat of the fluid; m_v is the density of the fluid (1 kg/L,); and ΔT is the temperature difference between inlet and outlet collectors (10°C).

The section of pipe can be calculated from the volumetric flow rate and velocity of the fluid P_v.

Prevention and Control of Legionella Exposure Risk

A problem that needs to be focused on in water systems for large facilities (hotels, prisons, hospitals, etc.,) is the presence of *Legionella*.

During the design phase of some facilities, a plant configuration to eventually prevent *Legionella bacteria* has already been furnished. Legionnaires' disease is contracted by breathing, by inhalation, or by aerosol microaspiration that contains the bacterium. The aerosol is formed by the droplets generated by water spray or the impact of water on solid surfaces. Most droplets are small; the more dangerous water droplets are those with a diameter less than 5 microns as they can more easily reach the lower respiratory tract. To ensure a reduction in the risk of legionellosis, the following preventive measures should be followed:

- Always keep hot water at a temperature above 55°C.
- Slide the water (either hot or cold) taps and showers that are not used for a few minutes at least once a week.
- Keep showers, jet showers, and speaker of the taps clean and free of fouling; replace as needed.
- Clean and disinfect all water filters regularly every 1–3 mo.
- Ensure that any changes made to the system, including new installations, do not create dead arms or pipes with no water or stream flows intermittently.
- Adhering to a point, the aim is to ensure a continuous thermal disinfection of hot water.
- Heating the water to 55°C results to, in fact, short-term elimination of *Legionella bacteria,* as evidenced by the Hodgson-Casey diagram taken as a point of reference for setting temperature and the time needed to implement thermal disinfection against *Legionella*.

However, in order to properly set up a continuous thermal disinfection, it is necessary that the water plant is at least maintained at 55°C.

It should be considered, in fact, that if the thermal head high facilities are not well insulated and well balanced between supply points and certain areas of the circulation thermal head high can be determined, as shown in the diagram below (Figure 17). So, even if hot water is supplied at a temperature below 50°C, there may be circulating in the networks of temperatures and can encourage the development of Legionella.

Large Systems

Solar systems are designed to be large to produce hot water for space heating. Possible applications include the following (see Figure 18): hospitals, home care for seniors, military barracks, hotels, gyms, prisons, and residential complexes—situations where the demand for heat is constant both during the day and at different seasons of the year.

They are called large systems when the surface of the solar field is greater than 100 m^2. The investments made to realize these plants are vital because of the current costs of the collectors; thus, before spending a lot of money, an in-depth energy audit to evaluate the requests of the users and assess the economic breakeven point should be undertaken. These systems, of course, are not able to meet the total energy demand, so they must be integrated into a conventional source.

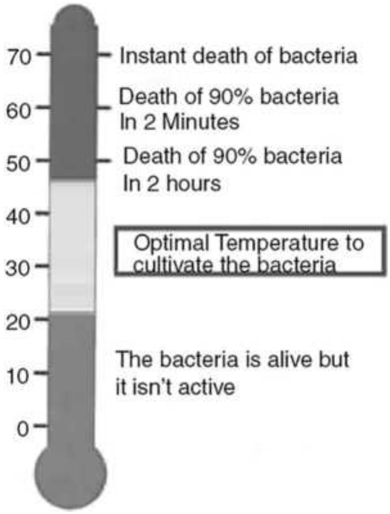

FIGURE 17 Behavior of the *Legionella* bacteria, depending on different temperatures.

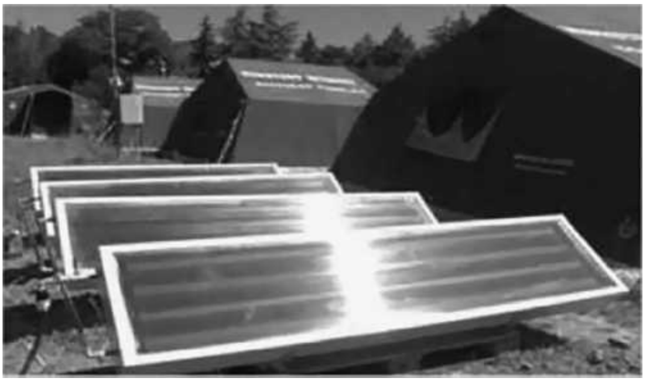

FIGURE 18 Abruzzo region post-earthquake emergency camps (2009).

In support of these investments often involved in campaign financing from the state, such as loans to grants and tax deductions on the cost of the material. In recent years, the problem of pollution and continuous increases in the cost of traditional energy sources have caused people to engage in new ways, i.e., try to change their old habits, often met by indiscriminate consumption of energy.

Solar Integrated Collector Storage System Innovations

The use of a solar integrated collector storage (ICS) system (see Figure 19) represents a well-established technology for heat storage in civil and industrial applications.

An innovative solar thermal device has been used as an integrated collector storage providing DHW (up to 50–80°C). Here, the collector also acts as a storage unit, without requiring an external vessel. This device was successfully used in several circumstances, especially in extreme situations such as in the post-earthquake tent cities or to feed remote users in developing countries.

The efficiency of this device is strongly related to the draw-off curve. In fact, it is strongly desirable that during the draw-off, the water temperature remains as high as possible. Presently, this aspect is not optimal, leading to a strong reduction of the water temperature (more than 50% when 50% of the hot water filling the collector was discharged).

The collector was designed for use in emergency situations or for feeding remote users. Then, very simple configuration was adopted.

A series of eight J-type thermocouples have been placed to measure the temperature during the thermal energy storage phase and during discharge. The accuracy of the thermocouples was ±1.5°C and the acquisition frequency was 0.88 Hz. Solar radiation fluctuations have been followed by a pyranometer system with an accuracy of ±10 μV/(W m^2). The eight thermocouples (seven have been used for monitoring the pipe and one for the ambient temperature) and the pyranometer have been connected through a thermocouple and RTD modules, with a National Instrument field point with Ethernet connection, and connected to a data processing system through LabVIEW, as shown in Figure 19.

During the charge phase, the pipe has been placed in vertical position in order to be completely filled with water and to eliminate the air. Then, it has been placed on its supports, with a tilt of 42°.

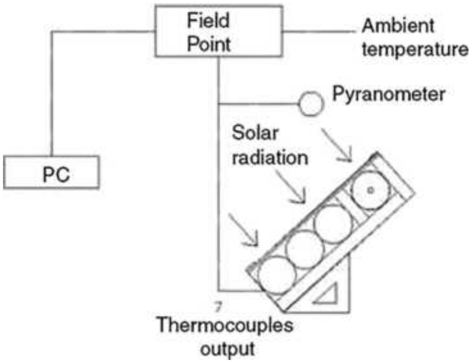

FIGURE 19 Experimental device used for the ICS prototype.

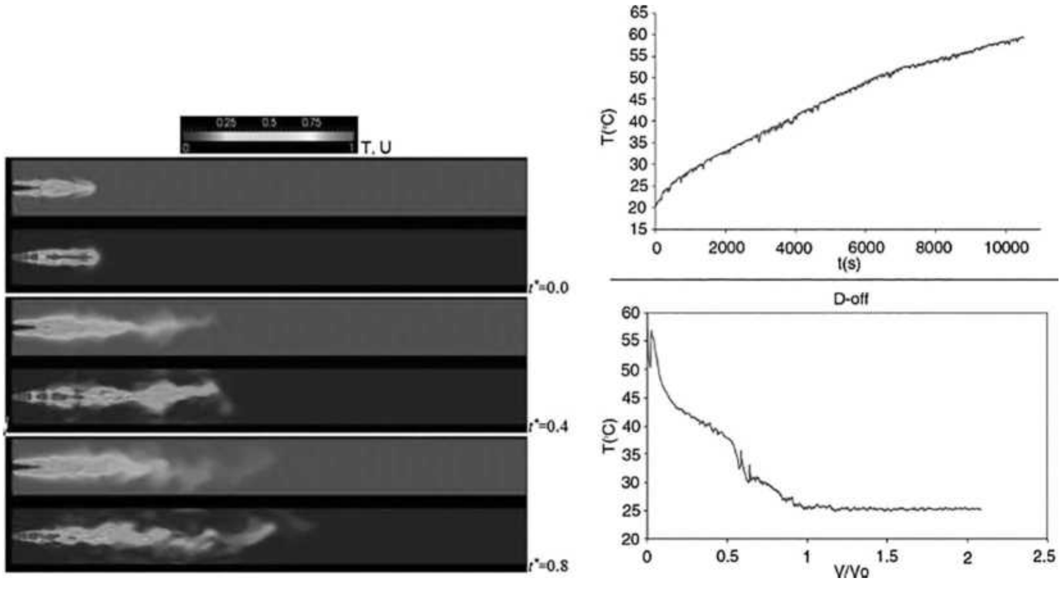

FIGURE 20 Longitudinal view of the temperature (top) and velocity magnitude (bottom) fields in three successive time steps.

The experimental analysis demonstrates that in the present configuration, the ISC has a reasonable performance in supplying hot water during the discharge phase.

Conclusions

The investments made to realize the plants are important because of the current costs of the collectors; therefore, before spending such quantity of money, it is better to undertake an in-depth energy audit to evaluate not only the requests of the users but also the breakeven point.

These plants are not able to supply the total energy demand; therefore, they should be integrated with a traditional source.

To support such investments, often there are financial aids from the state, such a free grant loan or allowances on the V.A.T. on the costs of the material.

In recent years, the pollution problem and the constant rise in the cost of traditional energy sources have resulted to users trying to find new solutions, changing old habits, often entailing excessive energy consumption.

Alternative Energy: Wind Power Technology and Economy

K.E. Ohrn

Introduction (Web Preview)

This entry is a broad overview of wind power. It covers a range of topics, each of which could be expanded considerably. It is intended as an introductory reference for engineers, students, policy-makers, and the lay public.

Wind power is a small but growing source of electrical energy. Its economics are well known; there are several large and competent manufacturers, and technical problems are steadily being addressed. Wind power can now be considered as a financially and operationally viable alternative when planning additional electrical capacity. However, as shown below, wind power is only a minor component of present energy sources.

World final energy consumption (2002)[1]: 100%
World final electrical consumption (2002)[2]: 16.1%
World final wind power consumption (2004)[3]: 0.15%

Wind power's main deficiency as a power source is variability. Since wind velocity cannot be controlled or predicted with pinpoint accuracy, alternatives must be available to meet demand fluctuations.

Wind power carries few environmental penalties and makes use of a renewable resource. It has the potential to become a major but not dominant part of the future energy equation.

History

People have used wind to move boats, grind grains, and pump water for thousands of years. Wind-powered flour mills were common in Europe in the 12th century. In the 1700s, the Dutch added technical sophistication to their windmills with improved blades and a method to follow the prevailing wind. Isolated farms in the last century used windmills to generate electricity until the availability of the electrical power grid became widespread.

Past interest in wind power has tended to rise and fall with fuel prices for the predominant method of electrical production—thermal plants burning oil, natural gas, and coal.

Current

Electrical Production

Although small, wind power is a fast-growing part of the energy picture. Since 1990, worldwide installed capacity has grown about 27% (Table 1).[3]

Business is good for the leading manufacturers of wind power devices. Sales have increased; the technology is stable and predictable, with low maintenance and high availability.

Geographical Distribution (Countries)

The European Union had around 72% of installed capacity in 2004, and Germany, Spain, and the United States accounted for 66.1%. Denmark, Spain, and Germany had by far the largest 2004 capacity in terms of MW per million populations, and 10.6% of the world's population had 81.9% of its wind power capacity. In 2004, Denmark produced about 20% of its electrical power from wind power in 2004 (Table 2).[3]

TABLE 1 Capacity Growth

Year	Capacity (MW)	Growth Rate Year-over-Year (%)
1990	1,743	13.8
1991	1,983	17.0
1992	2,321	20.7
1993	2,801	26.1
1994	3,531	36.5
1995	4,821	26.6
1996	6,104	25.1
1997	7,636	33.0
1998	10,153	33.9
1999	13,594	27.7
2000	17,357	66.3
2001	28,857	7.9
2002	31,128	26.9
2003	39,500	20.3
2004	47,500	13.8
	Average Growth Rate	26.7

TABLE 2 Capacity Distribution

	Wind Power Installed Capacity (MW)								
Country	2001	2002	2003	2004	One-Year (%)	Three-Year (%)	Population (millions)	Capacity (MW/Million)	Percent of World Capacity
Denmark	2,456	2,880	3,076	3,083	0.2	7.9	5.4	570.9	6.4
Spain	3,550	5,043	6,420	8,263	28.7	32.5	40.3	205.0	17.2
Germany	8,734	11,968	14,612	16,649	13.9	24.0	82.4	202.1	34.7
Netherlands	523	727	938	1,081	15.2	27.4	16.4	65.9	2.3
USA	4,245	4,674	6,361	6,750	6.1	16.7	295.8	22.8	14.1
Italy	700	806	922	1,261	36.8	21.7	58.1	21.7	2.6
UK	525	570	759	889	17.1	19.2	60.4	14.7	1.9
Japan	357	486	761	991	30.2	40.5	127.4	7.8	2.1
India	1,456	1,702	2,125	3,000	41.2	27.2	1080.4	2.8	6.3
China	406	473	571	769	34.7	23.7	1306.4	0.6	1.6
Total	22,952	29,329	36,545	42,736	16.9	23.0	3073		89.2

Manufacturing capacity in 2002 was largely confined to this group of countries, with five big vendors accounting for 76% of sales. European Union vendors accounted for 85% of manufacturing market share.[3]

Economics

Cost per kWh

Wind power is a viable method of producing electricity that is capital intensive with low operating costs. The cost of production compares favorably with traditional fossil fuel or nuclear plant costs.

The major cost elements of a modern wind power installation are as follows[3,5,9]:

Capital

Onshore: 1200–1500 USD/kW
Offshore: 1700–2200 USD/kW

Operating: usually about 1.5%–2.0% of capital cost per year.[12]

Capital costs include wind capacity survey and analysis, land surveying, permits, roads, foundations, towers and turbines, sensors and communications systems, cabling to transformers and substations, maintenance facilities, testing, and commissioning. By far the largest individual capital cost is the turbine (up to 75%).

Operating and maintenance costs include management fees, insurance, property taxes, rent, and both scheduled and unscheduled maintenance.

Financing costs are a major portion of energy production costs, making them very sensitive to interest rates, incentives and subsidization.

Energy production cost estimates vary considerably. Optimists in the industry, such as the British Wind Energy Association, quote a low of 4.8 USD cents per kWh for an onshore plant in an optimal location. Pessimists, like the Royal Academy of Engineering in the U.K., quote up to 13.2 USD cents per kWh for an offshore plant, partly by including a controversial 3.1 USD cents per kWh cost for “standby capacity” required to supply demand when wind power is not available (Table 3).

Capacity Factor

The power generated by a wind turbine depends on the speed of the wind, and on how often it is available. At any given site, this is measured by the capacity factor, or the ratio of actual generated energy

TABLE 3 Windower Costs

	Cents (US) per kWh			
Wind Power Costs	Wind Onshore	Wind Offshore	Coal CFB	Gas CCGT
RAE [15]	6.8	9.9	4.8	4.0
RAE 2[a]	10.1	13.2	9.2	6.0
EWEA [3]	5.5	8.5		
AWEA (5)	6.6			
AWEA 2[b]	5.4			
BWEA (minimum)[4]	4.8	6.9	4.8	4.8
BWEA (maximum)[c]	6.8	9.1	6.8	5.9
Euro to USD conversion (2004)				1.22
GBP to USD conversion (2004)				1.83

[a] Adds 3.1 cents per kWh for wind power backup capacity and 1.9–4.6 cents/kWh for coal and gas carbon capture.

[b] AWEA figures adjusted to delete 1.8 cents US/kWh production tax credit and are for onshore sites with different average wind speeds.

[c] BWEA figures for a range of site types in November 2004 and 1–2 cents/kWh for carbon capture.

Source: RAE, Royal Academy of Engineering[15]; BWEA, British Wind Energy Association[4]; EWEA, European Wind Energy Association[3]; AWEA, American Wind Energy Association.[5]

to the theoretical maximum. Wind power turbine electrical output rises as the cube of the wind speed. When wind speed doubles, energy output increases eightfold. A typical turbine begins to turn when wind speed is at 9 MPH and will cut out at 56 MPH for safety reasons.

Capacity factors vary by site but are typically in the range of 20%–30% with occasional very good offshore sites reaching 40%. The yearly energy output from a wind farm is given by the following formula:

Site

Power production costs, site size, site design, and energy output and variability will depend mainly on details about the wind. These details include wind speed, wind direction, and the geographical distribution of favorable wind profiles. During analysis of potential sites, most planners use high (60 m plus) anemometer towers—often several of them—to gather at least one year's data per site. These data are usually correlated with national meteorological observations, if these are available and suitable. If not available, it would be prudent to gather site data for a longer period of up to three years.

Investors and regulators are increasingly aware of the crucial nature of wind data in estimating the quantity and timing of potential power production at a specific site. This research is crucial to the financial analysis of a potential wind power venture.

Other site analysis factors are accessibility via road for heavy equipment, electrical grid proximity and capacity, land ownership, and environmental impact.

Location

Favored Geography

Many countries have developed wind charts of broad areas based on meteorological data gathered for weather and aviation purposes. These charts show potential areas for investigation, where wind strength is high and constant over long periods of the year. Once potential sites, and their extent, have been identified, on-site data measurements provide the basis for analysis and modeling of potential energy production for a specific site.

After wind modeling, the site's geographical, environmental, financing, and ownership issues can be explored in detail.

Generally, sites are either onshore or offshore. Onshore sites are cheaper to construct, but have lower capacity factors due to wind turbulence from nearby hills, trees, and buildings. Offshore sites can have more potential energy available due to higher wind speeds and lower turbulence, which also reduces turbine component wear. Good offshore sites can be near high-demand load areas such as coastal cities, which also increases transmission options. Aesthetic and noise concerns are often fewer offshore, and sea-bed environmental concerns can be lower than landuse concerns for an onshore site.

Sizing a Location

Wind farm towers are usually spread over a large area in order to minimize wake losses. A spacing of five rotor diameters is often recommended. In a typical wind farm, the land physically occupied by tower foundations, buildings, and roads is often less than 2% of overall land area.[6] The remaining land is quite suitable for agriculture and other uses.

Limits to Maximum Production

How much capacity exists to generate electricity from wind? Is it possible that we will require more energy than wind can provide? After surveying wind patterns in the United States and applying energy density and extraction calculations, Elliott and Schwartz[14] concluded in 1993 that 6% of the available U.S. land mass could provide 150% of then-current U.S. electrical consumption. Furthermore, the needed land would be sparsely affected by the wind farm installation, with the vast majority of it (95%–98%) unoccupied by tower foundations, roads, or ancillary equipment and suitable for farming, ranching, and other uses. This study excluded land that is environmentally or otherwise unsuitable, such as cities, forests, parks, wildlife refuges, and environmental exclusion areas.

In the European Union, potential wind power capacity is also larger than current electrical consumption.

Future

Projected Growth

Thanks to increasing concern over the environmental effects of greenhouse gas emissions, the rising cost of fossil fuels, and the impending decrease in availability of oil and natural gas, wind power has a bright future.

Current 25%–30% growth rates are likely not sustainable, due to equipment production volume constraints and limits to perceived need for further capacity. Given the Eurocentric, highly clustered nature of current installed capacity, there is significant potential for high-rate growth elsewhere. However, even in European countries like Germany and Denmark, steady growth will be driven by predicted cost reductions in the 10%–20% range and by regulatory and governmental initiatives aimed at reducing emissions from electrical energy production and transitioning to renewable resources.

Projected Cost

Wind power technology is well down the cost improvement curve, with costs having fallen to present levels, below ten cents USD per kWh, from over $1.00 U.S. in 1978. Costs for a medium-sized turbine have dropped 50% since the mid-1980s, reflecting increasing maturity in the market. Cost projections range from a further 9%–17% drop as installed capacity doubles in the near-term future.

Projected Production

With increasing governmental policy support and commitment, growth rates of 15%–20% appear achievable in five to ten years. But there is likely an upper limit to the amount of electrical energy that can be produced from the wind.

Reaching Maximum Production

Production limits for wind power are based on its variable nature. Other types of electrical production capacity will be needed to provide base-load electrical capacity in the event that there is little wind available. Wind power will then become one player in a mix of generating technologies.

Hydrogen Economy

As wind power becomes a larger portion of electrical supply, occasionally its supply will exceed demand. Rather than simply curtailing wind plant production, it is attractive to think of using this excess electrical power capacity to generate hydrogen via electrolysis. This has the effect of storing wind energy that would otherwise not be harvested. This energy, in the form of hydrogen, can be used directly as a nonpolluting fuel or as an input source to fuel cells to produce electricity at a later time.

When there is a significant hydrogen economy, with transmission lines, storage, and fuel cell capacity, this use for wind power will become a very attractive scenario.

Other Issues for the Future

Learning more about wind and forecasting—predicting the best locations, wind farm output, gusts, and directional shear.[10] This will help reduce financing costs when wind power plant output and impact on the grid are better understood and more predictable.

- Improving the control of demand through incentives around end-user load shedding, rescheduling and simple conservation methods. This could be used to offset wind power production shortfalls as an alternative to other forms of generation.
- Advancing aerodynamics specific to wind turbine blades and control systems.
- Designing extremely large wind tunnels to study wake effects minimization, structural load prediction, and energy output maximization at lower wind speeds.
- Enhancing power system capacity planning models to include wind farm components.
- Re-planting, or upgrading older mechanical and electrical components at existing wind farms.
- Wind farm siting further offshore and on floating platforms.
- Combining wind power and hydroelectric capacity by using surplus wind power to pump water behind dams and so store power that might otherwise be wasted.
- Determining how and whether to allocate full costs of environmental impact to fossil and nuclear plants.

Strengths and Weaknesses

Strengths

Environment

Wind power installations do not emit air pollution in the form of carbon dioxide, sulfur dioxide, nitrogen oxides, or other particulate matter such as heavy metal air toxins. Wind power installations do not use water or discharge any hazardous waste or heat into water. Conventional coal, oil, and gas electric power plants produce significant emissions of all kinds. Nuclear power plants produce dangerous and long-lasting radioactive waste. Greater use of wind power means less impact on health and the environment, particularly regarding climate change due to greenhouse gas emissions.

Renewable

Wind power produces energy from a resource that is constantly renewed. The energy in wind is derived from the sun, which heats different parts of the earth at different rates during the day and over the seasons. Unlike fossil and nuclear plants, the source of energy is essentially inexhaustible.

Costs

Wind power's costs are well known and are dropping to the point at which this technology is very competitive with other means of production. Fuel costs are nil, meaning that fuel costs have no uncertainty. Wind power costs should be more stable and predictable over the lifetime of the plant than power costs for fossil fuel plants.

Local and Diverse

Wind power plants provide energy source diversity and reduce the need to find, develop, and secure sources of fossil or nuclear fuel. This reduces foreign dependencies in energy supply, and reduces the chances of a political problem or natural disaster interfering with and diminishing the supply of electricity.

Quick to Build, Easy to Expand

Wind power plants of significant capacity can be constructed and installed within a year, a much shorter time than conventional plants. The planning time horizon is similar to conventional plants, given the need to accurately survey site wind characteristics and deal with normal environmental and related site issues. This means that capacity can be increased in closer step with demand than with conventional plants. With the right site and design, a wind power plant can be incrementally expanded very quickly.

Weaknesses

Natural Variability

A single wind farm produces variable amounts of energy, and its output is not yet as predictable as a traditional plant. As the geographical distribution and number of wind plants increases, and as research into predicting wind continues, these problems should be minimized, allowing cost-effective and orderly scheduling and dispatch of total grid capacity sources—but it is difficult to see traditional power sources disappearing entirely.

Connection to Grid

As the amount of electrical power supplied by wind power plants increases, concern increases over its effects on the electrical grid.

In order to maintain a reliable supply of electricity that matches demand, utility operators maintain emergency reserve capacity in order to deal with plant outages (failures) and unexpected demand across their entire system. This reserve is in the form of purchased power, unused capacity at conventional plants running below their maximum, or quick-start plants such as gas-fired turbines. Often, conventional plants on the grid are allocated a cost to cover this reserve based on their capacity (large plant, large reserve) and reliability (more outages, more reserve).

The industry is working on ways to determine and allocate this reserve cost for wind power plants. Yet to be agreed upon is the statistical basis for calculating such wind power plant reserve costs. Improvements in day-ahead wind forecasting will greatly reduce the uncertainty around wind plant output, and so decrease the cost burden to provide this reserve.

Several current estimates prepared for U.S. utilities show this reserve cost burden (or ancillary services cost) to increase with the amount of capacity provided by wind power, and to be in the range of 0.1–0.5 cents USD per kWh for penetrations between 3.5 and 29%. In no case was it thought necessary to allocate a reserve equal to 100% of the wind power capacity.[11] German experience is similar,[8] with no additional reserve capacity required for the 14% wind energy share of the national electrical consumption forecast for 2015.

When wind power supplies less than 20% of electrical consumption, these problems are not severe. At larger penetrations, reserves become a major issue. Interestingly, wind power plants may be subject to shutdown or voluntary power reductions in the event of coincident high wind, low demand situations. This is occasionally the case today in Denmark and Spain.

In some cases, wind power sites are situated far from the location of high electrical power demand, placing strain or potential overload on existing transmission facilities. In these cases, there are often cost, ownership and responsibility issues yet to be resolved.

Power quality problems around power factor, harmonic distortions, and frequency and voltage fluctuations are being successfully addressed in modern large production wind farms.[8]

This is one of the most difficult sets of issues facing the future of wind power as it matures from small-scale and local to large-scale penetration.

Local Resource Shortage

In a few places, high-quality wind power sites are not available or are already in production, leaving these places to import electrical power or use traditional sources.

Noise

Noise levels have decreased and are now confined to blade noise in modern units. Generator and related mechanical noise has been effectively eliminated. Noise, however, will always be a significant factor. Blade noise is described as a “whoosh, whoosh” sound, and is in the 45–50 decibel range at a distance of 200–300 m. This noise level is consistent with many national noise level regulations. However, this noise buffer zone adds to the overall land requirement for a wind power plant and so increases costs.

Visual Impact

Onshore wind farms are highly visible due to the height of towers and the size of the blades and generator. The impact of this varies with each person. Each wind plant operator needs to determine the levels of support and opposition from those who live and work within sight of the plant. Offshore plants attract fewer detractors than onshore plants—one of the reasons for their increasing popularity.

Offshore wind plants are less likely to cause unwanted noise since they are far from human habitation. This reduces turbine and blade design constraints and can lead to higher capacity factors.

Bird Impact

Bird deaths are a regrettable reality. The bird death rate at a specific wind farm project is quite variable. Several early wind farms (Altamont Pass, California, and La Tarifa, Spain) caused concern over death rates. The California Energy Commission estimates the death rate at Altamont (5400 turbines) to be 0.33–0.87 bird deaths per turbine per year.[16] The overall recent U.S. national average[13] is 2.3 bird deaths per turbine per year. Prudently located sites are off migration routes and not in nesting, overwintering, or feeding areas. Their tower designs do not offer nesting or even roosting places. In such locations, death rates are lower, and overall impact is much lower than that caused by other types of human activity.

Since climate change is a very serious environmental problem faced by bird populations, wind power and other renewables are an important part of the solution.

Technology

Overview

Wind turbine design has three major components, and there are large economies of scale in design.

- *Tower height:* Wind turbine energy output is proportional to the cube of wind speed. Since moving air (wind) is subject to drag and turbulence from its contact with the earth and the objects on the earth, wind speed increases with height (vertical shear). The higher the tower, the more advantage there is for power generation. The tradeoff is between tower costs and increase in power generation. Typically, tower heights are rising, and are currently in the 100 m range. Off shore, vertical wind shear is generally less than onshore, so towers can be shorter, with wave height clearance being the factor that determines tower height (Figure 1).
- *Blade diameter:* The power capacity (watts) of a wind turbine varies with the square of its blade diameter, because a blade with a larger diameter has a larger area available for harvesting the wind energy passing through it. The coefficient of performance defines the actual power capacity compared to the maximum—how much energy can be extracted from the wind compared to the available energy. Modern wind turbines can achieve a coefficient of performance approaching 0.5, very close to the theoretical maximum of 0.59 derived by Betz.[3,18] This maximum is derived from the concept that if 100% of wind energy were extracted, the wind exiting the turbine would be at zero speed, so no new air could enter the turbine. Larger capacity turbines benefit significantly from economies of scale in foundation and support costs as well as swept area (Figure 2).
- *Controls and generating equipment:* The turbine's hub (or nacelle) is the most costly component and contains the generator, gear boxes, yaw controls, brakes, cooling mechanism, computer controls, anemometer, and wind directional vane.

Generators

As the blades turn, they drive a generator to produce electricity. Generating capacity ranges from a few hundred kW to over 3 MW. In older designs, there is usually a 40:1 gearbox to match low, fixed rotor speeds (~30 RPM) to required generator speed (1200 RPM for a 60 Hz output, 6-pole generator).

FIGURE 1 Typical large wind turbine. Note entrance steps and utility pole at base for scale.

FIGURE 2 Site assembly of large wind turbine nacelles and blades.
Source: Photo courtesy of Suncor Energy, Inc.

The gearbox often incorporates brakes as a part of the overall wind turbine control system. Generators that operate at low RPM are available and are called direct drive generators. These would eliminate the gearbox.

In more modern designs, rotor speed is variable and controlled to optimize power extraction from the available wind. Generator output is converted to d.c. and then back to a.c. at the required grid frequency and voltage. The conversion equipment is sometimes located at a central part of the wind power plant.

This is an active area for ongoing technical innovation.

Blades

In order to maximize power capacity through size, blades are very long, up to 50 m. To minimize noise, they must turn slowly so as to reduce tip speed, the primary blade noise source. Typical rotation speeds are in the 10–30 RPM range. Blades are increasingly made from composites (carbon fibre reinforced epoxy resins).

Rotor blade aerodynamics[19] have much in common with the aerodynamics of a propeller or a helicopter blade, but they are sufficiently different that the aerodynamics of wind turbine blades is an evolving field. The difference is that wind turbine airflows are unsteady due to gusting, turbulence, vertical shear, turbine tower upstream shadow, yaw correction lag, and the effects of rotation on flow development. For example, at present it can be difficult to predict rotor torque (and therefore power output) accurately for normal turbine operating conditions. Further development of theory and modeling tools should allow the industry to improve rotor strength, weight, power predictability, power output, and plant longevity while controlling cost and structural life.

For a given site wind velocity, the rotor blade’s tip has very different air flow than its root, requiring the blade to be designed in a careful twist. The outer third of the blade generally produces two-thirds of the rotor’s power. The third nearest the hub provides mechanical strength to support the tip, and also provides starting torque in startup situations.

Each blade generally has lightning protection in the form of a metallic piece on the tip and a conductor running to the hub.

Some manufacturers place Whitcomb winglets at the blade tips to reduce induced drag and rotor noise, in common with aircraft wing design.

In order to control blades during high wind speeds, some are designed with a fixed pitch that will progressively stall in high wind speeds. Others incorporate active pitch control mechanisms at the hub. Such control systems use hydraulic actuators or electric stepper motors and must act very quickly to be effective.

Wind Sensors

Wind turbines incorporate an anemometer to measure wind speed and one or more vanes to measure direction. These are primary inputs to the control mechanism and data gathering systems usually incorporated into a wind turbine.

Control Mechanisms (Computer Systems)

Control systems are used to yaw the wind turbine to face into the wind, and in some designs to control blade pitch angle or activate brakes when wind gets too strong. In sophisticated cases, the controllers are redundant closed-loop systems that operate pumps, valves and motors to achieve optimum wind turbine performance. They also monitor and collect data about wind strength and direction; electrical voltage, frequency and current; nacelle and bearing temperatures; hydraulic pressure levels; and rotor speeds, vibration, yaw, fluid levels, and blade pitch angle. Some designs provide warnings and alarms to central site operators via landline or radio. Manufacturers do not release much detail about these systems, since they are a critical contributor to a wind turbine's overall effectiveness, safety, and mechanical longevity.

Role of Governments and Regulators

Governments play a large part in determining the role and scale of wind energy in our future mix of energy production capabilities.

Subsidies, Tax Incentives

As part of programs to encourage wind power production, the following are used in varying ways[7]:

- Outright subsidies, grants and no-interest loans.
- Tax incentives such as accelerated depreciation.
- Fixed prices paid for produced electrical power.
- Renewable energy quantity targets imposed on power utility operators.

Grid Interconnection and Regulatory Issues

Since many power utility operators are owned by governments, and most are regulated heavily, governments have a role to play in encouraging solutions to grid interconnection issues. There must be a political will to address issues, find solutions, and develop practices and different management strategies that will allow greater penetration of wind power into the electrical supply.

Improving Wind Information

Climate and environmental information is most often collected and supplied by national governments in support of weather and aviation services. Wind atlases are an invaluable resource to the wind plant planning process. National efforts to improve long-and short-term wind forecasting, atmospheric modeling tools, and techniques will benefit wind power projects' ability to forecast power output for long-term and short-term planning purposes.[10]

Environmental Regulation

In this controversial area, government can tighten its regulation of air quality, carbon emissions and other environmental areas. This would have the effect of increasing the apparent cost of conventional thermal electrical power, which is responsible for significant emissions. It is often argued that wind power would already be cost competitive if environmental and health costs were to be fully allocated to conventional oil, gas, and particularly coal-powered plants, or if such plants were required to make investments to significantly reduce emissions.

Conclusion

Western societies depend on a steady supply of energy, much of it in the form of electricity. Most of that supply comes from thermal plants that burn oil, natural gas, and coal, or from nuclear plants. Where will our electrical energy come from in the future? How will we keep our environment livable and healthy?

One part of this answer lies in wind power. Its costs are within reason; the technology has matured with some gains yet to be realized; it carries little environmental penalty; and the source of its energy is renewable. As long as the sun heats the earth, wind power will be available.

Wind power will not likely be the complete answer; it is an intermittent source because the wind doesn't always blow. But there is a very large amount of it available for us to harvest. As wind power moves quickly from small-scale to large-scale, its future path depends on governments and regulators as much as it does on technical innovators and manufacturers.

Electric Power: Microgrids

Ryan Hanna

Introduction

Microgrids are insular power systems embedded within the bulk power grid that use distributed energy resources (DERs), such as fossil fuel generators, renewable generators, and energy storage, to provide energy locally near the point of consumption (Figure 1). They may be small or large, for example, a single building or a campus with dozens of buildings, and they may be simple or complex, for example, consisting of a single backup generator or numerous DERs working in concert to provide primary power. In any case, their defining attribute is their ability to disconnect, or "island", from the larger grid during power outages, thereby shielding customers within from disruptions and improving the reliability of electric service. (Some taxonomies include remote or "off-grid" systems—those not embedded within a bulk grid.) Although microgrids vary widely in size, from tens of kilowatts to tens of megawatts, those powering a small commercial building (approximately hundreds of kilowatts) are indeed "micro" or on the order of 10^{-6} the capacity of the bulk U.S. power grid.

Since their inception, power systems have been built to provide electricity that is reliable and economic—two competing design criteria that require balancing (Billinton and Allan 1996). Today, a third criterion—that power systems provide carbon-free electricity in accordance with long-term climate stabilization goals—is now widely accepted. The climate criterion presents new and interesting design trade-offs for microgrids. Historically, the fossil fuel pathway—i.e., the use of fossil fuel generators, first diesel but more recently natural gas—has provided high levels of reliability at low cost. Given future projections for very low gas prices, it is likely to remain the status quo absent new carbon-minded policy. Some policies are emerging—typically in the form of restrictions on diesel use—while governments have variously supported low-carbon pathways such as combined heat and power (CHP), renewables with energy storage, biofuels, and hydrogen. Although some options remain far-off, consideration is important today because each pathway offers a fundamentally different vision for how microgrids interact with a decarbonized energy system. Pathways can differ in use of fuels, generators, load electrification, outside requirements for energy infrastructure, and, importantly, outcomes for carbon emissions and pollution.

Recent support for microgrids has stemmed from concern about potential impacts to power systems from an increasing frequency of severe weather, including wildfires, to which climate change is contributing. The conventional wisdom is that microgrids can increase grid reliability and resiliency while also

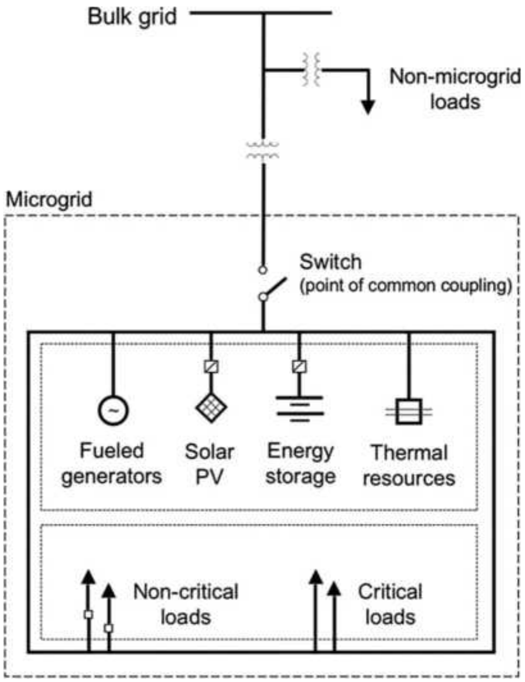

FIGURE 1 A simple representation of a grid-connected microgrid. Distributed energy resources (DERs) and loads comprise the microgrid and lie behind a single point of common coupling to the bulk grid. The microgrid can disconnect from and reconnect to the bulk grid and operate autonomously. (Fossil fuel and thermal energy networks are present but, for clarity, not pictured.)

helping to address climate change. An appraisal of decarbonization pathways, however, shows that this is not always so (Section "Decarbonization Pathways for Microgrids"), and comparison of cost, emissions, and performance helps explain where co-benefits and trade-offs exist. A picture of historical deployments and present-day activities around microgrids provides further context (Section "Microgrids, Past and Present"). Although the focus here is the U.S.A, deployments are on the rise globally, particularly in Asia Pacific (e.g., Australia, India, China, and Japan) where forecasted growth is in fact greatest and driven by deployment of remote systems in developing areas that lack grid infrastructure (Willette and Asmus 2019).

Microgrids, Past and Present

Microgrids are not a new phenomenon. Today, we recognize the earliest power systems—pioneered by Thomas Edison during the 1880s that provided lighting for hundreds of customers across a few New York City blocks—as microgrids. These grids, and hundreds in other cities, would first experience decades of expansion, as industry pursued larger customer bases and scale economies and governments mandated rural electrification in the 1930s–1940s to combat poverty (Tuttle et al. 2016), and later interconnection to increase redundancy and power plant utilization rates.

Centralized grids now underpin nearly all of the industrialized world, limiting the role for microgrids to niche applications. The high cost of microgrids has been justified where interconnection to the bulk grid is impractical or uneconomic, such as with island villages, military bases, and remote industrial facilities. In Alaska, diesel and hydropower microgrids power over 200 remote communities. It has also been justified where services within the bulk grid are deemed critical. Microgrids provide backup power for the health care industry, where hospitals must comply with emergency generator standards and maintain onsite a 96-hour supply of diesel fuel, as well as for the telecommunications industry's enormous network of cell towers, where the use of small (<10 kW) diesel generators and lead-acid batteries has dominated. More recently, incentives have supported the use of fuel cells—over 3,000 have been deployed since 2007 (Ma et al. 2017). Microgrids have also been economic in campus settings that have space and the institutional capacity for ownership and operation. Prominent examples include those at New York University, Princeton University, the Illinois Institute of Technology, the University of California San Diego, and the University of California Irvine, among others. Natural gas cogeneration forms the physical and economic backbone of many, providing significant cost savings on electricity, heating, and cooling.

Today, the role for microgrids is expanding as governments begin to take a proactive approach in guiding their development. State governments in the northeast U.S.A are seeking to create a role for "community" microgrids that embed pockets of resiliency into the grid and serve the public interest. Following severe weather in 2012 that caused widespread blackouts, Connecticut in 2013, Massachusetts and New Jersey in 2014, New York in 2015, and Maryland in 2019 each enacted a community microgrid grant program to increase resiliency at critical infrastructure such as hospitals, police and fire stations, wastewater treatment plants, public shelters, and municipal commercial areas. Recent power outages at the Atlanta, Las Vegas, Washington D.C., Los Angeles, Hamburg, and Amsterdam international airports have spurred funding for microgrids that support critical airport services.

Other jurisdictions are pursuing a market-based approach with the development of commercialization pathways that tie in to broader efforts to decentralize electricity generation. California is leading, having recently awarded $25.7 million for seven microgrids in 2014 that demonstrate "low-carbon" and "renewables-based" configurations and $45 million for nine microgrids in 2018 that demonstrate "repeatable, commercial-scale" configurations that support the state's emissions reduction goals. Hawaii passed legislation in 2018 to establish a tariff that defines the value of services exchanged between a microgrid and the bulk grid. In the Caribbean, Puerto Rico's post-Hurricane Maria reconstruction plans aim to decentralize generation on the island, and part of that vision includes a new regulatory framework for microgrids that encourages deployment by third-party (non-utility) providers. The island's goals are to increase reliability, and reduce fossil fuel consumption and carbon dioxide emissions, among others. The U.S. Virgin Islands is also rebuilding through microgrids, deploying two on the island of St. John comprised of diesel generators, solar photovoltaics (PV), and battery energy storage.

To what extent are these microgrids low-carbon? In all historical use cases, fossil fuel generators have been the preferred technology. This holds true today in the emerging community microgrid paradigm, despite falling prices for renewable energy and energy storage. For the programs in Connecticut (Microgrid Pilot Program Round 1 and 2) and New York (NY Prize Stage 2), for example, for which good data on installed or planned DERs exists, natural gas generators comprise 78% of total capacity, of which 61% is CHP, while PV comprises 4%, which is on par with diesel generators (also 4%). Battery storage, on a power capacity basis, comprises 3%. Five of the six microgrids supported by the New Jersey Energy Resilience Bank are based entirely on natural gas CHP. By contrast, California has set out to support renewable microgrids and its 2014 program produced 73% solar PV, 11% battery storage, and 15% fossil fuel generation by capacity. Programs in other jurisdictions remain too nascent to draw conclusions.

Each of these jurisdictions pushing microgrids has enacted climate policies that aim to decarbonize the power sector through mandated cuts in greenhouse gas emissions, procurement targets for renewable energy, or both. Puerto Rico and Hawaii have passed into law 100% renewable energy portfolio standards (RPS), for instance, while California has passed a 100% clean energy standard. The five northeast states with microgrid grant programs have RPS targets ranging from 25% to 50% by 2030. Accordingly, some have acted to limit fossil fuel use in microgrids. Puerto Rico's 2018 rules, for example, mandate renewable energy and restrict fossil fuel use in non-CHP generators in three ways: to 25% of the total microgrid energy output on an annual basis, by generator heat rate (not greater than 13,000 btu/kWh), and by the total microgrid energy input–output ratio (not greater than 2,500 btu/kWh). CHP generators qualify but must adhere to efficiency standards (useful thermal energy must be greater than 50%

of the total energy output) and generator heat rate (not greater than 7,000 btu/kWh). California's 2018 microgrid legislation (SB 1339) prohibits compensation for all diesel use and natural gas generators that fail to meet strict emission standards, effectively precluding non-CHP fossil fuel generators. By contrast, Hawaii, which is in the process of establishing a microgrid services tariff, has not set any prohibitions on fossil fuel use.

Decarbonization Pathways for Microgrids

Although the merits of particular choices for technology and fuel in microgrids are case-specific (Hanna et al. 2017; Flores and Brouwer 2018), an assessment of pathways generally should address the three power system design criteria—reliability, cost, and emissions. Table 1 summarizes that assessment qualitatively for the present day, with characteristics scored from very poor (––) to very good (++). It also includes the practicability of deployment, or dependency on outside energy infrastructure, as well as scalability, or the capability of the pathway to scale up to meet a significant portion of society's electricity needs. Power density, a watt per square meter (W/m^2) measure of the concentration of energy generation or consumption, is a useful metric with which to assess the capabilities of distributed generators that, unlike rural power plants, are confined by limited space in built environments. Here, it is a proxy for reliability.

The diesel pathway, or use of diesel reciprocating engines, is the historical pathway and taken in this assessment as the base case against which other pathways are scored. Diesel generators are technologically mature, highly versatile, and have high power densities and low cost. Overuse can significantly degrade local air quality, however, and many jurisdictions limit their application to emergency operation only, typically a few hundred hours per year. Thus, they are neither scalable nor desirable options for widespread decentralization; other solutions are needed. Figure 2 shows the physical features for technology choice and fuel that distinguish pathways.

Combined Heat and Power

Over 2,000 CHP systems across the U.S.A provide nearly 2.3 GW of capacity (Darrow et al. 2017). These systems are fossil fuel generators like reciprocating engines and turbogenerators that capture and use engine waste heat to supply building heating and cooling needs. In making use of heat that is otherwise dissipated to the environment, CHP provides two benefits: it increases the efficiency of fuel use, from 25–45% in standalone (i.e., non-CHP) generators to 65–80% in generators with heat recovery, and it reduces (and can eliminate) direct gas combustion for heating as well as electricity for cooling, thereby reducing greenhouse gas emissions in the commercial and residential sectors. CHP is successful in reducing emissions today because the combustion of gas to meet electrical and thermal energy demand in concert results in a lower carbon intensity (gCO$_2$/MJ) than the separate production of electricity from the bulk grid and heat from a gas boiler or furnace.

TABLE 1 Microgrid Pathways—Characteristic Technology Choice, Fuel Use, and Assessment[a]

Pathway	Technology	Fuel	Power Density	CO$_2$ Emissions	Pollutant Emissions	Cost	Practicability	Scalability
Diesel	ICE	Diesel	++	––	––	++	++	––
CHP	ICE-CHP	NG	++	–	–	+	++	+
All-electric (solar-plus-storage)	PV, BS, HP	None	–	++	++	–	++	+
Biomethane	ICE-CHP	Biomethane	++	+	–	–	+	––
Hydrogen	FC-CHP	Hydrogen	++	++	++	––	––	++

[a] *Abbreviations:* ICE (internal combustion engine), CHP (combined heat and power), PV (photovoltaics), BS (battery storage), HP (heat pumps), FC (fuel cell), and NG (natural gas).

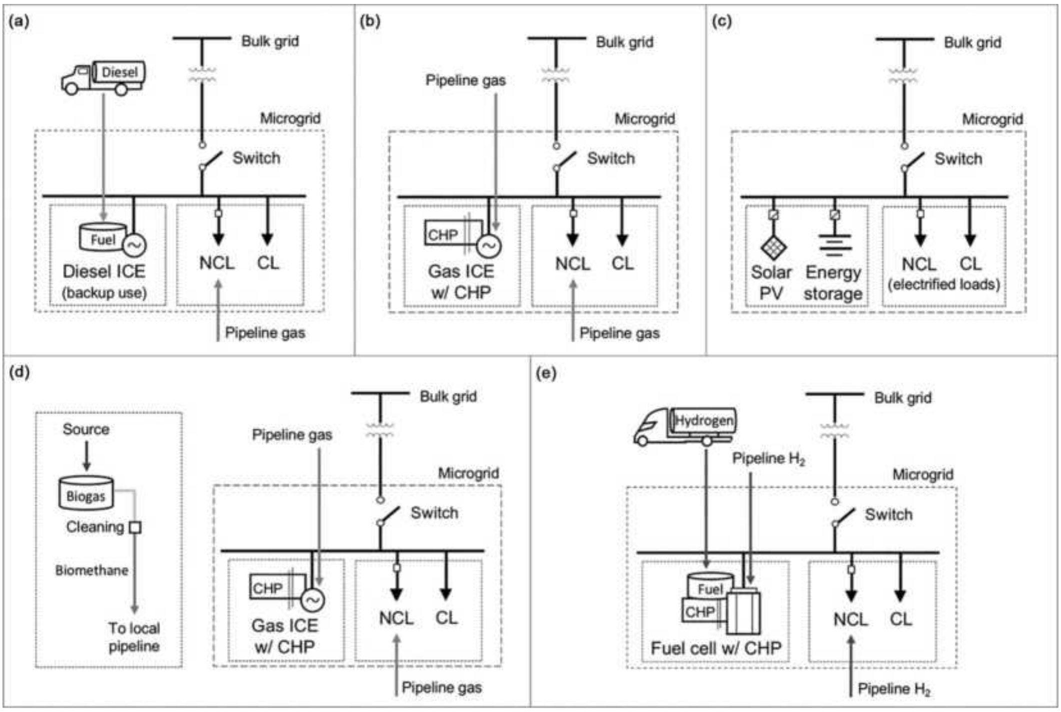

FIGURE 2 Physical features for technology choice and fuel that distinguish pathways from one another. The five pathways are (a) a diesel genset, (b) gas-fired genset, (c) solar-plus-storage (all-electric), (d) biomethane-fired genset, and (e) hydrogen fuel cell. All fueled gensets (less the diesel genset; b–d) make use of CHP. NCL denotes non-critical load, CL critical load, ICE internal combustion engine, CHP combined heat and power (i.e., infrastructure for capturing and using waste heat), and H_2 hydrogen.

Governments have supported CHP for decades as non-utility generators. For example, the Obama Administration in 2012 set a nationwide target of 40 GW of new capacity by 2020, while in 2010 the state of California set a target of 6.5 GW by 2030. Governments are now coupling support of CHP to microgrids. California and Puerto Rico, through new microgrid rules, are discouraging (or banning outright) the use of standalone generators while encouraging CHP use, while the community microgrid programs emerging in the northeast U.S.A are largely supporting natural gas CHP.

The central issue with CHP is its reliance on fossil fuels. The CHP pathway is therefore at most a low-carbon pathway. For this reason, it also lacks scalability, as local air quality regulations limit criteria pollutant emissions. Its ability to reduce carbon emissions depends on the carbon intensity of grid electricity, which is expected to decarbonize over time, as well as the presence of gas combustion in buildings, which are expected to electrify over time. The fossil CHP pathway is therefore limited in efficacy: it locks in long-lived fossil generation that is effective in reducing carbon emissions in the short term but whose effectiveness declines as the bulk grid decarbonizes. (Fuel switching from fossil gas to renewable gas could make CHP carbon-neutral—but that is a distinct pathway considered separately.)

All-Electric: Solar-plus-Storage

One alternative to the use of fossil fuels is to discard them entirely via a fuel-free "all-electric" pathway that pairs solar PV with electric storage such as lithium-ion batteries and that might further include electrified loads and heat pumps, deep energy efficiency, and demand response. PV and storage provide power and substitute for gas generators, electrified loads obviate gas combusted for heating, and responsive demand provides operational flexibility. Combinations of these technologies offer a legitimate path to zero carbon and zero pollution in microgrids.

Of all pathways, the solar-plus-storage option is perhaps the most touted by advocates of decentralization. It maps technologically to other transitions taking shape in the power sector, where utility-scale PV and batteries are emergent and electrification of load and responsive demand are expected to assume important roles in decarbonization. Like CHP, solar-storage microgrids are not dependent on technological breakthrough nor new energy infrastructure; they are proven solutions with numerous operational today, including three funded in 2014 by the State of California as well as many financed privately (Asmus et al. 2017).

Yet the solar-storage pathway faces fundamental challenges related to performance and applicability, while high costs remain an issue. Fundamentally, the use case for solar-storage microgrids is limited by the high power demand of modern cities and low power density of PV (Smil 2019). For example, an analysis of energy use for a selection of the most common types of buildings in the U.S.A shows power densities of 10–250 Wm^{-2}, with warehouses (5–10 Wm^{-2}), retail spaces (15–20 Wm^{-2}), schools (15–60 Wm^{-2}), and smaller office buildings (15–55 Wm^{-2}) constituting the lower end and hotels (150–165 Wm^{-2}), large offices (190–230 Wm^{-2}), and hospitals (235–260 Wm^{-2}) constituting the higher. Variation derives from thermal loads that differ by climate zone—in this example bounded by temperate coastal and hot inland conditions in southern California. In comparison, average annual solar irradiance in coastal and inland California is approximately 210 Wm^{-2} and 240 Wm^{-2}, respectively. With 19% efficient PV cells, PV power densities are 40–46 Wm^{-2}. Thus, only for a subset of these buildings—warehouses, retail spaces, schools, and small office buildings—is PV able to provide a surplus of energy on an annual basis. For the remaining buildings, 100–600% more space is needed for PV installations to achieve parity between annual energy demand and generation. In all cases, substantial energy storage is required to shift excess PV generation to the nighttime when operating in island mode. Demand response can reduce building power density during times of stress by turning off or delaying non-critical load, whereas building electrification increases building power density because it electrifies loads otherwise met with gas.

The solar-storage pathway also faces challenges of cost and performance. Compared to solar-storage microgrids, microgrids that further include fossil fuel generators can provide higher levels of reliability at lower cost because fossil fuel generators are inexpensive by comparison and with fuel reserves are able to supply power day and night. Because PV power is weather-dependent, microgrids depend heavily on storage during times of stress, possibly requiring significant oversizing of storage to ensure islanded operation. As such, microgrids with fossil generators outperform solar-storage microgrids on a reliability-per-cost basis.

Ultimately, low power density and lack of space for PV installations in urban environments limit scalability. Barring radical breakthroughs in cell efficiency or cost decreases for high-efficiency cells, distributed PV will remain unable to meet the power demand of much of modern civilization. A restriction on fossil generators achieves climate benefits but limits applicability because fossil generators are high–power-density DERs that are best suited to serving high-density urban areas. Absent new carbon-minded policy, such as carbon pricing, addressing resiliency and climate change simultaneously with solar-storage microgrids, requires sacrificing cost, performance, or both.

Biomethane

A second alternative to the use of fossil fuels is to substitute them with biomethane while keeping the generator. Biomethane, or renewable natural gas, is biogas that has been cleaned of impurities, upgraded to pipeline quality, compressed, and injected into the natural gas network. Biogas can be sourced from landfills, wastewater treatment plants, municipal solid waste, and manure, among others. Although its emissions when combusted are similar to those of fossil natural gas, biomethane is considered carbon-neutral because it displaces fossil gas in the power sector and when sourced from waste streams reduces emissions from the source sector (either industry or agriculture).

Although in some cases microgrids are collocated with a source of biogas—the MCAS Miramar microgrid in San Diego, California, which uses landfill gas, is one such example—production and consumption need not be physically linked. With such "directed" biomethane, a source facility captures and treats previously vented or flared biogas and injects it into the local gas network, displacing an equal volume of fossil gas as a result. The consuming generator, located perhaps tens or hundreds of kilometers distant, combusts pipeline gas locally but through reporting methodologies is credited with the combustion of the injected, carbon-neutral biomethane. Allowing for directed biomethane is practical because the load centers that microgrids serve may be located far from contracted biogas sources. It also enables market forces to identify the cheapest sources of supply. The University of California, as part of its 2025 carbon neutrality initiative, has contracted for directed biomethane to permit continued use of its CHP gas turbines (Meier et al. 2018).

The biomethane pathway is a carbon-neutral pathway and allows microgrids to retain use of fossil fuel generators. Microgrids can therefore achieve high levels of reliability and are not limited in applicability due to issues of power density. Nevertheless, issues of cost, scalability, and pollutant emissions constrain and limit its potential. In the short term, biomethane commands a price premium relative to fossil gas: prices for pipeline-ready biomethane are $10–24/mmbtu depending on the source (Sheehy and Rosenfeld 2017), while U.S. fossil gas prices stand near $3/mmbtu. Whether biomethane microgrids are cost competitive with fossil CHP microgrids depends on the contracted price for biomethane and prevailing carbon pricing; whether they are cost competitive with solar-storage microgrids requires granular analysis of performance and cost that considers local conditions such as electric tariff structures and rules limiting air pollution or pricing carbon. Although biomethane prices exceed those of fossil gas, governments have created policies and incentives to encourage the development of biogas resources, such as methane emission reduction targets and direct financial support for projects. However, the bulk of these incentives, notably the federal Renewable Fuel Standard (RFS) and Low-Carbon Fuel Standard (LCFS) in California, place emphasis on the use of biogas as an alternative transportation fuel rather than as a fuel for electricity generation. Competition with the transportation sector may constrict supply or increase price.

A second major issue is that long-term biogas resources are limited. The most recent estimate of U.S. biogas availability is 331 billion cubic feet per year or about 1–1.5% of U.S. fossil gas consumption (National Renewable Energy Laboratory 2013). Biogas may therefore provide for early adopters, but it lacks scalability to support a large customer base. As with fossil CHP microgrids, scalability might also become constrained jurisdictionally by air quality regulations. Developers could instead use fuel cells, which would emit only water vapor and carbon dioxide, but, at present, these command a significant cost premium compared to internal combustion engines and turbines.

Hydrogen

A fourth pathway, and the final discussed here, is the hydrogen pathway—the use of hydrogen fuel with engines and fuel cells. Although long-term visions for transitioning to hydrogen (Staffell et al. 2019) remain distant, the hydrogen pathway merits inclusion because it is the most promising in theory: it offers a path to reliable, scalable, pollution-free, carbon-free electricity. It is similar technologically to the CHP and biomethane pathways in its use of fueled generators and can further make use of fuel cells to provide pollution-free electricity. In either case, it is a zero-carbon pathway. Although today the majority of hydrogen is produced via steam methane reforming of natural gas, an underlying assumption of a future hydrogen system is production from renewable energy and electrolysis.

Hydrogen can be combusted in conventional spark-ignition engines and gas turbines with only small modification and efficiency losses and with emissions limited to water vapor and nitrous oxides (no carbon dioxide or carbon monoxide). A more efficient, cleaner, and ideal use of hydrogen is via electrochemical oxidation in fuel cells, where water vapor is the sole product. Hydrogen microgrids can provide high levels of reliability (i.e., they are not limited by low power densities) and are carbon-free.

They therefore match CHP and biomethane microgrids for provision of reliability and exceed them for emissions reductions, while the reverse is true in comparison with solar-storage microgrids.

Though the most promising, the hydrogen pathway faces the largest hurdles to implementation. Cost is a major issue in the short term, as hydrogen fuel commands a cost premium relative to fossil gas and the cheapest form of production remains steam methane reforming, which is carbon-intensive. Fuels cells also remain expensive relative to engines for prime power generation applications, although smaller deployments do exist today—notably over 3,000 hydrogen fuel cells that provide backup power for the telecommunications sector (Ma et al. 2019).

In the long term, the use of hydrogen places the largest demand of any pathway on new infrastructure outside the microgrid. Although hydrogen can be blended into the natural gas network in small amounts (concentrations larger than a few percent on a volume basis may embrittle pipeline materials), blending limits are a constraint and require that a future system of centralized hydrogen production use a dedicated transmission network. The development of hydrogen microgrids is therefore reliant on substantial build-out of infrastructure, including pipelines, production facilities, and storage sites—little of which exists today—and would require coordinated buy-in from the public, private industry, and government. Centralized hydrogen production also requires high penetrations of utility-scale renewable energy.

A ubiquitous hydrogen network for production and distribution, as envisioned in a future hydrogen economy, would make hydrogen microgrids fully scalable. In its absence, however, incremental scale-up is a challenge and the need today for distributed refueling networks limits applicability geographically. Experimentation with distributed refueling networks is ongoing, for example, with the U.S. Department of Energy's support for trigeneration fuel cells (U.S. Department of Energy 2016).

Conclusion

In the context of long-term climate stabilization goals, sustainable management and use of microgrids requires zero-carbon pathways for technology and fuel use. Competing objectives for reducing cost and emissions while increasing reliability preclude a single "best" pathway, while applicability and scalability should also be considered when planning long-term support for pathways. With respect to climate goals, the all-electric and hydrogen pathways are ideal because they make use of carbon- and pollution-free generation. The biomethane pathway is also ideal because it incents reductions in industrial and agriculture sector emissions, which must be brought to near-zero. Today, these pathways incur high costs, however, while low-cost options (diesel and CHP) are the least ideal. Aligning microgrid deployments with climate goals therefore requires action by policymakers. Carbon and pollution taxes, bans, or mandates for technology choice, and technology runtime limits are all policy options that can help encourage low-carbon investment choices. It is not the intent here to provide a ranking, however, and further work is needed to understand which options are best and why, or whether such policies are in fact sensible at this time given the nascency of the microgrid industry.

That microgrids be decarbonized to support climate stabilization goals assumes microgrids will play a non-negligible role in the future power system. Their future role remains uncertain, however, and will be guided by policy and market forces. There is another distinct possibility that microgrid deployments will remain limited in application, for example, to only the most critical of infrastructure. In such a scenario, it is possible that negative emissions in other sectors of the economy permit the continued use of fossil fuels in a relatively small number of strategic microgrids.

Energy Conservation: Benefits

Eric A. Woodroof,
Wayne C. Turner,
and Steven D. Heinz

Executive Summary

"It's not the age … it's the mileage" …

It is logical that a car driven 25% less each year will last longer. The same is true for most energy-consuming equipment, such as lights, motors, and even digital equipment. By turning "off "energy-consuming equipment when it is not needed, an organization can find a financial jackpot, which extends beyond the utility budget. *It doesn't matter how energy-efficient an organization is, there are savings from turning equipment "off" when it is not needed.* Listed here are some "secret" benefits of energy conservation and these are benefits that can be attained without a negative impact on productivity.

Budgetary Improvements

1. Efficient Net Income: When energy is conserved, utility budgets are reduced. This is no secret, but what is noteworthy is that conservation savings impact a bottom line far more efficiently than many other investment initiatives. *For example: an energy conservation program that saves $100,000 in operating costs is equivalent to generating $1,000,000 in new revenue (assuming the organization has a 10% profit margin). It is more difficult to generate $1,000,000 in new revenue, and would require more marketing, infrastructure, etc. Thus, the energy conservation/efficiency program is an investment with less risk and quickly improves cash flow.*

2. Extended Equipment Lives: If assets are lasting longer (owing to reduced operation per year), replacements are less frequent, thereby reducing capital budget requirements. *For example, if a lighting system is operating 30% fewer hours per year, it could last up to 30% longer. A 15-year replacement policy could be changed to 20 years.* Further savings could result from considering that if equipment lasts longer, then staff/engineering/project management time is reduced for reviewing new equipment proposals, evaluating competing bids, overseeing installation efforts, coordinating invoices and payables with accounting.
3. Reduced Maintenance Costs: When equipment runs fewer hours per year, maintenance material/labor requirements are reduced. *For example, if maintenance on a motor is done on a "run hour" basis and there are less "run hours" per year, there should be fewer maintenance visits. Further, if the motor is part of a ventilation system, air filter replacements would occur less often, reducing material and labor costs. Predictive maintenance technologies can also assist in this strategy and reduce the cost per horsepower by 50%. (Ameritech)*
4. Reduced Risk to Energy Supply Price Spikes*: For example, if less energy is consumed; the operational budget is less vulnerable when electric/gas/heating oil prices hit their seasonal spikes. The avoided costs can be worth millions to a large organization.*

Beyond the large financial benefits mentioned here, there are many strategic benefits of energy conservation, which can significantly add to your organization's "jackpot."

Long-Term Strategic Benefits

1. Ability to Sell "Carbon Credits": Organizations can claim emissions reductions from energy conservation. When energy is saved, power plants do not have to produce as much electricity, thereby reducing "smoke stack" emissions. *Emission benefits from energy conservation can be expressed in terms of "equivalent trees planted," or "equivalent barrels of oil not consumed."* There are environmental markets where "emissions credits" (from energy conservation) can be sold, generating revenue for an organization. These markets are already liquid in Europe (and are motivated by carbon-related legislation). California and other states already require emissions reporting and reductions, and federal regulations are in process that will open the door to a similar trading environment in the United States.[1]
2. Enhanced Public Image: Organizations that conserve/manage energy (thereby reducing emissions) can differentiate themselves as "environmentally friendly" and "good" members of a community. This can have tremendous political, strategic, competitive, and morale-building value for organizational leaders. Many benefits (such as attracting and retaining better employees, faculty, students, clients, suppliers, etc.,) result from being the "leader" in your field. A recent study showed that 92% of young professionals want to work for an organization that is environmentally friendly.[2] Even stock prices of corporations have been proven to improve dramatically (21.33% on average) when energy management programs are announced.[3]
3. Reduced Risk to Environmental/Legal Costs: If assets are replaced less frequently, an organization will generate less waste and be less vulnerable to environmental regulations governing disposal. (Disposal of batteries and fluorescent lamps is already regulated in most states) Greater environmental regulations are inevitable and unforeseen legal costs can pose a significant expense and political risk.[4,5]

As will be shown in the example on the next page, benefits 2–7 represent a significant improvement (18%–50%) to the original savings estimates.

Climate Change and Its Effect on Energy Conservation Approaches

"The Writing Is on the Wall..."

The glaciers are melting and climate change is here. Climate change is a result of changes in the Earth's atmosphere. The growth of "greenhouse gases" between 10,000 years ago and the 1800s was approximately 1% for that period. Since the 1800s, greenhouse gases have increased 33%. Thus, it is logical that this growth is due to human-caused activities with the dawn of the industrial age.

— Time Magazine-Special Report, December 2007. Also quoted by the UN Intergovernmental Panel on Climate Change-February, 2007 as well as the US EPA website: http://www.epa.gov.

The data is compelling and creating change in consumer choices.[6] Consumers are becoming more "green-minded" in their purchases, especially young people and college students. Studies show that more consumers are choosing to reduce their "carbon footprint," and thereby are choosing products, companies, and colleges that are more environmentally friendly. Carbon offset trading growth is greater than 200%: "in June 2007, the Chicago Climate Exchange reported that in the past 6 months, it had already traded 11.8 $MtCO_2e$—more than had been traded in the entire year of 2006"[7] and 69% of consumers shop for brands aligned with a social cause.[8] Federal and state governments are introducing legislation that will mandate carbon emissions reporting and management.[9] In September 2006, Governor Schwarzenegger signed the California Global Warming Solutions Act, which mandates a 25% cut in emissions by 2020 and an 80% cut by 2050. In summary, the need for a "carbon diet" is driving activity in the energy-conservation industry.

The "Good" News ...

Companies, colleges, and governments are responding to this growing "green" consumer market and competitors are innovating to be the "environmental leaders" of their fields. Hewlett-Packard says that in 2004, $6 billion of new business depended on answers to customer questions about the company's environmental record—a 660% growth from 2002.[10] "Sustainability efforts protect our license to grow" said Wal-Mart CEO Lee Scott in 2005.[11] Energy efficiency/conservation is ranked by corporate executives as the no. 1 way to reduce emissions in a cost-effective manner.[12] Because buildings contribute approximately 43% of the carbon emissions in the USA, an opportunity exists to reduce a large part of these emissions and become "environmental heros."[13] In addition, organizations perceived as more "environmentally friendly" can recruit better faculty, students, suppliers, and employees.[14] Finally, the "secret benefits" (discussed in the Executive Summary) are increasing in value and importance. *An energy conservation program is more valuable today because the material, waste, labor, emissions, and risk savings are more valuable in today's economy.*

A Simple Example to Demonstrate the "Secret Benefits"

A lighting conservation measure will serve as the example, although similar calculations could be applied towards motor systems. Motors and lights consume the majority of electricity in a typical building.[15] Computers and other digital equipment are also worth mentioning, because they can consume considerable amounts of energy, and it is noted that "plug loads" (computers, printers, and other digital equipment) have increased significantly during the past 20 years.

For this example, consider a large school with 10,000 light fixtures. Through a variety of energy conservation measures, it is common to reduce consumption by 25%.[16] First, we will calculate the dollar savings from electricity conservation. Then, we will show the "secret benefits," which have impacts beyond the utility budgets. A spreadsheet will illustrate the total savings/benefits.

Benefit 1: Reduced Utility Budget from Lighting Conservation

Assume the fluorescent lights are relatively new and consume 60 watts per 2-lamp fixture and operate 5000 hr/yr. (This example uses a standard T-8 lighting system, although the energy conservation savings would be even greater with a less efficient lighting system, such as a T-12.) Our baseline energy consumption is:

$$= \left(5000 \text{ hr/yr}\right)\left(0.060 \text{ kW/fix}\right)\left(10{,}000 \text{ fix}\right)$$

$$= 3{,}000{,}000 \text{ kWh/yr}$$

If the school pays approximately $.08/kwh, then the dollars spent on electricity for this lighting system:

$$= \$240{,}000/\text{yr}$$

Thus, a 25% reduction from the baseline usage would equal: 750,000 kWh/yr, or $60,000/yr in savings, *which goes immediately to the bottom line* and improves cash flow. Note that we will not count demand (kW) savings as the electrical load reduction would most likely occur during non-occupied hours (off-peak electrical rates). *However, it is not unusual for conservation programs to reduce both kWh and kW.* In addition to "direct dollar savings," there are tax rebates and credits available that can further improve the financial results from energy conservation/ efficiency programs/projects.

Benefit 2: The Value of Extended Equipment Lives (Reducing Capital Budgets)

If lights are used 25% less, the lighting system (ballasts) should last about 25% longer. Fluorescent fixture and wiring replacement costs are not included, as these components typically last longer than the ballast. We will address lamp life as a part of "maintenance costs" in Benefit 3. A lighting ballast is rated for 60,000 hr of operation. If the school operates the lights 5000 hr/yr, they would need to replace the ballasts at the 12th year and dispose of the old ballasts. If there are 5000 ballasts, each costing $25-$55 (material, installation, and disposal costs vary by geographic location), the replacement cost (minimum) at the 12th year would be:

$$= \left(\$25/\text{ballast}\right)\left(5000 \text{ ballasts}\right)$$

$$= \$125{,}000$$

Annualized replacement cost would be:

$$= \left(\$125{,}000\right)\left(1/12 \text{ yr}\right)$$

$$= \$10{,}417/\text{yr}$$

With a use rate of only 3750 hr/yr (a 25% reduction), the ballasts should last 16 years. If replacement occurs at failure or based on run time, these savings automatically occur. If replacements are planned in advance, planners should adjust their schedules to insure that savings are captured from extended equipment lives (not replacing assets pre-maturely). This would reduce the annualized replacement cost to:

$$= \left(\$125{,}000\right)\left(1/16 \text{ yr}\right)$$

$$= \$7813/\text{yr}$$

Thus, the Annualized Savings (calculated as the difference between the original replacement cost minus the reduced replacement cost) are:

$$= \$10{,}417/\text{yr} - \$7813/\text{yr}$$

$$= \$2604/\text{yr}\ (\text{at } \$25 \text{ per ballast})$$

Using the same equations, at $55/ballast, the annualized savings, (from replacing at 16 years instead of 12 years) would be:

$$= \$5729 \text{ per year}$$

Thus, due to extended equipment life, we have reduced the annualized replacement cost by a minimum of $2604/ yr to a maximum of $5729/yr.

Benefit 3: The Value of Reduced Maintenance Costs (Operating Expenses, Not Capital Replacements)

If the lights are used 25% less, the lamps should last about 25% longer. (Note that if lamps are turned "on" and "off " frequently at less than 3 hr intervals, the lamp's expected life will be reduced by approximately 25%, which would erode the savings in this category. Lamp life is rated at the factory by turning lamps on and off every 3 hr until they burn out. If the frequency of on/off cycling is less than 3 hr, lamp lives will decline by 25% on average. Therefore, turning a lamp off for longer periods is better than shorter periods. For example, it is better to find locations where you can turn off lamps for 5 hr out of 15 hr, instead of 1 min out of every 3 min, although the % time off is the same.) A typical fluorescent lamp life is 20,000 hr. With a use rate of 5000hr/yr, the school would need to replace lamps at the 4th year. If there are 10,000 lamps, each costing $3–$5 (material, installation, and disposal costs vary by location), the replacement cost (minimum) at the 4th year would be:

$$= (\$3/\text{lamp})(10{,}000 \text{ lamp}) = \$30{,}000$$

Annualized replacement cost would be $30,000/4 = $7500.

With a use rate of only 3750 hr, the lamps should last 5.3 years, thereby reducing the annualized replacement cost to:

$$= \$30{,}000/5.3 \text{ yr}$$

$$= \$5660/\text{yr}$$

Thus, Annualized Savings are:

$$= \$7500 - \$5660/\text{yr}$$

$$= \$1840/\text{yr}\ (\text{at } \$3/\text{lamp})$$

Using the same equations, at $5/lamp, the re-lamping cost would be $50,000 and the annualized savings from replacing at 5.3 years instead of at 4 years would be = $3066/yr.

Thus, due to extended lamp life, we have reduced the annualized maintenance cost by a minimum of $1840/yr to a maximum of $3066/yr.

Benefit 4: The Value of Reduced Risk to Energy Supply Price Spikes

Assume that on average, for one-quarter of the year, energy prices are 25%–50% higher ($.02–$.04 more per kWh) due to seasonal/supply spikes. Similar calculations could be used for systems that use natural gas, owing to its seasonal volatility.

If we are using less energy, we will pay less of a premium for the price spike. The avoided price spike premium is equal to:

$$= (\text{price premium})(\text{kWh saved})(\text{premium period})$$

$$= (\$.02/\text{kWh})(750{,}000\ \text{kWh/yr})(1/4)$$

$$= \$3750/\text{yr}$$

Using the same equations, a 50% price spike would represent an avoided premium worth:

$$= (\text{price premium})(\text{kWh saved})(\text{premium period})$$

$$= (\$.04/\text{kWh})(750{,}000\ \text{kWh/yr})(1/4)$$

$$= \$7500/\text{yr}$$

Thus, owing to reduced risk from price spikes, the avoided premiums are $3750–$7500/yr.

Benefit 5: The Value of Carbon Credits

According to the Environmental Protection Agency,[17] 1.37 lbs of CO_2 are created for every kWh burned. So, if we are saving 750,000 kWh/yr, the avoided power plant emissions would be equivalent to:

$$= (750{,}000\ \text{kWh saved})(1.37\ \text{Ibs of}\ CO_2/\text{kWh})$$

$$= 1{,}027{,}500\ \text{Ibs of}\ CO_2\ \text{saved per year F}$$

Translating lbs to Metric Tons:

$$= (1{,}027{,}500\ CO_2)(.000454\ \text{Metric Tons/Ib})$$

$$= 466.5\ \text{Metric Tons of}\ CO_2\ \text{saved per year}$$

These avoided power plant emissions could be claimed as "carbon credits" and sold to another party who wants to buy "carbon credits." An "aggregator" may be required to trade carbon credits in small quantities. Note that as of this printing, European prices for carbon credits are well over five times the price of carbon credits in the USA. The US carbon market is expected to follow Europe's lead as US regulations begin to take effect. Therefore, it is logical that the US prices will approach the European prices, which are currently at $34/metric ton.

Assuming for now a market price of $6 per metric ton, the additional revenue generated by selling the carbon credits would be:

$$= (466\ \text{Metric Tons of}\ CO_2/\text{yr})(\$6/\text{M} - \text{Ton})$$

$$= \$2799/\text{yr}$$

Using the same equations, at \$30 per metric ton, the additional revenue generated by selling the carbon credits would be:

$$= (466 \text{ Metric Tons of CO}_2/\text{yr})(\$30/\text{M} - \text{Ton})$$

$$= \$13{,}980 \text{ per year}$$

Thus, due to the new carbon market, there is a possible additional revenue stream worth a minimum of \$2799 to a maximum of \$13,980 per year from selling carbon credits. In addition, as carbon prices go higher … so does the value of this new revenue stream.

Benefit 6: The Value of Enhanced Public Image

Although calculation of this value is difficult and is not generalized here, it can be far greater than any of the benefits mentioned above. In today's "green-minded" economy, many organizations such as Patagonia, Google, GE, and Home Depot, have used "green" programs as a very effective marketing tool to differentiate themselves from the competition, achieve business objectives, secure and retain talent, improve productivity, and capture a greater market share.

The green-shaded area of Figure 1 shows the "equivalent environmental benefits" from avoided power plant emissions. These reductions/benefits can be published in various places to improve the organization's green image with employees, clients, students, suppliers, distributors, shareholders, and other groups relevant to the success of an organization.

Thus, due to energy conservation program, the school can claim environmental benefits equivalent to removing 1008 cars off the road, thereby improving the school's public image. Although not calculated here, the benefits of attracting better faculty, students, employees, etc., could far out-weigh all the benefit estimates in this entry.

See Figure 1 for additional expressions of environmental benefits.

Example: The "Secret Benefits" of Energy Conservation

	Additional Benefits Estimates	
	Min	Max
Assumptions: Baseline Electricity Expenses from the Lighting System = $240,000 per year. A 25% savings via basic energy conservation measures would yield $60,000 in savings/year	$/Year	$/Year
Value of "Secret Benefits" (most exist outside the utility budget)		
Benefit #2: Extended Equipment Lives (Avoided Annual Capital Costs)	$2,604	$5,729
Benefit #3: Reduced Maintenance Costs (Avoided Operational Expenses)	$1,840	$3,066
Benefit #4: Reduced Risk to Energy Price Spikes (Avoided Premium Costs)	$3,750	$7,500
Benefit #5: Selling Carbon Credits (emissions reductions via energy conservation)	$2,799	$13,980
Total Additional Value from Quantifiable "Secret Benefits">>>	**$10,993**	**$30,275**
% Savings of Baseline Electricity Expenses ($240,000/year) of the Lighting System	***4.6%***	***12.6%***
% Savings Improvement from Original Estimate of $60,000/year in Savings	***18.3%***	***50.5%***

FIGURE 2 Secret benefits of energy conservation. (Note: Estimates are Conservative because Dollar Values for Benefits #6 and #7 were not included here).

Benefit 7: The Value of Reduced Risk of Environmental/Legal Costs

Although calculation of this value is also difficult and is not generalized here, it can be very significant. The risk is real, but unknown. This is demonstrated by the following environmental disasters that significantly crippled or destroyed the organizations deemed responsible:

- The Union Carbide accident in Bhopal
- Love Canal's hazardous waste
- Mercury poisoning at Alamogordo, NM

It is also interesting to note that Exxon's penalties and fees were four times the actual clean-up costs for the Valdez oil spill.

More relevant to this entry is that emissions regulations are quite likely to become a standard in the United States. Organizations that are implementing energy conservation programs will have a regulatory advantage over those that do not. Inaction could pose legal risks.

Thus, due to its energy conservation program, the school in this example can reduce its risk from unknown environmental and legal risks that may arise in the future.

Fi@@g. 2 summarizes the dollar value from the benefits mentioned in this entry. The approach and calculations for these benefits could be used as a guide to identify the "secret benefits" of other energy consuming systems, such as HVAC and motors, etc.

Conclusion

This entry has presented additional benefits from energy conservation. The example described an energy conservation project that was achieving a 25% reduction in electrical consumption from the lighting system. Beyond obvious energy savings, the "secret benefits" 2–5 yield additional value worth $10,993 to $30,275 per year. *In other words, if energy conservation saves 25% of a utility budget, the "secret benefits" are worth an additional 4.6%–12.6%.*

Looking at this in a different way, the "secret benefits" contribute additional value worth a minimum 18% improvement from the original estimated savings of $60,000 per year. *In other words, if we value the secret benefits as worth only an additional $10,993, this represents a minimum improvement of 18% to our energy savings of $60,000. In addition, there is a $4660 value improvement for each $10 rise in US carbon prices.*

Finally, all estimates in this entry only included the quantifiable "secret benefits" (benefits 2–5). Actual values could be much higher when accounting for enhanced public image and a reduction in legal and environmental risks (benefits 6 and 7).

We hope that this entry motivates additional action for energy conservation, dollar savings, and environmental benefits.

Energy Conservation: Industrial Processes

Harvey E. Diamond

Introduction and Scope

Energy conservation is a broad subject with many applications in governmental, institutional, commercial, and industrial facilities, especially because energy costs have risen so high in the last few years and continue to rise even higher. Energy conservation in industrial processes may well be the most important application—not only due to the magnitude of the amount of potential energy and associated costs that can be saved, but also due to the potential positive environmental effects such as the reduction of greenhouse gases associated with many industrial processes and also due to the potential of the continued economic success of all of the industries that provide jobs for many people.

This entry will focus on energy conservation in industrial processes—where energy is used to manufacture products by performing work to alter feedstocks into finished products. The feedstocks may be agricultural, forest products, minerals, chemicals, petroleum, metals, plastics, glass, or parts from other industries. The finished products may be food, beverages, paper, wood building products, refined minerals, refined metals, sophisticated chemicals, gasoline, oil, refined petroleum products, metal products, plastic products, glass products, and assembled products of any kind.

This entry will distinguish industrial processes and the characteristics that differentiate them in order to provide insight into how to most effectively apply energy conservation within industries. The level of applied technology, the large amount of energy required in many cases to accomplish production, the extreme conditions (e.g., temperature, pressure, etc.,) that are frequently required, and the level of controls that are utilized in most cases to maintain process control will be addressed in this entry.

This entry will outline the analytical procedures needed to address energy conservation within industrial processes and will comment on general analytical techniques that will be helpful in analyzing energy consumption in industrial facilities.

Many of the main energy intensive processes, systems, and equipment used in industries to manufacture products will be identified and discussed in this entry and some common ways to save energy will be provided.

This entry will cover main energy intensive processes, systems, and equipment in a general format. If more in-depth instruction is needed for explanation of a particular industrial process, system, or type of equipment or regarding the analytical procedures required for a specific process, then the reader should refer to the many other articles included in this Encyclopedia of Energy Engineering and Technology, to references at the Association of Energy Engineers, to the references contained in this entry, and if further detail is still needed, then the reader should contact an applicable source of engineering or an equipment vendor who can provide in-depth technical assistance with a specific process, system, or type of equipment.

In addition to the analytical methods of energy conservation, managerial methods of energy conservation will be briefly discussed. The aspects of capital projects versus managerial and procedural projects will be discussed. The justification of managerial efforts in industrial processes will be presented.

Industrial Processes—Differentiation

Industrial processes require large amounts of energy, sometimes the highest level of technology, and often require very accurate process controls for process specifications, safety, and environmental considerations.

Industrial processes utilize an enormous amount of energy in order to produce the tons of production that are being produced within industrial facilities. Industrial processes utilize over one-third of the total energy consumed in America.[1] Consider the amount of energy that is required to melt all of the metals being manufactured, to vaporize all of the oil and gasoline being refined, to dry all of the finished products that are made wet, to heat all of the chemicals that react at a certain temperature, to vaporize all of the chemicals that must be distilled for purity, to vaporize all of the steam that is used to heat industrial processes, to mechanically form all of the metal objects that we use, etc.,—this list is too long to be fully included in this entry. This is an enormous amount of energy that produces all of the things that humans need and use—food, clothes, homes, appliances, cars, municipal facilities, buildings, roads, etc.

The level of technology required by current industrial processes is the highest in many cases and it is always at a high level in most industrial processes. Most industrial processes are utilizing technology that has been developed in the last 100 years or so, and consequently it has been further improved in the most recent years. Industrial processes most often utilize aspects of chemistry and physics in a precise manner in order to produce the sophisticated products that benefit people in our culture today. Very often, industrial processes require a very high or low temperature or pressure. Often they require a very precise and sophisticated chemistry and commonly they require highly technical designed mechanical processes. The application of electrical equipment and facilities in industrial processes is the highest level of technology for electrical power systems.

Industrial processes often require the highest level and accuracy of controls in order to produce products that meet product specifications, keep processes operating in a safe manner, and maintain environmental constraints. Due to each of these requirements or due to a combination of these requirements, the process controls for the processes within industrial facilities are often real-time Distributed Control Systems (DCSs), that are of the most sophisticated nature. A typical DCS for industrial processes functions to control process variables instantaneously on a real-time basis, whereby each process variable is being measured constantly during every increment of time and a control signal is being sent to the control element constantly on a real-time basis. The accuracy of a DCS in an industrial facility today is comparable to that of the guidance systems that took the first men to the moon

Most industrial facilities with DCS controls also utilize a process historian to store the value of most process variables within the facility for a certain increment or period of time. The stored values of these process variables are used for accounting purposes and technical studies to determine optimum operating conditions and maintenance activities.

Energy Conservation Analyses for Industrial Processes

In any industrial facility, the first analysis that should be performed for the purpose of energy conservation should be that of determining a balance of the energy consumed for each form of energy. This balance is used to determine how much energy is consumed by each unit, area, or division of the plant or possibly by major items of equipment that are consuming major portions of the energy consumed by the plant. This balance should be determined for each form of energy, whether it is for natural gas, electricity, coal, fuel oil, steam, etc., (see Table 1 for an example of an energy balance). It might be best that this determination not be called a balance (in that the numbers might not exactly come to a precise balance) but that it sufficiently quantifies the amount of energy consumed by each unit, area, or division of the plant. A better term for this determination might be an "Energy Consumption Allocation." The term balance is more usually applied to chemical and thermodynamic processes where heat and material balances are worked together mathematically to determine a calculated variable and the numbers have to exactly balance in order to arrive at the correct mathematical solution.

Once the amount of energy that is being actually consumed by each part of a plant has been determined, an energy consumption analysis should be performed for each item of energy consuming equipment and each major energy consuming facility in order to determine how much energy should realistically be consumed by each part of the plant. Notice that these calculations are called "realistic" as opposed to just theoretical because the object of these calculations is to determine as closely as possible how much actual energy each item of equipment or part of the plant should be consuming. By comparing these calculations with the actual energy consumption allocations mentioned above, it should be possible to obtain at least an initial indication of where energy is being wasted in a plant (see Table 2 for an example of an energy consumption analysis for a process feed heater). During the course of obtaining the values of process variables that are required to make these energy consumption analyses, it is

TABLE 1 Energy Balance

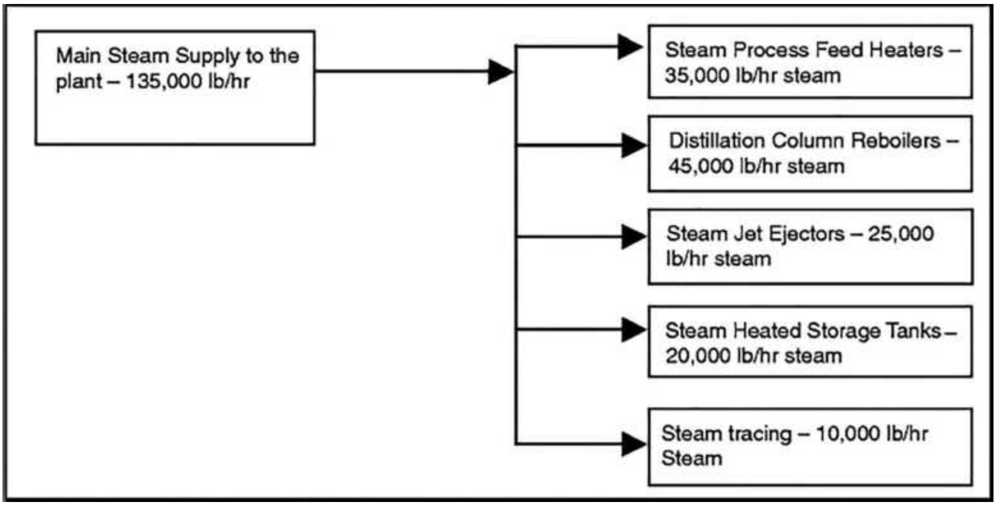

TABLE 2 Example of Energy Consumption Analysis: Process Feed HTR

- A process feed heater heats 1,199,520 lb/day of liquid feed material with a specific heat of 0.92 Btu/lb-°F, from 67 to 190°F. A realistic heater efficiency for this type of heater is determined to be 88%. The amount of realistic heat required for this heater is calculated to be: Q = 1,199,520 lb/day × 0.92 Btu/lb-°F × (190°F – 67°F) ÷ 0.88 = 154,247,367.3 Btu/day of realistic heat consumption.
- It is observed that this feed heater is consuming 186,143,720 Btu/day.
- This feed heater is being operated in a wasteful way and is wasting over 20% of its heat.

possible that indications will be observed of energy wastage due to the presence of an inordinate value of some process variable, such as too high or low of a temperature or pressure. When this type of indication is discovered, it usually also provides insight into what is operating in the wrong way to waste energy. There are numerous instances of energy wastage that can be discovered during these analyses, such as the inordinate manual control of a process, loose operational control of a process variable, or simply not shutting down a piece of equipment when it is not needed.

The analyses discussed in the above paragraph encompass all technical engineering science subjects, such as chemistry, thermal heat transfer, thermodynamics, fluid mechanics, mechanical mechanisms, and electrical engineering.

The next set of energy conservation analyses that should be performed are used to calculate the efficiencies of each item of equipment or facility to which efficiency calculations would be applicable, such as boilers, fired heaters, furnaces, dryers, calciners, and all other thermodynamic processes (efficiency calculations for boilers and other combustion equipment is available in the *Energy Management Handbook* by Wayne C. Turner and Steve Doty[2] and in the *Guide to Energy Management* by Barney L. Capehart, Wayne C. Turner, and William J. Kennedy)[3] and for electrical and mechanical equipment such as motors, pumps, compressors, vacuum pumps, and mechanical machinery. Once the actual efficiencies of any of the above have been determined, these numbers can be compared to the realistic efficiency for the type of equipment or facility that is prevalent throughout industry. These calculations and comparisons will also reveal wastage of energy and will frequently identify the causes of energy wastage and the possible issues to be corrected.

The next level of energy conservation analysis that may be performed is process analysis that can be conducted on a particular chemical, thermodynamic, thermal, fluid flow, mechanical, or electrical process. These analyses are usually performed by experienced engineers to examine the process itself and the process variables to determine if the process is being operated in the most effective and efficient manner. Here again, an indication will be provided as to whether or not energy is being wasted in the actual operation of the process. Chemical, thermo-dynamic, thermal, fluid flow, and other processes, as well as combinations of any of these processes can often require process simulation software such as PROMAX by Bryan Research and Engineering, Inc.,[4] in order to properly analyze these processes. The analysis of distillation columns, evaporators, and dryers can fall into this category. A good example would be the process analysis of a distillation column to determine if an effective and efficient level of reflux to the column and reboiler duty is being used.

Another analysis that has been very useful in the past few years in identifying energy conservation projects is Pinch analysis. This analysis is performed on thermodynamic and thermal processes in order to identify sources of energy within existing processes that can be used to supply heat for these processes instead of having to add additional heat to the entire process. The net effect is to reduce the amount of energy required for the overall process. The performance of a Pinch analysis on a particular process or facility will usually identify capital projects where revisions to the facility can be made to decrease the total amount of energy required. These are very often waste heat recovery projects. See "Use Pinch Analysis to Knock Down Capital Costs and Emissions" by Bodo Linnhoff, Chemical Engineering, August 1994[5] and "Pinch Technology: Basics for the Beginners."[6]

Main Industrial Energy Processes, Systems, and Equipment

This section provides an overview and a list of the more common energy intensive industrial processes that are used to manufacture products in industrial facilities. Most energy intensive industrial processes can be classified into about eight general process categories—process heating, melting, chemical reactions, distillation-fractionation, drying, cooling, mechanical processes, and electrical processes. These processes are intended to be the main general energy intensive processes that are most commonly used and to which variations are made by different industries in order to make a specific product. In this regard, this is an overview—these processes are often not the specific process but a general category to which variations can be made to achieve the specific process.

In the following paragraphs, each process will be discussed by addressing its description, what systems it utilizes, what products are generally made, how it uses energy, and frequent ways that energy can be saved.

Common energy consuming systems and equipment that work to manufacture products in industrial facilities are also listed below and discussed in the same manner as the main industrial processes, as they are also common to industrial facilities and are related to these processes.

Process Heating

- *Description.* The addition of heat to a target in order to raise its temperature. Temperatures can range from the hundreds to the thousands in industrial process heating.
- *Energy form.* Heat must be generated and transferred to the intended object or medium.
- *Energy unit.* Btu, calorie, joule, therm or watt-hour.
- *Examples.* The application of heat in order to heat feed materials, to heat chemical processes, to heat metals for forming, to heat materials for drying, to heat materials in a kiln or calciner, to heat minerals and metals for melting.
- *Applied systems.* Combustion systems, steam systems, thermal systems, hot oil systems, heating medium systems such as Dowtherm[7] or Paracymene,[8] and electrical resistance or induction heating systems.
- *Common equipment.* Boilers, furnaces, fired heaters, kilns, calciners, heat exchangers, waste heat recovery exchangers, preheaters, electrical resistance heaters, and electrical induction heaters.
- *Common energy conservation issues.* Keeping the heat targeted at the objective—proper insulation, seals on enclosures, eliminating leakage, and eliminating unwanted air infiltration. Control issues—maintaining sufficient control of the heating process, temperatures, and other process variables to avoid waste of heat. Management issues—shutting down and starting up heating processes at the proper times in order to avoid waste of heat and management of important process variables to reduce the amount of heat required to accomplish the proper process. Application of Pinch Technology—identify process areas where heat can be recovered, transferred, and utilized to reduce the overall process heat requirement. Waste heat recovery.

Melting and Fusion

- *Description.* The addition of heat or electrical arc energy at a high temperature in order to melt metals, minerals, or glass. The melting process involves more than just process heating, it involves fluid motion, fluid density equilibrium, chemical equilibrium, cohesion, and sometimes electromagnetic inductance. Reference: “The study showed that the fluid equations and the electromagnetic equations cannot be decoupled. This suggests that arc fluctuations are due to a combination of the interactions of the fluid and the electromagnetics, as well as the rapid change of the boundary conditions.”[9]

- *Energy forms.* Heat at high temperatures or electrical arc energy in the form of high voltage and high current flowing in an arc.
- *Energy units.* Heat, Btu, calorie, joule, or therm.
- *Electrical arc. kWhrs.*
- *Examples.* Melting of ores in order to refine metals such as iron, aluminum, zinc, lead, copper, silver, etc. Melting of minerals in order to refine minerals such as silica compounds, glass, calcium compounds, potassium alum, etc.
- *Applied systems.* Combustion systems, chemical reactions, and electrical systems.
- *Common equipment.* Blast furnaces, arc furnaces, electrical resistance heaters, and electrical induction heaters.
- *Common energy conservation issues.* Pre-condition of feed material—moisture content, temperature, etc. Feed method—efficiency of melting process effected by the feed method, feed combinations, and feed timing. Control of electromagnetics during melting and use of magnetic fields during separation. Over-heating can waste energy without yielding positive process results. Heat losses are due to poor insulation, the failure of seals, or lack of shielding or enclosure.

Chemical Reactions

- *Description.* Chemicals react to form a desired chemical, to remove an undesired chemical, or to break out a desired chemical. The chemical reaction can involve heat, electrolysis, catalysts, and fluid flow energy.
- *Energy forms.* Heat, electrolysis, and fluid flow.
- *Energy units.* Heat, Btu, calorie, joule, or therm.
- *Electrolysis. kWhrs.*
- *Fluid flow.* ft-lbs or kg-m.
- *Examples.* Reaction of chemical feed stocks into complex chemicals, petrochemical monomers into polymers, the oxidation of chemicals for removal, dissolving of chemicals to remove them, reaction of chemicals with other chemicals to remove them, the reaction of lignin with reactants in order to remove it from cellulose, the electroplating of metals out of solution to refine them.
- *Applied systems.* Feed systems, catalysts systems, heating systems, cooling systems, vacuum systems, run-down systems, separation systems, filtering systems, and electroplating systems.
- *Common equipment.* Reactors, digesters, kilns, calciners, smelters, roasters, feed heaters, chillers, pressure vessels, tanks, agitators, mixers, filters, electrolytic cells.
- *Common energy conservation issues.* Close control of heating and cooling for chemical reactions. Close control of all reaction process variables—balance of all constituents, amount of catalyst, proper timing on addition of all components. Management of feedstocks, catalysts, and run-down systems for proper timing and correct balance for highest efficiency. Pinch analysis of feed heating, run-down products, cooling system, etc. Conservation of heating and cooling—proper insulation, sealing, and air infiltration. Waste heat recovery.

Distillation-Fractionation

- *Description.* A thermo-dynamic and fluid flow equilibrium process where components of a mixture can be separated from the mix due to the fact that each component possesses a different flash point.
- *Energy form.* Heat and fluid flow.
- *Energy units.* Heat, Btu, calorie, joule, or therm.
- *Fluid flow.* Ft-Lbs or KG-M.
- *Examples.* Distillation-fractionation of hydrocarbons in oil and gas refineries and chemical plants. Distillation of heavy hydrocarbons in gas processing plants where natural gas is processed to remove water and heavy hydrocarbons.

- *Applied systems.* Feed heating systems, over-head condensing systems, reflux systems, reboil systems, vacuum systems.
- *Common equipment.* Distillation columns or towers, over-head condenser heat exchangers and accumulators—vessels, reflux pumps, reboiler heat exchangers, feed pumps, feed—effluent heat exchangers, vacuum steam jet ejectors.
- *Common energy conservation issues.* Feed temperatures, reflux ratios, reboiler duty. Close control on pressures, temperatures, feed rates, reflux rates, and reboil duty. Management of overall operation timing—running only when producing properly. Concurrent use of vacuum systems—only when needed. Pinch analysis for feed and effluent streams and any process cooling systems. Proper insulation and elimination of lost heat for fired heater reboilers.

Drying

- *Description.* The use of heat and fluid flow to remove water or other chemical components in order to form a more solid product.
- *Energy forms.* Heat and fluid flow.
- *Energy units.* Heat, Btu, calorie, joule, or therm.
- *Fluid flow.* Ft-Lbs or KG-M.
- *Examples.* Spray dryers that dry foods, sugar, fertilizers, minerals, solid components, and chemical products. Rotary dryers that dry various loose materials. Line dryers that dry boards, tiles, paper products, fiberglass products, etc. Other dryers that dry all kinds of products by flowing heated air over finished products in an enclosure.
- *Applied systems.* Combustion systems, steam systems, thermal heating systems, cyclone systems, air filter systems, incinerator systems, Regenerative Thermal Oxidizer (RTO) systems.
- *Common equipment.* Spray dyers, spray nozzles, natural gas heaters, steam heaters, electrical heaters, blowers, fans, conveyors, belts, ducts, dampers.
- *Common energy conservation issues.* Efficient drying process for the components being eliminated. Proper amount of air flowing through dryer for drying. Proper insulation, seals, and elimination of lost heat due to infiltration. Waste heat recovery.

Process Cooling

- *Description.* The removal of heat by a cooling medium such as cooling water, chilled water, ambient air, or direct refrigerant expansion.
- *Energy form. Heat.*
- *Energy unit.* Btu, calorie, joule, or therm.
- *Examples.* Cooling water or chilled water circulated through cooling heat exchanger, an air cooled heat exchanger, or a direct expansion evaporator that cools air for process use.
- *Applied systems.* Cooling water systems, chilled water systems, refrigerant systems, thermal systems.
- *Common equipment.* Cooling towers, pumps, chillers, refrigeration compressors, condensers, evaporators, heat exchangers.
- *Common energy conservation issues.* Use evaporative cooling as much as possible. Keep chillers properly loaded. Restrict chilled water flow rates to where 10°F temperature difference is maintained for chilled water. Limit cooling water pumps to the proper level of flow and operation. Apply Pinch analysis to achieve most efficient overall cooling configuration. Proper insulation, seals, and elimination of air infiltration.

Mechanical Processes

- *Description.* Physical activities that involve force and motion that produce finished products. Physical activities can be discrete or can be by virtue of fluid motion.
- *Energy form.* Physical work.
- *Energy unit.* Ft-Lbs or KG-M.
- *Examples.* Machining of metals, plastics, wood, etc.; forming or rolling or pressing of metals, minerals, plastics, etc.; assembly of parts into products; pumping of slurries thru screens or filters for separation; cyclone separation of solids from fluids; pneumatic conveyance systems that remove and convey materials or products and separate out solids with screens or filters.
- *Applied systems.* Machinery, electrical motors, hydraulic systems, compressed air systems, forced draft or induced draft conveyance systems, steam systems, fluid flow systems.
- *Common equipment.* Motors, engines, turbines, belts, chains, mechanical shafts, bearings, conveyors, pumps, compressors, blowers, fans, dampers, agitators, mixers, presses, moulds, rolls, pistons, centrifuges, cyclones, screens, filters, filter presses, etc.
- *Common energy conservation issues.* Equipment efficiencies, lubrication, belt slippage, hydraulic system efficiency, compressed air system efficiency. Control of process variables. Application of variable speed drives and variable frequency drives. Management of system and equipment run times.

Electrical Processes

- *Description.* The application of voltage, current, and electromagnetic fields in order to produce products.
- *Energy form.* Voltage-current over time; electromagnetic fields under motion over time.
- *Energy units. KWh.*
- *Examples.* Arc welding, arc melting, electrolytic deposition, electrolytic fission, induction heating.
- *Applied systems.* Power generator systems, power transmission systems, amplifier systems, rectifier systems, inverter systems, battery systems, magnetic systems, electrolytic systems, electronic systems.
- *Common equipment.* Generators, transformers, relays, switches, breakers, fuses, plates, electrolytic cells, motors, capacitors, coils, rectifiers, inverters, batteries.
- *Common energy conservation issues.* Proper voltage and current levels, time intervals for processes, electromagnetic interference, hysteresis, power factor, phase balance, proper insulation, grounding. Infrared scanning of all switchgear and inter-connections.

Combustion Systems

Combustion systems are found in almost all industries in boilers, furnaces, fired heaters, kilns, calciners, roasters, etc. Combustion efficiency is most usually a prime source of energy savings.

Boilers and Steam Systems

Boilers and steam systems may well be the most widely applied system for supplying process heat to industrial processes. "Over 45% of all the fuel burned by U.S. manufacturers is consumed to raise steam."[10] Boiler efficiencies, boiler balances (when more than one boiler is used), and steam system issues are usually a prime source of energy savings in industrial facilities.

Flare Systems and Incinerator Systems

Flare and incinerator systems are used in many industrial facilities to dispose of organic chemicals and to oxidize volatile organic compounds. Proper control of flares and incinerators is an issue that should always be reviewed for energy savings.

Vacuum Systems

Vacuum systems are used to evaporate water or other solvents from products and for pulling water from products in a mechanical fashion. Vacuum systems are also used to evacuate hydrocarbon components in the petroleum refining process. Vacuum systems are frequently used in the chemical industry to evacuate chemical solvents or other components from a chemical process. Steam jet ejectors and liquid ring vacuum pumps are commonly used to pull vacuums within these systems. The efficiencies of the ejectors and the liquid ring vacuum pumps can be a source of energy savings as well as the management of vacuum system application to production processes. Pneumatic conveyance systems that utilize a fan or blower to create a low-level vacuum are sometimes used to withdraw materials or products from a process and separate the matter within a screen or filter. For large conveyance systems, the efficiencies of the equipment and the management of their operation can be a source of energy savings.

Furnaces, Fired Heaters, Kilns, Calciners

The above comments on combustion systems are applicable to these equipment items and additional energy savings issues can be found relative to them.

Centrifugal Pumps

Centrifugal pumps are used widely in industries. The flow rate being pumped is a primary determining factor for the amount of power being consumed and it is sometimes higher than required. Good control of the pumping rate is an important factor in saving energy in centrifugal pumps. The application of variable frequency drives to the motor drivers can be a good energy saving solution for this issue.

Fans and Blowers

The flow rate for fans and blowers is analogous to the pumping rate above for centrifugal pumps. Good control of the flow rate and the possible application of Variable Frequency Drive (VFD) apply here as well for fans and blowers.

Centrifugal Compressors

Compressors are used widely in industry. The above discussions of flow rates, control of flow rates, and application of VFDs apply here as well. Centrifugal compressors frequently will have a recycle flow that is controlled in order to prevent the compressor from surging. Close control of this recycle flow at its minimum level is very important for compressor efficiency.

Liquid Ring Vacuum Pumps

As mentioned above in several places, liquid ring vacuum pumps are used widely in industry. The amount of sealing liquid that is recycled to the pump and the temperature of the sealing liquid are important determinates of the efficiency of the Liquid Ring Vacuum Pump (LRVP).

The above overview and list of industrial processes, systems, and equipment has been general in nature due to the limitations of this entry. Greater and more specific familiarity with each of these industrial energy intensive processes, systems, and equipment will yield greater applicable and effective insight into ways to save energy related to each of these items.

Capital Projects versus Improved Procedures

Energy conservation effort applied in industrial facilities can identify capital projects whereby the facilities can be changed in order to achieve greater overall energy efficiency or the efforts can identify changes to in day-to-day operating and maintenance procedures that can reduce waste of energy and also improve the overall efficiency of the facility. Frequently, energy-saving procedural changes to day-to-day operations and maintenance activities within an industrial plant can be identified by taking and recording operating data once the processes, systems, and equipment have been studied and analyzed for energy consumption. Procedural changes to operations and maintenance within an industrial plant can often amount to low costs or possibly no costs to the facility. This aspect of energy conservation is often overlooked by highly technical personnel that have worked hard to design industrial facilities because they have technically designed the facility very well for energy consumption considerations and the more mundane activities related to day-to-day operation and maintenance tend to not register in their highly technical perspective. None-the-less, a considerable amount of energy can usually be saved within most industrial processes, systems, and equipment due to changes in the way they are operated and maintained. A general tendency within industrial plants is that operations will often operate the processes and systems at a point that provides a comfortable separation between an operating variable and its limitation in order to understandably ensure no upsets occur within the process or system. However, with the cost of energy being what it is today, it is frequently found that a significant amount of energy can be saved by operating processes and systems more tightly and efficiently, even though it may require more attention, increased control, and the monitoring of process variables.

Effective Energy Management Systems

Another aspect of energy conservation that can be very productive in saving energy within industrial processes is that of an effective energy management system. An effective energy management system is comprised of operational and maintenance managers functioning in conjunction with an accurate and concurrent data collection system in order to eliminate waste and improve overall efficiency of industrial processes. It is not possible to manage any activity unless the activity is being properly monitored and measured with key performance metrics (KPMs). The data collection system part of an effective energy management system within any industrial facility provides the accurate and concurrent measurement data (KPMs) that is required in order to identify actions that are needed to eliminate waste of energy and improve overall efficiency of the facility. An effective energy management system is first built upon acquiring total knowledge of the facility down into every level of operation and maintenance of the facility. Such a level of thoroughness and complete analysis of energy consumption within a facility is sometimes referred to as *Total Quality Energy* management.[11] Once an effective energy management system has been established and is effectively controlling energy consumption of an industrial facility, it should be maintained, in effect, so that it will continue to monitor KPMs to maintain energy conservation for the facility. An effective energy management system within an industrial manufacturing facility can eliminate as much as two to three percent of the energy costs by eliminating waste of energy on a day-to-day operational and maintenance basis. In most industrial facilities, this level of cost reduction is significant and will justify an effective energy management system.

Current Need for Greater Energy Conservation in Industry

With the present cost of all forms of energy today, it would certainly seem logical that all of industry would be seeking greater energy conservation efforts within their facilities. Unfortunately, many corporate industrial managers are not aware of the true potential of conserving energy within their processes and facilities. Greater awareness of the ability to conserve energy on the basis of increased efficiencies of processes, systems, and equipment is needed; and also due to the application of an effective energy management system. For the good of society and environment, corporate industrial managers should be more open to the possibility of the improvement of industry that will work to sustain their business and improve the world that we live in. This is in opposition to corporate political thinking, which does not want to consider making changes and wants no one to interfere with their present activities. Human beings should be willing to examine themselves and make changes that will make things better. The same outlook should be applied to businesses and industry in order to make things better. Greater management support is needed in industry today to accomplish greater and very much needed increased energy conservation.

Current Application of Increased Energy Management

With the recent technological advancements that have been made in digital computer and communications systems, data collection systems can be implemented in industrial facilities in a much more cost effective manner. Wireless communication systems for metering and data collection systems have advanced dramatically in the last few years and network-based computer communication has enabled whole new systems for measurement and control. With all of these new fields of configuration for data collection systems, with the increased technology, and with the lower costs to accomplish data collection systems, it is now possible to apply energy management systems to industry today with much greater applicability. Hopefully this will be recognized and result in greater applications of effective energy management systems.

From recent observations, it appears that most of industry today is a candidate for improved and more effective energy management systems. In conjunction with the increased technology and lower cost potentials, it seems that there is a definite match between supply and need for the application of increased energy management systems.

Summary

Industrial processes have commonality in processes, systems, and equipment. There are logical and systematic analyses that can be performed in industrial processes that can identify ways to save energy. Effective energy management systems are needed in industry today and there are great possibilities to save energy in industrial processes. Energy can be conserved in industrial processes by analyses that will improve efficiencies, by implementation of procedures that eliminate waste, and by application of an effective energy management system.

Energy Master Planning

Fredric S. Goldner

Introduction

Developing an energy management program or more broadly energy master planning (EMP) is the process of transitioning an organization's culture from the traditional "fixed cost, line item" view of energy to one in which energy is recognized as the opportunity and risk that it has become.

An EMP can guide an organization in longer-range planning of energy cost reduction and control as part of their facility maintenance, management, and design. An EMP can even lead the energy budget to be recognized as a potential profit center and source of opportunity rather than just another business expense. An EMP moves beyond the confines of traditional engineering to include energy procurement, energy-related equipment purchasing, measurement and verification (M&V), staffing and training, communications, and setting energy consumption targets and tracking/feedback loop systems. The long-term perspective goes beyond simply cutting last year's energy use. It makes energy awareness part of the everyday operation and "mindset" of the organization.

If you're thinking this doesn't apply to your firm or clients because you're too small, think again. This approach works for an organization as small as a single site to an owner with half a dozen small buildings to Fortune 100 companies. The effort and level of detail vary, respectively, but the approach is basically the same. The good news is that there are resources available to assist professionals and the organizations they serve to understand the EMP process and get started on this path.

To be successful an organization must treat energy in the same business-like manner that they do all other major expenses, such as labor and materials. "If you can measure it, you can manage it"[1] is the catch phrase of Paul Allen, the energy manager at Disney World, who has been instrumental in implementing one of the most successful EMPs in the country. "Energy is a competitive opportunity

… Winners manage it effectively!" is the driving force of another highly successful program at Owens Corning. Many other organizations throughout this country and across the globe have recognized that to achieve significant and sustained energy cost control, organization needs to make energy management an integrated part of their business/operations. There are various ways to pursue the process, but a key requirement is an interdisciplinary mix of engineering/technical, behavioral, and organizational or management components. The EMP must be integrated into the basic business operations.

Unexpected Benefits

One of the most potent driving factors in many organizations' efforts to address energy issues is increased profitability that can be realized through reduced/optimized energy expenditures. Beyond the "bottom line" impacts, an EMP can also provide an organization with a more secure energy supply, reduced downtime of systems, improved equipment availability, reduction in maintenance costs/ premature system replacement expenditures, and overall productivity gains. Additional benefits that have been documented include quality-of-life improvements, enhanced product quality, better operational safety, reduced raw material waste in industrial plants, and increased rentability in commercial facilities. An often overlooked outcome of an EMP is the reduction of emissions, among other environmental impacts that help organizations become perceived as better corporate citizens.

As more companies move toward an integrated corporate strategy that links environmental, economic, and social considerations, the results of an EMP can be used to considerable public relations advantage. Ratings in one of the sustainability indices and publication of an annual sustainability report (using, for example, the Global Reporting Initiative guidelines) can give an organization a higher standing in the business community and can result in a higher level of trust by stockholders.

A Process for Optimization

Though energy prices are volatile, and energy security is often far from reliable, facilities now face leaner operating funds and increased directives to do more with less. Optimizing a facility's operations budget frequently means cutting energy costs. But how do you do so without cutting occupant comfort or productivity? How do you know where to start and what steps to take? And how do you persuade upper management that energy costs can be controlled?

While the general goal of an EMP is the same as that of conventional energy management, the two disciplines are far from identical. Traditional energy management, which is technically oriented, is essentially centered around the boiler or mechanical room. Energy master planning, on the other hand, is a business management procedure for commercial, institutional, and industrial operations. With this approach, it is not enough simply to manage installations. The process involves:

- Developing strategies
- Creating processes to fulfill those strategies
- Identifying barriers and finding procedures to overcome them
- Creating accountability
- Providing feedback loops to monitor and report progress

Clarification of the terminology for these disciplines is important, as the terms mean different things to different people. In other English-speaking nations, for example, the defining feature of "energy management" is the emphasis on integration with business practices to analyze, manage, and control energy. In the U.S., however, "energy management" has traditionally referred to developing technical and operational measures involving equipment handled by facility managers—not processes such as energy procurement and business planning usually handled by purchasing agents, production personnel, and corporate economists. A typical U.S. energy manager's responsibility rarely extends much beyond utility bill analysis, an occasional energy audit, or managing installation of system upgrades.

Though an EMP encompasses traditional efforts to cut energy costs, it also includes many steps not usually taken under standard energy management. Rather than being just equipment-oriented, an EMP starts long before a comprehensive energy audit and extends beyond commissioning of new systems. An EMP may be thought of as a road map to savings that starts before and continues after energy- efficiency measures are involved. Why do you need such a map? Because you can't get there if you don't know where "there" is. How many of us are willing to undertake a trip that will have costs and risks (like any business or personal decision) if we don't know where we are going? A map makes clear not just your final destination, but also how to get there—and it leaves no question about the starting point.

An EMP is a process to organize and improve your existing energy-related resources and capabilities. Resources, in this case, include standard operating procedures, institutional memory, and actual records (such as energy bills, plans and blueprints, and energy contracts). Capabilities include facilities staff familiar with mechanical room equipment, consultants for energy costs or usage, energy cost accounting and management systems, and meters and software that monitor them. Once organized and integrated, these resources and capabilities become powerful tools for managing energy and producing savings.

Today's Practices Found Wanting

Current thinking about managing energy often falls short of the EMP perspective. Today's energy management frequently reflects a short-term crisis mentality: A facility manager or energy manager concentrates on whatever immediate 'fires' have to be put out at his facility. By contrast, with an EMP mindset, the energy manager might first look to increase the efficiency of systems already in place and then move ahead to lay a solid foundation for improving performance via tight energy specs and training.

Current thinking is also often characterized by piecemeal 'solutions' that lead to short-sighted component replacement. When equipment breaks down, it gets replaced without anyone's asking whether this is the best option, long-term. Typically, business thinks in a quarterly mindset because of the short budget cycles of our economic system. That kind of "right now and right here" viewpoint creates situations in which life-cycle thinking is not possible because potentially higher initial costs are visible, but potential benefits tend to be invisible. As a result, when first cost becomes the main criterion for purchasing, such a focus distorts planning and decision-making. Too often, facilities choose the cheapest solution, based on the current quarter's budget, without realizing it could cost them more later.

A critical difference between energy master planning and conventional energy management is an orientation toward the future. With an EMP, you don't just look to increase the efficiency of systems already in place. Instead, you plan for new or changed loads based on your detailed information about the facility's long-term business strategy and projected growth.

Energy master planning deals with a longer timeframe than just simple payback periods. For example, typical financial constraints for a commercial building upgrade often dictate a 2- to 3-year timeframe. Energy master planning, however, looks deeper than simple payback and goes beyond merely reducing energy use. Therefore, an energy professional with an EMP considers life-cycle costs and views long-range planning of energy cost minimization/ optimization as part of overall facility maintenance, management, and design. To sustain the savings over time, an EMP calls for hiring an energy manager/ coordinator and setting up an energy team. But who is this energy leader? Not simply the facility manager wearing yet another hat, but rather, a highly trained and, often, certified specialist with sufficient acumen and expertise to understand, handle, and maintain whatever new energy systems and practices are to be put in place. Willingness to identify (from within the organization) or hire an individual with the required qualifications and to define his or her responsibility as managing energy rather than managing the facility is a requisite indication of senior management's true commitment to energy master planning. The policy guidance needs to come from senior management levels to convey "buy-in" throughout the management structure of the organization.

Improving Business as Usual

Energy master planning is one way of creating a new norm of "business as usual," taking its cues from time-tested business management practices. For example, rather than carrying out upgrade projects with a defined start and end point, an energy manager uses processes that continue to turn up new sources of savings. This requires a level of creativity for identifying and capturing new opportunities. If a chiller replacement is needed in Building A, for instance, a better approach might be to expand the capacity of the existing central chilled water plant in Building B and run piping from Building B to Building A.

Without an EMP, the Purchasing department often buys equipment and energy, rather than the Facilities department. And Facilities is so busy handling emergencies that they have little interaction with other departments in the organization, let alone industry groups or other end users. An EMP avoids either departmental isolation and turf wars by including representatives from such departments on the energy team. The team consists of more than an energy manager, facilities personnel, and design and construction specialists. To be effective, it needs to incorporate representatives from every department in the organization impacted by energy. This may mean including purchasing, accounting, engineering, environmental affairs, maintenance, legal, health and safety, corporate relations, human resources and training, public relations and marketing, and members from the rank and file (hourly employees).

Energy master planning is a significant challenge. It often rejects the status quo and may question existing components of an organizational culture that do not support energy master planning. If you have always done something one way, you don't necessarily have to perpetuate what could be a costly mistake. For example, using outdated specs (e.g., calling for T12 lamps instead of T8) allows inefficiency to continue.

Origins of the American EMP Approach

A common set of energy master planning definitions and processes has taken root in English-speaking countries other than the U.S. In the United Kingdom, the energy master planning concept has been practiced for well over a decade and vigorously promoted by the government's Action Energy program. It has been so successful that Canada, New Zealand, and Australia have each adapted the process to their own conditions.

In the U.S., there are a few recent models cover some, but not all, aspects of energy master planning management system for energy (MSE) 2000 is a specialized quality improvement standard (like ISO 14000), developed by Georgia Tech. It's an American National Standards Institute (ANSI)-approved management system for energy that covers all sectors, not only buildings. Georgia Tech offers a certificate program to train energy professionals in this standard. The Association of Energy Engineers delivers the Developing an Energy Management Master Plan and Creating a Sustainable Energy Plan Workshops to both 'real' and 'virtual' end users. Live presentations and online seminars present an energy master planning approach with strong emphasis on integration with business strategy.

Steps to an Energy Master Plan

To fill this gap in the U.S., the Energy Master Planning Institute (EMPI) was established and has developed a set of steps that lay out the process for applying energy master planning to a commercial, institutional, or industrial facility (See Figure 1). This model, which builds on accepted international approaches, offers US organizations a broad and integrated business approach for managing energy that is both strategic and sustainable.

The steps presented in Figure 1 appear sequential, but built into the energy master planning process are series of feedback loops, evident in Figure 1. These should not be overlooked, as they guarantee the viability of the process and offer many points for input from internal and external stakeholders, from the Chief Executive Officer (CEO) to boiler room personnel, and from the local community to organizational peers across the country.

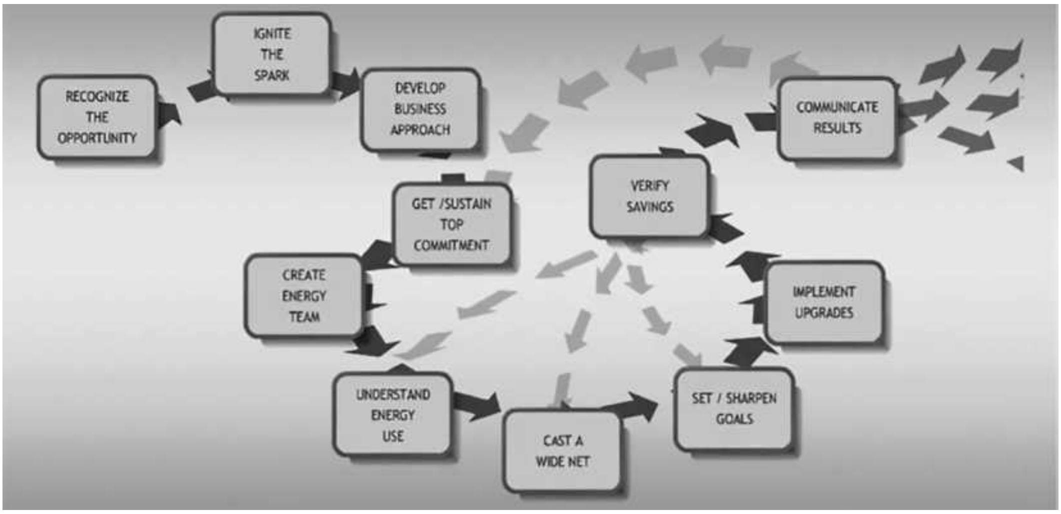

FIGURE 1 Energy Master Planning Institute (EMPI) steps to an energy master plan (EMP). Copyright 2004. Energy Master Planning Institute. All rights reserved.

Recognize the Opportunity

This is where the process starts—becoming aware of the facility's major energy-related opportunities and challenges. Whether it's the facility manager or the energy manager, whoever takes the initial action must define the opportunities and challenges succinctly so they can be clearly communicated. When the leader creates and implements an EMP, that plan can actually generate a revenue stream and gain recognition for the leader's contribution to the company's bottom line. By integrating energy concerns into the overall corporate business strategy, the energy budget will come to be seen as a potential profit center and source of opportunity—and not just an uncontrollable expense.

Ignite the Spark

Since top executives in an organization are the ultimate decision-makers, particularly concerning funding, it's critical to spark their attention early in the process. It's unlikely that the facility manager (or the energy manager, if there is one), has direct access to upper management, so the right individual to make the pitch to the CEO or Chief Financial Officer CFO must be identified. This could be someone along your management chain, or a consultant or board member or a senior officer in another department who can sell an idea at the top. To find the right person, it's important to understand the decision-making structure of your organization as well as the vision, mission, and long-term business plan.

Develop a Business Approach

To get access to senior executives and persuade them to listen to a new idea, you must speak to them in their own language—dollars/ft^2/year savings, not kWh. Since most executives have not been introduced to the bottom-line value of energy master planning, your task is to change management culture so executives no longer view energy as an uncontrollable expense. Part of the marketing message is that managing energy is no different from tracking, controlling, and accounting for the costs of raw materials, IT, personnel, safety, or the corporate fleet.

Obtain and Sustain Top Commitment

Without question, this step is the most difficult in the energy master planning process. Serious commitment from senior management means providing ongoing financial resources and personnel with appropriate credentials. A one-time memo of support is not effective. To secure top executive commitment, you must show how an EMP can support key business goals, such as growth, customer satisfaction, or a sharper competitive advantage. You might, for instance, explain that lower operating costs and increased energy efficiency can bring a higher level of occupant comfort, which, in turn, can mean a lower worker absentee rate—and, possibly, a greater employee retention rate. To gain top executive commitment, make sure that CEO and CFO see the dollar savings highlighted in the energy team's regular reports.

Top management commitment is the single most important goal in an effective and lasting EMP. Not only is it crucial to have this commitment, it must also be obvious to everyone throughout the organization. Top management should participate in the program start-up and continue to reinforce that commitment periodically with both words and actions. Such organizations as Walt Disney have achieved this top-level buy-in and gained significant and lasting bottom-line results from energy master planning.

Create an Energy Team

A middle manager in your organization may declare that energy master planning is only the responsibility of the Facilities department. However, when an energy team represents the company's broad interests, energy concerns can be successfully integrated into the overall business plan. Every department that's impacted by the organization's energy use should be invited to participate on the team. This includes

- Facilities
- Construction/engineering
- Purchasing
- Accounting
- Inventory
- Environmental, health, safety
- Legal
- Public affairs
- Property/asset management
- Leasing/real estate
- Risk management
- Security
- Financial service

This should result in the creation of an Energy Committee. Depending on the size of the organization, there may be separate Technical and Steering Energy Committees. In addition to representatives from the departments listed above it is important to include members of the rank and file (hourly employees or line workers). By including such folks in the planning process it allows not only those individuals, but their peers as well, to become aligned with the EMP objectives and particular initiatives during the early stages. Having these employees on the team helps the rest of the rank and file staff (who will be needed to carry out many of the activities) see the energy program as something other than 'just another management flavor of the month.' It also increases success, as feedback from these employees often helps address many of the nuts-and- bolts "bugs" in advance.

The energy team should be headed by an energy manager or coordinator. The energy manager needs to have a mix of technical, people, and communications skills, and must be enthusiastic. He or she should thoroughly understand the organization's operations and should report to someone as close to the top of the organization as possible, so he or she has the clout need to get things accomplished.

Understand the Organization's Energy Use

Conduct disciplined information analysis. Collect and use metered–not just billed–energy data, and analyze it with software designed to manage energy costs. "Fully understanding current energy use practices–the when, where and how much of energy consumption–in detailed qualitative terms is an essential precondition to energy management master planning."[2] For example, to determine exactly where the energy is going, specify and install sub-metering and a data acquisition system. Such tools will help you monitor and collect, as well as analyze, the meter data for electricity, fossil fuels, steam and condensate, and water. For loads of several hundred kW, it's advantageous to use interval meters that allow a close look at 15-minute interval or hour-by-hour use of energy, so you can see where peaks and valleys in usage occur. This kind of metering is also essential for internal billing. Besides establishing points of excessive usage, it can also help manage loads and pinpoint efficiency opportunities.

Cast a Wide Net

Casting a wide net means looking beyond the central plant for savings opportunities, such as lighting, office equipment, elevators, and localized process loads. It means making construction and equipment specs energy-conscious and creating ways to "enforce" such specs. For example, specifying T8 lamps for efficiency upgrades is not sufficient. The architecture, design, and construction staff should build T8s into their specs for non-energy-related upgrades, such as converting a library to training rooms. Casting a wide net also means revising inventory and purchasing practices to support energy efficiency. As in the example above, to ensure that the new installation continues to function properly, the purchasing specs need to list T8s, not T12s.

Set or Sharpen Goals

Once the organization's energy use is determined, strategic thinking linked to the long-term growth objectives will determine how much energy you should aim to save, where the savings should come from, and when those savings should occur. The energy manager along with the energy team, proposes a phase-one timetable with quantifiable goals to reduce energy use and operating and energy costs. Senior management, however, must mandate the goals and schedule or they carry no weight. Ideally, the CEO, CFO, or the Board issues a position calling for measurable reductions at the end of a 3-year fiscal cycle, based on current use: a percentage reduction in peak electrical demand across the entire facility, a reduction in annual kWh consumption of electricity, and a reduction in overall British Thermal Unit (BTU) for fuel per gross square foot. Lesser annual goals will help keep progress on track. A key is to set achievable goals, and then work to meet or beat them.

Implement Upgrades

Because energy managers generally have experience with efficiency upgrades, it is critical not to fall into old patterns of sporadic efforts and a piecemeal approach, with an eye on the quickest payback. To carry out an EMP, start the upgrade process with a comprehensive energy audit—not just a walk-through—to determine which upgrades will give the best results, not just the best rate-of-return. For example, in a commercial building operation, to avoid a rush upgrade for a new tenant, pre-audit all your buildings so you know what work needs to be done before that tenant signs their lease. Or, if you're considering recommissioning, look at it from the longer-term energy master planning perspective. Recommissioning may not be sufficient, as it means only the existing systems would operate more efficiently. But what if they need to be ripped out as part of the upgrade?

Don't fall into the common trap of focusing just on the high-profile, capital-intensive, projects. While a new chiller or micro-turbine cogeneration system may be a good photo opportunity, focusing on the less visible details can often provide the lion's share of savings through lower-cost measures that improve operations and maintenance (O&M) or maintenance and management practices.

Verify Savings

Once the upgrade process is underway, you must first validate the savings with a recognized technique such as the International Performance Measurement and Verification Protocol (IPMVP or MVP). However, instead of following the M&V protocol after the fact, build measurement and verification into the design—that is, install it as part of the upgrade—so you can identify the savings as soon as the device is turned on. Then, set up an energy accounting system that tracks usage and savings, thereby providing objective accountability. All too often energy management activities are not perceived as being of value because the energy team did not plan ahead and position themselves and theirs efforts for recognizable success. A North American floor coverings manufacturer reported how "in the past we would complete a project to find that we did not have the baseline or operational data to judge whether the project was successful."[3] How willing will management be to fund the next energy related project or initiative if the energy team cannot prove that prior efforts actually saved what was projected?

With an energy accounting system, everyone on the energy team will be working from the same data, and you can prepare regular progress reports, plus quarterly reports to the CFO and an annual report to the Board. This is critical: The energy team must account for the savings—or lack of savings-to senior management, using a feedback process so goals and targets can be reset if they aren't met. Use this process to verify energy use and to help identify any new opportunities for savings, and then to fine-tune your goals. If you fall short of your targets, you need to figure out why. Or perhaps you did meet your targets, but parts of the data were wrong. Perhaps the metering is off, or the energy accounting system needs readjustment. Regularly scheduled feedback from these reports will keep the energy master planning process up-to-date and realistic and will ensure accountability. One approach that has been successfully used in many organizations is the use of "energy report cards" and "intra-organizational listings/scorecards." Produced by the energy manager and sent out to all facilities/ operating groups/ departments on a monthly basis, these tools inform as well as motivate, based on the certainty that no one wants to be on the bottom of the list.

Communicate Results

Successful implementation of all stages of the EMP can be a useful vehicle for departmental—and personal—recognition. With a representative of the corporate PR office already on the energy team—enlist that individual's expertise for internal and external communications. Inform the organization's Board about the financial savings and improved asset value. Let the staff and community know about the environmental benefits. Apply for energy awards for national recognition in your sector. And use the good will generated by the success to keep the energy master planning process moving forward.

Tips for Success

From these steps to an EMP, two points emerge as the most critical to success.

The first is ensuring buy-in from the top, with a long term commitment and binding, formal statement of energy policy for the organization. Commitment to action also means that senior executives support the people in the middle—delegating authority to the energy manager or facility manager. If the EMP lacks commitment from the top down, no amount of effort by the energy manager will make it succeed. Once you've caught executives' attention, keep energy master planning on their radar screen by having the energy team build it into the organization's business plan. Such a commitment must also be apparent. Top management must continue to be seen (by all levels of staff) reaffirming their commitment, lest the EMP be perceived as just another short-term initiative of the organization.

The second critical component is line-management accountability, making specific individuals accountable for sustaining the savings. On the management side, executives need to mandate quantifiable goals and targets, strengthened by obligatory deadlines. Such requirements should even be built into job descriptions and evaluated as part of annual performance standards reviews. Likewise, incentives can be offered through these same personnel standards for individuals who meet their energy goals. Employee teams with day-to-day knowledge of the facility's operation can also be organized to identify additional opportunities for savings. At the upper level of the organization, corporate accountability for successful energy management can be communicated (and made public) through such mechanisms as the Global Reporting Initiative, especially in firms with sustainability principles that follow a "triple bottom-line."

Conclusion

Energy master planning is an effective and long-term shift in organizational cultures to address and adapt to the impact energy resources can have on their competitive posture and economic success. Energy is a universal raw material and is essential to the operation of almost every commercial, institutional, governmental, and even nonprofit organization. Significant changes to the basic structure of the energy supply chain and significant energy price volatility, driven by a wide range of political and physical events (e.g., climate change, weather), have made energy both a competitive opportunity and a risk requiring active long-term planning to manage. Energy master planning requires buy-in from top levels of an organization down through the rank and file, selection/hiring of a dedicated energy manager, and creation of an energy team with membership from across the organization. This team must be given the resources and top-level access to develop and implement long-term planning for procurement and operations throughout the organization that places a premium on lasting energy-use reductions and cost optimization, rather than "burst" efforts that provide quick and quickly forgotten energy management efforts.

Successful organizations do not exist on a quarterly basis. They plan for the long-term in all aspects of their operations. Experience has shown that organization-wide adoption of EMP is effective in optimizing energy costs and needs to ensure competitive posture and success in the long-term business reality in which organizations exist. This is the new bottom line for energy.

Energy: Solid Waste Advanced Thermal Technology

Alex E.S. Green
and Andrew R.
Zimmerman

Solid Waste, Solid Fuels, and Their Properties

In 2011 the United States was heavily (~50%) reliant on foreign sources for its liquid fuels and somewhat (~10%) dependent upon imports for its gaseous fuels. Our country is now expending “blood and treasure” in its efforts to stabilize regions of the globe that supply these premium fuels. Yet the United States is well endowed with solid fuels in the form of coal, oil shale, and substantial quantities of renewable but wasted solids. As part of a continuing long search for alternatives to oil,[1–10] this entry is focused on converting our solid waste to energy by advanced thermal technologies (SWEATTs) while mitigating environmental and economic problems. Table 1 is a list of United States’ abundant supply of solid waste (SW) whose organic matter can be converted into gaseous and liquid fuels as well as charcoal. The value society places on a specific fuel or energy type is very sensitive to its physical form as indicated in Table 2[11] which gives prices of various forms of energy in the United States at the beginning of 2010. The large carbon dioxide neutral (neither net producing nor consuming CO_2) plant matter components in Table 1 can help in greenhouse heating mitigation. The great diversity of physical and chemical characteristics of fuel wastes (feedstock) in Table 1 implies that the world now needs “omnivorous feedstock converters” (OFCs) to change these solid fuels into much more usable liquid or gaseous fuels or better solid fuels. Figure 1 is a conceptual illustration of an OFC adapted from a number of prior papers[8–10] in which a SW pyrolyzer–gasifier–liquifier–carbonizer is coutilized with a natural gas-fired combined cycle (NGCC) system, as will be discussed below.

Table 3 shows major ranks of coals as well as of peat, wood, and cellulose and their ultimate and proximate analyses as measured by industry for over a century. The numbers listed in columns labeled C, H,

and O (wt% of carbon, hydrogen, and oxygen, respectively) essentially apply to ideal carbon, hydrogen, and oxygen (CHO) materials by correcting measurements to their dry-, ash-, sulfur-, and nitrogen-free (DASNF) form. Then $[C]+[H]+[O] = 100$ and any two of the three variables fixes the third. In this work we mostly focus on the variables [O] and [H] which then essentially specifies [C]. The column labeled higher heating values (HHV) gives typical HHV in millions of joules per kilogram (MJ/kg) as measured with standard bomb calorimeters after allowing for the minor components.

Figure 2a is mainly a plot of [H] (solid diamonds with values read on the left scale) vs. [O] on the top scale for 185 representative DANSF CHO materials taken from ultimate analysis data available in the technical literature. The trend can be represented by $[H] = 6\ (1 - \exp([O]/2))$. The bottom scales give conventional coal ranks, some potential names for the biomass region, and some names that might foster more friendly discussions between the coal and biomass sectors. This [H] vs. [O] coalification plot shows that apart from the anthracite region, all natural DANSF feed-stock have [H] values that are close to 6%. The [H] and [O] coordinates of the three main components of all plant matter are lignin-6.1, 32.6; cellulose-6.2, 49.4; and hemi-cellulose-6.7, 53.3. Materials present in SW can depart substantially above and below the coalification curve. For example, the coordinates of polyethylene and polypropylene are 14.2 and 0, respectively.

TABLE 2 Market and Energy Prices, December 2010[11]

Fossil Fuels	Market Price	$/MMBtu
Crude oil	$84.93 $/Barrel	$14.64
Gasoline	$2.865 $/Gallon	$22.92
Diesel Fuel	$3.116 $/Gallon	$24.21
Natural gas	$3.56 $/MMBtu	$3.56
Liquid Propane (Gulf)	$1.11 $/Gallon	$12.19
Heating oil	$2.084 $/Gallon	$15.10
Electricity retail, resid.	12.02 c/kWh	$35.23
Coal	$47.25 $/ton	$2.00
Liquid Fuels		
Ethanol (Iowa)	$2.42 $/Gallon	$31.78
biodiesel (Iowa)	$4.13 $/Gallon	$34.96
Soybean oil (Central IL)	51.68 c/Lb	$30.40
No 2, Yellow grease	$32.88 $/cwt	$21.35
Solid Fuels		
Fuel pellets	$206.60 $/Ton	$12.91
Shelled corn	$5.37 $/Bushel	$11.76
Compost	$25.00 $/cu. yard	$3.63
Wheat straw	$80.00 $/Ton	$5.41
Grass hay (lg md bale)	$50.00 $/Ton	$3.33
DDGS	$156.00 $/Ton	$8.30

Cellulose	44	6	50	10	88	12	0.4	9	1600

C, H, and O are wt% of carbon, hydrogen, and oxygen, HHV = higher heating value (millions of joules per kilogram: MJ/kg), V_T = weight percent volatiles, FC = fixed carbon weight percent, Dens = g cm^{-3}, E/vol = relative energy density, charR = relative char reactivity.

The [C] vs. [O] data calculated with [C] = 100−[O]−[H] for DASNF feedstock are also shown in Figure 2A. When the smooth [H] vs. [O] formula is used one gets the smooth upper curve in relation to the data. This figure provides strong reasons for regarding peat and biomass simply as lower rank coals. The diagram suggests that coalification is a natural geophysical deoxygenating process. Much of this treatise on SWEATT will be devoted to attempting to bring some order to the confused literature on artificial pyrolysis, deoxygenating or carbonizing processes and their gaseous, liquid, and solid products. For many purposes, natural solid fuels could be ranked simply by [O] to replace the different ranking systems of various countries (a Tower of Babel!). For example, using 34-O for peat, called "turf' in Ireland, might help temper the "turfwars" in fuel sector competitions and in energy vs. environmental confrontations on the use of our available fuels.

HHV of various fuels measured with calorimeters are often reported along with proximate analyses. Representative values for the various coal ranks are given in the column labeled HHV in Table 3. The column labeled V_T gives representative "total volatiles," V_T, as determined by an American Standard Test Measurement Method. A solid sample is heated (pyrolyzed) in a platinum crucible at 950°C for 7 minutes. The weight percent loss due to the escaping volatiles is designated as the total volatile yield (V_T). The balance from 100% then represents the weight percent of the fixed carbon (FC) plus ash. The ash wt% is the weight percent remaining after combustion in full atmosphere at 750°C for 6 hours.

The columns of Table 3 labeled Dens and E/vol give the physical density (in g/cc) and relative energy density of the various natural solid fuels. These are important factors in determining handling and transportation costs. The column labeled charR gives some relative measures of the reactivity of the chars that are produced by the pyrolysis of these natural feedstock.

Figure 2b displays HHV data for the compilation of 185 materials after correction to DASNF cases. Most points within this scattered HHV data can be fit within a few percent by a two variable form of Dulong's formula:

$$\text{HHV in MJ/kg} = 34.9 - 0.453[\text{O}] + 0.829[\text{H}] \tag{1a}$$

Or

$$\text{HHV in MBtu/1b} = 15.00 - 0.194[\text{O}] + 0.356[\text{H}] \tag{1b}$$

The first form is simplified from the six-variable DuLong formula found by Channiwala and Parikh[12] who fit a large body of HHV measurements of biomass and other fuels. The smooth curve in Figure 2b shows the trend of the HHV vs. [O] when [H] = 6 (1 − exp([O]/2)) is used. When measured [H] values are

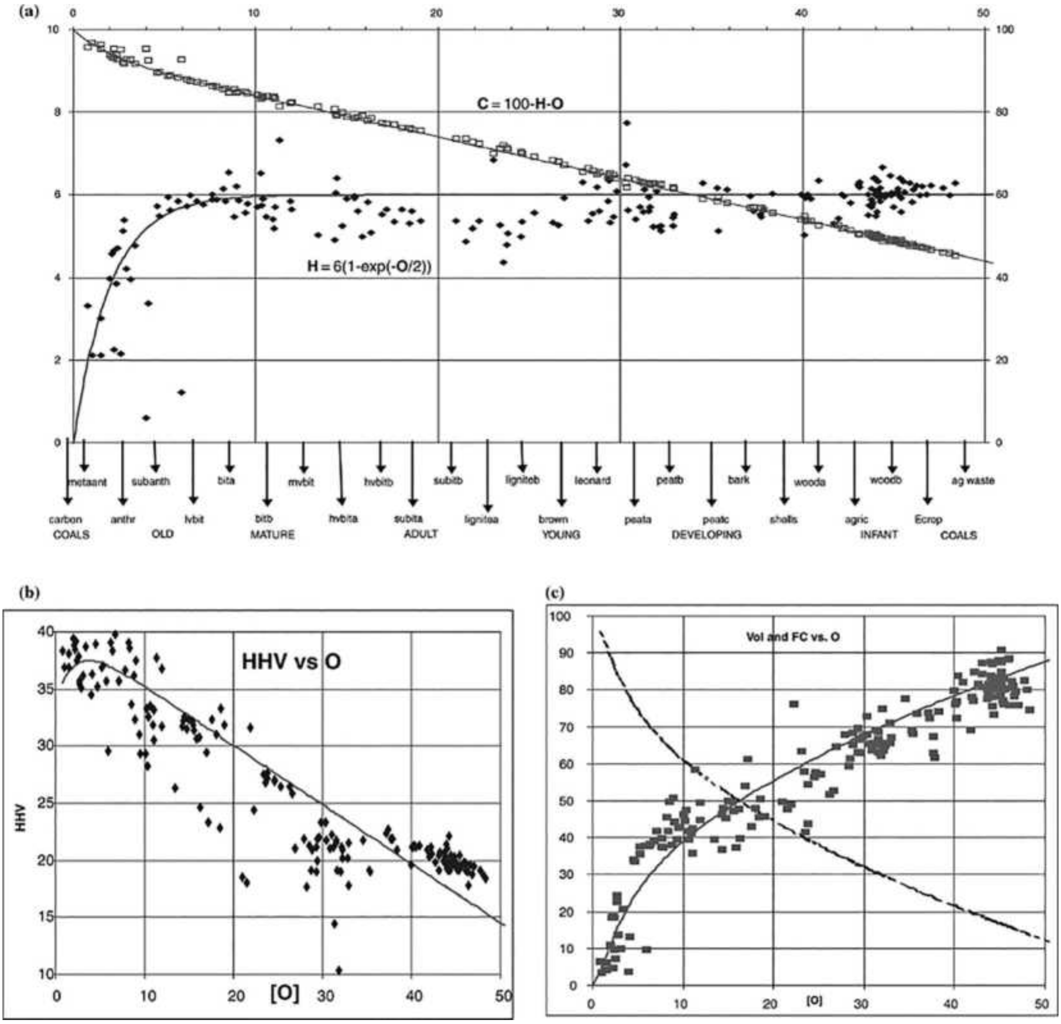

FIGURE 2 (a) Weight percentages of hydrogen [H, left] vs. [O, top] for 185 DANSF carbonaceous materials (diamonds) and additional solid waste materials (red circles). Classification labels are given at the bottom axis. (b) Higher heating values (HHV) of 185 carbonaceous materials (corrected to DANSF) vs. [O]. The smoothed curve represents: Eq. 1a when [H] = 6(1- exp([O]/2)) is used. (c) Total volatile weight percentages (left) vs. [O] for 185 DASNF carbonaceous materials (squares) from proximate analysis. The curve through the data points satisfies: $V_T = 62([H]/6)([O]/25)^{1/2}$. The analytic fixed carbon (FC) vs. [O] is shown as a dashed line.
Source: Green.[4]

used the HHV formula given fits within a few percent. From a HHV standpoint deoxygenating biomass by pyrolysis endows the char progressively with some properties of the higher ranks of coal except that chars tend to be more porous.

The general trends of total volatiles along nature's coalification curve can approximately be represented by the empirical formula $V_T = 62([H]/6)([O]/25)^{1/2}$. Note the rapidly increasing trend in V_T from low [O] materials to high [O] materials (Figure 2c). Because of the large production of volatiles by high [O] materials, pyrolysis of these materials is substantially equivalent to gasification. The [H] dimension is also important and small deviations of [H] from the smooth coalification path have a large impact on the volatile release.

The three diagrams in Figure 2 all indicate the importance of [O] in determining the fuel and carbonization or pyrolysis properties of organic materials. Coalification might be called nature's carbonization or deoxidization process whereas pyrolysis is an artificial process for carbonization or deoxidation of organic feedstock.

Global and U.S. Primary Energy Supplies

Figure 3a presents an overview of the world total primary energy supply (TPES) in 2004 (see International Energy Agency website). Among the major sources of energy, combustible renewables and waste (CRW, mostly biomass) need only be doubled to be together with coal and natural gas, and tripled to be competitive with petroleum. Note that the global CRW is currently about twice as large as nuclear. On the other hand, wind and solar must grow by factors of over 100 to become major global energy supplies.

This global TPES picture is not representative of the industrial world, particularly the United States today. Figure 3b shows the percentage subdivisions of the US TPES in 2007 when the total consumption

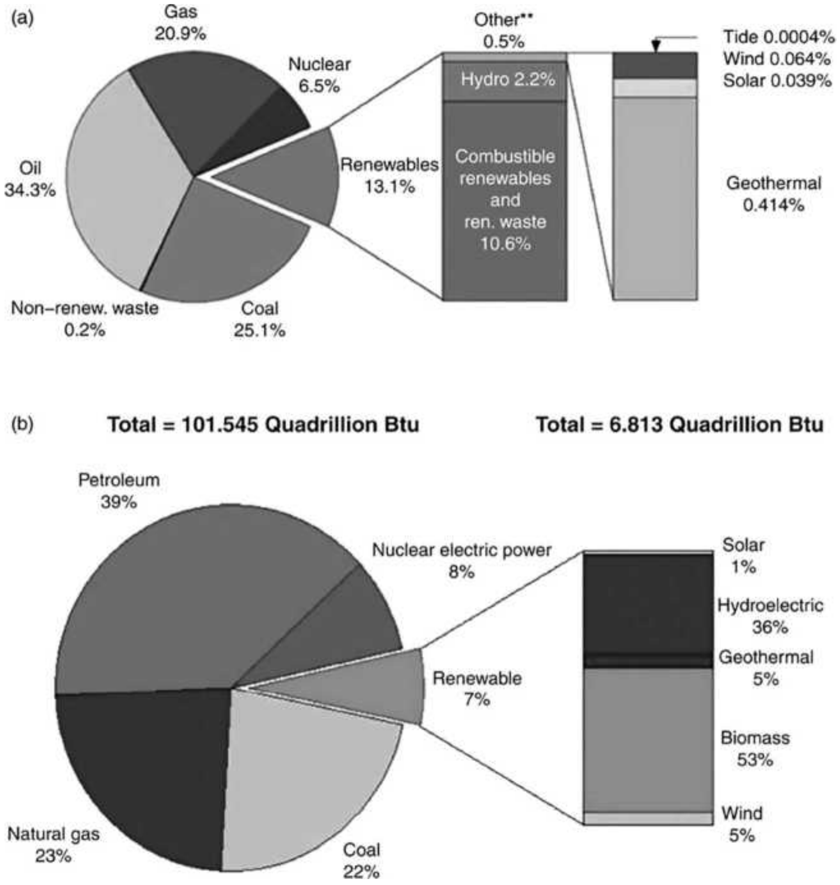

FIGURE 3 (a) Total primary energy supply (TPES) for the globe at 2004 (IEA Website). (b) TPES for the United States in 2007 (EIAWebsite). *TPES is calculated using the IEA conventions (physical energy content methodology). It includes international marine bunkers and excludes electricity/heat trade. The figures include both commercial and non-commercial energy. **Geothermal, solar, wind, tide/ wave/ocean. Totals in graph might not add up due to rounding.

Source: *IEA Energy* Statistics.

was over 101.5 quads, (quadrillion British thermal units (Btu)/annum or quads). It is seen that about 39% of our energy consumption is in the form of petroleum that is mainly consumed in our transportation sector. As Figure 3c illustrates renewables only constitute 7% of the U.S. TPES. The percentage subdivisions of these in 2007 are shown in the figure, and it is seen that biomass was 53% of the 7%. The major thrust of this work is that the solid wastes listed in Table 1, consisting mostly of biomass, were only a minor component (~3.5%) of the U.S. annual TPES, and could in the near term become a major component comparable to coal and natural gas, both still at about 23%. The more popular renewables, geothermal wind and solar, have much further to go than solid waste before becoming a major primary energy source in the United States. Since SWEATT is based on locally available solid waste, it would also create good non-exportable local industries and jobs while mitigating serious U.S. energy import and waste disposal problems. An Oak Ridge National Laboratory study[13] estimates the sustainable supply of the first few biomass categories in Table 1 at about 1.4 billion dry tons. The remaining categories should readily bring the total sustainable U.S. solid waste available to over 2 billion dry tons. Assuming a conservative HHV of 7500 Btu/lb, a simple calculation shows that with SWEATT technologies similar to those that are now in place in Japan, U.S. solid waste contribution to its primary energy supply could reach the 25% level.

Without a doubt, the biggest energy problem faced by the United States today is the need to find alternatives to oil.[1–3] In the 1970s and early 1980s, the United States focused heavily on alternatives to oil in the utility sector. The alternatives first were pulverized coal plants and in the late 1980s and 1990s, on NGCC systems. The U.S. and the globe have been slow in generating electricity by Solid Waste with Advanced Thermal Technologies (SWEATT) and flexible systems such as those illustrated in Figure 1.

It is important to differentiate secondary energy supplies (SESs) from the primary energy supplies (PESs) shown in Figure 3. Secondary energy supplies include steam, syngas, reactive chemicals, hydrogen, charges in batteries, fuel cells, and other energy sources that draw their energy from PESs. If a SES is converted to another type of energy, say mechanical energy via a steam turbine, the mechanical energy becomes a tertiary energy supply (TES). This TES can be converted to electrical energy using magnetic generators, in which case the electricity is a quaternary (QES) supply. In the case of electricity, the many conversions are usually justified since electricity can readily be distributed by wire and has so many uses as a source of energy for highly efficient electric motors, illumination systems, home appliances, computers, etc. Table 2 points to the high cost/value placed on electricity and on liquid fuels.

In many communities debates are underway as to whether increasing electricity needs should be met with the solid fuel coal, MSW, biomass via conventional steam and steam turbine generator systems, or via conversion to a gaseous fuel and using integrated gasifier combined cycle (IGCC) systems. Granting that the steam turbine route has had many advances over the last century, converting the solid fuel to gaseous fuel is increasingly being accepted as the ATT route of the future. The ATT route is not only driven by environmentally acceptable waste disposal needs and increased needs for electricity, but also by the need for liquid and gaseous fuels. A number of petroleum resource experts have recently advanced the date that the globe's supply of oil and natural gas will run out. The prices of oil and to a lesser extent natural gas now reflect this drawdown and are already high enough that conversion of organic matter in solid waste to liquid and gaseous fuels makes economic sense. We should recognize, however, that for the most part, cartels govern fuel prices not free markets. Thus we should not abandon alternative fuels efforts whenever cartels, for their interests, lower prices.

Advanced Thermal Technologies

The largest solid waste to energy systems in operation today are direct combustion municipal solid waste (MSW) incinerators with capacities in the range of 1000–3000 tons SW per day. In such mass burn systems, the organic constituents of the solid waste are combusted into the gaseous products CO_2 and H_2O. These have no fuel value but can be carriers of the heat of combustion as in coal and biomass boiler-furnace systems. Along with the flame radiation, these gases may be used to transfer heat to pressurized water to produced pressurized steam that drives a steam turbine-driven electric generator. The steam can also serve as a valuable SES to distribute heat for heating buildings, industrial processes, etc. The production and use of steam, along with the steam engine, launched the industrial age.

Instead of using the heat released to raise steam, in SWEATT systems the solid waste is first converted into gaseous or liquid fuels and, in pyrolysis systems, partly to char. The volatiles, gases, and vaporized liquids fuel then serve as a SES that can be used in efficient internal combustion engines (ICEs), combustion turbines or, in the future, in fuel cells, none of which can directly use solid fuels. Over the past century automotive and aircraft developments have pushed ICEs and gas turbines (GT) to very high levels of efficiency. Furthermore, with the use of modern high temperature GTs in NGCC systems, the heat of the exhaust gases can be used with a heat recovery steam generator (HRSG) to drive a steam turbine. Alternatively, the HRSG can provide steam for heating buildings or industrial applications of steam. These combined heat and power (CHP) system at this time make the most efficient use of the original solid fuel energy.

If one considers the United States' heavy dependence on foreign sources of liquid and gaseous fuels, the most challenging technical problem facing the United States today should be recognized as the development and implementation of efficient ways of converting our abundant domestic solid fuels into more useful liquid and gaseous fuels. In view of the diversity of feedstock represented in agricultural, municipal, or institutional solid waste, the United States and the world need an omnivorous feedstock converter such as is illustrated in Figure 1. Here, the right block represents a typical NGCC system, whereas the left block represents a conceptual Omnivorous Conversion System that can convert any organic material into a gaseous or liquid fuel.

We will first consider the gross nature of the output gas from biomass or cellulosic type material, the major organic components of most solid waste streams. Apart from minor constituents such as sulfur and nitrogen, the cellulosic feed types are complex combinations of carbon, hydrogen, and oxygen such as ($C_6H_{10}O_5$) that might serve as the representative cellulosic monomer.

ATT systems used to produce output can be divided into 1) air blown partial combustion (ABPC) gasifiers; 2) oxygen blown partial combustion (OBPC) gasifiers; and 3) pyrolysis (PYRO) systems. The three types of systems for converting waste into a gaseous fuel have many separate technical forms depending upon the detailed arrangements for applying heat to the incoming feed and the source of heat used to change the solid into a gas or liquid fuel. We use "producer gas" as a generic name for gases developed by partial combustion of the feedstock with air as in many traditional ABPC gasifiers that go back to Clayton's coal gasifier of 1694. We will use "syngas" for gases developed by partial combustion of the feedstock with oxygen as in OBPC gasifiers, which are mainly a development of the twentieth century. We will use "pyrogas" for gases produced by oxygen-free heating of the feedstock such as in indirectly heated (pyro)gasifiers. The objective is to replace the natural gas, that is, fossil fuel gas, that has a HHV, ~1000 Btu/cft = 1 MBtu/cft (with Btu $M = 1000$) with a biomass-generated fuel gas having similar energy and combustion qualities.

When an ABPC gasifier is used with cellulosic materials (cardboard, paper, wood chips, bagasse, etc.), the HHV of biomass producer gas is very low, 100–200 Btu/cft. Essentially, the useful product of partial combustion of biomass is CO that only has a HHV of 322 Btu/cft. Unfortunately, considerable CO_2 and H_2O are produced during partial combustion and together with the air-nitrogen these inerts substantially dilute the output gas. The "syngas" obtained from biomass with OBPC gasifiers is better, ~320 Btu/cft, since it is not diluted by the atmospheric nitrogen. However, because of the partial combustion it is still somewhat lower than the energy contained within the feedstock molecules. Additionally, the oxygen separator is a major capital cost component of an OBPC gasifier. With a Pyro system, the original cellulosic polymer is broken by the applied indirect heat to its monomers and then to the major pyro-products CO, CO_2, and H_2O as well as hundreds of hydrocarbons (HCs) and carbohydrates (HCOs), each with yields that depend upon the applied temperature, heating time, and particular processing arrangement. Cellulosic pyrogas can have heating values in excess of 400 Btu/cft.

Among the pyro-volatiles coming from pyrolysis systems are the paraffins (CH_4, C_2H_6, C_3H_8, …), olefins (C_2H_4, C_3H_6, …), acetylenes (C_2H_2, C_3H_3, …), and various carbohydrates, carbonyls, alcohols, ethers, aldehydes and phenols, and other oxygen-containing gaseous products. Attempting to find some patterns or regularities in the literature on products of pyrolysis from various natural and man-made fuels has been the goal of multiyear effort.[4–26] Table 4 is a list of the families of molecules that have been detected in pyrolysis volatiles and the rules that connect the family member, labeled by $j = 1, 2, 3, \ldots$ (see "The ASEM and Organization of Pyrolysis Products").

HC plastics such as polyethylene and polyolefins are heavily represented in many solid waste streams. Thus one might use (C_2H_4) as representative of the monomers in the plastic component of MSW or refuse-derived fuels (RDFs). Polyethylene pyrolysis products are dominated by C2–C4 olefins, acetylenes, and other HCs and at higher temperatures by H_2 as well as aromatics (Ar) and polynuclear aromatics (PNAs) identified in Table 4. On a per unit weight basis, all but H_2 have gross heating values in the range 18–23 MBtu/lb, similar to oil, whereas H_2 has a gross heating value of 61 MBtu/lb. On a per unit volume basis, polyethylene pyrolysis products have gross heating values ranging from 1 to 5 MBtu/cft whereas H_2 is 0.325 MBtu/ cft = 325 Btu/cft. Because natural gas is typically about MBtu/cft, we would expect the pyrogas from polyethylene to have a gross heating value comparable or greater than that of natural gas and much greater than cellulosic pyrogas.

In summary since cellulosic feedstock is already oxygenated compared with pure HC plastics, its pyrogas, syngas, and producer gas will all have considerably lower heating values than the corresponding gases from HC feedstock. From the viewpoint of maximizing the HHV of SW derived gas, Pyro gasification scores better than OBPC gasification, both of which score much better than ABPC gasification. Pyrolysis also leaves more of a solid residue in char-ash form than ABPC gasification or OBPC gasification. Figure 4 illustrates a typical pattern of evolution of the solid in an indirectly heated slow pyrolysis system.[27] For DASNF materials the asymptote of the solid (char) curve would represent the FC and the balance from 100% would represent the total volatiles. Figure 4 also shows a typical pattern of evolution of the tar and gas from wood feedstock in the pyrolysis of a small particle of wood when its temperature is raised at a slow rate such as 10°C/min. These curves are representative of results from the analytical semiempirical model (ASEM).

TABLE 4 Organization of Functional Groups by Families

Families	a	B	c
Paraffins	j	$2a + 2$	0
Olefins	$j+1$	$2a$	0
Acetylenes	$j+1$	$2a - 2$	0
Aromatics	$5+j$	$4+2j$	0
Polynuclear	$6+4j$	$6+2j$	0
Aldehydes	$j+1$	$2a$	1
Carbonyls	J	$2a$	1
Alcohols	J	$2a + 2$	1
Ethers	$j+1$	$2a + 2$	1
Phenols	$5+j$	$4+2j$	1
Formic acids	J	$2a$	2
Guaiacols	$6+j$	$6+2j$	2
Syringols 1	$7+j$	$8+2j$	3
Syringols 2	$8+j$	$10+2j$	4
Sugars 1	$4+j$	10	5
Sugars 2	$5+j$	$10+2j$	5

a, b, and c are the subscripts in $C_aH_bO_c$, $j = 1, 2, 3\ldots$

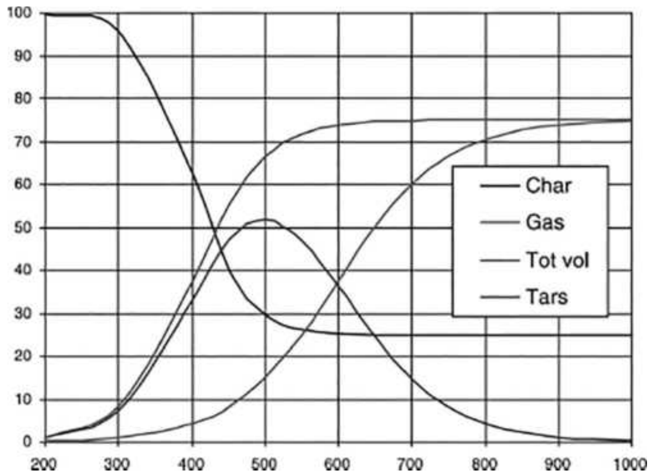

FIGURE 4 Typical pattern of evolution of char, tar, and gas from wood feedstock as temperature is raised at a slowly (10°C/min).

Studies of the evolution of chars, tars (volatiles condensable at standard temperature), gas (not condensable at standard temperature), and total volatiles have been carried out at heating rates (r) from 1°C/min to 1000°C/sec. Usually the heat rate is coupled to the temperature via a linear relationship such as $T = rt + \mathrm{T}_o$ (where t is time and T_o is an initial temperature). The dependence of these products upon temperature then changes dramatically from that shown in Figure 4 in ways that are difficult to track via standard kinetic modeling. However, they can be relatively easily represented via formulas used in the ASEM by letting the parameters of the model be simply dependent upon the heating rate. This approach is often dismissed as "just curve fitting" in academic circles where the search for models that depend upon fundamentals physical variables has become traditional. Unfortunately, in pyrolysis studies, because of the complexity of products released at various temperatures, this quest is still far from realization. Accordingly, it appears to some investigators that after the experimental assembly of reproducible scientific data (the first step of the scientific method), organizing the results in some robust analytical form (the usual second step of the scientific method) cannot only be useful for applications, but could help in achieving a fundamental model.

The ASEM and Organization of Pyrolysis Products

Proximate analyses of coal and biomass measured for over a century provide extensive data on total volatile content. However, quantitative data as to the molecular constituents in these volatiles have only been reported in recent years and a predictive method for identifying these molecules is still not available. This despite the fact that such knowledge could provide a more fundamental understanding of humankind's oldest technology (the use of fire). For control and application of a pyrolysis system it would be useful to have at least an engineering-type knowledge of the expected yields of the main products from various feedstock subjected to oxygen-free thermal treatment (pyrolysis).

In most attempts to describe the systematic of pyrolysis yields of organic materials such as coal and biomass, including the initial CCTL studies,[14–19] it has been customary to characterize the feedstock by its atomic ratios $y = \mathrm{H/C}$ and $x = \mathrm{O/C}$. In recent studies,[20–26] it has been found more advantageous to work with the weight percentages [C], [H], and [O] of the feedstock after correcting to DASNF conditions (i.e., pure CHO materials). Focusing on weight percentages appears to facilitate easier connections between the great complexity of compounds that evolve from pyrolysis and the gas, liquid (tar), and solid products of pyrolysis.

The ASEM is a phenomenological attempt to find some underlying order in the pyrolysis yields of any product $C_aH_bO_c$ vs. the [O] and [H] of the DASNF feedstock and the temperature (T) and time (t) of exposure. The ASEM was developed so as to be useful for a number of applications of pyrolysis.[18–26] Some progress has been made in including the time dimension but much more work remains on that front. When the time dimension is not an important factor, as in many cases of slow pyrolysis, the yield Y(T) as a function of temperature of each product for slow pyrolysis (or fast pyrolysis at a fixed time) is represented by

$$Y(T) = W\left[L(T:T_0,D)\right]^p\left[F(T:T_0,D)\right]^q \tag{2}$$

where

$$L(T:T_0,D) = \frac{1}{1+\exp\left((T-T_0)/D\right)} \tag{3}$$

and

$$F(T:T_0,D) = 1 - L(T) = \frac{1}{1+\exp\left((T-T_0)/D\right)} \tag{4}$$

Here $L(T)$ is the well-known logistic function that is often called the "learning curve." Its complement, $F(T) = 1 - L(T)$ thus might be called the "forgetting curve." For engineering applications this "curve fitting" approach provides a more robust and convenient means for organizing pyrolysis data than traditional methods that use conventional Arrhenius reaction rate formulas.[27] In the ASEM each product is assigned five parameters (W, T_0, D_0, p, q) to represent its yield vs. temperature profile. The objective has been to find how these parameters depend on the [H] and [O] of the feedstock and the *a, b, c* of the $C_aH_bO_c$ products for the data from particular types of pyrolyzers. Studies by Xu and Tomita (XT)[28] that gave data on 15 products from 17 coals at 6 temperatures have been particularly helpful in revealing trends of the parameters with [O] and [H]. In applying the ASEM to the CCTL data collection, the XT collection, and several other collections, a reasonable working formula was found for the yield of any *abc* product for any [O], [H] feedstock given by

$$Y(C_aH_bO_c) = W_{abc}z^{\alpha}h^{\beta}x^{\gamma}\ \left[L(T:T_0,D)\right]^p\left[F(T:T_0,D)\right]^q \tag{5}$$

where z = [C]/69, h = [H]/6, and x = [O]/25 and the parameters α, β, and γ. T_0, D, p, and q were found to have simple relationships to the feedstock and product defining parameters [H], [O], *a, b,* and c. The final ASEM formulas that fit the data could then be used to extrapolate or interpolate the XT results to any [H], [O] feedstock and temperature. Figure 5 gives an overview of the interpolated and extrapolated outputs $Y(T)$ for a selection of products for six representative feedstock along nature's coalification path.

Several hundreds, even thousands, of organic products of pyrolysis have been identified in the literature. Thus, to bring order from chaos will require some comprehensive organization of these products. Toward this goal, the ASEM approach groups products into the families as summarized in Table 4, which gives rules for the *a, b, cs* that connect these groups. This list can be subdivided into pure HCs, i.e., (C_aH_b), and the oxygenates (C_aH_bO, $C_aH_bO_2$, $C_aH_bO_3$, …, etc.). Isomers (groups with identical *a, b,* and *c*) can differ in detailed pyrolysis properties and hence parameters. We use $j = 1, 2, 3, \ldots$ to denote the first, second, third, etc., members of each group or the carbon number (n). In the most recent ASEM studies[20–26] of specific feedstock, pyrolysis formulas have been proposed and tested for the dependence of the W, T_0, D_0, p, and q parameters upon the carbon number of the product within each group. This makes it possible to compact a very large body of data with simple formulas and a table of parameters.

The case of polyethylene is an example of such a study. It is not shown on Figure 2a, as it is far removed from the coalification curve having the position [H] = 14.2 on the [O] = 0 axis. Without oxygen in the

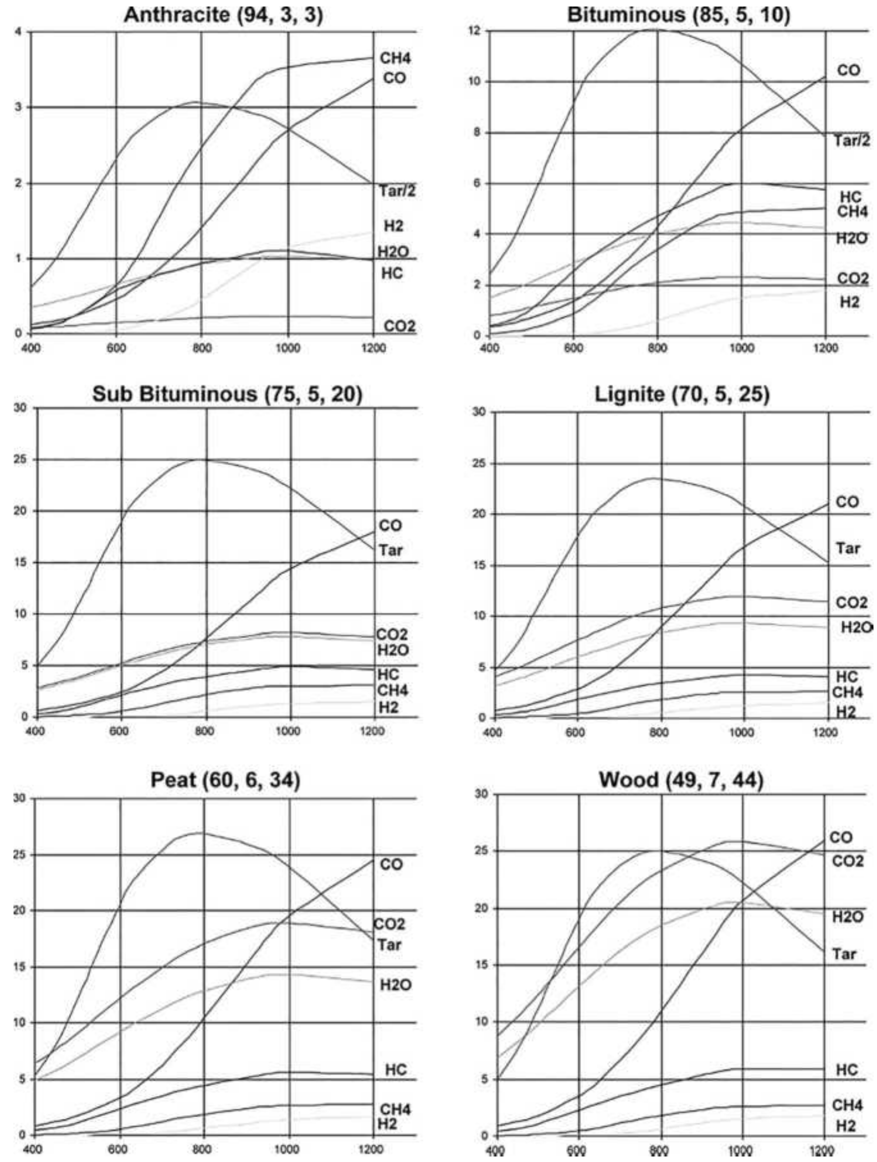

FIGURE 5 Weight percent yields (left axis) vs. temperature (in °C, bottom axis) of pyrolysis products of anthracite, bituminous coal, subbituminous coal, lignite, peat, and wood of ([C], [H], [O]) composition as shown. HC represents C2 and C3 gasses and aromatics.
Source: Green and Bell.[10]

feedstock, the pyrolysis products are much fewer and the ASEM is much simpler to use than with carbohydrates. Thus, only the first 6 rows of Table 4 are needed to cover the main functional groups involved in organizing the pyrolysis products of polyethylene. Figure 31.6 gives an ASEM-type summary of the product yields vs. temperature for polyethylene based on fits to the experimental data of Mastral et al.[29,30] at five temperatures that were constrained to approximately satisfy mass, [C], and [H] balances. Once the parameter systematic is identified, the ASEM representation can be used to estimate the pyrolysis product of polyethylene pyrolysis at any intermediate temperature or at reasonable extrapolated

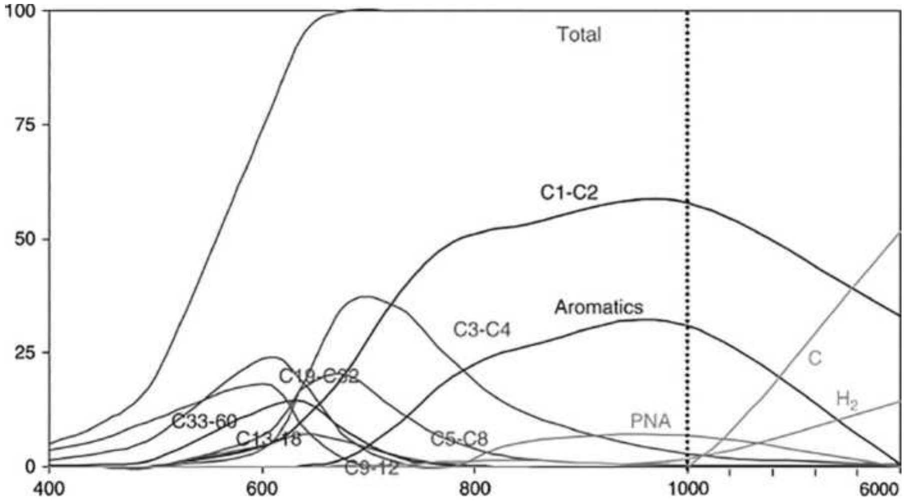

FIGURE 6 Weight percent yields (left axis) vs. temperature (in °C, bottom axis) of pyrolysis products of polyethylene in various hydrocarbon groups.
Source: Green and Sadrameli.[22]

temperatures. The experimental data was only available up to 850°C but the extrapolations to 1000°C were constrained in detail to conform to mass, [C], and [H] balances. Figure 6 also shows extrapolations to 6000°C that might be of interest if one goes to very high temperatures, for example, by plasma torch heating. Here we incorporate a conjecture that at the highest temperatures H_2 and C emerge among the products at the expense of the C1-C2 compounds as well as Ar and PNA components. While we have already found that an ASEM can begin to bring some order into pyrolysis yields, clearly there is a long way to go. When the time dimension is important, the overall search is for a reasonable function of seven variables [H], [O], a, b, c, T, and t. In comparison, Einstein's special theory of relativity only dealt with four variables x, y, z, and t.

Analytical Cost Estimation and SW-IGCC vs. NGCC

Before World War II (WWII) almost every town had its own gas works, mainly using coal as a feedstock. After WWII, cheap natural gas became available and became a major PES for home heating and cooking as well as for industrial purposes. In the 1980s, factory produced natural gas combined cycle (NGCC) systems became available and natural gas became a base load fuel source for many electric utilities. This hastened the drawdown of U.S. conventional domestic supplies and natural gas prices rose to high levels. However, natural gas prices have proven very volatile so that pursuing combinations of SWEATT with NGCC provides good flexibility in facing high energy price swings. For most biomass and plastic feedstock, pyrolysis is substantially equivalent to gasification.

Most comparative economic analyses use detailed life cycle analysis (LCA) or other forms of cost-benefit (C/B) approaches. However, it must be recognized that in recent years fuel costs, an important component of LCA, or C/B approaches have become so volatile that long-term projections based on assumed fuel cost can be grossly inaccurate. Fortunately, the economic feasibility of using a gasifier in front of a gas-fired system can be examined with simple arithmetic and algebra using an analytical cost estimation (ACE) method.[8–10] ACE takes advantage of the almost linear relationship between the cost of electricity (COE = Y) vs. cost of fuel (COF = X) observed in utility practice and in many LCA for many technologies, i.e.,

$$Y(X) = K + SX \tag{6}$$

In Eq. 6, Y is in ct/kWh (cents per kilowatt hour), X is in \$/MMBtu, and S is the slope of the $Y(X)$ line in ct/kWh/\$/ MMBtu or 10,000 Btu/kWh. S relates to the net plant heat rate (NPHR, see Chapter 37 in Stultz and Kitto[31]) via

$$S = \frac{\text{NPHR}}{10{,}000} \text{ or efficiency via } \mathrm{S} = \frac{34.12}{\text{Eff}} \tag{7}$$

A slope $S_{ng} = 0.7$ is now a reasonable assignment for a NGCC system reflecting the high efficiency of recent gas and steam turbines.

In Eq. 6 the parameter K is obviously the COE if the fuel comes to the utility without cost (i.e., $X = 0$). In previous studies,[8–10] $K_{ng} = 2$ was used as a reasonable zero fuel cost parameter for a 100-MW NGCC system.[32,33] This low number reflects the low capital costs of factory-produced gas and steam turbines in NGCC systems. In addition the contribution to the intercept K from operations and maintenance costs are reasonable. The K_{sw} for a solid waste-integrated gasification-combined cycle (SW-IGCC) system is higher than K_{ng} because the capital costs and operating cost must include the gasifier and gas cleanup system. The value of S_{sw} is also higher than S_{ng} because we must first make a SES producer gas, syngas, or pyrogas which involves conversion losses. A study of the literature[33–37] suggests that $S_{sw} = 1$ is a reasonable estimated slope for a SW-IGCC system. The X_{sw} for a SW-IGCC system that would compete with a NGCC system at various X_{ng} thus must satisfy

$$K_{\mathrm{SW}} + X_{\mathrm{SW}} S_{\mathrm{SW}} = K_{ng} + X_{ng} S_{ng} \tag{8}$$

It follows that the solid waste fuel cost X_{sw} that would enable a SWCC system to deliver electricity at the same cost as a NGCC system paying X_{ng} is given by

$$X_{\mathrm{SW}} = \frac{K_{ng} - K_{\mathrm{SW}}}{S_{\mathrm{SW}}} + X_{ng}\left(\frac{S_{ng}}{S_{\mathrm{SW}}}\right) \tag{9}$$

In the following, all X numbers are in \$/MMBtu and all Y and K numbers are in ct/kWh. Let us use Eq. 9 with $K_{kg} = 2$, $S_{ng} = 0.7$, $S_{sw} = 1$, and $K_{sw} = 4$ as reasonable estimates based on several SWCC analyses.[6–10] Then the first term in Eq. 9 is –2. Now when the $X_{ng} = 2$ to generate SWCC electricity at the same cost the solid waste provider must deliver the fuel at a negative price, i.e., pay the tipping fee of –0.7. However, if X_{ng} is near 6 as it has been several times between 2004 and 2010 the SWCC utility could pay up to 2.4 for the SW fuel. If the X_{ng} is at 12, the SWCC facility could pay 7.1 to the SW supplier. This X_{sw} price is much higher than that of coal whose delivered price (X_c) these days usually is in the 2 range. It is also much higher than a pulp and paper mill would pay for waste wood. This simple cost comparison is illustrated in Figure 7 that shows the opportunities for SWCC systems when natural gas prices are above say \$5/MMBtu. The results are slightly less favorable if the K_{sw} were higher say at $K = 5$. However, the conclusions that at high natural gas prices SWCC electricity becomes competitive with NGCC electricity would be similar. It is conceivable that Ksw could be held as low as 2 ct/kWh by retrofitting a NGCC system stranded by high natural gas prices. In this case the first term in Eq. 9 vanishes and the competitive $K_{sw} = (S_{ng}/S_{sw})X_{ng}$. This illustrates the main point that at high natural gas prices, with an ATT system, SW can be a valuable PES. Indeed, this simple algebraic–arithmetic exercise establishes the feasibility of a new paradigm in which solid waste (mostly biomass) can become potentially valuable marketable assets.

As described above, the values of K and S are the key factors in determining the COF_{sw} that can be used in a SW-integrated pyrolysis combine cycle (IPCC) to have the COE equal or less than the COE with a NGCC system at the available COF_{ng}. The ACE method can be extended to the use of SW or biomass with other technologies if we can identify the K and S for each technology. Where actual facilities

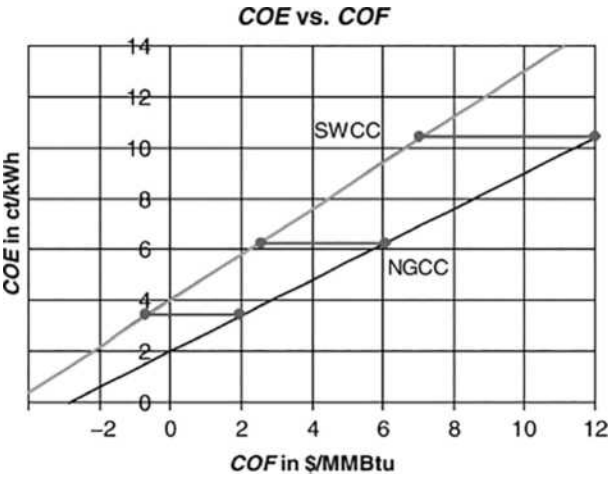

FIGURE 7 Cost of electricity (COE) vs. the cost of fuel (COF) for an solid waste combined cycle (SWCC) system and for a natural gas combined cycle (NGCC) system. COF comparisons of 2, 6, 12 dollar/MMBtu are indicated in red lines.
Source: Green and Bell.[10]

have been built and placed in operation, the K_s and S_s can be assigned on the basis of actual plant experience which is the case for many fossil fuel technologies. However, for new technologies proposed for the renewable age, some accepted form of C/B analysis is needed to provide COE vs. COF relationships. The ACE method cannot serve in this role. However, if a detailed C/B analysis or LCA is available at a particular power level, its *Y(X)* results can generally be cast into the Eq. 6 form which is generally more useful and transparent than tables of numbers. A major advantage of doing so is the possibility of then making reasonable *Y(X,P)* extrapolation to other power levels *(P)* on the basis of many years of economy of scale experience with a wide range of technologies.

The ACE method has been applied to reformulations of a large body of COE vs. COF calculations on biomass use presented in an Antares Group Inc. report (AGIR)[34] for a number of technologies. The technologies investigated in the AGIR were for systems in which 100 tons per day forest thinning were available in wild land–urban interface areas. This assumption limited the power level (*P*) for that technology quite severely. The technologies in the AGIR included a biomass-integrated gasifier combined cycle (B-IGCC) system, a B-IG simple cycle (B-IGSC) system, a B-IG internal combustion (B-IGIC) system, a biomass–gasification–coal co-firing B-IGCC system, a direct cofiring of biomass and coal in a coal steam boiler BCoSt, a direct use of biomass in a feed water heat recovery arrangement (FWHR), direct use of biomass in a Stoker fire boiler steam turbine (SFST) system, and direct firing in a CHP plant (CHP) with a steam market at $6/MMBtu. For each technology, it was possible to approximately represent the tabulated COE vs. COF results of their detailed economic analysis by Eq. 6 and to evaluate *K* and *S* for that technology at that power level.

The most interesting result of this ACE digest of the massive tables of the AGIR was that by slight extrapolations to higher power levels[9] the competitive results in several important cases were opposite to those for the power levels limited by the 100 tons biomass per day assumption.

Several other detailed economic COE vs. COF analyses have been used to refine ACE and generalize the ACE methodology. In particular, *K* has been broken into components $K = K_c + K_{\mathrm{om}} + K_{ne}$, where *c* stands for capital costs, om for operating and maintenance costs, and *en* for environmental costs. Establishing the magnitudes of these components for various technologies and power levels is still at the cutting edge of utility economic analyses, and there are large disagreements particularly on K_{en}. In one generalized component form of ACE (CACE) Eq. 6 is replaced by

$$Y(X,P)=K_{cr}\left(\frac{P_r}{P}\right)^{\alpha}+K_{omr}\left(\frac{P_r}{P}\right)^{\beta}+K_{er}\left(\frac{P_r}{P}\right)^{\gamma}+XS_r\left(\frac{P_r}{P}\right)^{\delta} \tag{10}$$

where K_{cr}, K_{omr}, K_{er}, and S_r are established on the basis of a detailed analysis at a reference power level P_r and α, β, γ and 5 are scaling parameters intended to reflect the tendency of per energy unit cost to go down as the power goes up (economy of scale). Table 5 lists CACE parameters extracted from a detailed analysis "Options for Meeting the Electrical Supply Needs of Gainesville" prepared by ICF Consulting.[35] Here the final COE is given in 2003 ct/kWh. The third and fourth cases NGCCc and NGCC-d have been added to better reflect the high volatility of natural gas prices that have ranged from \$1/MMBtu to \$16/MMBtu over the past 25 years.

The final column shows that at the reference power levels without the NGCCc case the IGCC scores the lowest COE as was concluded in the ICF report (ICFR). The value of the ACE analysis is that with a bit of algebra anyone can easily consider other fuel cost projections and other power levels (with the assigned values of α, β, γ and δ). Based on prior exploratory work and economy of scale investigations it was estimated that for costly field erected facilities $\alpha = \beta = 0.3$ are reasonable choices. However, with factory fabrication of gas and steam turbines these parameters might not follow the usual economy of scale pattern and that their α may be somewhat smaller in magnitude. Assigning a value for γ is a wide open question since environmental costs and methods of incorporating them into the COE are still highly debated issues.[36] Reasonable values for δ are also somewhat difficult to find. For NGCCs the author tentatively assigns close to zero or a very small value (~0.1) perhaps because the development of highly efficient aero-derivative turbines has proceeded on a wide range of power levels.

A Somewhat simper generalized formula for $Y(X,P)$ has been developed in the form [37]

$$Y(X,P)=\alpha C_{cr}\left\{\left(\frac{P_r}{P}\right)^{\gamma}\right\}\left(1+f_{om}\right)+SX\left(1+f_e\right) \tag{11}$$

Here, $\alpha C_{cr} = K_{cr}$ at a reference power level where C_{cr} is the specific capital cost for that facility in dollar per watt (\$/W or \$1000/kW) for that technology at the reference power level. Based on tabular data contained in the RA study a value $\alpha = 1.34$ was identified as the coefficient the approximately relates specific capital costs (in \$/W) to K_{cr} (in ct/kWh). This essentially is the COE when the fuel cost is free and OM can be ignored. As for economies of scale, based on an extensive literature survey. Green et al.[37] fond

TABLE 5 Analytical Cost Estimation (ACE) Results from ICFR for Five Technologies—Four Natural Gas Prices Are Assumed for the NGCC Technology

Technology	P_r	K_o	K_{om}	K_{en}	S_o	COF	COE
NGCC-a	220	0.598	0.234	−0.17	0.68	11.34	8.37
NGCC-b	220	0.598	0.234	−0.17	0.68	6.1	4.81
NGCC-c	220	0.598	0.234	−0.17	0.68	5	4.06
NGCC-d	220	0.598	0.234	−0.17	0.68	4	3.38
SCPC	800	1.491	0.299	0.714	0.93	1.91	4.28
CFB-CB	220	2.531	0.261	0.618	1.05	1.41	4.89
CFB-B	75	2.845	0.261	0.039	1.39	1.67	5.47
IGCC	220	2.2	0.196	0.407	0.86	1.41	4.02

COE = cost of electricity, COF = cost of fuel.

the different technologies had scaling parameters in the range $0.13 < \gamma < 0.33$. When no information is available one might use some intermediate gamma between these extremes or let $\gamma = 0$.

Typical dimensionless values for f_{om} can be identified for various technologies from the Antares report on 6 technologies, ICER on 5 technologies, and the RA study of 14 widely ranging technologies. In most cases they are less than unity and can be assigned within reasonable bounds on the basis of experience.

In Eq. 11 f_e is an added dimensionless "correction" to the delivered COF that reflects environmental costs not included in the cost charged by the utility but paid for by the public in other ways (reduced visibility, added coughs, higher cancer rates, etc.). The landmark RA[36] study that incorporated externalities into a levelized cost of energy analysis for 14 electric generating plants provided a basis for estimating the dimensionless externality correction f_e to the price of fuel. Table 6 translates RA's results for the 14 utilities using their minimum externality cost estimates into the generalized analytic cost estimation (GACE) analytical form of Eq. 11. As one sees these f_e are substantially larger than 1 for fossil fuel technologies but small (0.15) for a biomass system. Wind turbines, photo voltaic, and landfill gas systems do not have a fuel cost hence f_e cannot be assigned. However, these technologies are directly assigned externality C_{ex} by RA. The major uncertainty in the future COE is probably represented by the variable X, the externality parameter f_e, and possibly the power level of the facility. Having an explicit formula with these variables and parameters can help in bringing transparency to important policy decisions.

The GACE approach to reaching decisions in the face of large uncertainties might be viewed as application of the operations analysis methods used by one of the authors in WWII.[38] It will be interesting to compare this approach with recent European Union operations analysis effort for incorporating externalities in electricity-generating technology evaluations.[39]

Going back to the 2007 SWEATT study it mainly considered the competition between NG-fueled technologies and coal-steam-generated electricity. These included supercritical coal-burning units that reached efficiencies as high as 40%. However, when coal-steam turbine's expensive scrubber costs are included in the K_c and environmental costs in their K_{en} this technology did not compete compared with the IGCC. Thus a major conclusion of the 2007 SWEATT study was that the age of making gas has returned. At the same time the most favorable EEE position of natural gas among the fossil fuels is recognized.

TABLE 6 Roth-Ambs Externality Impacts on Cost of Electricity for 14 Technologies Using Low RA Estimates, Impacts, and Derived GACE Parameters

Technology	C/W	K_c	f_{om}	S	C_{of}	C_{ex}	f_e	COE	COE_e
Coal Boiler	1.80	2.81	0.36	0.995	1.06	4.45	4.20	4.86	9.29

COE_e are Roth-Amb's total *COE* with low externalities.

It should be noted that in an effort to minimize a major environmental externality, global warming, the U.S. Department of Energy is now investing a $4 billion plus effort in carbon capture and storage (CCS) technologies that first starts with oxygen-blown coal gasification. DOE funds will be matched by about $7 billion from the coal and utility industry. This effort could bring up to ten commercial demonstration projects online by 2016. The goal of the program is to provide the information needed to evaluate whether such CCS technologies are commercially deployable.

Mercury emission control has recently become mandatory for coal fired plants. Injecting activated carbon as a sorbent to capture flue gas mercury has shown the most promise as a near-term mercury control technology. The process is still in its early stages and its effectiveness under varied conditions (e.g., fuel properties, flue gas temperatures, and trace-gas constituents) is still being investigated.

Bioenergy and Biochar

During the first decade of the 21st century, the most widely pursued sources of renewable biofuels were fermentation of corn or corn stover leading to ethanol, anaerobic digestion of animal waste yielding methane, and compression of plant seeds to extract bio-oil. Since this Solid Waste to Energy by Advanced Thermal Technologies (SWEATT) work is focused on advanced thermal technologies (ATTs), we refer the reader to the literature on these non-thermal conversion methods. This section is largely devoted to the economic, environmental, and energy (EEE) impacts on SWEATT that the production of "pyro-char" or "black carbon" may have. These terms can be used to include many solid pyrolysis products that might serve as charcoal, biochar, or activated carbon. Charcoal and activated carbon are well documented in the technical literature. However, the literature on biochar is just developing. Biochar applications have recently inspired an International Biochar Initiative, a community of scientists and enthusiasts that envision large-scale conversion of waste biomass into biochar while generating energy at the same time.[40,41] This biochar can be applied to soils, both enhancing soil fertility and mitigating climate change by sequestering CO_2 drawn from the atmosphere.

Charcoal was used as early as 5000 BCE in the smelting of copper, and 2000 years later, it became commonplace in the smelting of iron and bronze. Charcoal was burned to produce temperatures in excess of 1000°C that are needed to produce these alloys. Other uses include blacksmith forges and household cooking, in which maximal heat with minimal smoke is desirable, and the filtering and removal of impurities such as in the spirit or sugar processing industries. Charcoal was commonly made in covered conical piles of wood, sometimes covered with earth, constructed so as to exclude air, thus attaining greater yields of charcoal. Its large-scale production is presumed to have led to widespread deforestation of Europe and Eastern North America in the 18th century, until coal supplanted charcoal as an industrial fuel.

In an extensive review, Antal and Gronli[42] have summarized knowledge of the production and properties of charcoal that has been accumulated over the past 38,000 years. They point out that biomass carbonization can be carried out, leading to high char yields (~30%) by the manipulation of pressure, moisture content, and gas flow involved in the process. The review also provides a good summary of measurements of the heat of pyrolysis from various plant feedstock that range from +0.7 MJ/kg (exothermic) to −0.3 MJ/kg (endothermic). When viewed in the light of the fact that the higher heating values (HHV) for most dry biomass are about 17 MJ/kg and pure carbon is 32 MJ/kg, it should be clear that, in any case, the heat cost of pyrolysis is small compared to the heat content of the feedstock. However, in various practical biomass pyrolysis arrangements, component system losses need to be kept as small as possible so that acceptable conversion efficiencies from the feedstock to the desired form of energy are achieved.

Conventional combustion technologies, or even advanced combustion systems, when applied to biomass/solid waste (SW), leave little carbon in the fly or bottom ash. Thus, it might be difficult to adapt these technologies to the useful production of pyro-char products. Air-blown partial combustion and oxygen-blown partial combustion systems might be adapted since they essentially take advantage of substoichiometric combustion to produce CO fuel rather than CO_2 and, depending upon the oxygen content of the feedstock, could leave a substantial carbon residue. The solid char residues produced during forest fires are an example of natural combustion under limited oxygen conditions. The charred woods and plastics remaining after building fires are further examples of limited oxygen combustion. An extensive technical literature is available on fire and fire protection technology that could be drawn upon if carbonization again becomes a widespread technology. Pyro-char or black carbon, when produced intentionally in partial combustion gasifiers or more efficiently in indirectly heated pyrolyzers, is now being referred to as "biochar." Some uses of biochar are quite ancient, while others are quite recent.[40–47]

It is only fairly recently that another ancient use of biochar has come to the wider attention of environmental scientists. *Terra preta* are small plots (20 ha, on average) of highly fertile Amazonian soils, enriched in organic carbon and nutrients, that are surrounded by Oxisols, typical of tropical soils, that are extremely depleted in nutrients and organic matter. Because *terra preta* are associated with high concentrations of charcoal and ceramic fragments, and can be dated to have formed between 800 BCE and 500 ACE, they are presumed to be anthropogenic, made either intentionally by some method of slash and char forestry for agricultural purposes or accidentally through the dumping of kitchen fire wastes over long time periods.[41] This discovery has inspired the current "biochar movement" and interest in identifying optimum methods of producing and using biochar. It is recognized that the optimum characteristics of biochar are still uncertain and are the subject of research.

The unique properties of some biochar, particularly its high adsorption capacity, can be attributed to its high surface-specific surface area (SA) as well as its surficial functional group content. Although charcoal can be "activated," that is, altered with physical or chemical treatment or by "carbonization," heating above 800°C, to produce extremely high SAs or oxidized surfaces, even non-activated biochars can possess some of these features. Biochar SA tends to increase with pyrolysis temperature but starting biomass type and pyrolysis atmosphere and duration of heating will also play a role. For example, Zimmerman[48] has reported N_2-BET SA of less than 13 m^2/g for a variety of biomass types pyrolyzed at 400°C (3 hr), including grasses as well as softwoods and hardwoods. At 525°C, SA ranged from 31 to 501 m^2/g, and at 650°C, 220–550 m^2/g. Between 800°C and 1000°C, SA of between 400 and 1000 m^2/g are commonly recorded by Downie et al.[44] These measurements, however, include only pores larger than a few nanometers (nm) in diameter. Surface present within micropores (pores smaller than about 1.5 nm in diameter), measured using CO_2 sorptometry, have yielded SA in the range of 160 to 650 m^2/g and have been found to be more strongly related to the ability of a biochar to sorb low molecular weight organic compounds and cations.[40,50]

One can envision a number of possible ways in which the sorbent properties of biochar could be utilized. First, much as activated carbons have been used for many centuries in a wide variety of industrial process that require the adsorption of noxious, odorous, or colored substances from gases or liquids, biochar could be used as a low-cost alternative, especially in circumstances where large volumes of material are required. Much like activated carbon,[51] biochar can be powdered to increase SA or granulated for use in fixed bed filtration systems. Although somewhat lower in SA and, thus, sorption capacity compared to activated carbons, its characteristics can be tuned via production conditions, for sorption of specific components. For example, biochar made from anaerobically digested bagasse has been shown to be a superior sorbent of metal including lead.[52] Its most cost-effective industrial use is likely to be in the areas of primary or secondary water treatment or in contaminant remediation as reactive media for surficial or subsurface permeable barriers such as trenches, wall barriers, funnels and gates, or landfill bottom linings. In all these cases, both the biochar C and the adsorbed C may be sequestered from the atmosphere and, thus, may be considered an additional C sink, or at least an avoided C source. With the 2010 EPA (Environmental Protection Agency) limitations on mercury emissions from coal plants and municipal waste incinerators, one might anticipate a large market increase for mercury-adsorbing activated or nonactivated carbons.

Much as black-carbon-enriched soil such as *terra preta* in the Amazon has been prized for centuries for its ability to produce sustained enhanced crop yields, it is presumed that biochar amendments to soil, if carried out properly, can increase soil fertility in both the United States and perhaps more critically in the third world where soil depletion is reaching critical levels. Some biochars have high cation exchange capacity, lending it the ability to adsorb and retain such essential plant nutrients as nitrate, ammonium, calcium, and potassium.[43,46] Biochars have also been shown to adsorb the critical anionic nutrient phosphate, though the chemical mechanism for this is unclear. Other positive agricultural effects may include better soil moisture retention and the encouragement of unique microbial populations that may be beneficial to plant growth.[53] Thus, while not yet shown on a large-scale basis, biochar amendment may reduce a farmer's costs for fertilizer and irrigation, while reducing runoff of environmentally damaging nutrients into surrounding surface waters and groundwater (cultural eutrophication) and reliance on inorganic fertilizers made using energy from fossil fuels (another CO_2 source).

A recent life-cycle assessment (LCA) study assessed the energy and carbon impacts of four biochar-cropping systems.[47] They found that, for late and early corn stover, switch grass, and yard waste as biomass feedstock sources, the net energy generated was +4116, +3044, +4899, and +4043 MJ t^{-1} dry feedstock, respectively. Most of the energy consumed was in either agrochemicals or feedstock drying, and most of the energy yield was in syngas heat. Net greenhouse gas emissions were negative for both stover types and yard waste, with the majority of the total reductions, 62%–66%, realized from C sequestration by the biochar. For switch grass, however, land use change and field emissions were high enough to drive net emissions to positive. The main conclusion of this LCA analysis was that the energy and carbon impact of small-scale use of pyrolysis systems using yard waste is the most economically favorable at this time. However, many numbers used in these calculations were, by necessity, broad estimates. Much more research is required to improve the inputs to these types of models.

Because of biochar's environmental stability, conversion of biomass to biochar represents a long-term transfer from a C pool rapidly cycling between biomass and the atmosphere to a pool held sequestered within soils or even aquatic sediments. Conversion of 1% of all biomass to biochar each year could reduce the atmosphere CO_2 by 10% in only 14 years (assuming 50% conversion efficiency and no biochar C degradation). These figures are certain not realistic, however. First, it has been shown that biochars degrade abiotically as well as microbially at rates ranging from C half-lives of a few 100 years (for lower-temperature chars, particularly those made from grasses) to 10^5years for higher-temperature chars with additional losses to be expected from leaching. Second, the amount of biomass that could be reasonably used as feedstock without using major quantities of fossil fuels in the process of gathering and transportation, and without endangering soil stocks, habitat, or human food resource security (i.e., without land-use conversion), is likely in the range of 2.27 Pg C $^{yr-1}$.[55] Aside from C sequestration and enhanced crop growth, further reduction in greenhouse gas concentration and associated climate change may be obtained via reductions in methane (CH_4) production associated with waste land filling and suppression of nitrous oxide (N_2O) production when biochar is added to soils[43,46] and energy extraction. Using this estimate of maximum sustainable feedstock generation and accounting for all possible benefits, biochar production could potentially offset a maximum of 12% of current anthropogenic CO_2-C equivalent emissions each year.[54] Another interesting finding of this study was that the greatest environmental benefits are to be had by the biochar approach in regions of infertile soils or where water resources are scarce. However, where soils are already fertile, and particularly in regions where coal emissions can be offset, bioenergy (see next section) may be a better approach.

It is hoped that production of biochars or application of biochar to soils may soon qualify as a "carbon offset" or be traded on the open market should a "C cap and trade" policy be implemented. The biochar concept has received formal political support in the U.S. and globally. The U.S. 2008 Farm Bill established the first federal-level policy in support of biochar production and utilization programs nationally and biochar has been included in the United Nations Framework Convention on Climate Change (UN-FCCC in Dec. 2009).

Bio-Liquid Fuels

Intensive use of liquid petroleum products, particularly diesel and gasoline, by automobiles, trucks, airplanes, trains, and ships in the 20th century drew down national and global reserves to the point that energy security has become a major concern of the United States, other industrial countries, and the globe in general. During this same period, CO_2, the major product of hydrocarbon combustion, has further increased from its preindustrial level of 280 ppm to its current level of 385 ppm. Global warming is now emerging as the biggest environmental problem of the 21st century and "What to do about CO_2" is the biggest environmental question.[56–59]

Producing liquid fuels from plants could potentially mitigate both security and environmental problems in countries that have land available that is not in food production. Plants use the sun's energy, the atmosphere's CO_2, and the soil's H_2O to make carbohydrates such as cellulosic matter and lignin. When biomass, or a converted form of it, is combusted (oxidized), the CO_2 is returned to the atmosphere as a part of a short-term cycle that can be considered *carbon neutral.* On the other hand, combustion of coal and petroleum fossil fuels adds CO_2 that had been extracted by plants from ancient atmospheres to today's atmosphere.

In contrast to solid and gaseous fuels, the convenience of energy storage and transfer makes liquid fuels much more useful in the transportation sector. Because ethanol, pyrolysis oil, vegetable oil, and biodiesel are biomass-derived liquid fuels that are closer to carbon neutral, they are now under rapidly increasing consideration as replacements of or supplements to conventional diesel and gasoline. The high monetary value of liquid fuels is illustrated in Table 2. Table 7 lists typical properties of these liquid fuels.

Technologies to convert plant simple sugars to ethanol go back to the beginnings of the wine, beer, and liquor industries thousands of years ago. In recent years, genetic manipulation[60] has led to microbes that can convert cellulose to ethanol as well. We refer the reader to the extensive biochemical literature for such recent developments. As compared to ethanol, vegetable oil, biodiesel and diesel in Table 7 have about twice the energy/volume, important in transportation applications.

The properties of pyrolysis oils vary over wide ranges depending upon the feedstock, the rate of heating, the temperature reached, catalysts used if any, the speed of quenching after the polymeric bonds are broken, and other specifics of the thermal processing. Fluidized bed systems with fast heat transfer followed by rapid quenching produce bio-oil yields ranging from 50% to 75% of feedstock weight, with pyro-gas and pyro-char representing most of the remainder material. Extensive R&D efforts are now underway to upgrade pyro-oils into more energy dense, water-free, and oxygen-reduced liquid fuels.[61]

Since the 1973 oil embargo, vegetable oils such as corn, soybean, canola, rapeseed, sunflower, palm, and coconut have been given serious consideration for liquid fuels.[62] In effect, this would be a return to what Rudolf Diesel used with his first compression ignition engine (CIE). Used vegetable oil from fast-food restaurants has become a favorite inexpensive source of such feedstock. The high viscosity of most vegetable oils presents CIE problems, but these problems can be overcome by suitable preheaters. Since the supply of used vegetable oil is limited, there has been rising interest in high-yield, non-food vegetable oils, such as *Jatropha, Camelina,* flax, and algae that can be grown on marginal lands.

TABLE 7 Some Key Properties of Biomass-Derived Liquid Fuels and Diesel

Fuel	C (wt%)	H (wt%)	O (wt%)	HV (MJ/kg)	Density (kg/m^3)	E/vol (GJ/m^3)	Visc. cs
Ethanol	52.2	13.0	34.8	22.6	790	17.9	1.1
Pyro-oil	~45	~8	~47	~18	~1000	~18	var.
Vegetable oil	74.5	10.6	10.8	40.4	906	36.6	46.7
Biodiesel	79.0	12.9	8.0	41.2	920	37.9	4.7
Diesel	87	13	0	45.3	852	38.6	3.2

The trend in bio-oil production is now towards converting vegetable oil to low-viscosity biodiesel by mixing it with an alcohol and a catalyst. In this esterification process, the oil's glycerin is replaced by the alcohol, making a mono-alkyl ester, which greatly reduces the viscosity and slightly increases the HHV. Biodiesel can be used in unmodified diesel engines as a sole fuel or in mixtures with diesel. Emissions of sulfur oxides and other regulated pollutants, apart from NO_x, are generally lower from biodiesel than from conventional diesel. Since biodiesel is derived from plants that were made with solar energy, it is considered approximately carbon neutral.

Several states are initiating non-food vegetable oil programs to meet transportation needs beginning with the fuel needs of agriculture and particularly the needs of the individual farmer. In the Pacific Northwest, canola (rapeseed) has[63] and is being studied but not yet adopted on a large scale because revenues from growing canola are generally somewhat lower than that from wheat. The differential is currently being subsidized in the form of a federal blender's credit of $1.00 per gallon to jump-start this new industry.

In Texas, flax, an annual plant and prolific biomass producer, is now under consideration as a source of vegetable oil for transportation applications. Flaxseed has long been used as the source of linseed oil, which is used as a component of many wood-finishing and other industrial products and as a nutritional supplement. In a description of recent developments by a Texas A&M researcher,[64] "It's kind of like [Texas] is coming full circle. Flax was grown on about 400,000 acres in the 1950s and Texas AgriLife Research at A&M had an active flax breeding program. Those varieties were known nationwide for having good cold tolerance. That's what we needed, a flax variety that was something you could plant in the fall, survive the winter, avoid late freezes, and produce seed in the spring. Now we're evaluating this as a possible biodiesel product or (one which) could be used in the vegetable oil industry."[64]

Florida is developing a bio-oil production program utilizing *Camelina sativa* planted on non-food-producing land.[65] When *Camelina* seed is cold pressed, 30% (by weight) oil is obtainable. The resulting pressed cake called meal has oil content between 10% and 12% (by weight) that can also be extracted with organic solvents, but this process is expensive. For biodiesel production to be economically competitive, it is essential to minimize production costs and maximize all potential revenue streams. The use of the meal as animal feed is one such stream. However, if non-food vegetable oil ever reaches its full transportation potential, the seed meal and plant residue would far exceed what could be consumed by existing cattle herds. With current budget deficits, the prospects for adequate subsidies in the future are not favorable. Thus, additional services or commodities must be developed to generate additional revenues.

In the spirit of this overall study of SWEATT, the use of on-site SWEATT systems to extract additional liquid fuel, energy, biochar, and specialty chemicals from the waste generated in a farmer's overall bio-oil production cycle warrants careful consideration. The meal produced by pressing the canola, flax, or *Camelina* seed and the plant stover could be dried and continuously fed into an on-site pyrolyzer yielding thermal energy, pyro-oil, biochar, and possibly activated carbon or other valuable products. The biochar then could be used together with local biosolids from wastewater sewage to restore or improve the farmer's soil. The pyro-oil could be collected and distilled off-site into additional transportation fuel and chemicals.[61] The thermal energy can be used on-site for heating, drying, hot water, and steam and other farm applications. Along with biochar and a productive outlet for sewage sludge (sometimes called biosolids) and its otherwise unusable water, such a comprehensive strategic program could provide cost-competitive renewable liquid fuel alternatives to diesel from imported petroleum.

The production of biodiesel in the United States increased from 75 million gallons in 2005 to 250 million gallons in 2006 and 450 million gallons in 2007, with an expected capacity of well over 1000 million gallons in the next few years.[66] This is still a small rate compared to over 60,000 million gallons of petroleum-based diesel consumed in the United States in 2009.

Sewage sludge represents a potentially large source of fatty acids for biodiesel production. After completion of the treatment cycle inside a sewage plant, these biosolids can be chemically processed to extract a biodiesel.[66,67] The waste residual solid and liquid can still serve for soil fertility enhancement thanks to its nitrogen, phosphate, and other mineral components.

The displacement of petroleum diesel can be further hastened and increased substantially with rendered animal fats, using thermal animal fat rendering technology, advanced greatly in 1811 by the French chemist Chevault. This technology has been further advanced by recent research and development.[68]

Recycling and SWEATT

Waste to energy is viewed by some groups as a threat to recycling, but the opposite is more likely the case. Municipal or institutional recycling programs in which the household sorts the SW for collective pickup can actually help maximize the return on waste components and minimize environmental problems. For example, if, at a given time, waste newspaper has no recycling value but, instead represents a disposal cost, preprocessing it for use as dry high-energy feedstock for SWEATT systems could be the optimum response. In effect, the marketplace could decide whether to recycle via the material recovery route or via an energy or fuel recovery route. Separation at the source generally requires simpler, less expensive preprocessing technologies than if all the waste sorting was carried out at the SWEATT plant. Sorting at the source also lends itself to a front-end pollution prevention program in which problem materials are separated and directed to hazardous waste facilities.[69,70]

Recycling with sorting at the source also facilitates application of beneficial feedstock-blending strategies. The analytical semi-empirical model (ASEM) study shows that polyethylene can serve as a rich source of energetic hydrogenic compounds. Thus, blending this plastic with biomass in a SWEATT pyrolysis system is expected to yield more energetic pyro-gas or pyro-liquid fuels and higher heat outputs than simple biomass. This has been demonstrated in high-temperature (1000°C) intermediate (between slow and fast) pyrolysis processing of Meals Ready to Eat (MRE) waste in which the heating value of the pyro-gas measured about 900 Btu/ft^3, quite close to the 980 Btu/ft^3 of natural gas. Food waste pyrolysis generally is expected to yield a low HHV pyro-gas (<150 Btu/ft^3). The high HHV of MRE pyrolysis is due to the large percentage of the ethylene monomer (C_2H_4) contributed by polyethylene plastic packaging. Plastics are used extensively in modern agriculture[71] and, after a growing season, present either a disposal problem or a good SWEATT feedstock blending opportunity. Alternatively, since plastics melt at relatively low temperatures, a sorting–recycling program together with very low temperature pyrolysis can relatively easily restore hydrocarbon plastics to liquid fuel forms.[72]

A Biomass Alliance with Natural Gas is a promising fuel blending strategy. Partial combustion gasifiers using biomass feedstock produce a low heating gas (~150 Btu/ ft^3) that will result in de-rating a natural gas-designed turbine-generator system. Coutilizing the biomass pyro-gas with natural gas can insure that the input energy requirement matches the output needs at least until the maximum rating of the generator is required. In a SW/biomass alliance with natural gas, an additional option becomes available when the SW comes from a recycling community. Then, the utility as a means of getting a richer gas to follow peak loads without calling upon the full use of natural gas might prepare and store high-energy plastics for increased use during times of high electricity demand. Another type of co-use strategy might be profitable if natural gas prices are low (≤$4/MMBtu) as they were at the end of 2011 and biodiesel is high (≥ $35/MMBtu). Then, the SWEATT system should be configured and operated and use the pyro gas yield supplemented by cheap natural gas to maximize the most valued pyro-liquid and pyro-chemical yields.[73] Many other opportunities for efficient co-use of domestic resources are described in the Proceedings of an International Conference on Co-utilization of Domestic Fuels.[6]

SWEATT: Summary and Conclusions

The acronym SWEATT was inspired by the senior author's (A.G.) recollection of Winston Churchill's historic call to arms in the darkest hours of World War II while admitting "I have nothing to offer but blood, toil, tears, and sweat." Today, the energy, environmental, economic, and security (EEES) problems of many nations are such as to bring to mind the problems of the World War II era and the need for bold imaginative solutions. The sustainable supplies of now wasted solids particularly in the United States that have an annual energy potential comparable to the total primary energy supply (TPES) contributed by coal as well as the TPES contributed by natural gas is a resource that should be a component of these solutions. Converting this SWEATT could multiply its current contribution to the U.S. TPES by a factor of about 10.

With low-energy density feedstock, minimizing transportations costs is very important. Thus, in addition to robust thermal technologies that can handle municipal solid waste (MSW), small on-site SWEATT systems have a particularly important role to play. Such systems should soon be available to harvest the energy and valuable chemicals in many of the SW categories listed in Table 1, most of which are greenhouse gas neutral and could gainfully be processed on-site, Table 1 does not list oil shale or tar sands in the United States that could substantially increase the available "solid waste" tonnage to address the U.S. need for liquid transportation fuels. A 2005 Rand study[74] shows that low temperature pyrolysis could be used to extract oils from domestic oil shale. The same can be said about hydraulic fracturing for the production of both oil and natural gas. Indeed this "fracking" might evolve as a big game changer if environmental concerns can be mitigated.

Marginal agricultural lands not in food production that could grow hardy, high-yield, fast-growing vegetable oil crops or can be improved to do so represent another form of waste that is gaining attention to solve energy security and climate change problems and particularly the need for biodiesel. Demonstration programs to date look favorable but the biodiesel price comes out higher than conventional diesel (see Table 2). Thus, it is important in such operations to generate additional revenue streams or to lower the costs of production. On-site SWEATT systems that convert the pressed seeds (meal) and plant residual (stover) into valuable pyro-oil, biochar, and thermal energy and reduce waste disposal costs could potentially make biodiesels more price competitive with diesel distilled from petroleum. It must be recognized, however, that imported petroleum is priced by cartels rather than a free market, Hence, countries poorly endowed with petroleum resources should not abandon biodiesel RD&D efforts or subsidies whenever this cartel to regain market share drastically lowers its price as in 1986.

Japan, a country with an outstanding sustainability record, has established the technical and environmental feasibility of large-scale conversion of SW to energy with thermal pyrolysis and gasification systems.[75] This should allay the concerns of environmentalists and risk-averse utility decision makers in other countries. A recent comprehensive report on the environmental performance of thermal conversion technologies throughout the world[76] identified more than 100 facilities that are using conversion technologies to convert MSW (mainly biomass) for energy production. The study used independently validated emissions data from operating facilities in five nations and found that pyrolysis and gasification facilities currently operating throughout the world with waste feedstocks meet each of their air quality emission limits. With few exceptions, most meet all of the current emission limits mandated in California, the United States, the European Union, and Japan. In the case of toxic air contaminants (dioxins/furans and mercury), every process evaluated met the most stringent emission standards worldwide. Facilities with advanced environmental controls are very likely to meet regulatory requirements in California. Thus, the report concludes that thermochemical conversion technologies possess unique characteristics that as a part of an integrated waste management system can generate useful energy and substantially reduce the amount of material that must be landfilled.

Finally, the following are our main conclusions:

The United States and most industrial nations are excessively reliant on imported oil for their liquid fuels and imported natural gas for their gaseous fuels.

The United States is well endowed with solid coal and oil shale, which can be converted into useful liquid and gaseous fuels by ATTs to mitigate its energy security problem, albeit not its problem of excessive CO_2 emissions.

The United States is also well endowed (~2 billion dry tons) with many forms of carbon-neutral forms of SW that can be converted to natural gas supplements, bio-liquid fuels, thermal energy, and pyro-char by on-site SWEATT systems.

ATTs are the fastest and most efficient SW to energy conversion methods. The high volatile content of biomass makes high-temperature pyrolysis of the biomass component of SW a direct form of gasification.

- If environmental and security externalities are included, renewable energy often compete with fossil fuel energy.

Approximate analytic representations of cost of electricity vs. the important controlling variables can be helpful in making SWEATT policy decisions in the face of highly volatile natural gas prices and uncertainties as to values assigned to externalities.

- Co-use of volatiles from the pyrolysis of SW with natural gas can be useful in overcoming a number of EEE problems.

SWEATT generally results in lower harmful emissions than traditional high-temperature waste to energy systems (incinerators).

- Given a free biomass source such as SW, SWEATT becomes cost competitive with NGCC energy production systems when NG fuel prices are above about $4/ MMBtu.
- Blending feedstock and including inexpensive catalysts can enhance production of energy and high-valued products.

Many areas of engineering research will be needed to optimize SWEATT systems.

The solid residuals of SWEATT, biochar, have potential value as soil amendments to boost fertility and as industrial and environmental adsorbents.

- The biochar dimension offers promise of achieving systems with carbon negativity. Thus, the economic profitability of pyrolysis SWEATT systems could be hastened if and when "C credits" or "C trading" becomes available.[40,41]
- Optimizing the production of pyro-char products and its characteristics for specific needs could enhance the economic and environmental benefits of SWEATT systems without greatly reducing its energy benefits.
- SWEATT can be used in parallel with other fuel-generating enterprises such as biodiesel production and presorted waste recycling operations to increase cost- competitiveness and maximize environmental benefit.
- At present, biochar might only deliver climate change mitigation benefits and be environmentally and financially viable as a distributed system using waste biomass, i.e., small-scale on-site SWEATT.[47]

Finally, the authors conclude that applications of SWEATT can play a significant role in the variety of solutions that will be needed to address today's EEES problems.

Acknowledgments

This work was partially supported by a grant from NSF- EAR #0819706, Geobiology and Low Temperature Geochemistry Program to A. Zimmerman. Alex Green would like to thank his many sponsors and collaborators in his quest for alternatives to oil that began in 1973 and in his work on On-Site SWEATT that began with Bruce Green in 1986. In this update effort, he acknowledges the help of Professor Nicholas Comerford, Dr. Deborah Green, and Julio Castro Vazquez.

Nomenclature and Acronyms Used in Chapter

ABPC	Air Blown Partial Combustion
ACE	Analytical Cost Estimation
AGIR	Antares Group Inc. Report
Ar	Aromatics
ASEM	Analytical Semi-Empirical Model
ATT	Advanced Thermal Technologies
BTU	British Thermal Units
CCTL	Clean Combustion Technology Lab
CHP	Combined Heat and Power
CIE	Compressed Ignition Engines
DANSF	Dry Ash, Nitrogen and Sulfur Free
EU	European Union
FC	Fixed Carbon
GACE	Generalized Analytic Cost Estimation
HHV	Higher Heating Values
HRSG	Heat Recovery Steam Generator
ICE	Internal Combustion Engines
IGCC	Integrated Gasifier Combined Cycle
MSW	Municipal Solid Waste
NGCC	Natural Gas-Fired Combined Cycle
NPHR	Net Plant Heat Rate
OBPC	Oxygen Blown Partial Combustion
OFC	Omnivorous Feedstock Converter
PES	Primary Energy Supplies
PNA	Polynuclear Aromatics
PYRO	Pyrolysis Systems
QES	Quaternary Energy Supply quads Quadrillion BTUs
RDF	Refuse Derived Fuels
SES	Secondary Energy Supplies
SW	Solid Waste
SWANG	Solid Waste Alliance with Natural Gas
SWEATT	Solid Waste to Energies by Advanced Thermal Technologies
TES	Tertiary Energy Supply
TPES	Total Primary Energy Supply
V_T	Volatiles
WEC	Waste to Energy Conversion

Energy: Walls and Windows

Therese Stovall

Introduction

The building envelope protects you from the weather, separating the indoor air that you have paid to heat or cool from the outdoor air. The walls, roofs, and windows form the major surfaces of this envelope. Energy travels through these surfaces along many paths and in many forms, such as unintended air leakage through a wall or sunlight streaming through a window. We can improve the energy efficiency of the building envelope if we carefully consider all of these energy pathways.

Here, we are focusing on energy efficiency, but keep in mind that each part of the building envelope performs multiple jobs under challenging conditions. The roof keeps out rain, hail, and snow; bakes in the hot summer sun; freezes in the cold winter night; and must be sturdy enough to survive a workman's boots. The walls must repel the rain, hold up the roof, stop the wind, and provide a rigid support for windows and doors. The windows have to let in the light, allow ventilation when they are open, and keep out drafts when they are shut. Any change we make to the building envelope to conserve energy must account for these multiple functions and the complex interactions between the envelope components.

Resistance to heat transfer is often expressed as an *R*-value. For a complete description of R-values and their use, please refer to the DOE Insulation Fact Sheet (http://www.ornl.gov/roofs+walls/insulation).

Building Types

Buildings fall into two main classes: high-rise and low-rise. The high-rise buildings are typically custom engineered with structural steel frames. Low-rise buildings are typically divided into commercial, low-rise multifamily, and single-family buildings. The high-rise, commercial, and low-rise multifamily buildings are more likely to have low-slope (often mislabeled as "flat") roofs, whereas the single-family houses are more likely to have pitched or steep-sloped roofs.

Construction methods can be roughly grouped according to the portion of the assembly performed on site and the portion performed at a factory. With today's engineered wood products and premade trusses, few buildings are strictly built on site; but we still refer to a stick-built building as the one where the greatest part of the assembly takes part on the construction site. At the other end of the spectrum are manufactured buildings that can be moved from one site to another with relatively little effort. In the middle are factory-built modular buildings and panelized construction. A factory-built modular building typically includes one or more modules that are placed on a permanent foundation. In some modular buildings, the windows are installed after the modules have been installed. A panelized building is closer to the site-built model, but will have major wall, floor, or foundation sections prebuilt and delivered to the site.

Every building must conform to local building codes, which can limit the material choices or construction methods. Many local building codes now include energy conservation clauses or incorporate the Model Energy Code or the International Energy Conservation Code.[1]

Walls

The walls make up most of the exterior surface area of many buildings and therefore the energy transported through these surfaces is very important. Wall issues vary according to the building type. A framed building is constructed with a wood or metal skeleton that provides structural support to both the building and all the other wall components. A framed wall is characterized by numerous parallel heat paths and multiple layers of different materials. A non-framed building uses bulk material, such as masonry or adobe, to provide the structural support. This type of building is characterized by a more homogenous heat path and relatively few layers of materials.

For either type of building, the connections between the wall and the roof and between the wall and the foundation are important construction details from an energy conservation standpoint. These connections can provide unintended air passageways and may be overlooked in the overall insulation scheme. An air drywall approach is an effective way to limit air leakage from walls, roofs, and windows. Here, a rubber gasket is fitted along the perimeter of the window frame and along the exterior wall's base board and ceiling plate to compensate for openings that occur as the wood changes shape with time. The gasket, once placed, seals against the drywall gypsum board and makes an airtight barrier.

Whether the wall is built on a frame or constructed from masonry, there is a wide selection of exterior siding choices. These include brick; wood, fiber cement, or vinyl siding; or an exterior insulation finish system (EIFS). For all of these facades, repelling rain and wind is often more complex than it looks. For example, a brick wall looks like a solid surface, but the mortar joints provide capillary paths for moisture, especially when subjected to wind-driven rain. Similar pathways exist for other cladding materials. For this reason, air gaps are often provided behind the outermost wall layer. Depending on the vent/drain arrangement, this may provide a true pressure-equalized rain screen or a simple break in the capillary path. Old-fashioned wood lap siding is a good example of a simple rain screen, as shown in Figure 1. The small air gap behind each wood layer is well vented and drained to the outside, so that the air pressure within the air gap is equal to the air pressure outside the wall. This pressure equalization reduces the moisture moving into the air space, and therefore reduces the amount of moisture available to penetrate the rest of the wall.[2,3]

Proper moisture management is important for energy conservation for two reasons. First, unmanaged moisture must be removed by additional ventilation, which entails the energy load needed to heat and cool the additional air mass. Second, moist building materials will always have a higher thermal conductivity than dry materials. When wet, some insulation materials become matted and lose the greater part of their insulating value.

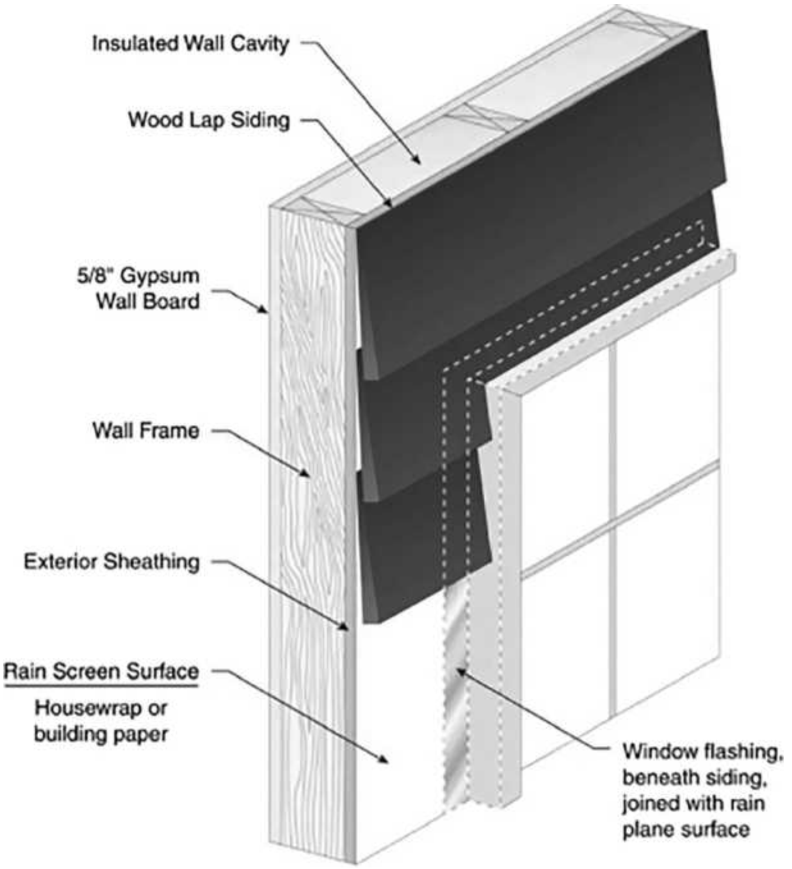

FIGURE 1 Simple rain screen within a typical wood lap siding wall.

Every wall system stores energy. This storage quality is called "thermal mass." The thermal mass can reduce the amount of heat lost or gained through the wall whenever the outdoor temperature varies above and below the indoor temperature on a daily basis. This occurs during the spring, summer, and fall for most of the United States, and during the winter as well for the southern regions. The relative benefit of thermal mass is therefore determined by both the wall properties and the climate. A wood-framed wall has very little thermal mass compared with a masonry wall. One study compared the energy consumed by a house with traditional wood-framed walls with a house constructed with masonry walls for six cities. Depending on the location and wall thickness, the more massive wall reduced the household energy use by an amount equal to increasing the traditional wall's thermal resistance by 10%–50%, with the savings greatest in Denver and Phoenix and least in Miami.[4]

Although we typically think of the exterior walls when we think about energy losses, the interior walls are also important. Air enters the wall cavity through a number of penetrations, some visible and some not. Holes made in the drywall to accommodate electrical outlets and plumbing connections also allow uncontrolled airflow. Other gaps are often present at the floor–wall and floor–ceiling connections. Therefore, it is important to provide a continuous top plate above every wall cavity. This top plate separates the interior wall cavity from the attic space, thus preventing a free flow of conditioned air from your house into the attic.

In addition to the energy used to heat and cool a building, energy is also embodied in the building materials and expended in the construction process. Among low-rise residential buildings, studies have shown that many of the building elements, including gypsum drywall, roofing materials, and carpeting, are common to all the wall types. But the wall type still makes a significant difference in the overall energy embodied in the building, with a wood-framed house containing about 15% less embodied energy than either a metal-framed or concrete house.[5,6]

Wood-Framed Walls

Wall construction methods and materials vary somewhat according to the local climate and natural resources, but most walls in the United States are made from wood framing with insulation between the studs, drywall on the inner surface, and exterior sheathing layer(s) (Figure 2). The wall studs used are either nominal 2 × 4, with a 3.5-in. cavity depth, or nominal 2 × 6, with a 5.5-in. cavity depth. Cavity insulation options for new construction include batts, a blown-in mixture of a foam binder and loose-fill insulation, blown-in loose-fill insulation secured by nets, or blown-in foam insulation.[8] In commercial buildings, high-density batts are sometimes used to provide both thermal insulation and acoustical buffering. In retrofit situations, professional installers can blow loose-fill insulation into the wall cavities by drilling a series of holes through the interior or exterior facade between each pair of adjacent studs.

Energy flows through the wood studs more easily than through the surrounding insulation. Most walls contain much more framing than you would think, as shown in Figure 3. In addition to the studs, there is additional wood framing around each window, around each door, at each building corner, where the wall sits on the foundation, where the roof sits on the wall, where an interior wall meets an

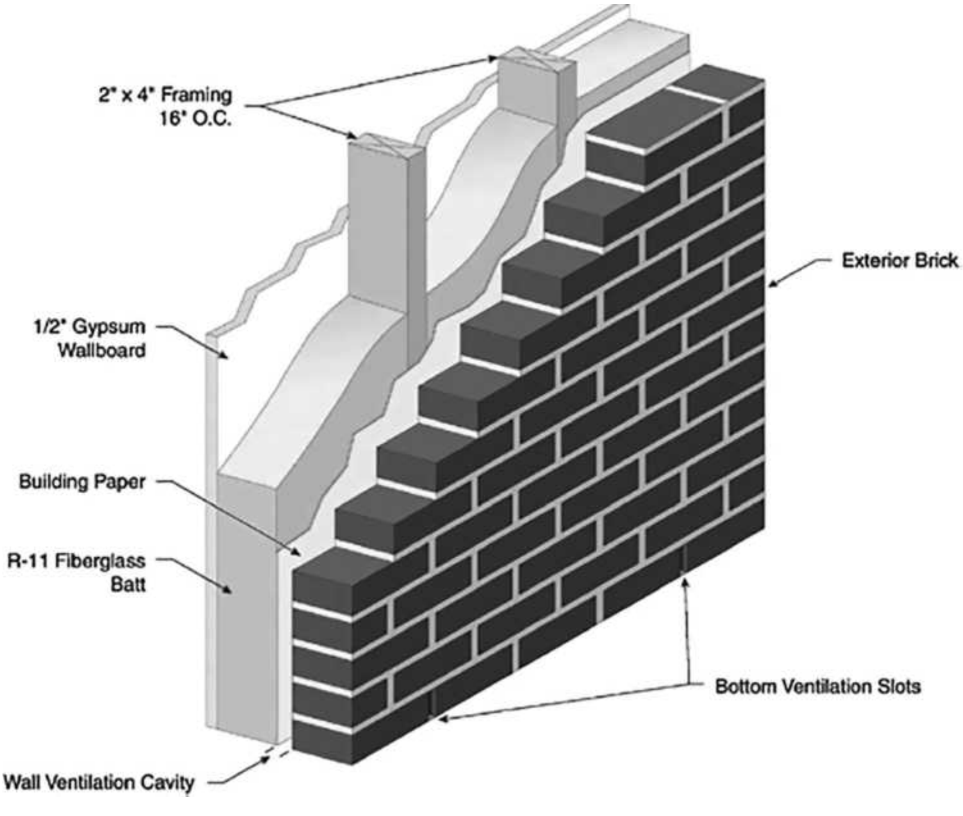

FIGURE 2 Typical wall structure for a wood-framed wall with brick cladding.

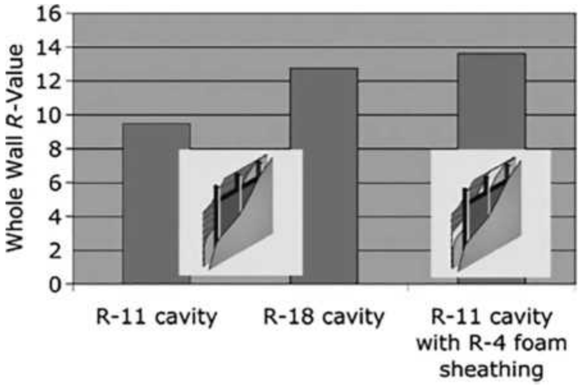

FIGURE 4 Whole wall *R*-values for wood-framed (nominal 2 × 4) walls on 16-in. centers with interior gypsum and exterior wood siding in a one-story ranch house.

exterior wall, and between floors in a multistory building. When you combine all of these thermal "short circuits," a wall (in a one-story ranch style house) filled with R11 insulation provides an overall performance of only R9–R10. If you replace that insulation with foam in the wall cavity, thereby increasing the cavity insulation from R11 up to about R18, you get an overall performance of R13 or an increase that is about half of the increased insulation value. One way to improve the thermal performance of a wall is therefore to place insulation between the studs and the exterior surface of the wall. For example, adding only 1 in. (R5) of foam sheathing to the R10 wall brings its overall R-value up to R14 (Figure 4).

Advanced framing techniques are available which reduce the amount of lumber required. These methods reduce the energy losses through the framing and allow more room for insulation. Many of these techniques also provide for improved air sealing.[10]

The wall sheathing provides a flat uniform surface to support the exterior air barrier, vapor retarder, and siding. If a wood product is used for the sheathing, it will also provide the structural stiffness needed at the building corners. If a foam insulation product is used instead, some form of additional bracing will be necessary at the corners. Sometimes a layer of foam is placed on top of a layer of wood product sheathing. This greatly improves the wall's thermal resistance because that layer covers the thermal short circuits provided by the wood frame. However, this configuration can require extra care during the finishing process, with longer nails needed to fasten siding materials. Also, specialty brick ties will be needed if a brick decor is selected for finishing the wall.

Steel-Framed Walls

Steel-framed walls share many of the characteristics of a wood-framed wall, but the steel components themselves have a very high thermal conductivity. Therefore, most steel-framed walls are built with a layer of foam sheathing to break that thermal pathway. There is also research underway to produce complex steel shapes to provide the structural support needed while providing a longer heat transfer pathway, and therefore greater thermal resistance.[11] Some metal-framed products also include an integral foam insulation element for the same reason. Connections between the walls and a steel-framed roof can be problematic from an energy point of view, especially if the steel framing extends out in the eaves. Such arrangements act like the fins on a heat exchanger and can cause excessive energy consumption if appropriate insulation arrangements are not included in the design. Steel-framed walls are most attractive where the heating loads are modest and where insect damage is more challenging.

Masonry Walls

Masonry walls can refer to walls with a masonry veneer, such as brick or stone, or to a wall where the masonry also provides the structural support, such as a poured concrete or concrete block wall. Such buildings are relatively resistant to the corrosive environment common near the ocean. Masonry also provides thermal mass that can both save energy and improve the interior comfort level in a hot climate with daily temperature swings. Aside from this thermal mass effect, masonry veneer walls share the same energy characteristics as other wood- or steel-framed walls.

Concrete Block and Poured Concrete

Full masonry walls are often used for foundations or basements. Whole houses built from masonry are popular in the warmer climates where termites and other insects are more populous. A full masonry wall can be built from concrete blocks or by pouring concrete into forms. For a load-bearing wall, steel reinforcement rods, or rebar, are used with either method to add strength. For a reinforced concrete block wall, reinforcing rods are placed vertically in the block cavities which are then filled with mortar. Steel wires or mesh are laid in the horizontal mortar joints to resist shear stress. In a poured concrete wall, the steel reinforcing rods are positioned both vertically and horizontally within the forms before the concrete is poured. Because these steel rods tend to be perpendicular to the heat transfer direction, they have little effect on the overall wall thermal resistance.

The thermal characteristics of a masonry wall vary, depending on the whether blocks or poured concrete is used and on the density of the concrete. But in general, the thermal resistance of the masonry portion of such walls will be very small, ranging from R1 to R2 for an 8-in. thick wall, even if the cores of a hollow concrete block are filled with perlite or vermiculite.[12] Foam board insulation, with a thermal resistance in the range of $5R$/in. is often used to increase the total thermal resistance of a masonry wall and can be placed on the inside and/or the outside surface. The foam board must be covered by some material with an appropriate fire rating, such as gypsum board. One study has shown that the thermal mass is more effective when the concrete is in good thermal contact with the interior building, i.e., when the insulation is placed on the outside of the wall.[13]

Autoclaved aerated concrete can be used in place of ordinary concrete for low-rise buildings. This type of concrete is much lighter than standard concrete, available in a variety of sizes and shapes, and may be reinforced. The autoclaved aerated concrete has a much higher R-value (1.25R/in.) than the standard concrete (0.05R/in.).[3] The overall R-value of a wall built with this material will depend on the shape and thickness of the concrete and on the thermal resistance of other wall components, such as air cavities. Several walls tested with aerated concrete (no facings applied), both in the traditional hollow concrete block and solid block forms, had R-values between 6 and 9.[14]

Precast Concrete

Walls can be made from reinforced concrete slabs that have been precast into the desired shape. Unless insulation is applied, these walls will have approximately the same thermal resistance as a site-poured concrete wall, i.e., about R1–R2 for an 8-in. thick wall. This construction method is more often used for larger buildings, such as apartment buildings or hospitals, but is also used for residential buildings. In the smaller buildings, the precast panels were first used for basement walls, but precast panels can be used for all exterior walls. The panels are precast and cured in the factory, thus avoiding weather limitations associated with pouring and curing concrete at the building site. The factory environment also allows the production of concrete that is stronger and more water resistant than site-poured concrete. Some of the panels are cast against foam insulation to improve the wall's R-value. In addition to the steel reinforcing, these walls can be produced with cavities for electrical wiring and rough openings. Some of the panels have been designed to provide the appearance of bricks and limestone, so that a new building will blend into an existing urban neighborhood. A crane is usually used to place the precast panels on top of a bed of crushed stone. The panels are then connected in place using weld joints or bolts and sealants. Installation for a typical residential unit can be completed in a single day.[15,16]

Insulated Concrete Forms

An insulated concrete form (ICF) wall is composed of a set of joined polystyrene or polyurethane forms that are filled with reinforced concrete, as shown in Figure 5. The joining methods vary from one manufacturer to another. Some have interlocking foam panels; others are linked with ties made from polypropylene or steel. The foam panels become a permanent part of the wall, providing a continuous layer of insulation on both the inner and outer wall surfaces. The concrete portion of the wall is reinforced with rebar positioned inside the forms before the concrete is poured to provide needed strength. The ICF walls can be covered on the outside with light-weight stucco, brick, or wood or vinyl siding. Gypsum board fastens onto the interior side. The attachment methods for these facing materials vary from one manufacturer to another. In the laboratory, the simple steady-state R-value of unfinished ICF walls varied from 12 to 18.[14] The time-varying effective energy performance of these walls is also determined by the temperature profile within the wall, which is improved by the walls' well-insulated thermal mass. Therefore, the ICF wall design provides both greater thermal mass and a higher thermal resistance than a typical 2 × 4 frame wall. Although the airtightness of any wall system tends to vary depending upon the expertise of the construction crew, an ICF wall is generally more airtight than a wood-framed wall.

A variant of the ICF wall uses forms made from a polystyrene–cement composite. The composite walls may have a greater thermal mass, but provide a significantly lower steady-state thermal resistance (about R8 for one 10-in. thick configuration).[14]

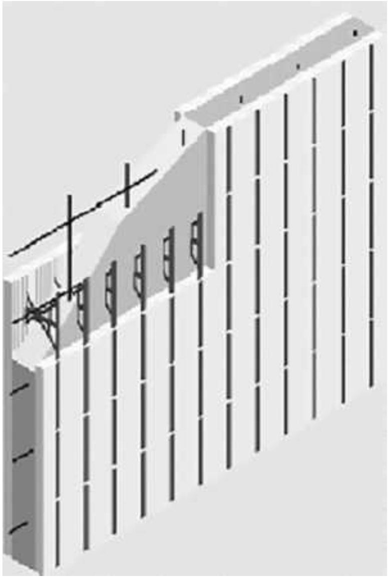

FIGURE 5 Insulated concrete form (ICF) wall.

Adobe

In parts of the southwest, adobe walls are popular because they absorb and store the daytime heat until it can be released to the cooler night air. Traditional adobe bricks are sun-dried, not fired, mixtures of clay, sand, gravel, water, and straw or grass. (For fired or stabilized bricks that are made to look like adobe, see the previous section on concrete masonry). The traditional production method produces a brick that swells and shrinks depending on its fluctuating water content. Adobe walls are relatively fragile and must be sealed with a protective covering.

The low compressive strength of the adobe bricks leads to the use of very thick (10–30 in.) walls that are seldom more than two stories high. These thick solid walls provide significant thermal mass. The thermal mass effect is especially important because the steady-state thermal resistance of these walls is not very great. A 14-in. thick wall would have a thermal resistance of from R2 to R10, depending on the density and water content of the wall. Insulation can of course be added to the interior or exterior face of the wall if covered with an appropriate coating.[17]

Exterior Insulation Finish Systems

The EIFS can be placed on a wood- or steel-framed wall or a masonry wall. In this system, a layer of polystyrene board insulation, one or more inches thick, is applied to the wall which is then covered with multiple coatings that produce the finished appearance of stucco. This wall system provides a continuous cover of insulation that breaks all the thermal short circuits associated with the framing materials and has the thermal advantage previously shown in Figure 4 for foam sheathing. The EIFS system has been and continues to be one of the most popular exterior claddings for commercial and institutional buildings. However, residential construction jobs often do not have the same high level of quality control and job oversight. This difference led to moisture-related problems in residential EIFS walls where moisture seeped into inadequately sealed window openings and became trapped within the walls.

Subsequent building failures led to the development of two classes of EIFS: barrier and drainable. Both classes are used in the commercial building class, but only the drainable system is allowed for residential construction in many locations. In the barrier class, the outer finish layer is designed to be the one and only weather-resistive barrier on the wall. In the drainable class, some form of spacer is placed between the polystyrene board insulation and a second weather-resistive barrier is located atop the wall's structural sheathing layer. This drain plane allows any moisture that seeps into the wall to drain safely out of the wall.[3]

Structural Insulated Panels (SIPS)

The SIPS walls are made by sandwiching foam insulation, typically 4–6 in. thick, between two sheets of a wood product, thus providing structural support, insulation, and exterior sheathing in a single panel. Each manufacturer specifies the proper method and materials to use when joining adjacent panels. Because the panels themselves have such a high thermal resistance, these joints are critical in maintaining a high thermal resistance for the whole wall. Walls have been measured with *R*-values of about R14 for a wall with a 3.5-in. thick foam core and about R22 for a wall with a 5.5-in. thick foam core.[14] The wall sections are relatively light and the exterior walls of a building can often be completed in a day. Two variations of the system include the use of metal sheets for the exterior skin and the use of alternative insulation materials.

Straw Bale Walls

Exterior walls can be made from stacked straw bales. The straw is a natural insulation material, but must be protected from the weather by an exterior surface, often a stucco-type finish applied over a wire mesh. Gypsum board can be used on the interior surface using a number of methods.[3] Experiments have shown that it is very important not to leave any air space between the straw and the surfacing material. Such air gaps work in concert with the hollow straw tubes to set up convection loops that may cut the overall thermal resistance from around R50 down to around R16.[18]

Windows

Transparent glass was first used for windows during Roman times. Technology has gradually advanced, improving the smoothness, strength, and clarity, and increasing the maximum size of manufactured glass. More recently, double-pane windows became popular as energy costs rose and the use of air conditioning became more common. By the mid-1990s, nearly 90% of all residential windows sold had two or more layers of glass.[19] The windows in older homes are being upgraded to double-pane windows as well; from 2000 to 2001, about nine million homeowners spent $15 billion on window and door replacements.[20] From 1990 to 2003, the replacement window market made up from 38% to 52% of the total window market.[21] However, in 2004, two-thirds of residential buildings and about half of the nonresidential building stock still had single-pane windows. The potential energy savings in this population is great, especially with the new selective coating techniques for glass.

Energy Transport

The primary function of windows is to let light and air into a building; so it is not surprising that the windows can be very challenging from an energy conservation point of view. Energy travels through a window by all three energy transfer phenomena, as shown in Figure 6.

The radiation portion of the energy transport includes short-wave radiation, or ultraviolet, that tends to fade the colors in fabric and paint; visible radiation, or light, that we desire; and long-wave radiation or heat. Long-wave radiation is a normal part of the solar spectrum. It helps to heat our buildings during the winter but increases our air conditioning load during the summer. Some values for the solar heat gain through a few prototypical windows are shown in Figure 7. Long-wave radiation also occurs between any two surfaces, traveling from the warmer surface to the cooler surface. Because the outside environment is warmer than the inside surfaces in the summer and the reverse in the winter, this

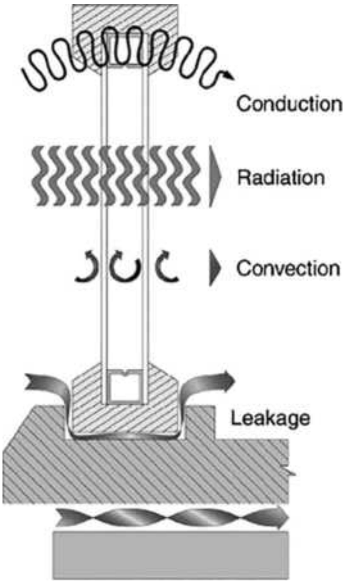

FIGURE 6 Energy traveling through windows.

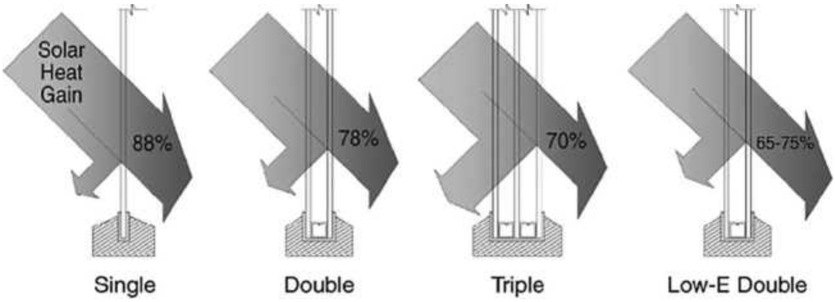

FIGURE 7 Solar heat gain through various windows.

long-wave radiation travels through the window and increases both our winter heating and summer cooling energy use. Newer windows have a “low-e” coating to reduce long-wave radiation and thus reduce the energy losses.

The conduction portion of the energy transport includes the heat that travels through the window frame and heat conducted through the glass pane(s) and through any gas between the panes. The energy that travels through the window frame and sashes is a complex function of the frame material(s), the shape (including any hollow cavities), and the exposed surface area. Each material used in windows has positive and negative qualities. In general, wood has a lower thermal conductivity than metal or plastic. However, wood is more likely to change in shape during its lifetime, so that sealing air leakage out of a wood window over a long time period may be more problematic. Also, wood is more susceptible to moisture damage and must be kept painted or varnished. Metal frames will conduct more heat than wood, but the exposed area can be reduced because the metal is a stronger material. Some of the best performance is found in windows that combine multiple materials. For example, a metal- or vinyl-clad window frame will require less maintenance than a wood window, but will conduct less heat than a solid metal or solid plastic frame. Some special gases, such as argon, have a lower thermal conductivity than air and are sometimes used to fill the gap between panes in multiple-pane windows.

The convection portion of the energy transport includes exterior air movement, or wind, across the glass surface; gas movement between the panes in a multilayer window; and air movement across the interior face of the window. The gas movement within a multilayer window is determined by the thickness of the gap, the height of the window, the gas temperature, and the temperature difference between the two panes of glass. Closed draperies or shades can reduce the air flow across the inside pane of glass.

The energy carried by air leakage falls into two major categories. As Figure 6 shows, some air leaks around the window frame itself. This leakage path should be sealed when the window is installed, although caulking around the frame of an existing window can also reduce the air leakage. Air also leaks through any moving joint in a window. These joints must be sealed by weather stripping or special gaskets that are built into the windows themselves.

Storm windows have been used for a long time and were very popular in northern climates before the introduction of multiple-pane windows. Storm windows require annual installation and storage and there are more glass surfaces to clean. Storm windows can be mounted on either the inside or outside of the window frame.[22] Tests have shown that the energy savings can be substantial when storm windows are added to an existing single-pane window. However, replacing an existing single-pane window with a modern double-pane window will save more energy than the addition of a storm window.[23,24]

Window Rating Systems

Considering the complexities of energy transport through windows, it can be difficult for consumers to compare one window with another. Fortunately, there are two important tools available to help with window selection. The National Fenestration Rating Council (NFRC) has developed a rating system that includes a standard label.[25] The U.S. Departments of Environmental Protection and Energy have cooperated in the production of an Energy Star label for windows.[26]

The NFRC label (Figure 8) shows four values: the *U*-factor, the solar heat gain coefficient (SHGC), the visible transmittance, and air leakage. Manufacturers may also choose to show a value for condensation resistance. The two most important factors used to rate the energy efficiency of a window are the

Manufacturer stipulates that these ratings conform to applicable NFRC procedures for determining whole product performance. NFRC ratings are determined for a fixed set of environmental conditions and a specific product size. NFRC does not recommend any product and does not warrant the suitability of any product for any specific use. Consult manufacturer's literature for other product performance information.
www.nfrc.org

FIGURE 8 National Fenestration Rating Council (NFRC) label.

U-factor and the solar heat gain coefficient. The *U*-factor is the inverse of the *R*-value (the label that is quoted for insulation), so that a lower *U*-factor indicates a slower rate of heat transfer for any given temperature difference.[27] The NFRC *U*-factor ratings for windows sold nowadays range from 0.2 to 1.2.[28] The SHGC ranges from 0 to 1 and measures how much heat from the sunlight incident upon a window will enter the building. Windows with lower SGHC ratings do a good job of blocking this heat.

The Energy Star label is available to windows that have been certified and labeled by NFRC and that meet special standards. The standards vary among the four NFRC climatic regions because of the tradeoff between desirable winter heating and undesirable summer heating. The four regions used by the Energy Star program for windows are shown in Figure 9 and Table 1 shows the required *U*-factors and SHGCs for each region.[29]

FIGURE 9 Energy Star's four regions used for window rating program.

TABLE 1 Energy Star Window Criteria

Climate Zone	U-Factor	Solar Heat Gain Coefficient G-Factor (SHGC)	
Northern	≤0.35	Any	
North/Central	≤0.40	≤0.55	
South/Central	≤0.40	≤0.40	Prescriptive
	≤0.41	≤0.36	Equivalent performance (excluding CA)
	≤0.42	≤0.31	
	≤0.43	≤0.24

Future Improvements

Researchers are working on a portfolio of window designs with automatic energy-saving features. Some forms of "smart" windows with switchable glazing have become commercially available, albeit at a relatively high cost. These windows vary the amount of light and heat transmitted based upon an electric current, which is usually programmed to respond to either the temperature or the amount of sunlight hitting the window. The electrochromic window uses a multilayer electrically conductive film where ions are moved from one layer to another by a short electrical signal. In one layer, the ions allow only 5% of the sunlight through the window; when the ions move to the other layer, 80% of the sunlight is transmitted. This system has the advantage that once the change from one state to another has been made, no electrical energy is required to maintain that state. Another switchable glazing, the suspended particle display (SPD) places a solution containing suspended particles between two glass panes. When an electrical charge is applied, the particles align and light is transmitted through the window. Without an electrical charge, the particles move about randomly, blocking up to 90% of the light. Other switchable windows are designed to provide privacy by changing from transparent to translucent, but are not effective at saving energy.[30,31] Another proposed window design includes sensors that automatically raise or lower a blind enclosed between two panes of glass based upon the outdoor temperature and solar radiation. This design admits solar radiation when it will help heat the house, but lowers the blind to block solar radiation when it will increase the air conditioning load.[32]

Conclusion

Walls and windows are often selected to achieve a desired appearance. Considering today's emphasis on energy conservation and overall sustainability, it is important to consider their thermal characteristics as well. Selecting more energy-efficient walls and windows will permit the building designer to specify a smaller heating and cooling system, so that often the total building cost is little more than that of a standard building. When you consider the reduced cost of heating and cooling the building during its lifetime, any added investment during construction is returned many times over.

Energy: Waste Heat Recovery

Martin A. Mozzo, Jr.

Introduction

In many industrial and commercial energy applications, only a portion of the energy input is used in the process. The remainder of the useful energy is rejected to the environment. This rejected energy may potentially be recaptured as useful energy through waste heat recovery. Not all rejected energy can be recovered due to quality, usefulness in a host's load profile, and/or economical reasons that may make its recovery infeasible. This entry will serve as a guide to waste heat recovery in order to provide a framework for the energy engineer to develop waste heat recovery projects. It will discuss the concept of quality vs quantity, engineering concerns in waste heat recovery, sample calculations for waste heat recovery, and the types of waste heat recovery equipment that can be used.

Concept of Quality vs. Quantity

While at first glance, a waste heat recovery project may appear feasible, this may not always be the case. The concept of quality vs. quantity plays an important role. For the purposes of this entry, there are three classifications of waste heat. These are: (1) high-grade waste heat, generally 1000°F and above; (2) medium-grade waste heat, generally in the range of 400°F–1000°F; and (3) low-grade waste heat, generally below 400°F. Typically, the higher the grade of waste heat, the better the application for a successful and economical waste heat recovery project. This is referred to as the "quality" of the waste heat. It is better to have marginal amounts of high quality waste heat than large quantities of lower-grade waste heat.

There are numerous reasons why higher quality waste heat recovery provides a better application. One reason is that the waste heat stream has a much higher temperature than the recovery medium, resulting in higher temperature differences, and, thus, waste heat recovery equipment sizes can be smaller. This is a result of the higher heat transfer efficiency between the waste heat stream at a higher temperature to a lower temperature heat recovery medium. Second, the recovery medium can take on many forms, namely air, steam, or hot water, whichever is best suited for the host facility, whereas, with lower quality heat recovery, the form may be very limited, especially with low- grade waste heat. For example, if you have a waste heat stream that is at 400°F, steam is not a viable heat recovery medium, as the temperature difference will be too low. Finally, cost and savings become important issues in regard to the quality of the waste heat recovery system. Generally, the higher the quality of waste heat, the lower the capital costs for waste heat recovery equipment. This is because better heat transfer efficiencies will be realized with heat recovery equipment. Additionally, the higher the quality of the waste heat stream, the higher the savings usually are. Thus, with lower costs and higher savings, simple payback periods will be shortened, a result which is generally well- received by management.

A word of caution should be offered regarding the quality of waste heat. There are vendors who will reduce the grade of the available waste heat so that their equipment can be used in a heat recovery application. One such vendor manufactured only low temperature heat transfer equipment, which he was trying to sell as waste heat recovery equipment. His proposals included the dilution of high-grade waste heat streams by mixing the high temperature waste heat stream with ambient air in order to bring the temperature down to levels that his equipment could handle. His argument was that the total Btu content of the waste heat stream was not changed, just the temperature. Unfortunately, in reducing the temperature and quality of the waste heat stream, the size of the heat recovery equipment had to be increased to recover the waste energy, and the type of waste heat recovery medium was limited. This results in higher costs, lower savings, and longer-term payback periods.

There is one instance where the dilution of a waste heat stream may be justified. Steel is usually used in the manufacture of waste heat equipment, and there is an upper temperature limit for the waste stream where steel can be used. A substitution of other materials, for example, ceramics, can be made; however, the capital costs may become too prohibitive. In this instance, the dilution of the waste heat stream may be justified to bring the waste stream temperature down for the safe operation of the waste heat recovery equipment. It should, however, never be diluted simply to enable the use of a particular piece of heat recovery equipment. The primary reason is that by diluting the waste stream, energy savings may decrease and equipment costs will definitely increase; thus, payback periods will increase, perhaps significantly.

Engineering Considerations

There are several engineering factors that must be evaluated when considering and designing a waste heat recovery system. In terms of steps, these are: (1) quantifying the waste heat stream; (2) determining the value of the waste heat stream; (3) evaluating the best form of heat recovery for the host facility; (4) determining the host site heat load profile; (5) determining the grade of waste heat; (6) determining the cleanliness and quality of the waste stream; and (7) selecting the proper waste heat recovery equipment by considering size, location, and maintainability.

The first step that should be executed is to quantify the waste heat stream by determining how many Btu/h are in the waste stream. The equation to calculate this is as follows:

$$Q = M \times \text{specific heat} \times \text{delta temp} \tag{1}$$

where Q = total heat flow rate of waste stream in Btu/h; M = mass flow rate in Lb/h; specific heat = for air, 0.24 (Btu/Lb/°F); delta temp = $(T_{\text{upper}} - T_{\text{lower}})$ in °F.

The specific heat (Cp) changes as the temperature of the air rises. For example, at 1000°F, Cp is 0.26. Since this value is higher than that of Eq. 1, using the lower value, rather than correcting for temperature, provides a conservative calculation of the total heat rate in the waste stream.

The mass flow rate (M) is calculated as follows:

$$M = \rho \times V \tag{2}$$

where M = mass flow rate in Lb/h; ρ = density of the waste stream in Lb/ft^3; V = volumetric flow rate in ft^3/h (in standard cubic feet).

Note that the value of Q is not the total amount of waste heat that will be recovered, but, rather, the total amount of waste heat that is ideally available for recovery. Not all of this waste heat will be recovered, or even can be recovered. The total amount that will be recovered will be determined by numerous other factors, such as the cleanliness of the waste stream and the form of recovery (i.e., high pressure, superheated steam, saturated steam, or hot water). This step is necessary in determining if there are sufficient volumes available for waste heat recovery.

One common mistake committed when quantifying the amount of waste heat available is assuming values for flow and/or temperatures without making measurements. Too often, actual conditions vary from assumed conditions, a variation that can often cause disastrous results in a waste heat recovery project. The cost of making actual field measurements is a small price to pay to obtain reliable data.

After the quantity of the waste stream is correctly determined, step two is to find the dollar value of the waste heat stream to determine how much capital cost a potential project can bear, or if it even makes economical sense. In all waste heat recovery projects, the heat recovered will displace a medium, such as steam, which would have to be generated using another piece of equipment, such as a boiler. This equipment likewise has a related efficiency, and the heat output is always less than the heat input. To determine the dollar value of the waste heat stream, use Eqs. 3 and 4 below:

$$\text{Value} = Q \times \text{unit cost} \tag{3}$$

where value = the dollar value of the waste heat stream, per hour; Q = total heat flow rate of waste stream in Btu/h as calculated from Eq. 1; unit cost = unit cost of the waste stream in dollars/Btu.

$$\text{Unit cost} = \frac{\text{fuel cost}}{\text{efficiency}} \tag{4}$$

where unit cost = dollars/Btu; fuel cost = cost for fuel displaced in dollars/Btu; efficiency = efficiency of unused equipment. For example, a steam boiler @ 75%.

The third through fifth steps tend to overlap and be interrelated, and are discussed together. In order for waste heat recovery to be acceptable to a host facility, its use must be consistent with current energy usage at the facility. To best apply waste heat recovery, the engineer needs to examine current energy usage patterns, heat loads for the site, and the quality of the waste heat that is available. The load factor of the waste heat recovery stream is the first thing to determine. For example, the waste heat recovery stream may be exhaust air flows from a process furnace that is periodic in nature, rather than a continuous operation. In this case, the best potential would be to return the waste heat to the process in some manner that allows the usage to follow the waste heat stream generation. Examples include utilization in a drying operation or as preheated combustion air for the process furnace. In another situation, the process furnace may run continuously and be of a high enough grade to generate steam; however, if the host facility only uses steam for heating in the winter, the loads do not match and, thus, steam is not a good recovery medium. On the other hand, there may be a need for large quantities of hot water in the facility, and the loads may match up. A thorough evaluation of both the source and operation of the waste heat and potential uses to recover the waste heat must be performed.

The sixth step, determining the cleanliness and quality of the waste stream, is important. If the waste heat stream is the product of the combustion of a natural gas-fired or fuel oil-fired operation, then the gases should be relatively safe for waste heat recovery. The important issue here would be the condensation of acidic liquids in the products of combustion gas stream, especially if fuel oil is used. This condensation would happen if the temperature of the waste stream is allowed to drop to low temperatures, typically below 300°F. The waste stream could also contain a burn-off from the product itself, which could condense on the waste heat recovery equipment and cause blockages. Here, it is best to maintain the exit temperature significantly above the condensation temperature to avoid the formation of acids or other potential hazards from the waste stream.

If the waste heat stream contains the products of combustion and the products of the process, great care must be exercised when utilizing the waste heat. The selection and design of waste heat recovery equipment could lower the waste heat exhaust temperature below acceptable levels, resulting in condensation or blockage problems with the heat recovery equipment. When unsure of the condensation temperatures and the effect on the heat recovery equipment, simple tests must be conducted to obtain this information.

Some actual examples wherein the waste heat stream was dirty and created problems follow. The first was an air-to-air heat recuperator used in a process operation. The products of combustion gases were dirty, creating a buildup on the heat exchanger. A soot blower was used to remove the buildup on a periodic basis; however, this was not totally successful. During actual heat recovery operations, the soot blowers could not remove the buildup adequately. A solution to this problem occurred accidentally. The operation was a 24 h/five days a week, and by mistake one weekend, the soot blower was left on, while the waste heat recovery equipment was shut off. Because the buildup and the heat exchanger were composed of different materials, the heat exchanger and the buildup thermal contraction rates were different. As a result, the soot blower was able to break up the buildup on the heat exchanger surfaces. This method was then used to clean the heat exchanger each week. The efficiency of the heat exchanger did decrease somewhat during the week, though not significantly. During the weekend, the buildup was blasted off the heat exchanger surface, thus increasing the heat exchanger's efficiency at the beginning of another week.

The second example did not turn out as well. In this scenario, the quality of the waste heat stream was low, and the products of combustion, combined with product burn-off, created a dirty waste stream. As a result, a serious problem quickly developed. With the waste heat recovery system in operation, gas products in the waste heat stream condensed on the heat exchanger surfaces, and within a very short period of time, the heat exchanger was completely blocked. The only corrective action was to remove the waste heat recovery equipment from service and steam clean it, a very costly operation that eventually resulted in the failure of the project.

The seventh step in the design of a heat recovery system is the selection of the waste heat recovery equipment. Descriptions of several different types of equipment are given in another entry in this encyclopedia. Selection of the proper piece of equipment will be based on the quality of available waste heat; the recovery fluid that can be generated, i.e., steam, hot water, or air; the location of the equipment; and the maintenance capabilities of the host facility. While the first two criteria should be obvious, the last two are sometimes neglected.

The location where the equipment is to be placed is important. It obviously should be close to the waste heat stream, yet should not interfere with the other equipment involved in the generation of waste heat, for example, a process furnace. The equipment also must not be squeezed into an area where maintainability is an issue. Sufficient access for maintenance and overhaul must be included since these pieces of equipment will require periodic maintenance. Accessibility to perform maintenance is not just desirable, but mandatory.

Sample Calculations

This section describes some sample calculations that are used in the design of waste heat recovery systems. The first step is to calculate the amount of waste heat that is available for recovery. This is done using Eq. 1.

Example—Waste heat is available in the form of hot products of combustion from a natural gas-fired furnace. Assume that there are no contaminants in the waste heat stream. Measurements indicate that there are 14,000 available actual cubic feet per minute (ACFM) flowing from a process at 1000°F. The actual volumetric flow must first be converted to standard cubic feet per minute (SCFM) at 60°F, using the following equation:

$$\text{SCFM} = \text{ACFM} \times (T_{\text{absolute}} + 60)/(T_{\text{absolute}} + T_{\text{actual}}) \tag{5}$$

where SCFM = standard cubic feet per minute; ACFM = actual cubic feet per minute; T_{absolute} = 460°F; T_{actual} = actual gas temperature.

Using the data available here,

$$\text{SCFM} = 14{,}000 \times \left(460 + 60\right) / 460 + 1000\big) = 4{,}986\ ft^3/\text{min}$$

Since the product of combustion is essentially air, a good approximation of the density of the gases is similar to that of air at standard conditions, or $\rho = 0.074$ Lb/ft^3.

Using Eq. 2, we can calculate the mass flow rate for the waste stream as follows:

$$M = \rho \times V = 0.074 Lb/ft^3 \times 4{,}986 ft^3/\text{min} \times 60\text{min}/h = 22{,}139\ Lb/h$$

The next step is to calculate how much waste heat is available for transfer to the heat recovery system. The upper temperature has been given as 1000°F. The lower temperature will be determined by the medium used for heat recovery, that is, steam, hot water, or air, as well as the cleanliness and condensation temperature of the waste stream.

To continue the sample calculations, we will use three different applications of heat recovery mediums: 125 PSIG steam, the hot water required at 350°F, and pre-heated combustion air at whatever final temperature is available. Each of these applications is analyzed separately.

The first heat recovery application medium is saturated steam at 125 PSIG (140 PSIA). From steam tables, we find the enthalpy for saturated liquid (h_f) to be 324.82 Btu/Lb. and for saturated vapor (h_g) 1193.0 Btu/Lb. Thus, we need 868.18 Btu for every pound of steam (1193.0–324.82). The temperature of steam at this pressure is 353°F. For this temperature of steam, we can take the waste stream down to approximately 400°F without the risk of condensation (since condensation usually does not occur above about 325°F). Using Eq. 1, we can calculate the available waste heat as follows:

$$Q = 22{,}139 Lb/h \times 0.24\ Btu/Lb/^\circ F \times \left(1000 - 400\right) = 3{,}188{,}041\ \text{Btu/h} = 3.188041\text{MMB}tu/h$$

This waste heat stream's value can be calculated using Eqs. 3 and 4. Assuming we have natural gas priced at \$8.00/MMBtu in a steam boiler with an efficiency of 75%, the value becomes:

$$\text{Unit cost} = \$8.00/\text{MMBtu}/0.75 = \$10.67/\text{MMBtu}$$

$$\text{Value} = \$10.67/\text{MMBtu} \times 3.188{,}042\ \text{MMBtu/h} = \$34.00/\text{h}$$

To obtain steam mass flow, we must use Eq. 6 below:

$$M_s = \frac{Q}{\left(h_g - h_f\right)} = \frac{3{,}188{,}041\ \text{Btu/h}}{(1193.0 - 324.82)\text{Btu/Lb}} = 3{,}672\ Lb/h \tag{6}$$

The second heat recovery application medium will be hot water leaving the heat recovery equipment at 250°F, using the same waste stream. Water will be supplied to the heat recovery equipment at 200°F. With the temperatures involved, we can take the waste stream down to approximately 300°F, provided this low temperature does not cause any condensation issues. For the purposes of this example, we have determined that condensation occurs below 325°F. We will use 350°F as our lower limit. Using Eq. 1, we can calculate the available heat as:

$$Q = 22{,}139\ Lb/h \times 0.24\ Btu/Lb/^\circ F \times \left(1000 - 350\right)$$

$$= 3{,}453{,}711 Btu/h$$

In this case, we need to determine the mass flow rate, expressed as gallons per minute (GPM), of hot water we can heat from 200 to 250°F. Eq. 7 below provides the methodology:

$$Q' = 500 \times V \times \left(T_{\text{upper}} - T_{\text{lower}}\right) \tag{7}$$

where Q' = total heat recovered in Btu/h; V = volumetric flow rate of water in GPM. 500 is the constant used to convert GPM to Lb of water per hour.

To calculate the volume of water required for this system, we calculate:

$$V = \frac{Q'}{500 \times \left(T_{\text{upper}} - T_{\text{lower}}\right)}$$

$$= \frac{3{,}453{,}711\ Btu/h}{500 \times (250 - 200)} = 138\ \text{GPM}$$

Thus, our waste heat recovery system will generate approximately 138 GPM of hot water raised from 200 to 250°F.

The third heat recovery application medium is an air- to-air recuperation system. The waste stream is the same as in the previous example, providing 3,453,711 Btu/h (assuming that 350°F will be the lower limit that we can go to without condensation issues). The recovery medium will be air applied as pre-heated combustion air with an input temperature of 75°F. In this system, we need to provide a set volume of combustion air to the waste heat recovery equipment, so we are interested in finding the final temperature of the pre-heated combustion air.

Using equation

$$Q = M \times 0.24 \times \left(T_{\text{upper}} - T_{\text{lower}}\right)$$

$$3{,}453{,}711\ Btu/h = 50{,}000 Lb/h \times 0.24 Btu/Lb - {}^\circ F \times \left(T_{\text{upper}} - 75\right)$$

Solving for T_{upper} we get 362.8°F

Heat Recovery Equipment

There is a variety of equipment manufactured and/or sold as heat recovery equipment. The following is a list of some more common types of equipment.

1. Waste heat steam recovery—This piece of equipment can be either a water-tube or fire-tube boiler that uses the hot waste heat gas stream to heat boiler feed water to generate either low-pressure or high-pressure steam. Typically, this piece of equipment is called a heat recovery steam generator (HRSG). The unit can be a heat recovery-specific piece of equipment; however, some boiler manufacturers will sell their boilers without a burner package and call them HRSGs. This type of boiler can lose some of its effectiveness as a steam generator; however, it still is an acceptable piece of equipment. The reason for the decrease in recovery effectiveness is solely based on the possibility that the waste heat stream temperature will be somewhat lower than the burner flame temperature.
2. Recuperator—This piece of equipment is generally an air-to-air heat exchanger that transfers heat from the waste heat gas stream to air on the recovery side of the heat exchanger. This air can be used as pre-heated combustion air, or host make-up air in the facility.
3. Shell and tube heat exchanger—This piece of equipment consists of a bundle of tubes within a steel shell. It is usually used for water-to-water heat recovery. One of its uses may be to recover

heat from a boiler condensate blow down on the shell side to heat up boiler feed water on the tube side.

4. Fin-tube heat exchanger—This type of heat exchanger uses air (usually the waste heat stream) blowing across finned coils that contain water. A typical application for this type of heat exchanger is using boiler products of combustion gases to preheat boiler feed water. Plugging of the finned coils could be a problem if the fins are closely spaced, the exhaust gases are dirty, or the condensation temperature (of the gases) is approached.
5. Plate and frame heat exchanger—This piece of equipment consists of two frames sandwiching thin plates. It is usually used with fluids of relatively low temperature, which flow through alternate plates. Since the plates are thin, heat transfer is usually good; however, both fluid streams need to be relatively clean or the exchanger will plug up.
6. Heat wheels—These are typically used in low temperature applications, such as the exhaust of environmental (space) air coupled with the introduction of outside air. The two ducts, outside and exhaust air, must be adjacent to one another so that the wheel turns through both ducts. The wheel will turn at low revolutions per minute (RPM) collecting the waste heat or cooling, depending on what season it is, and exchange the heat or cooling to the outside air being introduced to the facility.
7. Heat pipes—This equipment consists of a pipe heat exchanger with the interior containing a coolant. The coolant is alternately vaporizing and condensing between an exhaust and outside air stream, exchanging cooling and heating between the two air streams. The exhaust air and outside air ducts must reside together in the same manner as a heat transfer wheel.
8. Run-around coils—These are similar to heat pipes in operation. They cool or heat exhaust air and outside air streams. Their typical construction is a finned water coil with air blown across the coil. The advantage of the run-around coil is that the exhaust air and outside air ducts can be physically separated. The disadvantage is that a pump, with pumping power, is required. Additionally, if the coils are subject to freezing conditions, then a water/glycol solution must be used. This solution will decrease the effectiveness of the heat transfer.

Summary

The purpose of this entry has been to provide the energy engineer with some general guidelines to applying waste heat recovery. There are numerous applications in the industrial, institutional, and commercial sectors where waste heat recovery can be used cost effectively. The best applications are situations wherein the waste heat stream is of high quality, produced for many hours of the year, preferably 24/7, with a heat load that matches the waste heat availability. Care must be taken by the engineer to ensure that the waste heat stream will not block or destroy the waste heat recovery equipment.

There are also numerous pieces of equipment that can be used for waste heat recovery. These include steam boilers, hot water boilers, recuperators, coil heat exchangers, shell and tube heat exchangers, plate and frame heat exchangers, heat transfer wheels, heat pipes, and run-around coil systems.

Fuel Cells: Intermediate and High Temperature

Xianguo Li,
Gholamreza Karimi, and Kui Jiao

Introduction

The three major types of low-temperature fuel cells are discussed in a separate entry entitled "Fuel Cells: Low Temperature." This entry will elaborate on the intermediate- and high-temperature fuel cells including high-temperature proton exchange membrane fuel cells (HT-PEMFCs), phosphoric acid fuel cells (PAFCs), molten carbonate fuel cells (MCFCs), and solid oxide fuel cells (SOFCs). The HT-PEMFCs can be considered as the PEMFCs with membranes and other cell components that can tolerate temperatures above 100°C. The operating temperature range of HT-PEMFC is about between 100°C and 200°C. It is still at the laboratory research level mainly due to the durability issue of the membrane at high temperatures and is expected to be more suitable for stationary rather than automotive applications due to its slower start-up characteristics (higher operating temperature to be reached) than the conventional PEMFC. The PAFC is the most commercially developed fuel cell. It is being used in applications such as hospitals, hotels, offices, and schools. It can also be used in larger vehicles such as buses. The operating temperature range of PAFC is between 160°C and 220°C, and its efficiency is about 40%. The high-temperature MCFCs and SOFCs have advantages over conventional energy-generating systems in terms of reliability, fuel flexibility, modularity, low emission of NO_x and SO_x pollutants, and environmental friendliness. They also show relatively high tolerance to trace levels of impurities in the gas stream. In addition, due to their high operating temperatures typically in the range of 600°C to 1000°C, hydrocarbon fuels such as methane and natural gas can be reformed within the stack, eliminating the need for expensive external reformer systems. The high operating temperatures requires that most applications for these fuel cells be limited to large, stationary power plants. The high-quality heat produced can be used in cogenerated hybrid power systems such as space heating, industrial processing, or even in steam turbines to generate more electricity, improving the system efficiencies to high levels (up to 90%).

High-Temperature Proton Exchange Membrane Fuel Cells

The HT-PEMFCs with operating temperatures higher than 100°C have attracted growing interests in the past decade. By comparing with the conventional PEMFCs operating at around 80°C, the HT-PEMFCs with elevated operating temperatures feature faster electrochemical kinetics, simpler water management (presence of liquid water can be neglected), higher carbon monoxide tolerance, and easier cell cooling and waste heat recovery. The operating temperature range of HT-PEMFC is about between 100°C and 200°C.

Although HT-PEMFCs have many attractive features, technical challenges still remain and are mostly related to the PEM. The durability issue of the PEM at high temperatures is the reason that the HT-PEMFC remains at the laboratory research level. The conventional PEMs (e.g., Nafion membrane) widely used in PEMFCs suffer significant decrement in mechanical strength at the high operating temperature of HT-PEMFCs, and the much lower relative humidity (RH) in HT-PEMFCs than in conventional PEMFCs due to the significantly increased vapor saturation pressure with temperature also results in severe reduction of the proton conductivity of the conventional PEMs. Therefore, developing PEMs with high mechanical strength at temperatures higher than 100°C and with high proton conductivity in anhydrous environments becomes the major challenge, and most of the previous HT-PEMFC-related researches focused on this important issue.

Among the different high-temperature PEMs being developed, polybenzimidazole (PBI) membranes have been recognized as promising PEMs when doped with a strong oxo-acid (e.g., phosphoric acid or sulfuric acid) for HT-PEMFCs. At present, the phosphoric-acid-doped PBI membrane perhaps offers the best combination of durability and proton conductivity for HT-PEMFCs. The durability of HT-PEMFC with this type of PEM is over 6000 hr under continuous operation, and the durability with frequent start-stop cycles is still questionable. The durability issue and the previously mentioned slow start-up make the HT-PEMFC more favorable for stationary rather than automotive applications. Since most of the cell components are similar between PEMFC and HT- PEMFC, it is expected that the cost of HT-PEMFC is similar to conventional PEMFC.

Phosphoric Acid Fuel Cells

The PAFC is the most advanced type of fuel cells and is considered to be "technically mature" and ready for commercialization after nearly 30 years of RD&D and over half a billion dollars expenditure. Therefore, the PAFC has been referred to as the first-generation fuel cell technology. Unlike the alkaline fuel cell systems that were primarily developed for space applications, the PAFC was targeted initially for terrestrial applications with the carbon-dioxide- containing air as the oxidant gas and hydrocarbon-reformed gas as the fuel for electrochemical reactions and electric power generation.

The basic components of a PAFC are the electrodes consisting of finely dispersed platinum catalyst or carbon paper, silicon carbide matrix holding the phosphoric acid, and a bipolar graphite plate with flow channels for fuel and oxidant. The operating temperature ranges between 160°C and 220°C, and it can use either hydrogen or hydrogen produced from hydrocarbons (typically natural gas), ethanol, or methanol as the anodic reactant. In the case of hydrogen produced from a reformer with air as the anodic reactant, a temperature of 200°C and a pressure of as high as 8 atm are required for better performance. PAFCs are advantageous from a thermal management point of view. The rejection of waste heat and product water is very efficient in this system and the waste heat at about 200°C can be used efficiently for the endothermic steam-reforming reaction. The waste heat can also be used as a cogeneration for space heating and hot water supply.

However, the PAFC cannot tolerate the presence of carbon monoxide and H_2S, which are commonly present in the reformed fuels. These contaminants poison the catalyst and decrease its electrochemical catalytic activity. A major challenge for using natural gas reformed fuel, therefore, lies in the removal of carbon monoxide to a level of less than 200–300 ppm. Carbon monoxide tolerance is better at the operating temperature of above 180°C. However, removal of sulfur is still essential. Further, the PAFC has a lower performance, primarily due to the slow oxygen reaction rate at the cathode. Therefore, PAFC is typically operated at higher temperature (near 200°C) for better electrochemical reactivity and for smaller internal resistance, which is mainly due to the phosphoric acid electrolyte. As a result, PAFC exhibits the problems of both high- and low-temperature fuel cells, but possibly none of the advantages of either option.

The PAFC system is the most advanced fuel cell system for terrestrial applications. Its major use is in on-site integrated energy systems to provide electrical power such as in apartments, shopping centers, office buildings, hotels, and hospitals. These fuel cells are commercially available in the range from 24 V, 250 W portable units to 200 kW on-site generators. PAFC systems of 0.5–1.0 MW are being developed for use in stationary power plants of 1–11 MW capacity. The power density of PAFC system is about 200 mW/cm^2, and the power density for 36 kW brassboard PAFC fuel cell stack has been reported to be 0.12 kW/kg and 0.16 kW/L. One representing PAFC system is the PC-25 from the International Fuel Cells in Connecticut (the United States). It costs about \$3000/kW, while the conventional thermal power generation system costs only about \$1000/kW. In fact, present PAFC systems can offer reasonable durability and performance, and the cost is the primary issue that hinders the commercialization of PAFC.

Molten Carbonate Fuel Cells

Introduction

The MCFC is often referred to as the second-generation fuel cell because its commercialization is normally expected after the PAFC. It is believed that the development and technical maturity of the MCFC is about 5–7 yr behind the PAFC. At present, the MCFC has reached the early demonstration stage of precommercial stacks, marking the transition from fundamental and applied R&D towards product development. MCFCs are being targeted to operate on coal-derived fuel gases or natural gas. This contrasts with the PAFCs, as discussed earlier, which prefer natural gas as primary fuel.

The MCFC operates at higher temperature than all the fuel cells described so far. The operating temperature of the MCFC is generally around 600–700°C, typically 650°C. Such high temperature produces high-grade waste heat that is suitable for fuel processing, cogeneration, or combined cycle operation, leading to higher electric efficiency. It also yields the possibility of utilizing carbonaceous fuels (especially natural gas) directly, through internal reforming to produce the fuel (hydrogen) ultimately used by the fuel cell electrochemical reactions. This results in simpler MCFC systems (i.e., without external reforming or fuel processing subsystem), less parasitic load, and less cooling power requirements, hence higher overall system efficiency as well. The high operating temperature reduces voltage losses due to reduced activation and ohmic and mass transfer polarization. The activation polarization is reduced to such an extent that it does not require expensive catalysts as low-temperature fuel cells do, such as PAFCs and PEMFCs. It also offers great flexibility in the use of available fuels, say, through in situ reforming of fuels. It has been estimated that the MCFC can achieve an energy conversion efficiency of 52%–60% (from chemical energy to electrical energy) with internal reforming and natural gas as the primary fuel. Some studies have indicated that the MCFC efficiency of methane to electricity conversion is the highest attainable by any fuel cell or other single pass/simple cycle generation scheme.

Basic Operating Principle

A schematic of a MCFC is illustrated in Figure 1. A MCFC consists of two porous gas-diffusion electrodes (anode and cathode) and a carbonate electrolyte in liquid form. The electrochemical reaction occurring at the anode and the cathode is

$$\text{Cathode}: \frac{1}{2}O_2 + CO_2 + e^- = CO_3^{2-}$$

and the net cell reaction is

$$H_2 + \frac{1}{2}O_2 = H_2O$$

Beside the hydrogen oxidation reaction at the anode, other fuel gases such as carbon monoxide, methane, and higher hydrocarbons are also oxidized by conversion to hydrogen. Although direct electrochemical oxidation of carbon monoxide is possible, it occurs very slowly compared to that of hydrogen. Therefore, the oxidation of carbon monoxide is mainly via the water–gas shift reaction

$$CO + H_2O = CO_2 + H_2,$$

which, at the operation temperature of the MCFC, equilibrates very rapidly at catalysts such as nickel. Therefore, carbon monoxide becomes a fuel, instead of a contaminant as in the previously described low-temperature fuel cells. Direct electrochemical reaction of methane appears to be negligible. Hence, methane and other hydrocarbons must be steam reformed, which can be done either in a separate reformer (external reforming) or in the MCFC itself (the so-called internal reforming).

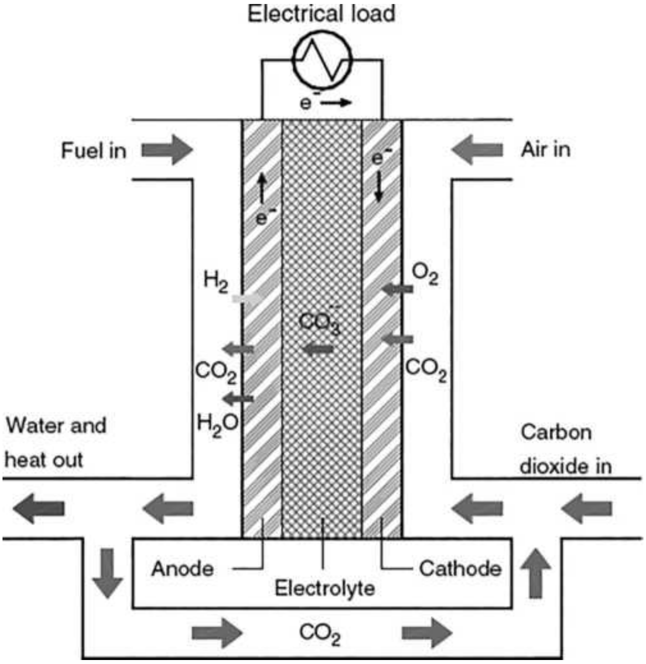

FIGURE 1 Schematic of a MCFC.

As a result, water and carbon dioxide are important components of the feed gases to the MCFCs. Water, produced by the main anode reaction, helps to shift the equilibrium reactions to produce more hydrogen for the anodic electrochemical reaction. Water must also be present in the feed gas, especially in low-Btu (i.e., high CO content) fuel mixtures, to avoid carbon deposition in the fuel gas flow channels supplying the cell, or even inside the cell itself. Carbon dioxide, from the fuel exhaust gas, is usually recycled to the cathode as it is required for the reduction of oxygen.

The MCFCs use a molten alkali carbonate mixture as the electrolyte, which is immobilized in a porous lithium aluminate matrix. The conducting species is carbonate ions. Lithiated nickel oxide is the material of the current choice for the cathode, and nickel, cobalt, and copper are currently used as anode materials, often in the form of powdered alloys and composites with oxides. As a porous metal structure, it is subject to sintering and creeping under the compressive force necessary for stack operation. Additives such as chromium or aluminum form dispersed oxides and thereby increase the long-term stability of the anode with respect to sintering and creeping. MCFCs normally have about 75%–80% fuel (hydrogen) utilization.

Acceptable Contamination Levels

MCFCs do not suffer from carbon monoxide poisoning, and in fact, they can utilize carbon monoxide in the anode gas as the fuel. However, they are extremely sensitive to the presence of sulfur (<1 ppm) in the reformed fuel (as hydrogen sulfide, H_2S) and oxidant gas stream (SO_2 in the recycled anode exhaust). The presence of HCl, HF, and HBr causes corrosion, while trace metals can spoil the electrodes. The presence of particulates of coal/fine ash in the reformed fuel can clog the gas passages.

Major Technological Problems

The main research efforts for the MCFCs are focused on increasing the lifetime and endurance and reducing the long-term performance decay. The main determining factors for the MCFC are electrolyte loss, cathode dissolution, electrode creepage and sintering, separator plate corrosion, and catalyst poisoning for internal reforming.

Electrolyte loss results in increased ohmic resistance and activation polarization, and it is the most important and continuously active factor in causing the long-term performance degradation. It is primarily a result of electrolyte consumption by the corrosion/dissolution processes of cell components, electric potential-driven electrolyte migration, and electrolyte vaporization. Electrolyte evaporation (usually Li_2CO_3 and/or K_2CO_3) occurs either directly as carbonate or indirectly as hydroxide.

The cathode consists of NiO, which slowly dissolves in the electrolyte during operation. It is then transported towards the anode and precipitates in the electrolyte matrix as Ni. These processes lead to a gradual degradation of cathode performance and the shorting of the electrolyte matrix. The time at which shorting occurs depends not only, via NiO solubility, on the CO_2 partial pressure and the cell temperature but also on the matrix structure, i.e., on the porosity, pore size, and, in particular, thickness of the matrix. Experience indicates that this cell shorting mechanism tends to limit stack life to about 30,000 hr under the atmospheric reference gas conditions, and much shorter for real operating conditions.

Electrode (especially anode) creepage and sintering (i.e., a coarsening and compression of electrode particles) result in increased ohmic resistance and electrode polarization. NiO cathodes have quite satisfactory sinter and creepage resistance. Creep resistance of electrodes has an important effect on maintaining low contact resistance of the cells and stacks. The corrosion of the separator plate depends on many factors, such as the substrate, possible protective layers, composition of the electrolyte, local potential and gas composition, and the oxidizing and reducing atmospheres at the cathode and anode, respectively. Poisoning of the reforming catalyst occurs for direct internal-reforming MCFCs. It is caused by the evaporation of electrolyte from the cell components and condensation on the catalyst, which is the coldest spot in the cell, and by liquid creep within the cell.

Technological Status

MCFC technology is in the first demonstration phase and under the product development with full-scale systems at the 250 kW to 2 MW range. The short-term goal is to reach a lifetime of 40,000 hr. It is estimated that the capital cost is about $1000–1600/kW for the MCFC power systems. The cost breakdown is, at full-scale production levels, about one-third for the stack, and two-thirds for the balance of the plant. It is also generally accepted that the cost of raw materials will constitute about 80% of total stack costs. Although substantial development efforts supported by fundamental research are still needed, the available knowledge and number of alternatives will probably make it possible to produce precommercial units in the earlier part of the coming decade at a capital cost of $2000–4000/kW. Precompetitive commercial units may be expected some years later by which time further cost reduction to full competitiveness will be guided by extensive operating experience and increased volume production.

Applications

The MCFC is being developed for their potential as baseload utility generators. However, their best application is in distributed power generation and cogeneration (i.e., for capacities less than 20 MW in size), and in this size range, MCFCs are 50% to 100% more efficient than turbines—the conventional power generator. Other applications have been foreseen, such as pipeline compressor stations, commercial buildings, and industrial sites in the near term and repowering applications in the longer term. Due to its high operation temperature, it only has very limited potential for transportation applications. This is because of its relatively low power density and long start-up times. However, it may be suitable as a powertrain for large surface ships and trains.

Solid Oxide Fuel Cells

Introduction

SOFCs have emerged as a serious alternative high- temperature fuel cell, and they have been often referred to as the third-generation fuel cell technology because their commercialization is expected after the PAFCs (the first generation) and MCFCs (the second generation).

SOFC is an all-solid-state power system, including the electrolyte, and it is operated at high temperature of around 1000°C for adequate ionic and electronic conductivity of various cell components. The all-solid-state cell composition makes the SOFC system simpler in concept, design, and construction; two-phase (gas–solid) contact for the reaction zone reduces corrosion and eliminates all the problems associated with the liquid electrolyte management. The high-temperature operation results in fast electrochemical kinetics (i.e., low activation polarization), without the need for noble metal catalysts. The fuel may be gaseous hydrogen, H_2/CO mixture, or hydrocarbons because the high-temperature operation makes the internal in situ reforming of hydrocarbons with water vapor possible. It is specially noticed that CO is no longer a contaminant; rather, it becomes a fuel in SOFCs. Even with external reforming, the SOFC fuel feedstock stream does not require the extensive steam reforming with shift conversion as it does for the low-temperature fuel cell systems. More important, the SOFC provides high-quality waste heat that can be utilized for cogeneration applications or combined cycle operation for additional electric power generation. The SOFC operating condition is also compatible with the coal gasification process, which makes the SOFC systems highly efficient when using coal as the primary fuel. It has been estimated that the chemical-to-electrical energy conversion efficiency is 50% to 60%, even though some estimates go as high as 70% to 80%. Also, nitrogen oxides are not produced and the amount of carbon dioxide released per kilowatt hour is around 50% less than for power sources based on combustion because of the high efficiency.

Basic Operating Principle

As mentioned earlier, both hydrogen and carbon monoxide can be oxidized in the SOFCs directly. Hence, if hydrogen or hydrogen-rich gas mixture is used as fuel, and oxygen (or air) is used as oxidant, the half cell reaction becomes (Figure 2)

$$\text{Anode}: H_2(g) + O^{2-} = H_2O(g) + 2e^-$$

$$\text{Cathode}: 2e^- + \frac{1}{2}O_2(g) = O^{2-}$$

$$H_2(g) + \frac{1}{2}O_2(g) = H_2O(g).$$

and the overall cell reaction becomes

Note that g represents gaseous phase.

However, if carbon monoxide is provided to the anode instead of hydrogen, the anode reaction becomes

$$\text{Anode}: CO(g) + O^{2-} = CO_2(g) + 2e^-$$

with the cathode reaction remaining the same, the cell reaction becomes

$$CO(g) + \frac{1}{2}O_2(g) = CO_2(g)$$

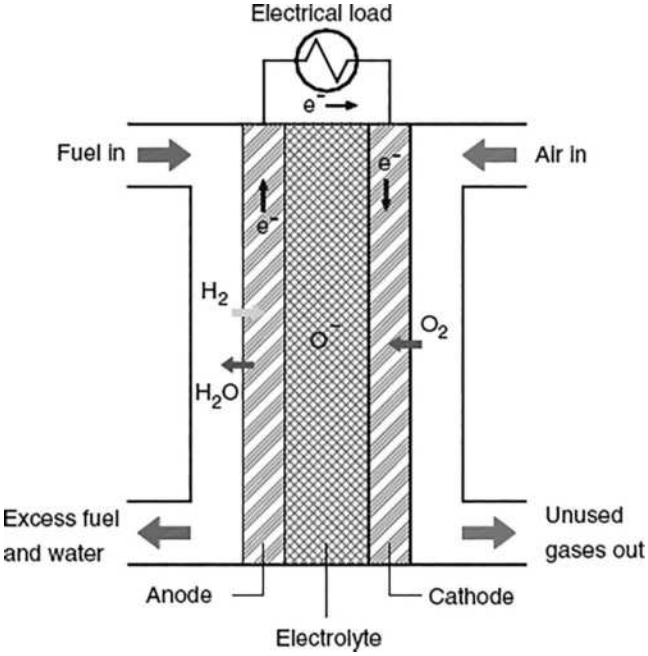

FIGURE 2 Schematic of SOFC.

If the fuel stream contains both hydrogen and carbon monoxide as is the case for hydrocarbon reformed gas mixture, especially from the gasification of coal, the oxidation of hydrogen and carbon monoxide occurs simultaneously at the anode, and the combined anode reaction becomes

$$\text{Anode}: \text{a H}_2(\text{g}) + \text{b CO} + (\text{a}+\text{b})\text{O}^{2-} = \text{a H}_2(\text{g}) + \text{b CO}_2 + 2\ (\text{a}+\text{b})\text{e}^-$$

Consequently, the corresponding cathode and overall cell reaction become

$$\text{Cathode}: \frac{1}{2}(\text{a}+\text{b})\text{O}_2 + 2(\text{a}+\text{b})e^- = (\text{a}+\text{b})\text{O}^{2-}$$

$$\text{Cell}: \frac{1}{2}(\text{a}+\text{b})\text{O}_2 + \text{a H}_2 + \text{b CO} = \text{a H}_2\text{O} + \text{b CO}_2$$

The solid electrolyte in SOFCs is usually yttria-stabilized zirconia (YSZ); thus, a high operating temperature of around 1000°C is required to ensure adequate ionic conductivity and low ohmic resistance. This is especially important because the cell open-circuit voltage is low, compared with low-temperature fuel cells, typically around 0.9–1 V under the typical working conditions of the SOFCs. The high-temperature operation of the SOFCs makes the activation polarization very small, resulting in the design operation in the range dominated by the ohmic polarization. The conventional material for the anode is nickel-YSZ-cermet, and the cathode is usually made of lanthanum-strontium-manganite. Metallic current collector plates of a high-temperature corrosion-resistant chromium-based alloy are typically used.

Acceptable Contamination Levels

Because of high temperature, the SOFCs can better tolerate impurities in the incoming fuel stream. They can operate equally well on dry or humidified hydrogen or carbon monoxide fuel or on mixtures of them. However, hydrogen sulfide (H_2S), hydrogen chloride (HCl), and ammonia (NH_3) are impurities typically found in coal gasified products, and each of these substances is potentially harmful to the performance of SOFCs. The main poisoning factor for SOFCs is H_2S. Though the sulfur tolerance level is approximately two orders of magnitude greater than other fuel cells, the level is below 80 ppm. However, studies have shown that the effect of hydrogen sulfide (H_2S) is reversible, meaning that the cell performance will recover if hydrogen sulfide is removed from the fuel stream or clean fuel is provided after the contaminant poison has occurred.

Major Technological Problems

The high-temperature operation of the SOFCs places stringent requirements on materials used for cell construction, and appropriate materials for cell components are very scarce. Therefore, the key technical challenges are the development of suitable materials and the fabrication techniques. Of the material requirements, the most important consideration is the matching of the thermal expansion coefficients of electrode materials with that of the electrolyte to prevent cracking or delamination of SOFC components either during high-temperature operation or heating/cooling cycles. One of the remedies for the thermal expansion mismatch is to increase the mechanical toughness of the cell materials by either developing new materials or doping the existing materials with SrO and CaO.

The electrode voltage losses are reduced when the electrode material possesses both ionic and electronic conductivities (the so-called mixed conduction), for which the electrochemical reactions occur throughout the entire surface of the electrode rather than only at the three-phase interface of, e.g., the cathode, the air (gas phase), and the electrolyte. Therefore, it is important for performance enhancement to develop mixed-conduction materials for both the cathode and anode, which have good thermal expansion match with the electrolyte used and good electrical conductivity to reduce the ohmic polarization that dominates the SOFC voltage losses.

Another focus of the current development is the intermediate-temperature SOFCs operating at around 800°C for better matching with the bottoming turbine cycles and lessening requirements for the cell component materials. Again, appropriate materials with adequate electrical conductivity are the key areas of the development effort, and thermal expansion matching among the cell components is still necessary.

Technological Status

There are three major configurations for SOFCs: tubular, flat plate, and monolithic. Even though SOFC technology is in the developmental stage, the tubular design has gone through development at Westinghouse Electric Corporation since the late 1950s and has been demonstrated at user sites in a complete operating fuel cell power unit of nominal 25 kW (40 kW maximum) capacity. The flat plate and the monolithic designs are at a much earlier development status typified by subscale, single cell, and short stack development (up to 40 cells). The present estimated capital cost is $1500/kW, but it is expected to be reduced with improvements in technology. Therefore, the SOFCs may become very competitive with the existing technology for electric power generation. However, it is believed that the SOFC technology is at least 5 to 10 years away from commercialization.

Applications

SOFCs are very attractive in electrical utility and industrial applications. The high operating temperature allows them to use hydrogen and carbon monoxide from natural gas steam reformers and coal gasification plants, a major advantage as far as fuel selection is concerned. SOFCs are being developed for the large (>10 MW, especially 100 to 300 MW) baseload stationary power plants with coal as the primary fuel. This is one of the most lucrative markets for this type of fuel cells.

A promising field for SOFCs is the decentralized power supply in the megawatt range, where the SOFC gains interest due to its capability to convert natural gas without external reforming. In the range of one to some tenths of a megawatt, the predicted benefits in electrical efficiency of SOFC-based power plants over conventional methods of electricity generation from natural gas can only be achieved by an internal-reforming SOFC. Thus, internal reforming is a major target of present worldwide SOFC development.

Concluding Remarks

A summary of the preceding discussion, including the operational characteristics and technological status of the intermediate- and high-temperature fuel cells, is given in Table 1. Note that the costs for PAFC, MCFC, and SOFC are for stationary power systems.

HT-PEMFC is still at the laboratory research level mainly due to the durability issue of the membrane at high temperatures and is expected to be more suitable for stationary rather than automotive applications due to its slower start-up characteristics (higher operating temperature to be reached) than the conventional PEMFC. PAFC is the most commercially developed fuel cell operating at intermediate temperatures. PAFCs are being used in applications such as hospitals, hotels, offices, and schools with relative high conversion efficiency. The high-temperature fuel cells like MCFCs and SOFCs may be most appropriate for cogeneration and combined cycle systems (with gas or steam turbine as the bottoming cycle). The MCFCs have the highest energy efficiency attainable from methane to electricity conversion in the size range of 250 kW to 20 MW, whereas the SOFCs are best suited for baseload utility application

TABLE 1 Operational Characteristics and Technological Status of Intermediate- and High-Temperature Fuel Cells

Type of Fuel Cells	Operating Temperature (°C)	Power Density (mW/cm^2), (present) Projected	Projected Rated Power Level (kW)	Fuel Efficiency	Lifetime Projected (hr)	Capital Cost Projected ($/kW)	Application Areas
HT-PEMFC	100–200	(600) >900	1–1000	45–70	>40,000	35	Transportation, space
PAFC	160–220	(200) 250	100–5000	55	>40,000	3000	Dispersed and distributed power
MCFC	600–700	(100) >200	1000–100,000	60–65	>40,000	1000	Distributed power generation
SOFC	800–1000	(240) 300	100–100,000	55–65	>40,000	1500	Baseload power generation

operating on coal-derived gases. It is estimated that the MCFC technology is about 5 to 10 years away from commercialization, and the SOFCs are probably years afterwards. In addition, due to the high operating temperatures and fuel reforming of MCFC and SOFC, the management of the exhaust gases (e.g., NO_x and SO_2) is important due to the environmental concerns.

Fuel Cells: Low Temperature

Xianguo Li
and Kui Jiao

Introduction

Fuel cell technology has been developed and improved dramatically in the past two decades, and this has once again captured public attention as well as the industry's attention concerning the prospect of fuel cells as practical power sources for terrestrial applications. Fuel cell is a highly energy-efficient and environmentally friendly technology for power generation that is also compatible with alternative fuels and renewable energy sources and carriers for sustainable development.

Fuel cell offers additional advantages for both mobile and stationary power generation applications. Fuel cell, as an electrochemical device, has no moving components except for peripheral equipment. As a result, its operation is very quiet, virtually without vibration and noise, thus capable of on-site cogeneration with no need of long distance power transmission lines that consume approximately 10% of electric energy delivered to consumers in North America. Its inherent modularity allows for simple construction and operation with possible applications for baseload electricity generation, dispersed, distributed, and portable power generation, because it may be made in any size from a few watts up to a megawatt-scale plant with equal efficiency. Its fast response to the changing load condition while maintaining high efficiency makes it ideally suited to load following applications. Its high efficiency represents less chemical, thermal, and carbon dioxide emissions for a given amount of power generation.

At present, fuel cell technology is being routinely used in many specific areas, notably in space explorations, where fuel cell operates on pure hydrogen and oxygen with over 70% efficiency and drinkable water as the only by-product. Fuel cell technology is also being widely used for terrestrial applications; impressive technical progress has been achieved in terms of higher power density and better durability as well as reduced capital and maintenance and operation cost, and is driving the development of competitively priced fuel-cell-based power generation systems with advanced features for terrestrial use, such as utility power plants and zero-emission vehicles. In light of decreasing fossil fuel reserves and increasing energy demands worldwide, fuel cell will probably become one of the major energy technologies with fiercest international competition in the 21st century.

The major terrestrial commercial applications of fuel cells are electric power generation in the utility industry and as a zero-emission powertrain in the transportation sector. For these practical applications, the efficiencies of fuel cells range somewhere from 40% to 65% based on the lower heating value (LHV) of hydrogen. Typically, the cell electric potential is only about 1 V across a single cell, and it decreases due to various loss mechanisms under the operational conditions. Thus, multiple cells are required to be connected together in electrical series in order to achieve a useful voltage for practical purposes, and these connected cells are often referred to as a fuel cell stack. A fuel cell system consists of one or multiple fuel cell stacks connected in series and/or parallel and the necessary auxiliaries whose composition depends on the type of fuel cells and the kind of primary fuels used. The major accessories include thermal management (or cooling) subsystem, fuel supply, storage and processing subsystem, and oxidant (typically air) supply and conditioning subsystem.

In light of the recent advancement in fuel cell technology and its potential impact on municipal utilities, the energy delivery marketplace, and transportation sector, an assessment of the current state of fuel cell technology has been conducted. The result of this study is described in the first and second parts of this report, which summarizes the state-of-the-art technology for the seven major types of fuel cells, including

- Alkaline fuel cells (AFCs)
- Proton exchange membrane fuel cells (PEMFCs)
- High-temperature PEMFCs (HT-PEMFCs)
- Direct methanol fuel cells (DMFCs)
- Phosphoric acid fuel cells (PAFCs)
- Molten carbonate fuel cells (MCFCs)
- Solid oxide fuel cells (SOFCs)

A critical parameter that determines the potential applications of each type of fuel cell is the operating temperature. For instance, AFCs, DMFCs, and PEMFCs have potential applications in transportation because they do not produce much heat (which otherwise would have to be eliminated by some cooling device) and, as a result of this, have a very short start-up period (a few minutes). These types of fuel cells are discussed in this entry.

On the other hand, HT-PEMFCs, PAFCs, MCFCs, and SOFCs producing high-temperature heat are more complex to run and are better fit for stationary applications like combined heat power generation or CHP. The fuel cells under this category will be discussed in a separate entry entitled “Fuel Cells: Intermediate and High Temperature.”

The study was based on a literature review and search of technical databases, and recent advancement of fuel cell technology has been identified and delineated for each of the seven major types of fuel cells listed above. The following sections describe each of the three low- temperature fuel cells. Their technological status is presented with respect to their basic operating principle, acceptable contamination levels, the state-of-the-art technology, major technical barriers to commercialization, their economics and suitability for utility, and transportation applications.

Alkaline Fuel Cells

AFCs give the best performance among all the fuel cell types under the same or similar operating conditions when running on pure hydrogen and oxygen. Hence, they are among the first fuel cells to have been studied and taken into development for practical applications, and they are the first type of fuel cells to have reached successful routine applications, mainly in space programs such as space shuttle missions in the United States and similar space exploration endeavors in China and Europe, where pure hydrogen and oxygen are used as reactants. Because of their success in space programs, AFCs are also the type of fuel cells on which probably the largest number of fuel cell development programs have begun in the world in an effort to bring them down to terrestrial applications, particularly in Europe, and almost all the AFC development programs have come to an end. In recent years, AFC with solid electrolyte membrane has attracted people's attention once again. Because with solid electrolyte membrane, AFC can be expected to offer similar or better power density and durability when compared with PEMFC. In addition to its most efficient energy conversion mechanism among all the fuel cell types, it is becoming a promising candidate for energy conversion in automotive applications.

The AFCs have the highest energy conversion efficiency among all types of fuel cells under the same operating condition if pure hydrogen and pure oxygen are used as reactants. That was one of the important reasons that AFC was selected for the U.S. space shuttle missions. The AFCs used in the shuttle missions are operated at about 200°C for better performance (i.e., high energy conversion efficiency of over 70% and high power density, which is critical for space applications), and the alkaline electrolyte is potassium hydroxide (KOH) solution immobilized in the asbestos matrix. As a result, the AFCs operate at high pressure in order to prevent the boiling and depletion of the liquid electrolyte. Consequently, these severe operating conditions of high temperature and high pressure dictate extremely strict requirement for cell component materials that must withstand the extreme corrosive oxidizing and reducing environment of the cathode and anode. To meet these requirements, precious metals such as platinum, gold, and silver are used for the construction of the electrodes, although these precious metals are not necessary for the electrochemical reactions leading to electric power generation. Each shuttle flight contains 36 kW AFC power system. Its purchase price is about $28.5 million, and it costs NASA additional $12–19 million annually for operation and maintenance. Although the manufacturer claims about 2400 hr of lifetime, NASA's experience indicates that the real lifetime is only about 1200 hr. With sufficient technology development, 10,000 hr are expected as the life potential (or upper limit) for the AFC system. This belief is based on the nature of the AFC systems and the data accumulated on both stacks and single cells.

The typical working temperature of AFC power systems aimed at commercial and terrestrial applications ranges from 20°C to 90°C, and the electrolyte is KOH solution (30%–35%) or solid electrolyte membrane. There are five different cell types investigated:

1. Cell with a free liquid electrolyte between two porous electrodes
2. ELOFLUX cell with liquid KOH in the pore systems.
3. Matrix cell where the electrolyte is fixed in the electrode matrix
4. The falling film cell
5. Cell with solid electrolyte membrane

Research groups are working on the development of technical AFC systems; the group name and the current status of the work are listed below:

- Siemens, Erlangen, Germany: stopped working on the AFCs
- VARTA AG, Kelkheim, Germany: terminated working on preparation of technical electrodes and technical fuel stacks in 1993
- GH, Kassel, Germany: stopped working on preparation of technical electrodes and technical fuel cell stacks in 1994
- ISET, Kassel, Germany: stopped working on technical AFC systems in 1994
- DLR-ITT (German Aerospace Research Establishment), Stuttgart: stopped working on the investigation of the degradation of technical electrodes, the development of new catalysts for AFC, and the theoretical simulation of stacks and systems in 1994
- ELENCO, Antwerpen, Belgium: stopped working on electrodes, stacks, and systems, as well as bus demonstration program (it went bankrupt in 1995)

- Royal Institute of Technology, Stockholm: working on the field of stationary fuel cells powered by biofuels
- Hoechst AG, Frankfurt: terminated working on AFC electrodes and stopped development of the falling film cell
- Technical University, Graz, Austria: planning an investigation of degradation effects
- Zevco with headquarters in London: demonstration of AFCs for mobile applications, particularly for bus with ELENCO's technology
- University of California, Riverside, California: development of solid electrolyte membrane for AFC

The following is a list of some selected technical applications and demonstration projects in Europe in recent years:

- Space applications: the space applications are the development of an AFC system for the European space shuttle HERMES (Siemens, ELENCO, VARTA/GHK) and the bipolar matrix AFC system Photon for space applications (Ural Electrochemical Integrated plant).
- Vehicles: applications of AFCs in vehicles are as follows:
  1. Forklift truck of VARTA AFC
  2. VW Van, 14 kW ELENCO AFC and battery
  3. VW van, 17.5 kW Siemens AFC
  4. Submarine, 100 kW Siemens AFC
  5. EUREKA-Bus, 80 kW ELENCO AFC and battery
- Decentralized energy supply: these supplies comprise the following:
  1. A meteorological station, 5 W, VARTA AFC for long-term operation
  2. A TV-transmitting installation Ruppertshain, 100 W VARTA AFC
  3. A mobile current supply unit for the Belgian Geological Service, 40 kW ELENCO AFC
- Energy storage: the solar hydrogen demonstration plant in Neunburg vorm Wald, 6.5 kW Siemens AFC, and the solar hydrogen system at Fachhochschule Wiesbaden, 1.2 kW ELENCO AFC, are typical examples. Many problems concerning AFCs are described in the literature. The most important problems are the following:
  - Preparation method of the electrodes: the electrodes consist of porous material that is covered with a layer of catalyst. Generally, it is very difficult to distribute the catalyst at the surface and to produce a defined pore system for the transportation of the reactants.
  - Costs of the electrode, stacks, and fuel cell systems: the preparation of electrodes with noble metal catalysts is very expensive. In general, the electrodes are manufactured in a small-scale production with high overhead costs.
  - Lifetime of the electrode/degradation: the electrolyte is very corrosive and the catalyst materials are sensitive to high polarization. Using nickel and silver as catalysts, in order to reduce the costs of the fuel cell, leads to a high degradation of these catalysts. This problem is expected to be solved or abated with solid electrolyte membrane.
  - Diaphragm made of asbestos: the diaphragm of low- temperature AFCs is made of asbestos. This material is hazardous for health, and in some countries, its use is even banned. Therefore, new diaphragms should be developed, but it is difficult to find a material with a similar behavior in alkaline electrolyte. This issue is solved when solid electrolyte membrane is used.
  - Carbon-dioxide-contaminated fuel and oxidant streams (carbonating of electrolyte and electrodes): the electrolyte intolerance of carbon dioxide is the most important disadvantage of air-breathing AFCs with reformate gases from primary fossil fuels. This problem is expected to be solved or abated with solid electrolyte membrane.

Other problems associated with the AFC power systems are the concern on the safety and reliability of AFC power systems, mainly related to AFCs with liquid electrolyte. For example, the liquid KOH electrolyte contained in an asbestos matrix can only withstand a 5 psi limit of pressure differential between the anode and cathode reactant gases. This dictates the need for sophisticated pinpoint pressure control during the operation including transient, start-up, and shutdown process. It is also a safety issue because of its greater likelihood of mixing of the reactants occurring in the AFC system with the possibility of a serious fire breaking out. In terms of general safety considerations, the use of the corrosive potassium hydroxide electrolyte in the AFCs represents the need for hazardous handling, and the handling of asbestos matrix poses potential hazard to one's health. With flowing reactant gases, the potential for the gradual loss of the liquid electrolyte, drying of the electrolyte matrix, reactant crossover of the matrix, and ensuing life-limiting reactant mixing (or actual AFC stack failure due to fire) is very real in the AFC system. Moreover, the liquid electrolytes, like potassium or sodium hydroxide, do not reject carbon dioxide; even the 300–350 ppm of carbon dioxide in the atmospheric air is not tolerated (carbon dioxide concentration in both cathode and anode gases must be less than 10–100 ppm by volume), while terrestrial applications almost invariably require the use of atmospheric air as oxidant due to technical and economic considerations. For municipal electric applications, hydrocarbon fuels, especially natural gas, are expected to be the primary fuel, and their reformation into hydrogen-rich gases invariably contains a significant amount of carbon dioxide, e.g., steam reforming of the natural gas results in the reformate gas consisting approximately of 80% hydrogen, 20% carbon dioxide, and a trace amount of other components such as carbon monoxide. Carbonaceous products of aging and corrosion shorten AFC life; they degrade the alkaline electrolyte. Whether originating as impurities in the gaseous reactants or from some fuel cell materials, oxides of carbon will chemically react with the alkaline electrolyte and produce irreversible decay, which will decrease performance and shorten life. Consequently, AFCs with liquid electrolyte have been restricted to specialized applications where pure hydrogen and oxygen are utilized.

The revival of this technology seems to have started in recent years, mainly due to the development of solid alkaline electrolyte membrane. For AFCs with solid electrolyte membrane, most of the above-mentioned problems can be solved or abated. The solid electrolyte membrane makes the AFC technology comparable with PEMFC in terms of safety, cost, power density, and durability. In addition, since AFC has the most efficient energy conversion mechanism among all the fuel cell types, it therefore also has higher possibility to use no-precious catalyst than PEMFC. Nevertheless, AFC with solid electrolyte membrane is still at its early stage of development; the cost, durability, and performance are expected to be further examined and improved, and the transport phenomena inside the cell need to be investigated as well.

Proton Exchange Membrane Fuel Cells

Introduction

The PEMFC is also called solid polymer (electrolyte) fuel cell. It is perhaps the most elegant of all fuel cell systems in terms of design and mode of operation. It was the first type of fuel cell that was put into practical application (in Gemini space missions from 1962 to 1966). It consists of a solid polymeric membrane acting as the electrolyte. The solid membrane is an excellent proton conductor, sandwiched between two platinum-catalyzed porous carbon electrodes. It has fast start capability and yields the highest output power density among all types of the fuel cells. Because of the solid membrane as the electrolyte, there is no corrosive fluid spillage hazard, and there is lower sensitivity to orientation. It has no volatile electrolyte and has minimal corrosion concerns. It has truly zero pollutant emissions with potable liquid product water when hydrogen is used as fuel. As a result, the PEMFC is particularly suited for vehicular power application, although it is also being considered for stationary power application, albeit to a lesser degree.

The proton-conducting polymer membrane belongs to a class of materials called ionomers or polyelectrolytes, which contain functional groups that will dissociate in the presence of water. The dissociation produces ions fixed to the polymer and simple counterions that can freely exchange with ions of the same sign from the solution. The current available polyelectrolytes have cation as the counterion. In the case of hydrogen, the cation is proton. Therefore, the membrane must be fully hydrated in order to have adequate ion conductivity. As a result, the fuel cell must be operated under conditions where the product water does not evaporate faster than it is produced, and the reactant gases, both hydrogen and oxygen, need to be humidified. Therefore, water and thermal management in the membrane become critical for efficient cell performance, are fairly complex, and require dynamic control to match the varying operating conditions of the fuel cell. Because of the limitation imposed by the membrane and problems with water balance, the operating temperature of PEMFCs is usually less than 100°C, typically at 80°C. This rather low operating temperature requires the use of noble metals as catalysts in both the anode and cathode side with generally higher catalyst loadings than those used in PAFCs.

Currently, the polymer electrolyte used is made of per-fluorinated sulfonic acid membrane, or it is essentially acid, though in solid polymeric form. Hence, PEMFCs are essentially acid electrolyte fuel cells, with its operational principle essentially the same as PAFCs. As a result, most of PEMFC design, material selection, component fabrication, etc., are similar to those of PAFCs. The only difference is the humidification of reactant gases dictated by the membrane performance. Reactant humidification is often achieved by a number of techniques, e.g., by passing gas stream through a water column, by using in-stack humidification section of cell and membrane arrangement, and by spraying water into the reactant streams. In the early stage of the PEMFC development, the membranes were based on polystyrene, but since 1968, a Teflon-based product named “Nafion” by DuPont is used. This offers high stability, high oxygen solubility, and high mechanical strength.

Basic Operating Principle

The schematic of a single PEMFC is illustrated in Figure 1. The PEMFC requires hydrogen gas as the fuel and oxygen (typically air) as the oxidant. The half-cell reactions are

$$\text{Anode}: H_2 = 2H^+ + 2e^-$$

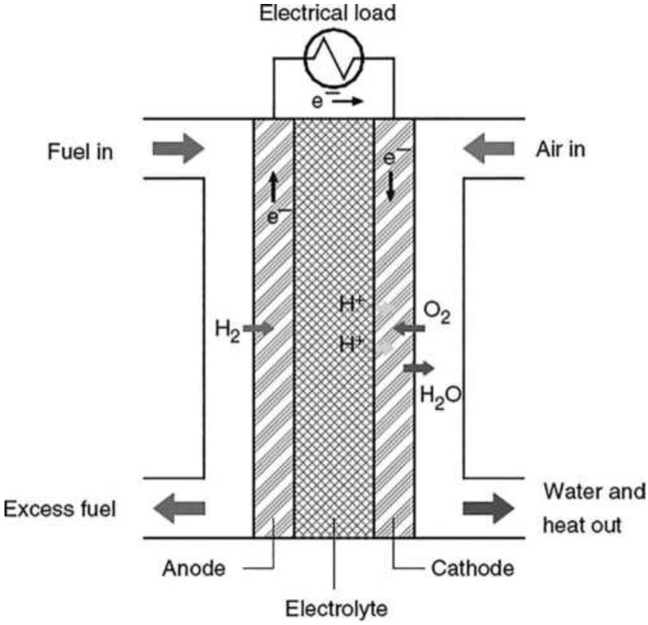

FIGURE 1 Schematic of a PEMFC.

$$\text{Cathode}: 1/2\,O_2 + 2H^+ + 2e^- = H_2O$$

and the overall cell reaction is

$$H_2 + 1/2\,O_2 = H_2O \; + \; \text{Heat Generated} + \text{Electric Energy}.$$

The current PEMFCs use perfluorinated sulfonic acid membrane as the proton-conducting electrolyte; carbon paper or cloth as the anode and cathode backing layers; and platinum or its alloys, often supported on carbon black, as the catalyst. The bipolar plate with the reactant gas flow fields is often made of graphite plate. The stoichiometry is around 1.1 to 1.2 for the fuel and 2 for the oxidant (oxygen). The PEMFCs usually operate at about 80°C and 1–8 atm pressure. The pressures, in general, are maintained equal on either side of the membrane. Operation at high pressure is necessary to attain high power densities, particularly when air is chosen as the cathodic reactant.

To prevent the membrane dryout leading to local hot spot (and crack) formation, performance degradation, and lifetime reduction, both fuel and oxidant streams are often fully humidified, and the operating temperature is limited by the saturation temperature of water corresponding to the operating pressure. The product liquid water formed at the cathode can dissolve in the electrolyte membrane or be removed from the cell by the excessive oxidant gas stream. The accumulation of liquid water in the cathode backing layer blocks the oxygen transfer to the catalytic sites, thus resulting in the phenomenon called "water flooding," causing performance reduction. Local hot and cold spots will cause the evaporation and condensation of water. Thus, an integrated approach to thermal and water management is critical to PEMFCs' operation and performance, and a proper design must be implemented.

Cold Start

In winter conditions, it is unavoidable for vehicles driving below the freezing point of water (0°C); therefore, for successful commercialization of PEMFC in automotive applications, rapid start-up from subzero temperatures must be achieved, which is referred to as "cold start" of PEMFC. The major problem of PEMFC cold start is that the product water freezes when the temperature inside the PEMFC is lower than the freezing point of water. If the catalyst layer is fully covered by ice before the cell temperature rises above the freezing point, the electrochemical reaction may be stopped due to the blockage of the reaction site. In addition, ice formation may also result in serious damage to the structure of the membrane electrode assembly. Most of the present PEMFCs employ various assisted cold start methods such as resistance heating using DC from batteries, coolant heating, hot air blowing, and catalytic hydrogen/oxygen reaction inside the PEMFC. The cold start performance can also be improved by design optimizations. Membrane thickness, ionomer content in catalyst layer, total heat capacity of the cell, and cell insulation are all important design factors to improve the cold start performance.

Acceptable Contamination Levels

As an acid electrolyte fuel cell operating at low temperature, the PEMFC is primarily vulnerable to carbon monoxide poisoning. Even a trace amount of CO drastically reduces the performance levels, although CO poisoning effect is reversible and does not cause permanent damages to the PEMFC system. Further, the performance reduction due to CO poisoning takes a long time (on the order of 2 hr) to reach steady state. This transient effect may have profound implication for transportation applications. Therefore, the PEMFC requires the use of a fuel virtually free of CO (must be less than a few parts per million). Also, high-quality water free of metal ions should be used for the cell cooling and reactant humidification to avoid the contamination of the membrane electrolyte. This requirement has a severe implication on the materials that can be used for cell components. On the other hand, carbon dioxide does not affect PEMFC operation and performance except through the effect of reactant dilution (the Nernst loss).

Major Technological Problems

For practical applications, PEMFC performance in terms of energy efficiency, power density (both size and weight), durability, and capital cost must be further improved. This can be accomplished by systematic research in the following:

i. New oxygen reduction electrocatalysts: This includes the development of non-precious catalyst and the reduction of precious metal platinum and its alloys loading from 4 mg/cm^2 to 0.4 mg/cm^2 or lower without affecting the long-term performance and the lifetime, as well as the development of CO-tolerant catalysts.
ii. New types of polymer electrolyte with higher oxygen solubility, thermal stability, long life, and low cost. A self-humidified membrane or a polymer without the need of humidification will be ideal for PEMFC operation and performance enhancement with significant simplification of system complexities and reduction of the cost.
iii. Profound changes in oxygen (air) diffusion electrode structure to minimize all transport-related losses. The minimization of all transport losses is the most promising direction for PEMFC performance improvement.
iv. Optimal thermal and water management throughout the individual cells and the whole stack to avoid local hot and dry spot formation and to avoid water flooding of the electrode.
v. Optimal design from single-cell component to system level to enhance the cold start performance.

Figure 2 illustrates the schematic of a PEMFC stack and its major components. In addition to the above issues, the development of low-cost lightweight materials for construction of reactant gas flow fields and bipolar plates is one of the major barriers to PEMFCs' large-scale commercialization. The successful solution to this problem will further increase the output power density, and it includes an optimal design of flow fields with the operating conditions, as well as an appropriate selection of materials and fabrication techniques. It has been reported that as much as over 20% improvement in the performance of PEMFC stacks can be obtained just by appropriate design of flow channels alone. The current leading technologies for bipolar plate design include the following: injection-molded carbon-polymer composites, injection-molded and carbonized amorphous carbon, assembled three-piece metallic, and stamped unitized metallic.

Technological Status

PEMFCs have achieved a high power density of over 2.2 kW/L, perhaps the highest among all types of the fuel cells currently under development. It is also projected that the power density may be further improved with unitized metallic (stainless steel) bipolar plates. The U.S. Department of Energy reported that the capital cost of 80 kW automotive fuel cell system costs in volume production (projected to 500,000 units per year) is $61/kW in 2009, and the future target is $35/kW. It is expected that PEMFC technology is about 5 to 10 years from commercialization, and precommercial demonstration for buses and passenger vehicles is under way with increasing intensity. The first demonstration for residential combined heat and power application has began at the end of 1999, and application of PEMFCs in powering portable and mobile electronics such as laptops has already been started.

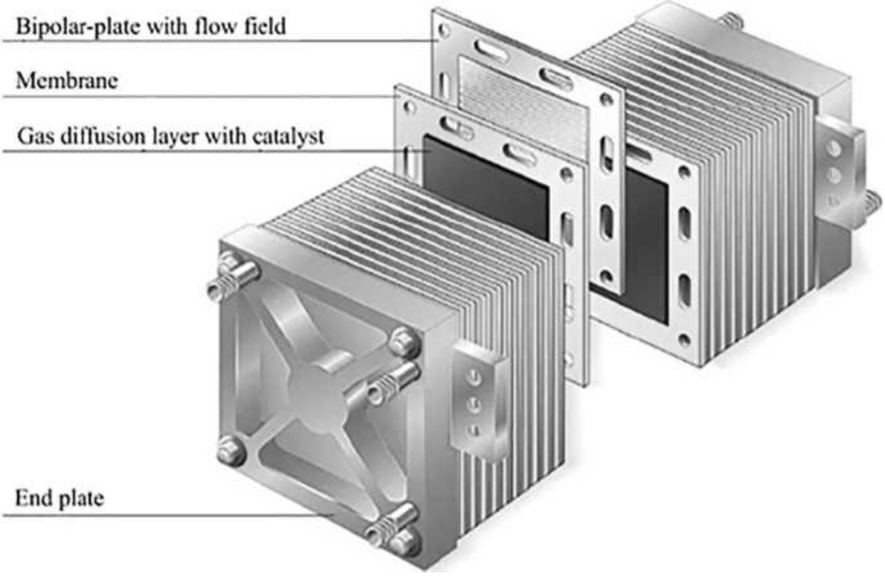

FIGURE 2 Schematic of a PEMFC stack and its components. (Source: Ballard Power Systems: http://www.ballard.com.)

Applications

PEMFCs have a high power density, a variable power output, and a short start-up time due to low operating temperature; the solid polymer electrolyte is virtually corrosion free and can withstand a large pressure differential (as high as 750 psi reported by NASA) between the anode and cathode reactant gas streams. Hence, PEMFCs are suitable for use in the transportation sector. Currently, they are considered the best choice for zero-emission vehicles as far as present-day available fuel cell technologies are concerned. Their high power density and small size make them primary candidates for light-duty vehicles, though they are also used for heavy-duty vehicles. For high-profile automobile application, pure hydrogen and air are used as reactants at the present. However, conventional gasoline and diesel engines are extremely cheap, estimated to cost about \$30–\$50/kW. Therefore, the cost of PEMFC systems must be lowered in order to be competitive with the conventional heat engines in the transportation arena.

For electricity generation from the hydrocarbon fuels, a reformer with carbon monoxide and sulfur cleaning is necessary. It is estimated that the cost of the reforming system is about the same as the fuel cell stack itself, which is also the same as the cost of other ancillary systems. Apart from the high cost, the optimal chemical-to-electric conversion efficiency is around 40%–45%, and the low operating temperature makes the utilization of the waste heat difficult, if possible at all; for the reforming of hydrocarbon fuels, cogeneration of heat and combined cycles can be applied. On the other hand, conventional thermal power plants with combined gas and steam turbines have energy efficiency approaching 60% with a very low capital cost of \$1000/kW. Therefore, the best possible application of the PEMFC systems interesting to utility industry is the use of PEMFCs in the size of tens to hundreds of kilowatts for remote region, as well as a possibility for residential combined heat and power application.

In addition, NASA has been conducting a feasibility study of using the PEMFC power systems for its space programs (mainly space shuttle missions) in place of its current three 12 kW AFC power modules. As discussed in the "Alkaline Fuel Cells" section, NASA is motivated by the extremely high cost, low lifetime, and maintenance difficulty associated with its current AFC systems.

Direct Methanol Fuel Cells

Introduction

All the fuel cells reviewed above for commercial applications require the use of gaseous hydrogen directly or liquid/solid hydrocarbon fuels, e.g., methanol, reformed to hydrogen as the fuel. Pure oxygen or oxygen in air is used as the oxidant. Hence, these fuel cells are often referred to as hydrogen-oxygen or hydrogen-air types of fuel cells. The use of gaseous hydrogen as a fuel presents a number of practical problems, such as storage system weight and volume as well as handling and safety issues especially for consumer and transportation applications. Although liquid hydrogen has the highest energy density, the liquefaction of hydrogen needs roughly one-third of the specific energy, and the thermal insulation required increases the volume of the reservoir significantly. The use of metal hydrides decreases the specific energy density, and the weight of the reservoir becomes excessive. The size and weight of a power system are extremely important for transportation applications, as they directly affect the fuel economy and vehicle capacity, although they are less critical for stationary applications. The low volumetric energy density of hydrogen also limits the distance between vehicle refueling.

Methanol as a fuel offers ease of handling and storage, and potential infrastructure capability for distribution. Methanol also has a higher theoretical energy density than hydrogen (~5 kWh/L compared with 2.6 kWh/L for liquid hydrogen). Easy refueling is another advantage for methanol. However, in the conventional hydrogen-air or hydrogen-oxygen fuel cells, a reformer is needed, which adds complexity and cost as well as production of undesirable pollutants such as carbon monoxide. The addition of a reformer also increases response time.

Therefore, direct oxidation of methanol is an attractive alternative in view of its simplicity from a system point of view. The DMFCs utilizing proton exchange membrane (PEM) have the capability of efficient heat removal and thermal control through the circulating liquid, as well as elimination of humidification required to avoid membrane dryout. These two characteristics have to be accounted for in the direct and indirect hydrogen systems that impact their volume and weight and, consequently, the output power density.

Basic Operating Principle

Figure 3 illustrates the basic operating principle of a DMFC. The DMFC allows the direct use of an aqueous, low-concentration (3%), liquid methanol solution as the fuel. Air is the oxidant. The methanol and water react directly in the anode chamber of the fuel cell to produce carbon dioxide and protons that permeate the PEM and react with the oxygen at the cathode. The half-cell reactions are as follows:

$$\text{Anode}: \mathrm{CH_3OH}(1)+\mathrm{H_2O}(1)=\mathrm{CO_2}(\mathrm{g})+6\mathrm{H}^+ +6\mathrm{e}^-$$

$$\text{Cathode}: 6\mathrm{H}^+ +6\mathrm{e}^- +3/2\mathrm{O_2}(g)=3\mathrm{H_2O}(1)$$

and the net cell reaction is

$$\mathrm{CH_3OH}(1)+3/2\mathrm{O_2}(g)=\mathrm{CO_2}(\mathrm{g})+2\mathrm{H_2O}(1).$$

Because the PEM (e.g., Nafion membrane) is used as the electrolyte, the cell operating temperature must be less than the water boiling temperature to prevent the dryout of the membrane. Typically, the operating temperature is around 90°C, and the operating pressure ranges from 1 atm to several atmospheres.

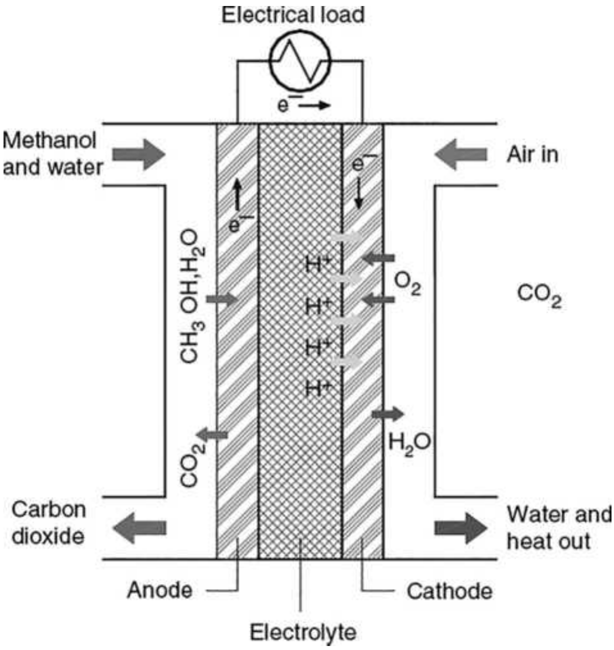

FIGURE 3 Schematic of DMFC.

Acceptable Contamination Levels

The system is extremely sensitive to carbon monoxide (CO) and hydrogen sulfide (H_2S). Carbon monoxide may exist as one of the reaction intermediaries and can poison the catalyst used. There are arguments whether CO is present in the anode during the reaction. Sulfur may be present if methanol is made of petroleum oils and needs to be removed.

Major Technological Problems

The PEM used in the DMFCs is the same as that employed in the PEMFCs. Since the electrolyte in DMFCs is essentially acid, expensive precious metals (typically platinum or its alloys) are used as the catalyst. However, the most serious problem is the so-called "methanol crossover." This phenomenon is caused by the electro-osmotic effect. When the protons migrate through the electrolyte membrane, a number of water molecules are dragged along with each proton, and because methanol is dissolved in liquid water on the anode side, methanol is dragged through the membrane electrolyte to reach the cathode side together with the protons and water. Fortunately, the methanol at the cathode is oxidized into carbon dioxide and water at the cathode catalyst sites, producing no safety hazards. However, the methanol oxidation in cathode does not produce useful electric energy. The development of a new membrane with low methanol crossover is a key to the success of DMFCs.

Such a low methanol crossover membrane has a number of advantages. First, it reduces the methanol crossover, enhancing fuel utilization and, hence, energy efficiency. Second, it reduces the amount of water produced at the cathode, leading to a lower activation and concentration polarization, thus allowing higher cell voltage at the same operating current. Third, it allows higher methanol concentration in the fuel stream, resulting in better performance.

Technological Status

Although methanol itself has simpler storage requirements than hydrogen and is simpler to make and transport, its electrochemical activity is much slower than that of hydrogen; that is, its oxidation rate is about four orders of magnitude smaller than that of hydrogen. Also, the conversion takes place at low temperature (about 80–90°C), and the contaminant problem is one of the serious issues.

The state-of-the-art performance is an energy conversion efficiency of 34% (from methanol to electricity) at 90°C using 20 psig air, that is, a cell voltage of 0.5 V (corresponding to a voltage efficiency of 42%) together with the methanol crossover accounting for 20% of the current produced (equivalent to a fuel efficiency of 80%). This 20% methanol crossover occurs when the fuel stream used is an aqueous solution containing only 3% methanol. It has been projected that with the better membrane developed by the University of Southern California (USC) and improvement of membrane electrode assembly, a cell voltage of 0.6 V can be achieved with only 5% methanol crossover. This is equivalent to 50% voltage efficiency and 95% fuel efficiency, resulting in an overall stack efficiency of 47% (from methanol to electricity). The DMFC system efficiency will be lower due to running the necessary auxiliary systems. Since the current DMFCs basically use the same cell components, materials, construction, and fabrication techniques as the PEMFCs, it is therefore expected that the system and component costs will be similar to that of the PEMFCs.

Applications

DMFCs have low power density due to the sluggish reaction kinetics of methanol, but high volumetric energy capacity since the volumetric energy density of methanol is high. These characteristics make DMFCs unlikely suitable for high power density applications such as powering large vehicles, but ideal for smaller applications such as laptops, cellular phones, digital cameras, battery chargers, or other electronic devices. Current DMFC systems are available with power outputs from 25 W to 5 kW with durations up to 100 hr between refueling operations. DMFCs therefore feature longer working period and shorter refueling/recharging time than conventional lithium batteries. In addition, since methanol can be made from agriculture products, the use of methanol is also compatible with renewable energy sources to allow for sustainable development.

Concluding Remarks

A summary of the preceding discussion, including the operational characteristics and technological status of the three major types of low-temperature fuel cells, is given in Table 1.

For stationary power generation in the utility industry, the economic fuels of today and in the near future are the fossil fuels. Although AFCs have the best performance when operating on pure hydrogen and oxygen, the liquid electrolyte's intolerance of carbon dioxide eliminates its role for utility

TABLE 1 Operational Characteristics and Technological Status of Various Low-Temperature Fuel Cells

Type of Fuel Cells	Operating Temperature (°C)	Power Density (mW/cm^2), (Present) Projected	Projected Rated Power Level (kW)	Fuel Efficiency	Lifetime Projected (hr)	Capital Cost Projected ($/kW)	Application Areas
AFC	<90	(100–400) >300	10–100	4070	>10,000	35	Space, transportation
PEMFC	50–90	(600) >900	1–1000	45–70	>40,000	35	Transportation, space
DMFC	90	(230)	0.025–5	34	>10,000	35	Portable electronic devices, transportation

applications. However, the development of solid electrolyte membrane for AFC lifts the curtain of revival of this technology. The cost of PEMFCs has been significantly reduced in recent years, and it is expected to be comparable with internal combustion engines. PEMFCs are believed to be the most promising candidate for transportation application because of their high power density, fast start-up, high efficiency, and easy and safe handling. DMFCs are most suitable for portable applications such as laptops, cellular phones, digital cameras, battery chargers, or other electronic devices, because they have low power density but high energy capacity.

Global Climate Change: Gasoline, Hybrid-Electric, and Hydrogen-Fueled Vehicles

Robert E. Uhrig

Introduction

It is theoretically possible for plug-in hybrid-electric light transportation vehicles to utilize electricity provided by electric utilities to displace almost 75% of the energy of gasoline used for light transportation vehicles (automobiles, SUVs, pickup trucks, minivans, etc.). It was also shown that replacing this gasoline energy with electricity would require 200–250 GW of new electrical generating capacity. Calculations show that about 930 GW of new electrical generating capacity would be required to produce hydrogen by electrolysis to replace all hydrocarbon fuels used in all U.S. transportation systems (including heavy trucks, aircraft, military vehicles, etc.). Hence, the choice of fuels for of these new electrical generating plants could have a large environmental impact if a significant fraction of gasoline used for light and heavy vehicle transportation was replaced by electricity or hydrogen.

Greenhouse Gases

Sunlight enters the atmosphere striking the earth, and it is reflected back towards space as infrared radiation (heat energy). Greenhouse gases absorb this infrared radiation, trapping the heat in the atmosphere. Until about 150 years ago, the amount of energy absorbed was about the same as the amount of energy radiated back into space. At that time, this equilibrium was upset, and the concentration of greenhouse gases—especially CO_2 (carbon dioxide)—began to increase. The concentration is continuing to increase at a rate that seems to parallel the increase in production of CO_2. During the same period, the average temperature of the atmosphere increased with subsequent climate changes in a manner that is thought by many to be a cause–effect relationship.[1]

The principal greenhouse gases are water vapor (60%–65%) and CO_2 (20%–25%). Water vapor stays in the atmosphere for a relatively short time—a matter of hours or days—whereas CO_2 has an average residence period of about a century. As a result, the amount of water vapor remains relatively constant related to the rate at which it is produced by weather phenomena, while CO_2 tends to accumulate as the amount emitted increases. All other greenhouse gases (10%–20%) such as methane, ozone, nitrous oxide, and carbon monoxide tend to have less effects on the atmosphere over time because of their small quantities or short residence times. Hence, the only greenhouse gas considered in this analysis is CO_2.

In contrast with the “well to wheels” approach that includes the emissions produced by processing the original fuel, this analysis starts with the fuel used to generate electricity or to produce hydrogen. This simplification does not materially change the relationship between the emissions of greenhouse gases by the various processes analyzed.

Models Used for Analyses

The models to quantitatively evaluate the greenhouse gas emissions, specifically carbon dioxide, when electrical energy or hydrogen is used to replace gasoline as an automotive fuel are those used in the author’s previous publications.[2,3] These models were based on information provided by or extrapolated from data provided by the Department of Energy (DOE) Energy Information Administration (EIA).[4]

These models utilize the following data:

1. There were 225 million light transportation vehicles in the United States in 2004, including 133 million automobiles and 92 million light truck-based vehicles (sport utility vehicles, vans, pickup trucks, passenger minivans, and delivery vans).
2. On any given day, 50% of these vehicles traveled less than 32.2 km (20 mi).
3. The average distance traveled by each vehicle in the United States was 19,749 km/year (12,264 mi/year). This distance traveled by each average vehicle is derived from the 9 million barrels of oil per day used to make gasoline for the 225 million light vehicles having an average fuel consumption of 8.51 km/l (20 mi/gal), the approximate average gasoline mileage reported by EIA.[4]

4. The quantitative index used for comparing electricity and hydrogen produced by different methods using different source fuels is kilograms of CO_2 per vehicle-year (pounds per vehicle-year) for the average distance traveled by each vehicle in the United States—19,749 km/year (12,264 mi/year). Actual emissions of specific vehicles may be greater or less than the values presented here depending upon whether the fuel consumption of the particular vehicle is greater or less than the average value of 8.51 km/l (20 mi/gal).

CO_2 Emissions for Gasoline-Fueled Light Vehicles

TerraPass, a vendor dealing in carbon dioxide emission credits, has developed a "carbon dioxide calculator" that gives the emission of carbon dioxide for virtually all American automobiles for the past 20 years.[5] Experimenting with this calculator shows that the quantity of carbon dioxide, the most important greenhouse gas from combustion of gasoline in internal combustion engines, emitted per unit of time is a direct function of the amount of gasoline used in that time. This calculator utilized the fact that the combustion of 1 gal of gasoline emits 2.35 kg of CO_2 per liter (19.56 lbs of CO_2 per gallon) of gasoline. Because the average gas mileage in our model is 8.51 km/l (20 mi/gal), the annual emission of carbon dioxide is

$$\frac{19749\text{ km/year}\times\text{kg CO}_2\text{ per liter}}{8.51\text{ km/liter}}=5458\text{ km/vehicle}-\text{year}$$

$$\left(11{,}997\ lb\ CO_2\ \text{ per vehicle-year}\right)$$

Clearly, the amount of CO_2 for smaller vehicles is less than for larger vehicles because the gasoline mileage is greater. However, the model for this analysis deals with average vehicles that achieve 8.51 km/l (20 mi/gal)—the reference performance used for all comparisons.

CO_2 Emissions for Micro, Mild, and Full Hybrid Vehicles

Because of the energy to propel all traditional types of hybrid vehicles is provided by gasoline, we will utilize the increased fuel mileages assigned in the author's earlier publication[3] and reduce the total CO_2 emissions for traditional hybrid-electric vehicles accordingly, as shown in Table 1.

These values are for hybrid vehicles of a size corresponding to a traditional vehicle that attains 8.51 km/l (20 mi/gal). A larger or smaller vehicle would have higher or lower emissions, respectively.

CO_2 Emissions for Plug-In Hybrid-Electric Vehicles

The model utilized in the author's hybrid article[3] has half the vehicles traveling 24.2 km (15 mi) per day on electricity, or 8816 km (5475 mi) per year. The other half of the vehicles travel 56.4 km (35 mi) per day, or 20,572 km (12,775 mi) per year on electricity. These assumptions result in an average of 14,694 km (9125 mi) per year on electricity for all vehicles.

TABLE 1 Emissions for Hybrid-Electric Vehicles

	Gasoline Mileage		CO_2 per Vehicle-Year	
Type Hybrid	km/l	mi/gal	Kg	lb
Micro hybrid	9.35	22	4,955	10,906
Mild hybrid	10.62	25	4,362	9,598
Full hybrid	12.32	29	3,761	8,274

The second half of these vehicles must also travel an additional 5055 km (3139 mi) per year as a full hybrid using gasoline at 12.32 km/l (29 mi/gal). Because the average total distance traveled by each car per year is 19,749 km (12,264 mi), the distance traveled using gasoline is 25.6% of the average distance each vehicle travels. The other 74.4% of this distance is traveled using electricity generated by a utility using nuclear fuels, fossil fuel, solar energy (wind, hydro, or photovoltaic systems), or renewable energy systems. Such a substitution of electricity for gasoline would save 6.7 million of the 9.0 million barrels of oil per day used in the United States for light vehicle transportation.

Electricity Generated Using Nuclear, Solar, and Renewable Fuels

Plug-in hybrid vehicles have two sources of CO_2—the CO_2 emitted due to operation in the full-hybrid mode and the CO_2 emitted in generating the electrical energy used for the rest of the time. Because nuclear, solar, and renewable fuels generate a net of zero CO_2, the only CO_2 generated is by operation in the full-hybrid mode for 25.6% of the distance traveled. Hence, the emission is 25.6% of the value in Table 1 for a full-hybrid, 964 kg (2122 lb) per vehicle-year.

Electricity Generated Using Fossil Fuels (Natural Gas, Oil, and Coal)

When the electricity is supplied by utilities using fuels that emit carbon dioxide during combustion, this CO_2 from generating electricity must be added to the CO_2 of the full-hybrid operation discussed above. Data on actual emissions from fossil power plants in the United States for 1999 (the last year for which complete data is available), provided by EPA and (DOE) (DOE-EIA 1999) show the emission rates in Table 2.

A reasonable average of 0.374 kWh/km (0.603 kWh/ mi) for the expenditure of electrical energy for hybrid vehicles that would be comparable to a vehicle getting 8.51 km/l (20 mi/gal) of gasoline using an internal combustion engine. Previously in this entry, it was shown that the average distance traveled by all plug-in hybrid vehicles while operating on electricity alone was 14,694 km/year (9125 mi/year). Hence, the electricity used is

$$\left(14{,}694\text{ km/year}\right) \times \left(0.374\text{ kWh/km}\right) = 5{,}496\text{ kWh/year}.$$

If we multiply this value by the amount of CO_2 emission per kilowatt-hour for the three fossil fuels given in Table 2 and add the 964 kg/vehicle-year (2122 lb/vehicle-year) of CO_2 for operation in the hybrid mode, we get the results for fossil fuels given in Table 3.

TABLE 2 Emission Rates for Fossil Fuels

Fuel to Generate Electricity	% of Total Generation	CO_2 Emission Rate kg/kwh	CO_2 Emission Rate lb/kwh
Coal	51.0	0.952	2.095
Oil	3.2	0.895	1.969
Natural gas	15.2	0.600	1.321
Renewables	0.6	0 (net)	0 (net)
Non-fossil[a]	30.0	0	0

Hydrogen-Fueled Vehicles

The emission of carbon dioxide from vehicles utilizing electricity generated with fuel cells operating on hydrogen is negligible except for the emissions from the various processes used to produce the hydrogen. These emissions of carbon dioxide from the production processes must be taken into account to give a valid comparison with emissions of greenhouse gases from the other vehicle configurations and their potential impact upon climate and weather modification.

Steam Methane Reforming

Some 95% of hydrogen used today is produced by steam methane reforming (SMR) from natural gas (~98% methane—CH_4). The two steps of SMR are

$$CO_4 + H_2O + \text{Heat}(206\text{ kJ/mol}) \overset{\text{Catalyst}}{\rightarrow} CO + 3H_2$$

$$(\text{Steam Reforming Reaction})$$

$$CO + H_2O \overset{\text{Catalyst}}{\rightarrow} CO_2 + H_2 + \text{Heat}(41\text{ kJ/mol})$$

$$(\text{Water–Gas Shift Reaction})$$

The hydrogen comes from the methane and the steam. The steam reforming reaction is endothermic with the required 206 kJ/mol heat energy normally produced by combustion of some of the methane. The water-gas shift reaction is exothermic, providing 41 kJ/mol heat energy that, if recovered, can reduce the amount of methane burned. Then the methane burned has to provide only the net 165 kJ/mol that represent ~17% of the total methane energy. About 3.3 mol of hydrogen (~83% of the theoretical maximum of 4 mol of hydrogen from CH_4) are produced for each mol of methane. A well-designed SMR plant will yield hydrogen having about 80% of the energy of the methane supplied. Unfortunately, SMR produces CO_2 in both the methane combustion and in the water–gas shift reaction.

Emissions of Vehicles Using Hydrogen Produced by SMR

In an earlier publication,[3] it was established that 0.228 kWh/km (0.367 kWh/mi) of mechanical energy at the tire- pavement interface corresponded to 8.51 km/l (20 mi/gal). If we use the following efficiencies:

- 70% efficiency for the electric motor drive (electricity to mechanical energy at the tire-pavement interface), the same used in the above reference,
- 60% efficiency (hydrogen to electricity) for the fuel cell, and
- 85% efficiency is distributing and dispensing the hydrogen to the fuel cell, the needed energy of the hydrogen input to the fuel cell is

$$\frac{0.228\ kWh/km}{0.70\times0.60\times0.85}$$
$$=0.638\ \text{kWh/km}\ (1.028\text{kWh / mi})$$

of hydrogen energy. Because the average total distance traveled per vehicle is 19,749 km/year (12,264 mi/year), the total kilowatt-hour per vehicle-year is

$$(19749\ \text{km / year})\times(0.638\ \text{kWh of H}_2\ \text{energy / km})$$

$$=12607\ \text{kWh of H}_2\ \text{energy / vehicleyear.}$$

The energy of hydrogen (lower heating value) is 119.9 MJ/kg (51,600 Btu/lb), so the amount of H_2 used per year is

$$\frac{12607\ \text{kWh per vehicle} - \text{year}}{119.9\ \text{MJ / kg}\times0.278\ \text{kWh / MJ}}$$
$$=379\text{kg H}_2\ \text{per vehicle} - \text{year}$$

$$(834\ lb\ H_2\ \text{per vehicle-year})$$

Goswami indicates that SMR produces a net of 0.43 mol of CO_2 for each mol of H_2 produced using SMR.[7] Because the molecular weights of CO_2 and H_2 are 44 and 2, respectively, the specific CO_2 emission can be calculated by

$$(0.43\ \text{mol}\ CO_2\ /\ mol\ H_2)\times\frac{(44\ gm\,/\,\text{mol}\ CO_2)}{(2\ gm\,/\,\text{mol}\ H_2)}$$
$$=9.46\ \text{gm CO}_2\ /\ \text{gm H}_2=9.46\ \text{kg CO}_2\ /\ \text{kg H}_2$$

and the total emission of CO_2 per vehicle-year is

$$(379\ \text{kg H}_2\text{per vehicle} - \text{year})$$

$$\times(9.46\ kg\ CO_2\ \text{per}\ kg\ H_2)$$

$$=3{,}585\ \text{kg CO}_2\ \text{per vehicle} - \text{year}$$

$$(=7{,}888\ \text{lb CO}_2\ \text{per vehicle} - \text{year}).$$

Emission for Vehicles Using Hydrogen Produced by SMR with Heat Provided by a High-Temperature Nuclear Reactor

Recent work in Japan has demonstrated the feasibility of substituting high-temperature heat from a gas-cooled nuclear reactor to replace the heat supplied by the combustion of methane. This increases the amount of hydrogen produced to 4 moles per mole of methane and eliminates the CO_2 produced by combustion of methane, but not the CO_2 produced by the water–gas shift reaction. The overall reaction of the steam reforming and water shift reactions is the production of 1 mole of CO_2 and 4 mol of hydrogen for each mole of CH_4. Hence, multiplying this ratio by the molecular weights and the amount of hydrogen used per year gives

$$\frac{1\text{ mol CO}_2}{4\text{ mol H}_2}\times\frac{44}{2}\times 379\text{ kg H}_2\text{ per vehicle}-\text{year}$$

$$=2{,}084\text{ kg CO}_2\text{ per vehicle}-\text{year}$$

$$\left(4{,}586\ lb\ CO_2\text{ per vehicle-year}\right).$$

Emissions for Vehicles Using H_2 Produced by Electrolysis

Conventional electrolysis of water to produce hydrogen is a well-developed technology and production units as large as 10 MWe are commercially available today. However, the typical overall efficiency of hydrogen production using electrolysis based on the thermal content of the generating plant fuel is about 25% today, consisting of two components—about 33% efficiency in converting fossil or nuclear fuel to electricity and about 75% in using electricity to separate water into hydrogen and oxygen. If a high-temperature gas-cooled reactor or a modern high-efficiency gas-fired combined cycle plant is used, the overall efficiency in producing hydrogen could approach 45%.

A leading manufacturer of electrolysis equipment indicated that 1 MW of electricity can generate 0.52 ton (1040 lb) of hydrogen per day or 0.473 kg H_2/kW day (1.04 lb H_2/kW day).[8] In the case of SMR, it was calculated that the hydrogen required per year for a vehicle using hydrogen to travel 12,260 mi/year was 379 kg of H_2/ vehicle-year (832 lb/vehicle-year). Hence, the amount of electricity required per year is

$$\frac{\left(379\text{ kg H}_2\text{ / year}\right)\times\left(24\text{ h / day}\right)}{0.473\text{ kgH}_2\text{ / kW day}}=19{,}230\text{ kWh / year.}$$

The carbon dioxide emitted for hydrogen-fueled vehicles is the carbon dioxide emitted in producing the electricity required to produce the hydrogen. The choices of fuel for generating electricity are coal, oil, natural gas, nuclear energy, and solar energy (wind, photovoltaics, and hydro). Hence, the emissions of carbon dioxide are the product of the kilowatt-hour per year and the appropriate emission per kilowatt-hour from Table 2 for the fuel used.

Emissions for Vehicles Using H_2 Produced by Electrolysis Using Solar, Nuclear, and Renewable Energy

Because none of these energy sources emit carbon dioxide when generating electricity, there are no emissions of greenhouse gases associated with these arrangements.

Emissions for Vehicles Using H_2 Produced by Electrolysis Using Fossil Energy (Coal, Oil, and Natural Gas)

The emissions of carbon dioxide for these fossil fuels are the products of the 19,230 kWh/year and the appropriate emission per kilowatt-hour for the fuel as given in Table 2. The results are shown in Table 4.

TABLE 4 Emissions for Fossil Electrolysis

Fuel	kg CO_2/Year	lb CO_2/Year
Natural gas	11,538	25,384
Oil	17,211	37,963
Coal	18,307	40,276

Emissions for Vehicles Using H_2 Produced by Thermochemical Processes

The overall efficiency of the thermochemical process of producing hydrogen, such as the sulfur–iodine process, approaches 50% at 900°C, while the overall efficiency of the electrolysis process is about 25%. Hence, for the same fuel, the carbon dioxide emissions will be half as much for thermochemical processes as for electrolysis.

Emissions for Vehicles Using Hydrogen Produced by Thermochemical Processes Using Solar, Nuclear, and Renewable Energy

Because none of these energy sources emit carbon dioxide when generating electricity, there are no emissions of carbon dioxide associated with these arrangements.

Emissions for Vehicles Using Hydrogen Produced by Thermochemical Processes Using Fossil Energy (Natural Gas, Oil, and Coal)

The emissions of carbon dioxide for these fossil fuels are half of those for electrolysis, as shown in Table 4. The results are shown in Table 5.

Results and Conclusions

The results of this analysis are presented in Tables 6 and 7, which provide emissions of carbon dioxide for the various hybrid and hydrogen-fueled vehicle arrangements for the reference case of 8.50 km/l (20 mi/gal) for the average vehicle being driven 19,749 km/year (12,264 mi/year).

TABLE 5 Emissions for Hydrogen Produced by Thermochemical Processes by Fossil Fuels

Fuel	kg CO_2year	lb CO_2year
Natural gas	5,769	12,692
Oil	8,605	18,932
Coal	9,153	20,138

TABLE 6 Comparison of Emissions of Carbon Dioxide for Hybrid Vehicles

Vehicle Emissions of Carbon Dioxide	kg CO_2 Vehicle-Year	lb CO_2 Vehicle-Year
Reference gasoline vehicle average 8.51 km/l (20 mi/gal)	5,500	12,000
Micro-hybrid vehicle 9.35 km/l (22 mi/gal)	4,950	10,900
Mild-hybrid vehicle 10.62 km/l (25 mi/gal)	4,350	9,600
Full-hybrid vehicle 12.32 km/l (29 mi/gal)	3,750	8,300
Plug-in hybrid vehicle		
Electricity generated with nuclear	950	2,100
Electricity generated with solar energy	950	2,100
Electricity generated with renewable	950	2,100
Electricity generated with natural gas	4,250	9,400
Electricity generated with oil	5,900	13,000
Electricity generated with coal	6,200	13,700

Vehicle travels 19,749 km (12,264 mi) per year.

TABLE 7 Comparison of Emissions of Carbon Dioxide for Hydrogen-Fueled Fuel Cell Vehicles

Vehicle Emissions of Carbon Dioxide	kg CO_2/Vehicle-Year	lb CO_2/Vehicle-Year
Reference gasoline vehicle utilized an average 8.50 km/l (20 mi/gal)	5,500	12,100
Vehicle uses hydrogen produced using SMR	3,600	7,900
Vehicle using hydrogen produced using SMR with heat supplied by		
High temperature gas cooled reactor	2,100	4,600
Vehicle using hydrogen produced using electrolysis with electricity		
Produced using natural gas	11,550	25,400
Produced using oil	17,200	37,900
Produced using coal	18,300	40,300
Produced using nuclear energy	0	0
Produced using solar energy (wind, hydro, and photovoltaic)	0	0
Produced using renewables	0	0
Vehicle using hydrogen generated using a thermochemical process with heat		
Generated using natural gas	5,750	12,700
Generated using oil	8,600	18,900
Generated using coal	9,150	20,100
Generated using nuclear energy	0	0
Generated using solar energy (wind, hydro, and photovoltaic)	0	0
Generated using renewables	0	0

Vehicle travels 19,749 km (12,264 mi) per year.

Plug-In Hybrid-Electric Vehicles

In Table 6, the vehicle emissions of CO_2 for all traditional hybrid-electric vehicles are inversely related to the gas mileage. The gasoline mileage for micro, mild, and full hybrids are assumed to be 9.35, 10.62, and 12.32 km/l (22, 25, and 29 mi/gal), respectively. These are reasonable overall values for the newer, larger hybrid vehicles that have larger gasoline engines and electric motors such as the Toyota Highlander and Honda Accord hybrids. The rounded emissions in Table 6 for electricity generated using oil and coal are greater than for the reference case of gasoline. However, the emission of a plug-in hybrid vehicle where the electricity is generated by nuclear or solar energy is less than 20% of the reference gasoline case. Hence, the only way to significantly improve the greenhouse gas situation if plug-in hybrids are implemented on a large scale is to use only nuclear energy, solar (wind, hydro, or photovoltaic) energy, or renewables to generate the needed electricity. Because hydro power is virtually out of the question due to limited sites and environmental concerns, renewables have large land requirements, and both photovoltaic and wind are intermittent in nature with availabilities of less than about 30%, nuclear power would appear to be the primary choice.

Hydrogen-Fueled Fuel Cell Vehicles

The vehicle emissions of CO_2 for hydrogen-fueled fuel-cell-driven vehicles are presented in Table 7, where the emissions have been rounded off. Because fuel cells do not emit CO_2, the only emissions are from the processes used to produce the hydrogen. The carbon dioxide emissions for hydrogen produced by steam methane reforming, electrolysis, and thermochemical methodologies are given.

Perhaps the most important observation is that, contrary to the widespread belief that hydrogen-fueled vehicles produce no greenhouse gases, the emissions for hydrogen- fueled vehicles vary widely depending upon the method used to generate the electricity or heat to produce the hydrogen. In the case of electrolysis, in which the electricity is generated using nuclear, solar, and renewable energy, the average annual emissions per vehicle-year are negligible. However, the emissions for fossil fuels (natural gas, oil, and coal) are about 11,500, 17,200, and 18,300 kg/year (25,300, 37,800, and 40,200 lb/year), respectively—almost three times those for plug-in hybrid vehicles. These are extremely large emissions compared to almost any other method investigated here.

The emissions for producing hydrogen for a hydrogen- fueled vehicles using SMR produces CO_2 by two methods: combustion of some of the methane to drive the reaction and the water–gas shift reaction. These reactions produce about 3600 kg (7900 lb) CO_2 per vehicle-year, about the same as a full-hybrid vehicle.

If the heat required to drive the reaction in steam methane reforming can be supplied by an outside source such as a high temperature gas cooled reactor, then the emission of CO_2 is reduced to about 2100 kg (4600 lb) per vehicle- year.

The conclusion is that using hydrogen in fuel cells to propel vehicles is a complex process with many steps (converting thermal energy to electricity to hydrogen to electricity to propelling the vehicle), each consuming considerable energy. Hence, the resulting CO_2 emissions when fossil fuels are used to generate the electricity for electrolysis or thermochemical processes are correspondingly high. Given the concerns about the influence of CO_2 on weather and climate, it seems compelling that fossil fuels not be used in producing electricity for electrolysis or thermochemical processes to produce hydrogen for transportation.

Heat Pumps

Lu Aye

Introduction

This entry provides foundation knowledge about heat pumps for both professional and non-professional readers. A brief history of heat pumps, basic terms used in the heat pump industry and research and the fundamentals of heat pumps are presented. Working principles of the thermoelectric heat pump, the absorption heat pump, the gas compression heat pump and the vapor compression heat pump are explained by using schematic diagrams. Performance parameters of the heat pump systems—coefficient of performance (COP), energy efficiency ratio (EER), primary energy ratio (PER), and ambient energy fraction (AEF)—are also discussed.

Major advances have been made in heat pump technologies over the last 35 years. "Heat pump systems offer economical alternatives of recovering heat from different sources for use in various industrial, commercial and residential applications."[1] Heat pumps in their various and diverse forms allow one to harness, in a cost-effective manner, solar energy that has already been stored in the atmosphere and biosphere. To make a fair systematic comparison with other systems that provide the same thermal output, AEF may be used. The concept and the method of estimating the AEF are discussed. The relationships between the AEF, the heating coefficient of performance (HCOP) and PER are also presented. The short-term and long-term potential use of the heat pumps and corresponding greenhouse gas (GHG) emissions are discussed.

Brief History

Although most people are familiar with the common household refrigerator, the concept of using such a device to provide heating rather than cooling is less widely understood. The basic operational principle of this machine called the heat pump, however, was laid down in thermodynamic terms by Lord Kelvin, the first professor of natural philosophy at the University of Glasgow, Scotland, in the middle of the 19th century. Whereas the thermodynamic principle of the heat pump was found in 1852, it was not until 1855 that it was realized for producing heat by means of an open-cycle mechanical vapor recompression unit in Ebensee, Austria.[2] Much later, the closed vapor compression process was used for generating useful heat. After World War II, heat pump units for air-conditioning homes and individual rooms became common. Now, heat pump technology is well known as one of the energy conservation technologies.

Fundamentals

A heat pump is a thermodynamic system whose function is to heat, at the required temperature, with the aid of heat extracted from a source at lower temperature.[3] Heat pumps are devices designed to utilize low-temperature sources of energy that exist in atmospheric air, in lake or river water, and in the earth. These sources are referred to as "ambient energies." Heat pumps can also be operated using waste heat from commercial and industrial processes, thereby upgrading this to the required temperature level for some thermal process operations.[4]

The heat pump can be considered as a heat engine in reverse.[5] A heat engine removes heat from a high-temperature source and discharges heat to a low temperature and in doing so can deliver work (see Figure 1). Heat pumps capture heat energy from low-grade sources and deliver at a higher temperature. They require external work (W) to upgrade the heat absorbed (Q_L) (see Figure 2). Note that the heat energy flows from a low-temperature heat source to a higher application temperature. This is the

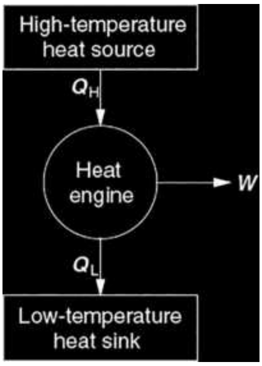

FIGURE 1 Thermodynamic model of a heat engine.

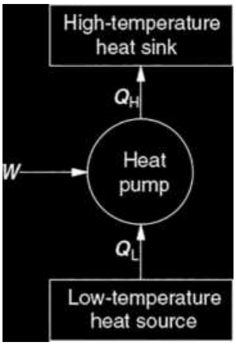

FIGURE 2 Energy flow of a heat pump.

TABLE 1 Commonly Used Heat Sources

Heat Source	Temperature Range (°C)
Ambient air	–10 to 15
Building exhaust air	15–25
Groundwater	4–10
Lake water	0–10
River water	0–10
Seawater	3–8
Rock	0–5
Ground	0–10
Wastewater and effluent	>10

reverse of the natural flow direction of heat from a higher temperature to a lower temperature. For ideal conditions without heat losses, the energy balance of a heat pump provides (Eq. 1):

$$Q_{\mathrm{H}} = Q_{\mathrm{L}} + W \tag{1}$$

where Q_H is the useful heat delivered, Q_L is the heat absorbed and W is the work input.

The useful heat delivered is always greater than the work input to the heat pump for ideal conditions.

The technical and economic performance of a heat pump is closely related to the characteristics of the heat source. Table 1 lists current commonly used heat sources. Ambient and exhaust air, soil and groundwater are practical heat sources for small heat pump systems, whereas sea/lake/river water, rock (geothermal) and wastewater are generally used for large heat pump systems.[6]

The fundamental theories of heat pumps and refrigerators are the same. In engineering practice, a distinction is made between heat pumps and refrigerators. The principal purpose of the latter device is to remove heat from a low-temperature heat source, and the purpose of the former device is to supply heat to a high-temperature sink. In many practical devices, the heating and cooling elements are interchangeable. The term *reverse cycle air conditioner* is frequently applied to heat pumps with interchangeable heating and cooling elements. In Japan and in the United States, reversible air-conditioning units are called heat pumps, and in Europe, the term *heat pump* is used for heating-only units.[2]

Carnot Coefficient of Performance (Theoretical Cop)

The heating performance of a heat pump is measured by the HCOP. The HCOP is the ratio of the quantity of heat transferred to the high-temperature sink to the quantity of energy driving the heat pump (see Figure 2).

$$\mathrm{HCOP} = \frac{Q_{\mathrm{H}}}{W} \tag{2}$$

In the Carnot ideal heat pump cycle, the heat is delivered isothermally at T_H and received isothermally at T_{L}. By using the laws of thermodynamics and definition of entropy, it can be shown that the Carnot HCOP is given by Eq. 3.

$$\mathrm{HCOP} = \frac{T_{\mathrm{H}}}{T_{\mathrm{H}} - T_{\mathrm{L}}} = \frac{T_{\mathrm{L}}}{T_{\mathrm{H}} - T_{\mathrm{L}}} + 1 \tag{3}$$

No practical heat pump constructed can have a better performance than this theoretical ideal HCOP. The best that our practical heat pump cycles can do is struggle towards achieving this ideal performance.[5]

Facts about Heating Relevant to Heat Pumps

It is argued that heat pumps are very energy efficient and therefore environmentally benign. The International Energy Agency (IEA) Heat Pump Centre provides the basic facts about heat supply and discusses the value of heat pumps.[7] The basic facts about heating explained are as follows:

- Direct combustion to generate heat is never the most efficient use of fuel.
- Heat pumps are more efficient because they use renewable energy in the form of low-temperature heat.
- If the fuel used by conventional boilers were redirected to supply power for electric heat pumps with HCOP of 3.5 to 4.5, about 35–50% less fuel would be needed, resulting in 35–50% less emissions.
- Around 50% savings are made when electric heat pumps with HCOP of 4.5 are driven by combined heat and power (CHP) or cogeneration systems.
- Whether a fossil fuel, nuclear energy or renewable energy is used to generate electricity, electric heat pumps make far better use of these resources than do resistance heaters.
- The fuel consumption, and consequently the emissions rate of an absorption or gas-engine heat pump is about 35–50% less than that of a conventional boiler.

Because heat pumps consume less primary energy than conventional heating systems, they are an important technology for reducing the unwanted air pollutants such as respirable particulate matters (PMs), carbon monoxide (CO), nitrogen oxides (NO_x), sulfur dioxide (SO_2), and carbon dioxide (CO_2) that harm the human environment.

Heat Pump Types

Five major types of heat pump may be identified in the literature.[8,9] These are the following:

- the magnetic heat pump
- the thermoelectric heat pump
- the absorption heat pump
- the gas compression heat pump
- the vapor compression heat pump

The Magnetic Heat Pump

The magnetic heat pump requires a solid magnetic material and it is based on the magnetocaloric effect. The magnetocaloric effect is the heating and cooling of a magnetic material in response to the application and removal of a sufficiently high external magnetic field.[10] The principle of the magnetic heat pump is shown in Figure 3.[11] With thermal Switch 1 off and thermal Switch 2 on, a magnetic field is applied to the solid magnetic material. The solid magnetic material is heated up above the heat sink temperature and heat will flow to the heat sink. Next, thermal switch 1 is on while thermal switch 2 remains on, and the magnetic field is partially removed; this cooled down the magnetic material to the heat source temperature. Thermal switch 2 is then off while the magnetic field is totally removed, completing the cooling of the magnetic material, and the magnetic material gains the heat from the heat source. Thermal switch 2 is then on and a magnetic field is applied to heat the magnetic material. Then, thermal switch 1 is off and the cycle is repeated to transfer heat from the low-temperature heat source to the higher-temperature heat sink.

The magnetic heat pumps do not use ozone-depleting refrigerants, and they have compact configuration, low noise, high efficiency, high stability, and longevity. They have great applicable prospects.[12,13]

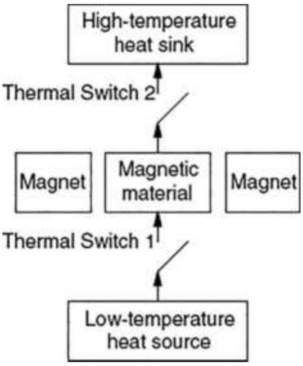

FIGURE 3 Schematic of a magnetic heat pump.

The Thermoelectric Heat Pump

The thermoelectric heat pump uses the Peltier effect. Two materials with different thermoelectric properties (*p* type and *n* type) are arranged to form hot and cold junctions and are connected in series with a direct current voltage source (Figure 4). These devices do not have moving parts and the cooling and heating elements may be reversed simply by changing the direction of the electric current. Current commercially available thermoelectric heat pumps have efficiencies that are well below those of vapor compression heat pumps. They are generally used in conditions where the solid-state nature (no moving parts, maintenance-free) outweighs efficiency, e.g., cooling of electronic components and small instruments.

The Absorption Heat Pump

An absorption cycle is a heat-activated thermal cycle. The absorption heat pump can be considered as a heat engine driving a heat pump (see Figure 5). All absorption cycles include at least three thermal exchanges with their surroundings (i.e., energy exchange at three different temperatures). For the system to operate, the generator temperature (T_g) must be greater than the condenser temperature (T_c) and the absorber temperature (T_a), must in turn be greater than the evaporator temperature (T_e).

The components of a simple single-effect absorption system are as follows:

- generator (desorber)
- condenser
- refrigerant expansion valve
- evaporator

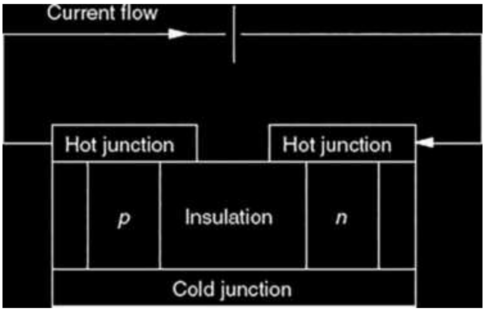

FIGURE 4 Schematic of a thermoelectric heat pump.

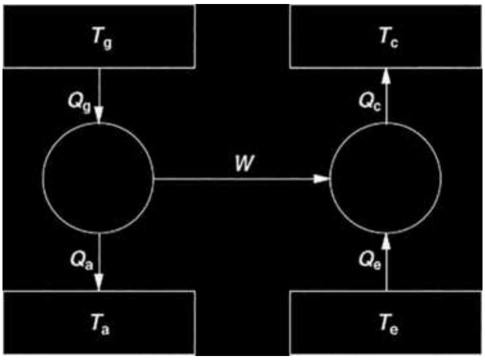

FIGURE 5 Thermodynamic model of an absorption heat pump.

- absorber
- pump
- solution heat exchanger
- solution pressure reducer
- connecting pipes

The absorption system utilizes a sorbent–refrigerant pair, lithium bromide and water, and water and ammonia, being the most widely used. A schematic of the continuous absorption heat pump system is shown in Figure 6. The major exchanges with its surroundings are thermal energy, plus a small amount of mechanical work at the pump to transport the working fluids.

A high-temperature heat source supplies heat to the generator to drive off the refrigerant vapor from solution. The condenser receives the refrigerant vapor from the generator. In the condenser, the refrigerant changes phase from vapor to liquid and heat is rejected at a medium temperature. The refrigerant expansion valve reduces the pressure of the refrigerant from the condensing pressure to

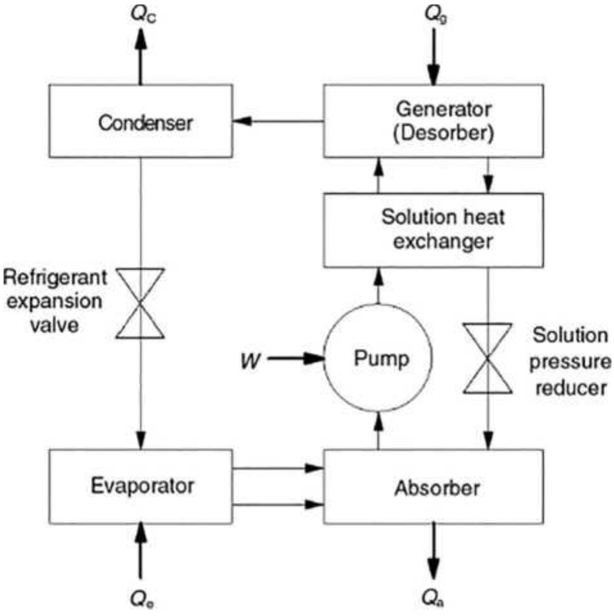

FIGURE 6 Simple absorption cycle.

the evaporating pressure. In the evaporator, the liquid refrigerant collects the low-temperature heat and changes to vapor phase. In other words, the working fluid (refrigerant) provides the cooling effect at the evaporator and the vaporized refrigerant enters the absorber. The strong-concentration sorbent absorbs the refrigerant vapor and becomes a weak solution. Note the heat rejected at the absorber. The low-pressure weak solution (refrigerant and sorbent) is pumped to the solution heat exchanger to exchange heat with the strong-concentration sorbent. The solution pressure reducer accepts the high-pressure strong solution from the generator and delivers low-pressure strong solution to the absorber. The generator receives the high-pressure weak solution from the solution heat exchanger and separates the refrigerant and sorbent.

The Gas Compression Heat Pump

Gas compression heat pumps use a gas as the working fluid. Phase changes do not occur during the cycle of operation. Major components of a gas compression heat pump system are as follows:

- gas compressor
- high-pressure heat exchanger
- gas expander (or turbine)
- drive motor
- low-pressure heat exchanger

A schematic of a gas compression heat pump is shown in Figure 7. The gas is drawn in to the compressor and compressed. The hot high-pressure gas delivers heat at the high-pressure heat exchanger. At the expander (turbine), the high-pressure gas does expansion work that assists to drive the compressor. In general, the external work input to the compressor-expander system is provided by a drive motor.

The Vapor Compression Heat Pump

Almost all heat pumps currently in operation are based on either a vapor compression or an absorption cycle.[14] Heat pumps and refrigerators of the vapor compression type utilize a working fluid that undergoes phase changes during operation. The phase changes occur principally during the heat collection and rejection stages of the cycles. The phase-changing processes occurring in the vapor compression heat pumps are accompanied by extremely favorable heat transfer conditions. Boiling agitation in evaporators and dropwise condensation in condensers make the heat transfer rates very high, which helps to improve the system efficiency. To carry out evaporation and condensation, any practical heat pump uses four separate components as illustrated in Figure 8:

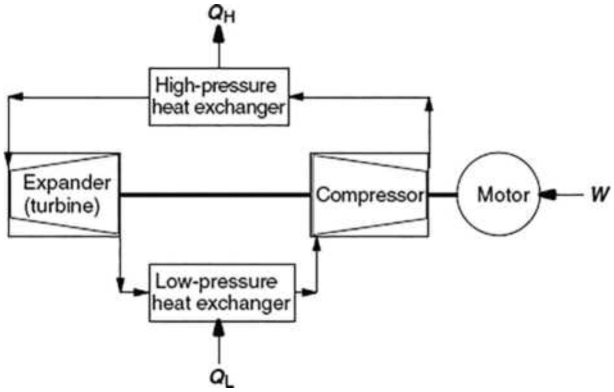

FIGURE 7 Schematic of a gas compression heat pump.

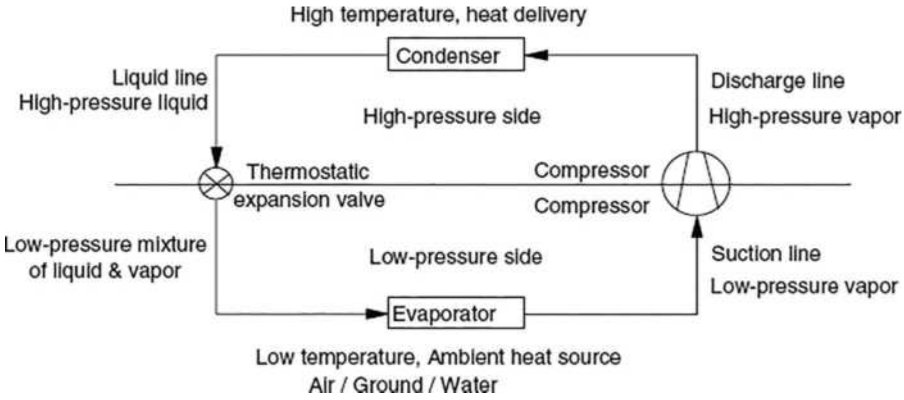

FIGURE 8 Schematic diagram of a vapor compression heat pump.

- compressor
- condenser
- expansion device
- evaporator

The compressor is the heart of the vapor compression heat pump system. By using mechanical power, the compressor increases the pressure of the working fluid vapor received from the evaporator and delivers it to the condenser. The working fluid condenses and provides useful heat at the condenser. The pressure of the liquid working fluid coming out of the condenser is reduced to the evaporating pressure by an expansion device. The low-grade heat is collected at the evaporator and the phase of the working fluid changes from liquid to vapor. The working fluid enters the compressor in vapor form to repeat the cyclic flow.[15]

Compressors used in practical units are generally of the positive displacement type: either reciprocating or rotary vanes. In practice, nearly all vapor compression heat pumps use thermostatic expansion (T-X) valves because of the availability of the valve to handle a wide range of operating conditions and because of the fact that the pressure reduction is essentially isenthalpic. These valves, which are relatively low-cost devices, control the liquid working fluid flow to the evaporator by sensing the superheat condition of the working fluid leaving the evaporator. Such control ensures that nearly all of the available evaporator surface is covered with a forced convection nucleate boiling film with consequential excellent heat transfer characteristics in the evaporation process.

Reversible circuit heat pumps for building cooling and heating are equipped with a four-way exchange valve that can be operated automatically or manually. This valve enables the normal evaporator to become the condenser and the normal condenser to become the evaporator so that the machine can be made to operate in reverse fashion. This arrangement is often incorrectly called reverse-cycle operation because of the end effect achieved—i.e., the interchange of roles for the cooling and heating parts of the circuit. It would be better to call this reverse-flow operation as the basic thermodynamic cycle remains the same for each mode of operation.

In general, vapor compression heat pumps are classified in many different ways. One method commonly used distinguishes among air, water and ground sources of low-temperature energy, and also between the high-temperature energy delivery medium (i.e., air or water). In such a classification, the most common types of heat pump units would include air-to-air units and water-to-water units. Solar energy could also be captured at the evaporator as a heat source. These types of heat pumps are called solar-assisted and solar-boosted heat pumps.[16]

Changes in condensing and evaporating temperatures affect the work input required at the compressor and consequently the COP. Decreasing the condenser or increasing the evaporator temperatures will

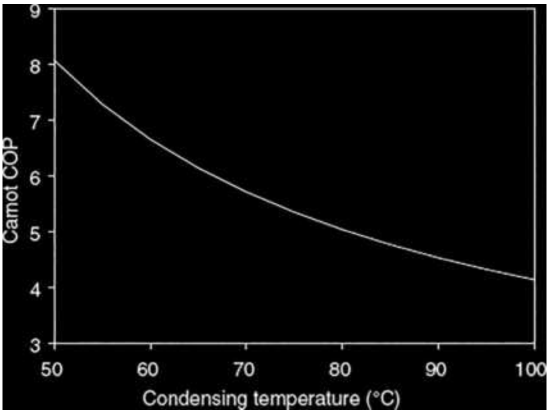

FIGURE 9 Effect of condensing temperature on ideal COP (evaporating temperature = 10°C).

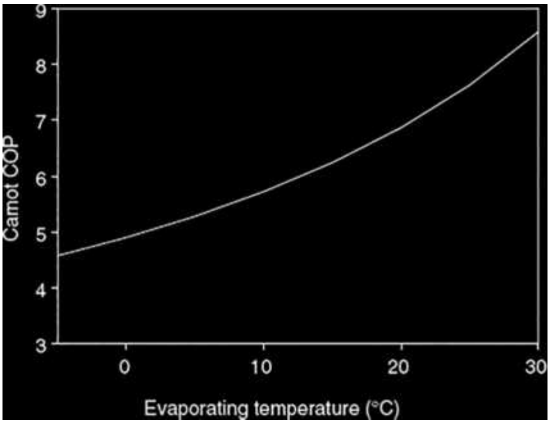

FIGURE 10 Effect of evaporating temperature on ideal COP (condensing temperature = 70°C).

decrease the compressor work and increase the COP. Figure 9 shows the effect of condensing temperature on COP for a fixed evaporator temperature. The effect of the evaporating temperature on the COP for a fixed condenser load temperature is shown in Figure 10. For simplicity, these curves have been obtained assuming operation on the ideal heat pump cycle—i.e., the Carnot cycle of two isothermal and two isentropic (reversible adiabatic) processes not allowing any practical deviations. Although the COP values for real machines will be substantially lower, the trend will be the same.

Performance Parameters

This section defines and explains some performance parameters that are used to compare various heat pumps for a particular application and also presents the relationships among them.

SCOP and EER

System coefficient of performance (SCOP) is defined as output heating capacity per unit of power input to the system (see Eq. 4).

$$\text{SCOP} = \frac{\text{Heating capacity (W)}}{\text{Power input (W)}} \tag{4}$$

SCOP is a dimensionless number that measures the performance of a heat pump. If the heating capacity is expressed in units other than watts, it is called heating energy efficiency ratio (HEER). Heat pumps sold in the United States are often stated in terms of HEER (see Eq. 5).

$$\text{HEER} = \frac{\text{Heating capacity (Btu/hr)}}{\text{Power input (W)}} \tag{5}$$

Seasonal heating energy efficiency ratio (SHEER) is the time average HEER value for the heating season, and it is also known as seasonal performance factor (SPF). In the equation described, HEER has a unit of "Btu/hr per W." It should be noted that 1 Btu/hr = 0.2928 W. Therefore, the relationship between HEER and SCOP can be expressed as in Eq. 6.

$$\text{SCOP} = \text{HEER} \times 0.2928 \tag{6}$$

Primary Energy Ratio

The HCOP provides a measure of the usefulness of the heat pump system in producing heat from work. It does not express the fact that energy available as work is normally more useful than energy available as heat. To assess different heat pump systems using compressor drives from different fuel or energy sources, the PER is applied. The PER takes into account not only the heat pump COP but also the efficiency of conversion of the primary fuel into the work that drives the compressor. PER is defined as in Eq. 7.[5] This can be also expressed as in Eq. 8.

$$\text{PER} = \frac{\text{Useful heat delivered by heat pump}}{\text{Primary energy consumed}} \tag{7}$$

$$\text{PER} = \frac{Q_{\text{H}}}{E_{\text{pe}}} = \frac{Q_{\text{H}}}{W} \cdot \frac{W}{E_{\text{pe}}} = \text{HCOP} \cdot \eta_{\text{pp}} \tag{8}$$

where Q_{H} is the load, E_{pe} is the primary energy used by the heat pump system, and η_{pp} is the power plant efficiency.

The drive energy of heat pumps is most commonly electricity. "Ideally a heat pump where free work is available should be contemplated e.g., wind or water power."[5] Consider an electric heat pump powered by a conventional power plant fueled by a non-renewable energy (see Figure 11). The power plant efficiency, η_{pp}, is up to 58% for oil- or gas-fired combined-cycle power plants currently available on the market. The PER is equal to the HCOP for direct power generation from renewable ambient energy sources such as solar and wind.[2] This concept is illustrated in Figure 12.

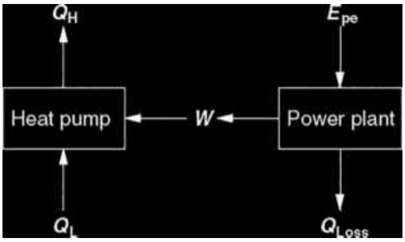

FIGURE 11 Energy flow of a conventional electric heat pump.

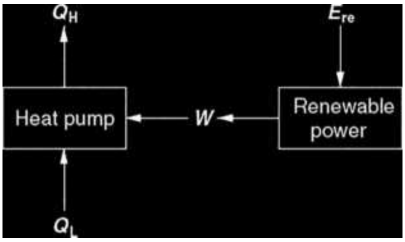

FIGURE 12 Energy flow of a renewable electric heat pump.

The amount of renewable or ambient energy spent (used up) to produce work for the heat pump is equal to the amount of work (i.e., $E_{re} = W$). For this case, by definition, $\eta_{pp} = 1$.[2] It should be noted that unlike the losses in a fossil fuel power plant, the unused ambient energy passing through the renewable power plant is still in the form of ambient energy and it is available to be used.

Ambient Energy Fraction

To make a fair systematic comparison of heat pumps and other systems that provide the same heat output, the term *AEF* was developed by Aye et al.[17] The term *solar fraction* is widely understood, accepted and used in the solar energy field. It is defined as the fractional reduction of purchased energy when a solar energy system is used.[18] It is the fraction of the load contributed by the solar energy, which can be calculated by Eq. 9.

$$f = \frac{L - E}{L} = \frac{L_s}{L} \tag{9}$$

where L is the load, E is the auxiliary energy supplied to the solar energy system, and L_s is the solar energy delivered.

Similar to the solar fraction of a solar system, the term AEF of a heat pump can be defined as the fraction of the load contributed by the ambient energy, which may be calculated as in Eq. 10.

$$\text{AEF} = \frac{Q_H - E_{pe}}{Q_H} = 1 - \frac{E_{pe}}{Q_H} = 1 - \frac{1}{\text{PER}} = 1 - \frac{1}{\text{HCOP} \times \eta_{pp}} \tag{10}$$

Figure 13 illustrates the relationship between the AEF and the PER.

Table 2 shows the AEFs of a heat pump, which has a HCOP of 3.5, for various electric power plants. It can be clearly seen from Table 2 that for the same heat pump, the AEF may vary from 1% to 71% depending on how electricity is generated for driving the heat pump compressor. The AEF for the renewable

electricity–driven heat pump is the highest (71%). The renewable energy used is only 29% (i.e., 100% – 71%) of the total thermal load. The energy use of the brown coal electricity-driven heat pump is 99% of the total thermal load (i.e., 0.99 MJ of brown coal energy is required for 1 MJ of thermal load). Table 3 shows the effect of heat pump COP on the AEF of a heat pump powered by a renewable source.

Heat Pump Applications

Heat pumps have been used for domestic, commercial, and industrial applications.

Domestic applications are as follows:

- provision of space heating
- provision of hot water
- swimming pool heating

Commercial and industrial applications are as follows:

- space heating
- water heating
- swimming pool heating
- drying and dehumidification
- evaporation and boiling
- desalination

Potential for the Use of Heat Pumps

In 2000, the primary energy used in buildings was 149 EJ, and the world total primary energy used was 387 EJ.[20] The building sector represented 38% of the total primary energy use and 34% of the total GHG emissions in 2000. Price et al.[20] reported that, in 2004, the emissions from the building sector, including the electricity consumed, were 8.6 Gt CO_2, 0.1 Gt $CO_{2\text{-e}}$ N_2O, 0.4 Gt $CO_{2\text{-e}}$ CH_4, and 1.5 Gt $CO_{2\text{-e}}$ halocarbons (including CFCs and HCFCs). These emissions arise from the following:

TABLE 4 GHG Saving Potential of Heat Pumps (Space Heating, Space Cooling, and Water Heating Applications) for the Building Sector

	2004	2010	2020	2030
GHG emissions from buildings (GtCO2-e)	6.5	7.5	9.6	12.4
Heat pump market share (%)	3	5	14	36
HCOP	3.5	3.7	4.1	4.5
Average power plant efficiency (%)	30	36	48	65
Global average PER	1.05	1.33	1.98	2.93
GHG saving (Mt CO2-e)	9	100	657	2911

- direct combustion of fossil fuels in residential and commercial buildings, amounting to 3.3 $GtCO_2$ (almost 1.7 $GtCO_2$ from combustion of oil, around 1.3 $GtCO_2$ from gas, and about 0.3 $GtCO_2$ from coal)[21]
- indirect or upstream CO_2 emissions from the demand of electricity and district heat were about 5.4 $GtCO_2$[21]
- combustion of biomass produces N_2O and CH_4 equivalent to 0.5 $GtCO_{2\text{-e}}$
- refrigerant or working fluid (halocarbons) leakages accounting for 1.5 $GtCO_{2\text{-e}}$

In 2004, about 60% of total GHG emissions generated by the building sector (6.5 $GtCO_{2\text{-e}}$ out of 10.7 $GtCO_{2\text{-e}}$) is estimated to be due to space heating, space cooling, and water heating. Heat pumps can meet these requirements in all types of buildings. Many low-temperature industrial heating requirements can also be met by heat pump technology. It is apparent that heat pumps have a large potential for saving energy and GHG emissions due to buildings. Energy and GHG saving potential of heat pumps can be estimated by using PER, one of the heat pump performance parameters presented. Table 4 shows the estimated GHG saving potential. The following assumptions were made for these estimations until 2030:

- annual GHG emissions growth rate for the building sector is 2.5%
- annual market growth rate for vapor compression heat pump is 10%
- HCOP improvement is 1% per annum
- annual global average power plant efficiency improvement is 3%

The GHG reduction potential of about 3 $GtCO_{2\text{-e}}$ in 2030 was estimated for the building sector alone. The IEA Heat Pump Centre reported a minimum of 0.2 $GtCO_{2\text{-e}}$ saving potential by industrial heat pumps in 1997, an estimation based on a study by project Annex 21. The total GHG reduction potential of 1.2 $GtCO_{2\text{-e}}$ was estimated in the year 2010 by IEA HPC. “This is one of the largest that a single technology can offer and this technology is already available in the market place.”[22]

Conclusions

The fundamentals of heat pumps have been presented together with the working principles of the thermoelectric heat pump, the absorption heat pump, the gas compression heat pump and the vapor compression heat pump. It should be noted that vapor compression heat pumps driven by electricity dominate the current market. Heat pumps are very energy-efficient and therefore environmentally benign compared to other available heating technologies. The technical and economic performance of a heat pump is closely related to the characteristics of the heat source.

Various performance parameters are available for comparing heat pumps; HCOP and HEER are the most widely used. PER and AEF can be used to compare various heat pump systems systematically and fairly. The AEF of an electric heat pump depends on the HCOP and the power plant efficiency based on the primary energy used. The AEF is highly dependent on the type of power plant used to generate the electricity that drives the heat pump compressor. Heat pumps driven by renewable electricity offer the possibility of reducing energy consumption significantly. In the future, the AEF may be used widely as a performance parameter of heat pumps since energy resource issues are becoming more important.

Acknowledgments

I wish to thank Emeritus Professor William W. S. Charters, former Dean of Engineering at the University of Melbourne, who introduced me to heat pump technology and for supporting my career and research in heat pumps.

Hydroelectricity: Pumped Storage

Jill S. Tietjen

Introduction

The dynamics of electric utility system operation are such that integrating large amounts of intermittent or variable renewable energy resources (such as wind and solar) will require energy storage mechanisms. Wind and solar resources are weather dependent—they generate power when the wind blows or the sun shines—they are often unavailable at times when the electric utility's requirement for power is at or near peak levels. Wind generation is often at its peak output when the requirement for electricity is at or near its lowest levels. Pumped storage hydro is a commercially available technology that has been in use for more than 100 years to provide generation when it is most beneficial. The operational benefits of pumped storage hydro enhance the ability of the power system to accommodate renewable generation while meeting reliability requirements. These benefits will allow renewable generation to become a more significant portion of electric utility generation portfolios around the world.

This entry describes the dynamics of utility system operation. This is followed by information on wind and solar renewable energy resources and the historical experience with how and when the wind blows and the sun shines, enabling these resources to produce electricity. An overview of various energy storage mechanisms is provided, followed by a more in-depth discussion of pumped storage hydro. Information on how electric utilities use pumped storage hydro is followed by a discussion of how pumped storage hydro can be integrated with and provide benefits for renewable energy resources.

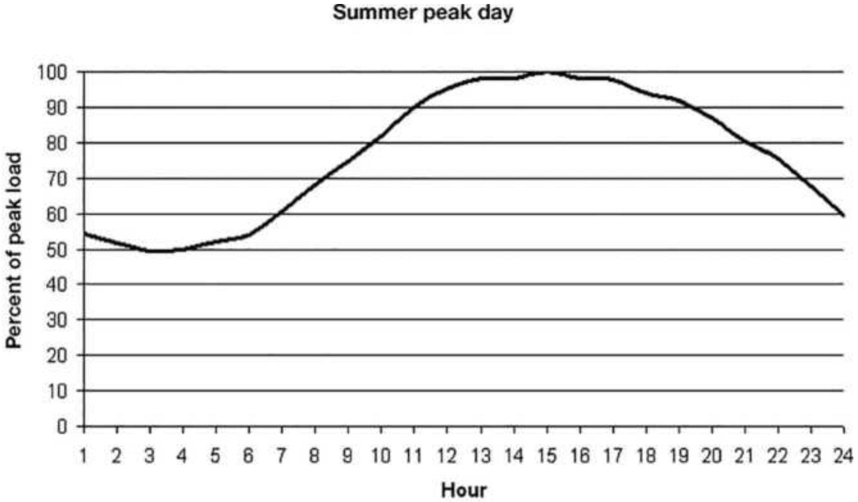

FIGURE 1 Electric customer demand—summer peak day.

Dynamics of Utility System Operation

Demand for electricity is constantly changing—with the hour of the day, the season—and it is dependent on customer behavior. Heating and cooling needs of consumers comprise a significant portion of the demand for electricity. Electric system operators balance the demand for electricity with its supply as electricity has to be used as soon as it has been generated. Generally, there is a greater demand for electricity in the summer (hot temperatures) and winter (cold temperatures) than in the more moderate temperatures associated with the spring and fall. In the aggregate, customers use more electricity during the day and less at night (see Figure 1 where 1 A.M. is hour 1, noon is hour 12, and midnight is Hour 24). Demand patterns change from minute to minute and from one hour to the next. Power system operators must manage the changes that occur with each of the demand fluctuations to balance the system and keep the lights on.[1,2]

Hour-by-hour changes in demand are normally managed by increasing or decreasing the set of resources that need to be operating to meet demand in that hour (unit commitment). Minute-by-minute fluctuations in demand are managed by directing the more flexible resources to increase or decrease their output. Every few seconds, system operators change the generation on specific generating units up or down to keep the system in balance.[1] By balancing fluctuations between supply and demand, system operators provide an ancillary service referred to as regulation. Some generating units, such as combustion turbines and conventional hydroelectric power, are particularly suited for providing regulation as they can operate across a wide range of generating levels. Baseload coal-fired units and nuclear units generally cannot operate with this level of flexibility. Highly variable generation resources such as wind and solar require a significant increase in the regulation capability of on-line generating resources in order to establish the required real-time balance between generation and demand.[3]

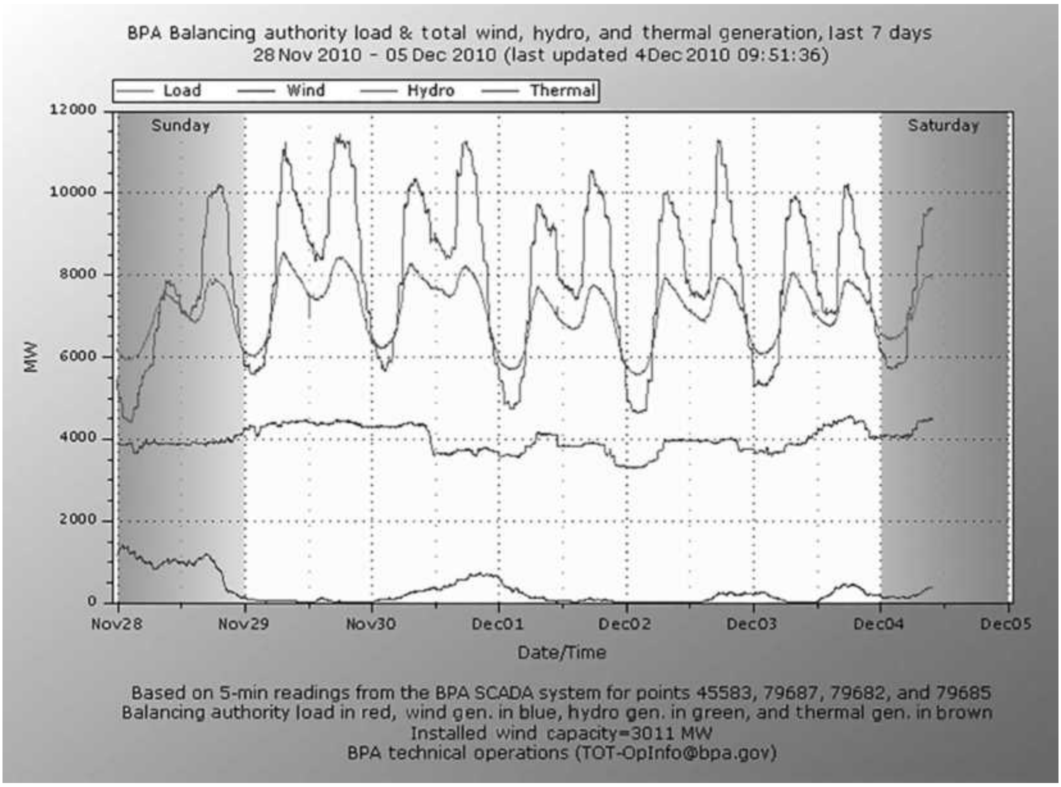
Wind and Solar Resources

Renewable energy resources other than hydroelectric are appearing in more and more utility generation portfolios in significant numbers. This trend is being driven by efforts to reduce carbon emissions and other greenhouse gases worldwide and by specific regulatory or other mandates to increase the percentage of capacity and the energy generated by these renewable resources. Due to advances in technology, tax incentives, and cost reductions, wind resources and solar resources are becoming ever more common.

However, these two types of technology present a major challenge to the operators of utility systems: they only generate electricity when the wind blows or the sun shines but electric load and electric generation must be balanced at each instant from on-line generation. The system cannot absorb or provide extra energy beyond the generating resources operating at any given time. Thus, when the wind dies down or the sun goes behind a cloud, the electric utility must have another generation resource ready and able to provide backup electricity almost instantaneously. Due to the variability of the electric generation from these resources, solar and wind resources are often referred to as intermittent resources. Solar resources generate electricity during the daylight hours. However, the sun is most intense around noon whereas the peak demand for electricity generally occurs in the evening hours in the summer and in a bimodal manner (early morning/evening) in the winter. These patterns mean that the peak availability of solar energy does not occur at the same time as the utility peak; the term used for this by the industry is *non-coincident.*

Wind resources tend to be much more non-coincident with a utility's peak demand than solar resources (see Figure 2).[4] In fact, wind energy resources often peak at night when the electricity demand is at its lowest levels.[5]

Energy storage technologies offer a way to continue the encouragement of the development of wind and solar resources to maximize the value of the energy they provide and to enable the electric utility system to operate reliably once those resources have been added.



BPA Balancing authority load & total wind, hydro, and thermal generation, last 7 days
28 Nov 2010 - 05 Dec 2010 (last updated 4Dec2010 09:51:36)

Storage Technologies

Energy storage technologies are expected to play an important role in the integration of intermittent resources into the electricity grid worldwide. Energy storage involves a device that accepts electrical energy from the grid, converts it into an energy form suitable for storage, and then converts it back into electricity, which then, minus efficiency losses, is returned to the grid. Energy storage enhances the performance and economics of the power system, as it allows the capture and storage of renewable energy resources for later use, thus preserving resources. Energy storage can also be a valuable instrument for providing operational flexibility.[2,6]

Technologies that provide the ability to store intermittently generated power can smooth out the variations in the hour-by-hour, minute-by-minute, and second-by-second availability experienced by wind and solar resources. Energy storage can increase the usefulness of wind power by absorbing excess wind generated overnight and supplying that power to the grid during peak daytime hours. It can also help grid operators deal with the second-by-second variability of wind and solar by providing additional regulation service.[5]

Energy storage technologies also can help utilities provide the power quality and reliability required by increasingly complex and sensitive equipment. Energy storage devices improve system responsiveness, reliability, and flexibility, while reducing capital and operating costs for both suppliers and customers. Suppliers can use energy storage for transmission line stabilization, spinning reserve, and voltage control, which means customers would receive improved power quality and reliability.[7]

Many generating resources cannot be shut down during the off-peak period and must be kept in operation at minimum levels. For some utilities, a particular challenge is having more resources that must be kept operational during off-peak hours than the level of load demanded from customers. Energy storage technologies provide a sink for this minimum load energy. In addition, some energy storage technologies, such as pumped storage hydro, can actually provide load when needed to meet system minimum generation requirements.

In total, benefits of energy storage technologies include the following:[8]

- Enhancement to the value of intermittent renewable energy resources on the power grid by firming their energy.
- Improvement in power quality by providing ancillary services such as voltage regulation, spinning resources, and so forth.
- Ability to store low-value, excess energy when power supplies exceed demand until the energy can be economically used to meet load.
- Enhancement of the flexibility of the existing transmission grid.
- Relief of transmission congestion to defer capital expenditures on system upgrades.
- Conversion of less costly off-peak energy into higher- value on-peak power.
- Reduction of problems associated with minimum generation requirements.

The types of energy storage technologies in service and being evaluated worldwide include the following:[9–11]

- Batteries: sodium-sulfur (NaS), vanadium redox flow (VRB), lithium-ion, lead-acid, nickel-cadmium, nickel-metal hydride, zinc-bromine
- Pumped storage hydro
- Compressed Air Energy Storage (CAES)
- Electric double-layer capacitors
- Superconducting Magnetic Energy Storage (SMES)
- Flywheel systems
- Thermal

TABLE 1 Energy Storage Technology Development Status

Commercial	Precommercial	Demonstration Phase	Developmental
Pumped storage hydro		Electrochemical capacitor	Lithium ion (grid applications)
		Flywheel	
Flywheels (local power quality)	Flywheel (grid device)	Hydrogen loop	SMES (grid applications)
CAES		Zinc-bromine battery	
Lead-acid battery (distribution level)		Vanadium redox battery	
Nickel-cadmium battery (distribution level)			
NaS battery (distribution level)			

- Regenerative fuel cells
- Hydrogen

The commercialization status of each of the energy storage technologies is shown on Table 1.[12,13]

The technology that presents the largest scale for utility application (up to 1000 MW), is able to handle large quantities of energy, and is already in the most widespread use is pumped storage hydro.[14,15]

Pumped Storage Hydro

Pumped storage hydro is a form of hydroelectric power generation for electric utilities that incorporates an energy storage feature.[16] The water, the source of potential and kinetic energy, moves between two reservoirs—an upper and a lower one—with a significant vertical separation (see Figure 3).[17] Water is stored in the upper reservoir until such time as the utility determines it is economic to use it to produce electricity for the system. The water in the upper reservoir is stored gravitational energy.[18] When the water is released, the force of that water spins the blades of a turbine that connects to a generator that produces electricity.[19]

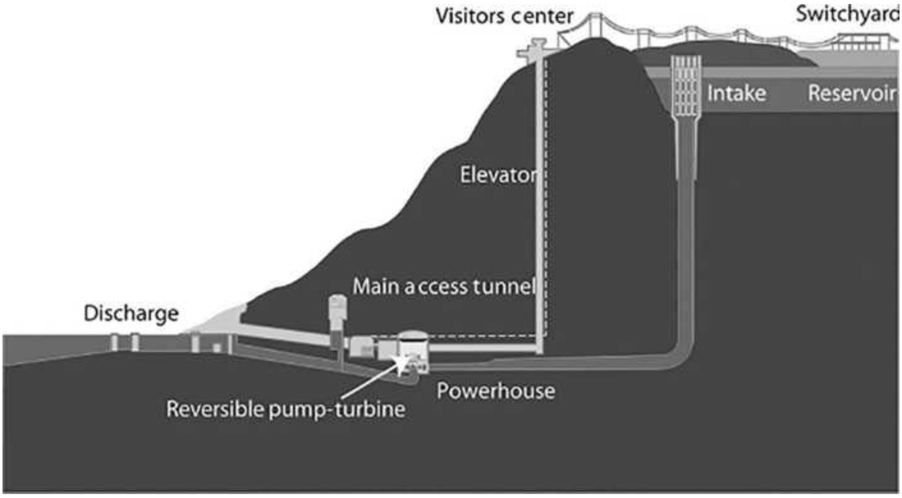

FIGURE 3 Schematic diagram of pumped storage hydro.
Source: Courtesy of the Tennessee Valley Authority.

Water is generally released from the upper reservoir to produce electricity during peak hours or during times of system need. After passing through the turbines, the water is discharged into the lower reservoir. At night and on weekends or during light load or off-peak hours, water is pumped up from the lower reservoir into the upper reservoir by the turbines that have now been reversed to work as electric-motor-driven pumps. Figure 4 shows the upper and lower reservoirs of the Rocky Mountain Hydroelectric Plant in Georgia, United States.

In the upper reservoir, the water is essentially stored energy. Water can be stored for a long time or a short time in the upper reservoir, depending on the needs of the utility (see Figure 5 for a view of the upper reservoir of the Taum Sauk Project in Missouri, United States). A vertical separation of at least 100 m (328 ft) is generally necessary to make a pumped hydro facility economic.[20] This height difference between the upper and lower reservoirs is called the head. The amount of potential energy in the water is directly proportional to the head, so the greater the height, the more energy that can be stored in a reservoir of a given size.[16,21]

Pumped storage hydro is the most widespread energy storage system in use on power networks. Its main applications are for energy management, frequency control, and provision of reserve. Pumped hydro storage may make use of any generating resource on the system. It can be used to absorb temporary generating surpluses, to capture economic energy resources that would otherwise not be utilized, and to allow other generating resources to stay on-line by meeting their minimum generating requirements.[22]

Innovations in variable speed motors have helped these plants operate at partial capacity and greatly reduced equipment vibrations, increasing plant life.[23] Efficiency of any specific pumped storage facility, which is primarily dependent on the height between the upper and lower reservoirs, ranges from 70% to 85%. Many of the proposed pumped storage projects in the United States are off-stream from main stem rivers and either use existing reservoirs or are completely closed-loop projects. As such, the environmental impacts resulting from new pumped storage projects are significantly less than traditional large conventional hydroelectric power projects.[24]

Pumped storage hydro was first used in Italy and Switzerland in the 1890s to enable those utilities to store surplus nighttime output from run-of-river hydro stations for use in meeting their peak power demand requirements the following day. In 1929, the first major pumped storage hydroelectric plant, Rocky River, was built in the United States in New Milford, Connecticut. By 1933, reversible pump turbines with motor generators had become available. The turbines could operate both as turbine generators and, in reverse, as electric-motor-driven pumps.[24–26]

About 3% of total global generation capacity, over 127 GW, is pumped storage capacity. In 2010, the European Union had nearly 40 GW of pumped storage capacity in operation. In 2010, 42 projects provided more than 23 GW of pumped storage capacity in the United States. The largest pumped storage facility in the United States is in Bath County, Virginia, which has a capacity of 2100 MW. Pumped storage plants are characterized by long construction times and high capital expenditures.[27–30]

Technology Description

In conventional hydroelectric generation, hydraulic turbines rotate due to the force of moving water (its kinetic energy) as it flows from a higher to a lower elevation. This water can be flowing naturally in streams or rivers or it can be contained in man-made facilities such as canals, reservoirs, or pipelines. Dams raise the water level of a stream or river to a height sufficient to create an adequate head (height differential) for electricity generation.[31]

If the dam stops the flow of the river, then water pools behind the dam to form a reservoir or artificial lake. As hydroelectric generation is needed by the electric utility, the water is released to flow through the dam and powerhouse. In other cases, the dam is simply built across the river and the water in the river moves through the power plant or powerhouse inside the dam on its way downstream.[32] This latter type of hydroelectric facility is referred to as run-of-river.

In either case, as the water actually moves through the dam, the water pushes against the blades of a turbine causing the blades to turn. The turbine converts the energy in the form of falling water into rotating shaft power to turn a generator to produce electricity. The mechanical efficiency of hydroelectricity is high, about 95%. Availability of the generators is about 90%.[32–34]

The selection of the best turbine for any specific hydroelectric site is primarily dependent on the head (the vertical distance through which the water falls) and the water flow (measured as volume per unit of time) available. Generally, a high-head plant needs less water flow than a low- head plant to produce the same amount of electricity.[33,35]

The power available in a stream of water is

$$P = \eta^{*}\ \rho^{*}\ g^{*}\ h^{*}\dot{V},$$

Where η is turbine efficiency, ρ is power (joules per second or watts), g is acceleration of gravity (9.81 m/sec^2), h is head (meters, this is the difference in height between the inlet and outlet water surfaces), and $\dot{V}$ is flow rate (cubic meters per second).[36]

This equation can be roughly approximated as:

$$\text{POWER}(\text{kW}) = 5.9 \times \text{FLOW} \times \text{HEAD},$$

where FLOW is measured in cubic meters and HEAD is measured in meters.[37] In general terms, 1 gal/sec falling 100 ft can generate 1 kW of electrical energy.[38]

Hydroelectric power is generally found in mountainous areas where there are lakes and reservoirs and along rivers. Hydroelectric power currently provides about 10% of all of the electricity produced in the United States. Hydroelectricity provides about one-fifth of the world's electricity. Worldwide capacity of all hydroelectric capacity as of 2008 was approximately 850,000 MW.[32,38,39]

Producing electricity from hydropower is so economical because once the dam is built and the equipment has been installed, the flowing water has no cost. In addition, the dams are very robust structures and the equipment is relatively mechanically simple. Hydro plants are dependable and long lived, and their maintenance costs are low compared to most other forms of electricity generation, including fossil-fired and nuclear generation.[35] Traditional hydroelectric power once comprised almost 40% of U.S. electricity production. Due to land use issues in developed areas, the potential to build additional traditional hydroelectric facilities is limited and their relative contribution to the generation portfolio in the United States will continue to decrease. There is a significant effort in the United States to explore the utilization of existing dams and infrastructure to add power at dams that currently do not have associated electricity generation. At present, there are approximately 80,000 dams in the United States, of which about 2400 have powerhouses. Pumped storage hydro generation facilities capture many of the system benefits associated with traditional hydroelectric power.

Pumped storage hydro generation is a specific kind of hydroelectric generation requiring an upper and lower reservoir and special equipment that can both generate power as water flows downhill and then reverse and serve as a pump to move the water back uphill. This requirement for location in suitable topological areas limits the geographic flexibility of pumped storage hydro and, at least in Europe, means that most cost-effective sites have already been developed. Some existing conventional hydropower dams are, however, being upgraded with pumped storage capacity. In addition, seawater pumped storage facilities are being examined and a pilot project in Japan has been developed to research the feasibility of using seawater as opposed to freshwater.[40] Modular pumped storage systems, discussed in the next section, may provide additional siting opportunities.

Facility Description

A pumped storage hydropower plant typically has three major components: the upper reservoir, the lower reservoir, and the pumping/generating facilities (see Fig. 3). The water from the upper reservoir used for electricity generation is allowed into the intake shaft through the opening of the headgates. Water moves through the high-pressure shaft and steel-lined power tunnel until it reaches the turbines in the powerhouse.[16] The water turns the turbines that then drive the generators to produce electricity. The water then moves through the tailrace tunnel until it is discharged into the lower reservoir. Water discharge capacity in the upper reservoir can require from several hours to several days.[24]

Pumped storage facilities can be categorized as "pure" or "combined." Pure pumped storage plants, also referred to as closed loop, continually shift water between an upper and a lower reservoir.[29] Combined pumped storage plants also generate their own electricity like conventional hydroelectric plants through natural steam flow. Closed-loop pumped storage systems use closed water systems that are artificially created instead of natural waterways or watersheds and can be as large as traditional large hydroelectric power stations. The water for closed-loop storage usually is only put into the system when it begins operation, either from groundwater or possibly from municipal wastewater.[31,41] Old iron ore quarries and other types of old mines are being examined for use as reservoirs for closed-loop systems worldwide.[42,43]

The efficiency of pumped storage plants generally ranges from 70% to 85%. This means that 70–85% of the electrical energy used to pump the water into the upper reservoir is actually generated when water flows back down through the turbines to the lower reservoir. The losses of energy are primarily related to the mechanical efficiency losses during conversion from flowing water to electricity. Such losses are higher with older designed equipment.[41]

Today, there are three kinds of pumped storage hydro plants available. The most commonly used is a basic version utilizing single or synchronous speed machines that cannot be regulated in pump mode. The pumps can only be run at full capacity or not run at all. Some of these plants use a combined pump and turbine unit instead of two separate units. The compact size of the equipment is beneficial when the plant is built underground.[44]

The second type of pumped storage hydro facility is called "hydraulic short circuit," which allows more flexible operation. Pumps and turbines can be operated simultaneously. The pump can still only operate at full capacity. When large amounts of excess electricity are available, the turbine reduces capacity and more water is stored.[44]

The third type of plant uses variable speed pump technology in order to quickly adapt to fluctuating grid frequency. The operator is able to control how much power is consumed by the pumps. This type of pumped storage plant can experience a round-trip efficiency of 85%.[45]

Environmental Issues

Issues related to permitting of conventional hydroelectric and on-steam pumped storage hydroelectric facilities include factors relating to establishing both the reservoirs themselves and the operation of the facilities. Establishing the reservoirs may involve flooding of land currently in use for other purposes. During operation, the level of the water in both the upper and lower reservoirs fluctuates, which can lead to environmental concerns as well:[46]

- Water resource impacts—stream flows, reservoir surface area, groundwater recharge, water temperature, turbidity, oxygen content
- Biological impacts—displacement of terrestrial habitat, alteration of fish migration patterns, other impacts due to changes in water quality and quantity
- Potential damage to archaeological, cultural, or historic sites
- Visual quality changes
- Loss of scenic or wilderness resources
- Increased risks of landslides and erosion
- Navigation impacts
- Gain in recreational resources

These concerns are much less significant for closed-loop pumped storage plants that are not associated with natural waterways and watersheds. Usually, closed-loop pumped storage plants are specifically not located near existing rivers, lakes, streams, and other sensitive environmental areas to avoid the regulatory lag time and complexity associated with combined pumped storage hydroelectric facilities.[31,46]

In addition to closed-loop systems, underground powerhouses and lines are being used around the world to mitigate the environmental effects of pumped storage projects and reduce visual surface disturbances.[26]

TABLE 2 Countries with Pumped Storage Installed or under Construction

Argentina	India	Slovakia

Installed Facilities Worldwide

Pumped storage facilities are currently installed in many countries around the world (see Table 2) and numerous new facilities are under construction.[27,47]

Electric Utility Usage of Pumped Storage Hydro

Pumped storage facilities use power from available generating resources to pump water into the upper reservoir when it is cost-effective to do so (often at night). This allows the utility to have the water to use during higher load periods the next day to generate electricity at the pumped storage facility. Figs. 6 and 7

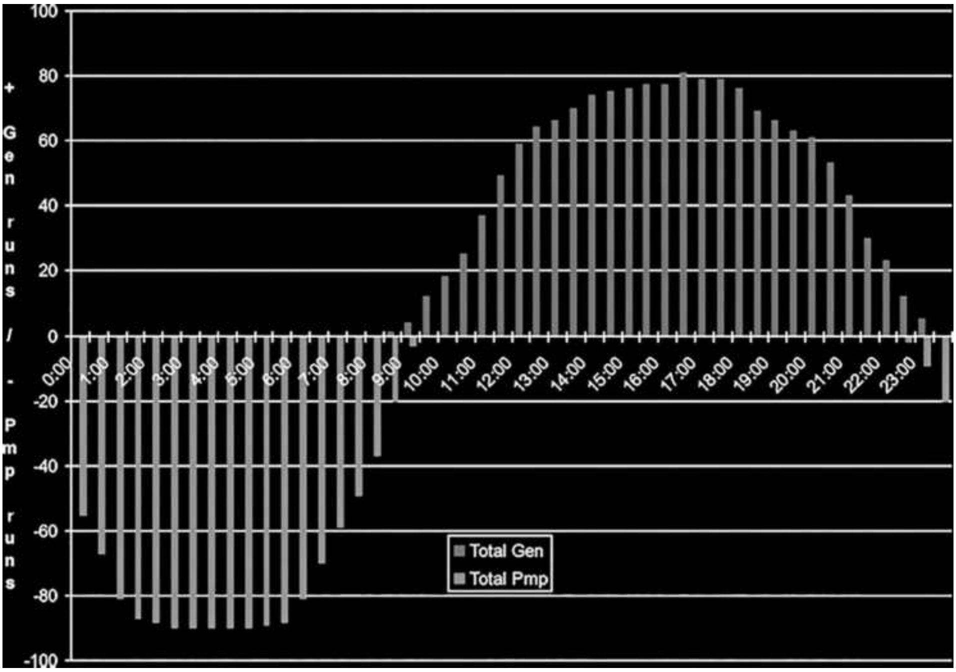

FIGURE 6 Pumped storage unit—typical summer operation.
Source: Courtesy of Oglethorpe Power Corporation.

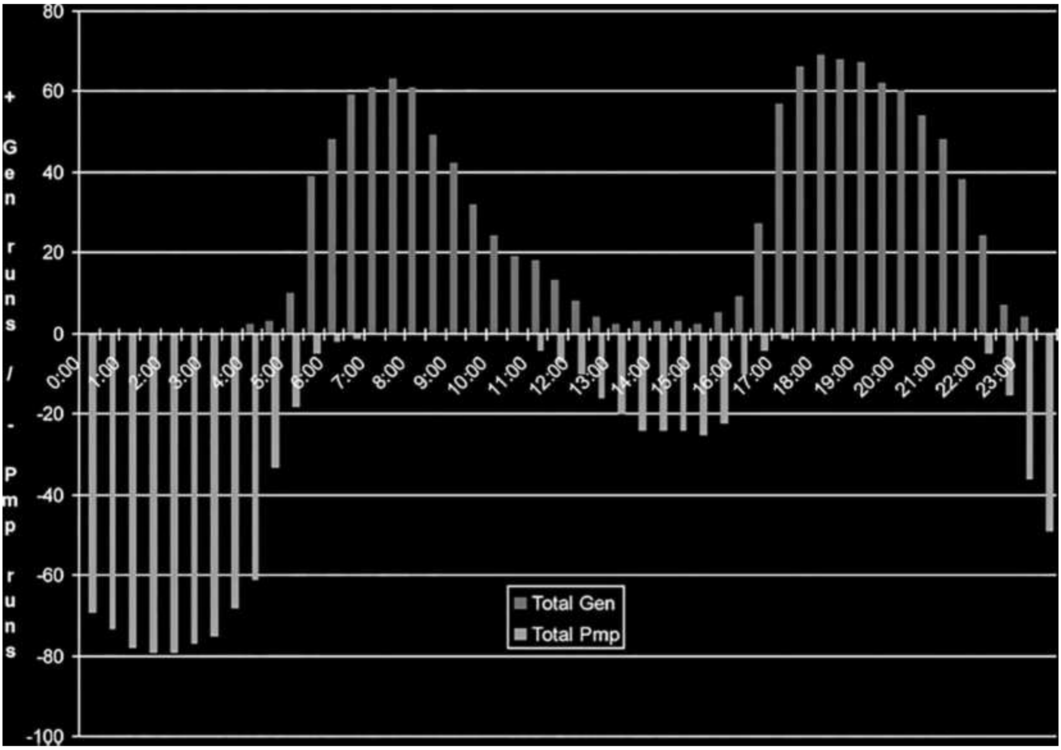

FIGURE 7 Pumped storage unit—typical winter operation.

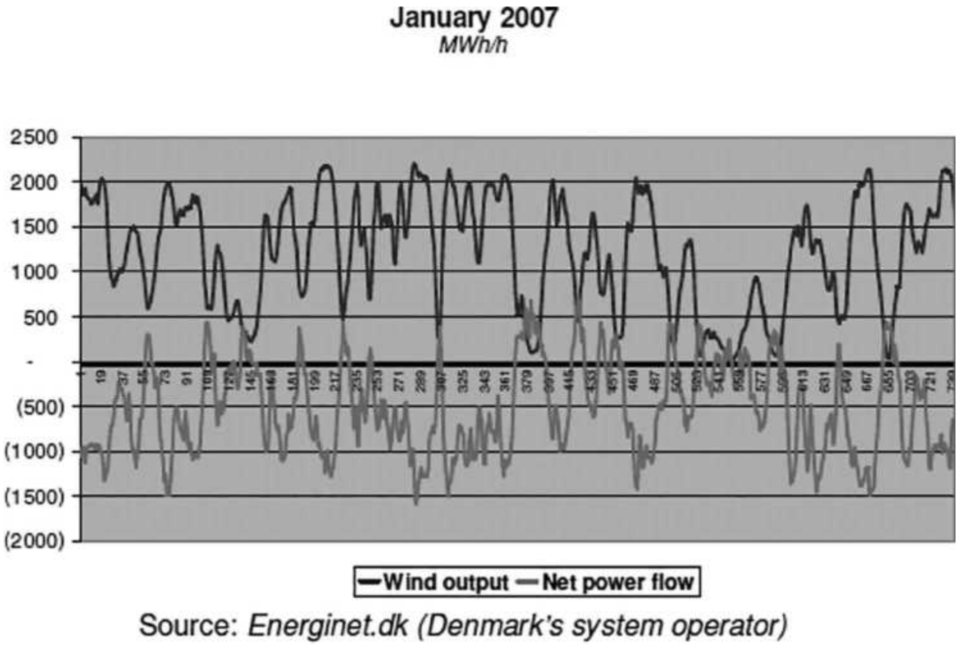
show the typical operational patterns for pumped storage usage by a utility in each of the summer and winter periods. Power is generated by the pumped storage facility during the higher load hours across all seasons and pumping occurs in the off-peak hours and lower load hours.

Conventional hydroelectric power and pumped storage are actively being used as energy storage for Danish wind generation. Electricity from wind turbines in Denmark is stored in Norway's and Sweden's large, conventional storage reservoirs and then is sent back to Denmark during periods of low wind generation.[48–50] Pumped storage hydro projects in Germany are also critical to maintaining grid reliability and stable power flows within Denmark. Denmark has no native load balancing, so those balancing services are provided via its interconnections with Germany, Norway, and Sweden.[11] The curves in Fig. 8 demonstrate the non-coincident behavior of the wind generation versus the load demand from January 2007.[51]

How Pumped Storage Hydro Can Benefit Renewable Energy Resources

Pumped storage hydro is one of the best available energy storage mechanisms for use on electric utility systems. Pumped storage hydro allows utilities to integrate renewable energy resources such as wind and solar and helps to optimize the operation of the utility grid. Pumped storage hydro helps utilities achieve maximum efficiency for the power-generating system through load shifting. The ability for fast ramping provides a myriad of benefits from serving as spinning reserve to maintaining power system stability to providing voltage control.[52] Pumped storage hydro units can perform black starts and



Source: Energinet.dk (Denmark's system operator)

FIGURE 8 Western Denmark—wind output and net electricity flows.

deliver electricity within a few seconds. Modern pumped storage plants have the highest efficiency of all energy storage systems— 85%.[3,44]

Because of their ability to both pump and generate, pumped storage hydro units provide a load-shifting device for system operators. Pumped storage hydro can firm intermittent resources by absorbing excess generation at times of high output and low demand and releasing that stored energy during peak demand periods. Pumped storage hydro units can help systems avoid minimum generation problems and serve as critical backup facility during periods of excessive demand on the grid system.[3,30,53–56] Pumped storage hydro provides system operators a variety of ways to help balance portfolios from rapid starts and stops to generation in peak load hours.

Pumped storage hydro can move from idle position to full load very quickly, often in seconds, if so designed.[53,57]

This capability allows pumped storage units to provide system frequency control, regulation, and voltage control and to compensate promptly for the loss of other generating units or transmission lines. It allows pumped storage units to count for spinning reserve and standby reserve/ black start units. Typical ramping characteristics of modern pumped storage projects are as follows:[58]

• Shutdown to on-line	60–90 sec
• On-line to full-load generating	5–15 sec
• Spinning to full-load generating	5–15 sec
• Shutdown to normal pumping	6 min
• Spinning to normal pumping	60 sec

Rapid ramping is particularly desirable in the case of a unit becoming unavailable or forced out of service or on utility systems with high amounts of intermittent resources such as solar and wind. For example, the Dinorwig pumped storage facility in North Wales, United Kingdom, can go from 0 MW to full capacity of 1320 MW in 12 sec and can usually maintain this level until other generating units on the utility's system can be brought on-line. This makes pumped storage plants the "race cars" among power-generating facilities.[16,20,41,59] Pumped storage hydro projects can charge or discharge over a 2, 6, or even 12 hr period, as necessary for the utility. The Dinorwig station in North Wales, for example, has an energy storage capacity equivalent to about 5 hr of operation at full capacity. Most of Japan's modern pumped storage projects have energy storage capacity equivalent to 6 to 8 hr of operation at full capacity. The upper reservoirs for many of Japan's pumped storage projects are designed for long-term seasonal storage and drawdown.[26,53]

The dynamic, rapid response capabilities make pumped storage hydro highly valuable for keeping electrical grids stable and reliable with higher percentages of renewable resources, especially as pumped storage hydro can provide both real and reactive power.[59] The ability of pumped storage hydro to produce watts (real) and vars (reactive) power enables system operators to better ride out any system disturbances such as the loss of a major generating unit or transmission line or the significant instantaneous increase or decrease in available energy from renewable resources.

Pumped storage hydro contributes no greenhouse gas emissions and thus assists utilities, and countries, achieve a lower carbon footprint. Utility systems that utilize pumped storage units are also able to operate their thermal units more efficiently—with fewer stops and starts—also contributing to overall reduced emissions.[53,60]

Depending on its location, pumped storage hydro may help optimize transmission line loadings and defer the need for additional transmission assets. Pumped storage units near load centers can operate in condenser mode to generate or absorb reactive power as may be required for system voltage regulation.[53,60]

Conclusion

Energy storage devices in the form of pumped storage hydro facilities offer many benefits to utilities including the integration of the intermittent renewable resources—wind and solar. Due to the weather-dependent nature of these renewable resources and the fact that much wind generation is non-coincident with utility peak demands, pumped storage hydro provides a way for utilities to utilize the renewable resources more efficiently and more cost-effectively. Where topologically feasible, the reliability benefits associated with the rapid ramping capabilities of pumped storage hydro, in conjunction with the many other positive operational capabilities, will drive development of this energy storage technology worldwide for many years to come.

Integrated Energy Systems

Leslie A. Solmes
and Sven Erik
Jørgensen

Introduction

On August 6, 2003, the Board of Governors of the Electric Power Research Institute reported, "… there is a growing concern that the electricity sector's aging infrastructure, workforce, and institutions are losing touch with the needs and opportunities of the 21st Century. The investment gap—inadvertently reinforced by the regulatory uncertainty of electricity restructuring—is exacting a significant reliability cost that is seen as just the tip of the iceberg in terms of the electricity infrastructure's growing vulnerability to capacity, reliability, security, and service challenges."[1]

On August 14, 2003, the northeast United States experienced power failure that impacted 50 million consumers in the United States and Canada. The front page of the *Financial Times* stated, "Public to pay for power upgrade. Energy Secretary (Spencer Abraham) warns that much of the $50bn (billion) bill will be passed on to customers." The headline that followed on page 3 was, "Failure of the power came as little surprise to experts. Wake-up call was just latest alarm."[2] Energy supply investments are needed, but the public cost for energy should decline.

What does not get front-page headlines are the billions of dollars needed to upgrade unreliable, old, customer energy supply production and distribution systems like heat, air conditioning, and water. One example is APPA: The Association of Higher Education Facilities Officers. APPA reported in 1995 that the backlog of deferred maintenance for colleges and universities was $26 billion.[3] The major portion of this backlog was needed for utility systems upgrades. The problem has not gone away.

Investments in electricity generation and transmission systems are essential for social and economic well-being. Upgrade and expansion of customer production and distribution systems are equally essential and costly. These needs are not problems but opportunities—*huge investment opportunities.*

Electric utilities are large industrial customers who use massive amounts of energy—more than any other industry. The second law of thermodynamics states that every time one form of energy is converted into another form, some energy is lost. On average, two-thirds of the British thermal unit (BTU) value of the fuels used to produce electricity is thrown away as waste heat. More BTUs are lost in converting and transporting electricity to consumers. Consumers, in turn, convert electricity to heat energy to heat water, heat buildings, and cook. Consumers also burn fuels to produce heating, cooling, and process steam and distribute it to the end use. Every conversion and transportation event causes BTU loss.

The opportunity to save energy in producing and transporting electricity, heat, steam, and chilled water is enormous. However, it requires utilities and customers to plan and invest together. Investing in reliable electricity that is efficient, competitive, and environmentally friendly, and that offers the greatest financial benefits to utilities and their customers is directly related to how utilities and customers select, implement, and manage investments in electric, heat, and cooling capacity and dispatching of all forms of energy.

A comprehensive, integrated energy supply investment assessment at Illinois State University (ISU) offers a case study of the financial opportunities and energy savings for both ISU and the electric utility. Investment implementation roadblocks related to cultural practices and risk aversion are discussed. Through use of an integrated, energy supply system investment methodology adapted from development of independent power plants and a Web-based business plan software tool, incentives to overcome cultural inertia and manage life-cycle project risks are detailed. Examples of dynamic Web-based reports serve as a communication medium among the project team members and allow them to conduct real-time asset management. Finally, profits from electric utility and customer collaboration are highlighted.

Integrated Solution

Imagine if electric utilities could reduce the number of new plants and transmission facilities and instead invest in customer heating, cooling, process steam, or other heat energy needs with on-site electricity generation and load shifting technologies. Imagine that both utilities and consumers could benefit financially by integrating their energy supply investments and reducing the amount of energy consumed.

Culturally, electric utilities and customers have diametrically opposed business goals. Utilities want to sell the most energy at the highest price possible. Customers want to purchase the least amount of energy to reliably meet their operating requirements at the lowest cost. Investments in integrated energy supply systems not only create energy efficiency and emission reduction but also result in economic benefits to both utilities and consumers. Let us use a case study from ISU to demonstrate how to create valuable investment for both utilities and customers.

In 1999, ISU determined that they could fix their facilities operating budget at their 1997 level for 20 years by investing $37.56 million in utility and building systems infrastructure upgrades. Annual budget savings were conservatively estimated to be $3.45 million per year with debt service at $3 million. Net present value ranged from $8.7 to $13 million.

Five megawatts of on-site electricity generation was planned. Using the waste heat and load shifting technologies, electricity load was leveled and reduced by 3.2 MW. The electrical capacity addition to the grid was 8.2 MW. More than half of the waste heat from electrical generation became useful energy. Owing to ISU's level load, the utility was able to gain greater use of its existing power plants by supplying the remaining electricity required by ISU on a 24/7 basis.

History

For nearly 30 years, the development of energy business plans, using an integrated systems methodology with investments sized to meet the business goals of the end users, has demonstrated the ability to:

- Finance millions of dollars of infrastructure upgrades from operating budget savings
- Level electricity load requirements
- Reduce BTU consumption and unit costs
- Improve energy reliability and operating productivity

So why were so few of these opportunities implemented? Customers are not in the utility business. Instead, they are focused on investments that provide products and services. As a result, no energy savings or investment occurs.

More importantly, the problem has been, "How to communicate and manage risks?" How to insure risks associated with energy price escalation, building the project on time and budget, costs of financing and ownership, equipment performance, and changes in business goals can cause major headaches. What business manager in his or her right mind would risk his or her career on a performance-based investment that cannot be measured or managed?

At the same time, as customers were struggling to update their heat/steam and cooling systems, electric utility generation investments almost stopped. The risks associated with building central electricity generation plants on time and budget, the rising cost of financing, the uncertainty of the regulatory world, and competition from independent power producers strangled central power plant development.

On both sides of the meter, risks associated with energy systems investments caused inaction. Investing in efficient energy supply systems requires integration. Integrated investment in a dynamic marketplace demands that all stakeholders have the ability to measure, manage, communicate, and report project status at any point in time.

Stakeholders

An energy supply investment team or stakeholders include the following: chief executive; financial, budget, facilities, and utilities managers; engineering, procurement, construction, capital planning, maintenance, and information technology personnel; contractors; facility occupants; financiers; and investment partners. Every member of the team contributes to the assumptions that go into energy supply systems planning and implementation.

Once energy master plan assumptions are adopted, each team member now knows the complete game plan and his or her performance requirements. As the plan is implemented and measured over time, each team member is responsible for communicating changes that will occur. Instantaneously, the impact of these changes on the total project performance and each team member's area of responsibility must be calculated, compared with the original plan, and reported to all team members. Team members can, in turn, adjust and manage their area of responsibility.

Web-Based, Real-Time Communication and Reports

To conduct the investment communication necessary to manage energy investments, it is essential to conduct energy planning, investment, and asset management using a dynamic, Web-based tool. The tool should not only compare project investment options but also provide timely updates of business plan assumptions based on market changes so that all project team members can communicate and manage change. Businesses and organizations require adoption and commitment to an operating software system that is their master business planning and asset management standard. Web-based workflow connects all the elements of integrated energy systems needed to manage market and business interactivity and create the lowest energy unit cost at the highest reliability.

Using the ISU project, let us look at the kinds of reports that team members will need to see. Presented here are five examples: Executive Summary, Pro Forma, Cogeneration, Steam, and Chilled Water Operating Calculations. Note that although the ISU project includes cogeneration, each consumer is encouraged to assess all on-site generation options that apply to the facility/site situation.

Table 1 and Figure 1 are life-cycle examples of a preliminary engineering, implementation, and financial assessment of an infrastructure investment strategy for ISU. This project analysis was conservatively conducted and included all campus buildings and utility systems. In summary, the

TABLE 1 ISU Executive Summary

Executive Summary			
Illinois State University - Test Case 3			
Current utility budget			$7,833,897
Energy cost savings			
Facility efficiency recommendations			$1,264,034
Electrical generation			$1,880,989
Steam production			$392,913
Chilled water production			$(89,549)
Water			$0
	Total utility budget savings	$3,448,386	
	Percent of current utility	**44.02%**	
Project costs			
Facility efficiency recommendation			Electrical generation $3,595,110
	$2,625,000		
Steam systems			$4,260,000
Chilled water systems			$10,707,100
Infrastructure			$7,100,000
Engineering/contingencies			$5,657,442
Additional project costs			$2,069,200
	Total EPC cost	$36,013,851	
	Annual debt service	$3,049,409	
	Energy budget savings: Debt service	**113.08%**	
Unit energy costs			
Average cost for purchased electricity			$0,046 /kWh
Average cost for cogenerated electricity			$0,043 /kWh
Average cost for steam			$6,994 /KLbs
Average cost for chilled water			$0,312 /ton-hr

FIGURE 1 ISU pro forma.

university could fix its 1997 utility budget at $7.8 million for 20 years and finance $37.5 million in facility and utility systems upgrades. The cash flow benefit came from simultaneously installing highly efficiency equipment, efficiently sizing and dispatching equipment, providing for fuel switching, reducing the amount of BTUs needed to provide reliable service, and lowering the BTU unit costs needed to serve the university.

The investment reflects a capital investment, which included a 5 MW gas turbine, new boiler, boiler plant upgrades, a new boiler structure, steam and condensate lines, electric chillers, thermal energy storage system, new chiller structure, chilled water building loop and distribution system upgrades, lighting conversions, air-side HVAC upgrades, new equipment control system, system recommissioning, electrical distribution systems upgrades, a new substation, energy information management system, and $5 million in asbestos abatement. Total capital costs were estimated to be more than $28 million. Engineering, procurement, construction, and contingency costs were $5.6 million with additional costs for permitting, legal fees, start-up, and numerous other project costs estimated at more than $2 million. The financing term is 20 years with an interest rate of $5.85 and a debt service reserve of $1.5 million.

Note the area called *Unit energy costs*. Unit costs including capital, O&M, and energy are averaged by system including costs for purchase of electricity. Change in the technology solutions to any system impacts the BTU unit costs for the other systems. For example, if ISU were to purchase steam from another provider, the unit costs for electricity and chilled water would be impacted. This Executive Summary represents one plan option. To gain the greatest BTU value at the lowest combined BTU unit costs, numerous project options should be compared.

Figure 1 presents the annual cash flow of the master energy plan for the project life. Additional reports shown later detail the operating calculation assumptions associated with each of the project utility systems' financial reports. Cogeneration, steam, and chilled water operating calculation reports are shown in Tables 2–4.

Once a capital investment strategy is identified, decision-makers will want to see an assessment of what might happen if the assumptions change. Risks in an infrastructure investment largely include changes in assumptions related to energy growth and cost escalation, getting the project built on time and within budget, financing costs, and long-term operating and maintenance costs. Table 5 shows a range of cost impacts to the project if the initial assumptions were to change by −20%, −10%, or −5%. Notice that the project shown stays healthy at −5% but loses money at −10%. Its project analysis should analyze worse- and best-case scenarios and be prepared to modify the project or find a way to mitigate the risks.

An executive Summary, supplemented by systems operating assumptions, a life-cycle financial pro forma, and sensitivity analysis are essential to gain the approval from top management to proceed with the project. Although this assessment demonstrated that the opportunity for upgrading the university infrastructure was significant, the project was not implemented.

Planning Methodology

The OA methodology slide presented in Figure 2 is a summary of the myriad assumptions that are needed to create a life-cycle business plan for any facility.

Starting with the first step or lowest level of the OA methodology pyramid, the planning process begins with identifying the facility, its owner, and the business goals associated with the use of the facility over the life of the proposed debt. Infrastructure goals can range from environmental improvements, to business expansion, comfort needs, new operating modifications, financing requirements, and code compliance. For ISU, the university wanted to fix its energy budget and finance all infrastructure capital backlog.

Using a life-cycle approach, the growth assumptions should reflect the energy systems impacts associated with the facility use business goals. For ISU, these included growth of electricity, steam, and chilled water for 20 years on a year-by-year basis. Cost escalation estimates by year were also inputted individually for electricity, natural gas, other fuels, budget growth, O&M, and general inflation. Detail of base year budget and tax status is the last group of assumptions usually required to determine the business situation for the facility. Obviously, ISU is a tax-exempt entity.

Turbine output		35,460,480 kWh/Yr.					0 kWh/Yr.
Annual fuel usage		397,157 MMBtu					0 MMBtu
Annual fuel cost		$1,247,074					$0
Annual O&M cost		$0					$0
Annual steam output		0 KLbs.					
Fuel chargeable to power		0 Btu/kWh					
							Annual
Cost breakdown:							
Fuel		0.0352 $/kWh					$1,247,074
O&M		0.0000 $/kWh					$0
Debt service & returns		0.0077 $/kWh					$271,297
Total		**0.0428** $/kWh					
Current avg. cost		0.0558 $/kWh					
Projected avg. Cost		0.0460 $/kWh					
Weighted avg. Cost		0.0444 $/kWh					
Customer Savings from Cogeneration:							$1,609,693
Saving Without Debt Service							$1,880,989

Determining the assumptions for ISU's business situation (the first step of the pyramid) begins to highlight the risks associated with a final business investment. Just estimating the costs for purchase of natural gas or electricity for the next 20 years is a major guess. As planning continues up the pyramid, the stability of the entire project can be compromised by changing assumptions at the base. Having the capability to automatically update and integrate the impacts of changes in cost and growth assumptions or any other baseline assumption greatly improves the team's ability to manage and report these impacts.

Step 2 of the pyramid, first offers the ability to determine the base year energy consumption, loads, and costs associated with purchasing and producing steam/heat, cooling, and electricity. Further data input is needed to describe each system's equipment, age, operating characteristics, maintenance requirements, and other data to calculate each system's BTU unit costs.

At this stage, a status quo business situation pro forma should be run to determine the life-cycle costs of what the business entity will spend if no investments are made. The planner should also chart the facility energy load requirements for electricity, steam/heat, and chilled water energy over time when compared with the equipment capability for each system to provide reliable service. For example,

TABLE 3 ISU Steam Operating Calculations

FIGURE 3 Twenty-five-year steam peak demand.

use reliable and efficient. Lighting, controls, commissioning, air-side HVAC improvements, and other end-use thermal and electrical improvements need to be identified. For example, if lighting retrofits are implemented, the load demand for heating and cooling will change. A new peak demand line or adjusted baseline (square line) is added to the peak demand growth chart. Now, the planner is ready to select and assess the benefits of new energy supply systems' equipment solutions. The Base case demand (circle line) shows the reduction in steam energy or thousand pounds per hour demand that resulted from the improvement in equipment efficiency. The old baseline assumptions are modified to incorporate the new project technology solution assumptions.

Before running a new pro forma, the planner must input assumptions for how the project will be implemented (Step 4). What are the schedule; financing structure; costs for engineering, procurement, construction, contingency, permitting, start-up, and project management; legal fees; and the myriad other costs associated with implementing the project? Who will own the project? How will it be financed? What are the annual principal and interest payments? Are there tax benefits? All these assumptions are inputted so a full life-cycle cost pro forma can be run to compare the new business plan with the status quo or baseline. ISU Executive Summary and Pro Forma show the comparison of ISU's new business plan with its status quo.

We have now reached the top of the pyramid. Step 5 is the business plan. Look at the assumptions that enter into each business investment and asset management decision. The very bottom of the pyramid requires the planner to begin by guessing the cost escalation for primary fuels, electricity, labor, maintenance, inflation, and budgets over the life of equipment. Debt terms could be 20 years. Now, factor in the business growth planned for that same period of time and try to project the increases or decrease in business growth for electricity, heat, and cooling energy. Planners have not begun to deal with equipment selection and performance or the assumptions associated with implementation to get a project financed, built on time and within budget, and other investment assumptions that impact investment risks.

Weakness in each level of assumptions could make the entire investment crash. The dynamic nature of changing energy prices coupled with business changes is already enough to discourage anyone from pursuing integrated energy investments by using the old-fashioned paper plan approach. Assumptions in a Web-based plan enable constant updates and integrated, real-time impact reporting.

Asset Management

Let us put all those assumptions into a Web model and automate the update of critical assumptions like time-of-day energy pricing, equipment performance, and load changes. In addition, let us approach the investment in a manner that allows the user to turn on and turn off equipment or conduct fuel switching based on unit costs. Further, let us integrate price signals into equipment controls to automate the activity. Let us look at what new capital planning does to the investment. Let us evaluate proposals from potential business partners to determine the value of laying of risk and measuring results.

Software abounds for the following:

- Metering, accounting, billing, tracking, profiling, and verification
- Equipment energy management, measurement, optimization, and automated dispatching
- Integrated energy engineering analysis, calculating technology applications for energy and water consumption, load, and cost savings
- Enterprise energy management for energy systems analysis and optimization
- Conversion of hand-drawn prints to an AutoCAD database
- Work order management

The software listed can be accessed, reported, and analyzed for timely decision-making using Web-based information management software.

What does not abound are software systems that provide for developing, managing, and reporting integrated energy supply investments. Nobody ties supply side energy efficiency investment altogether into a financial pro forma, yet all the energy information software described above can be used to update and manage the investment.

Let us create a communication and reporting platform where the entire business investment team can view real time reports. Reports show the financial pro forma and operating calculation for each and all facilities that need to be reviewed. The reports can be delivered from anywhere, disaggregated at any level of granularity, evaluated compared with any time sequence, rearranged, and put back together.

All team members are required to work together to create each project's assumptions and present the project for management approval. This includes risk assessment and mitigation options. Each team member will know his or her job requirements associated with each project and can be evaluated based on meeting his or her portion of the investment plan performance. In addition, each team member is responsible for communicating market and business changes in the business plan assumptions with the rest of the team.

Now let us connect and integrate consumer energy information systems to electric utility supply systems. What if the utility was able to coordinate dispatching of its generation and transmission options with consumer energy supply systems dispatching? The optimum use of all investments in energy supply systems can result. Not only does efficiency and emissions control occur, but also fewer new electric central plants and transportation investments will be needed. Everyone gains greater productivity through modernization, efficiency, and communication. Less energy is consumed.

Risk Management

For decades, independent power producers have set up limited liability corporations (LLCs) and financed generation project based on the strength of performance contracts for sale of energy, purchase of primary fuels and standby power, financing, engineering/procurement/construction (EPC), and operation/maintenance.

All of these risks can be mitigated contractually. The question is, What is it worth to have business relationships or partners who will take the risks compared to the facility owner assuming the risk? The fun part of having a Web- based business plan is that it is easy to assess the value of laying off risks onto other business entities. Comparison of proposals can be integrated into the Web-based energy plan and compared with the cost to the facility owner. During the course of EPC, the plan can track the actual costs and schedule. Constant monitoring and updating of the Web plan strengthen the ability of both owner and contractor to make decisions and communicate project development.

Risks associated with purchase of fuels or electricity are often most difficult for building owners to control. In addition, regulatory changes and changes in business goals can significantly impact long-term investments. With the economic and political strength of electric utilities, the fact that building and operating energy supply systems are their core competency, and the direct links electric companies have to fuel supply opportunities, both consumers and utilities can benefit from partnering.

Energy service companies, worldwide, are in business to earn profits by taking these risks. However, supply system investments often are not integrated. Methods of asset management and reporting are varied and often subject to dispute.

Profits

Profits to electric companies from partnering with consumers can be expansive. For example, institutions especially often have EPC rules, and situations where the project cost for EPC can be very high—as much as a 100% increase in capital costs. This situation leaves a lot of room for having a business arrangement where another company is paid a profit to build the project and demonstrate equipment performance.

Profits can result:

- By adding value to customer energy systems investments and sharing the savings
- Through implementation of EPC contracts
- From operating and maintaining customer energy supply systems
- From sale of primary fuels
- From sale of heat, chilled water, water, and wastewater
- By investing in customer infrastructure
- From tax benefits
- By gaining emissions credits
- Through access to customer information to dispatch integrated systems
- From advanced growth management information
- From firm power sales contracts
- Through optimization of current supply systems' fixed capital
- From reduced financing costs

In turn, the customer is able to upgrade his or her infrastructure, improve the reliability of energy systems, control facility operating budget, and gain an experienced partner who can manage the short- and long-term investment risks. Emissions are reduced, and productivity is increased, often with no customer debt on his or her balance sheet.

Any and all of these benefits are possible depending on the specific site and partnering options. Another paper could be written describing the structure and value of integrated, energy supply systems business opportunities. The benefits to all suppliers and customers include the ability to:

- Finance millions of dollars of infrastructure upgrades from operating budget savings
- Level electricity load requirements
- Reduce BTU consumption and unit costs
- Improve energy reliability and operating productivity
- Communicate and manage energy supply systems risks

Conclusion: "Big Collaboration, It Is Now and the Subject Is Energy" [4]

Thomas Friedman in his book, *The World Is Flat,* recognizes, "One of the unintended consequences of the flat world is that it puts different societies and cultures in much greater direct contact with one another."[51] Promoting electric utility and customer partnering seeks a change in different cultures. Friedman's vision of a radical new approach to energy use and conservation is not just among countries to jointly develop clean alternative energies.[61] Part of the radical new approach is closer to home—be- tween electric utilities and their customers. Inherent in the solution to energy resource efficiency is a radical new approach to earning profits from value-added. To achieve this, new relationships must be developed. Trust is built from sharing a commitment to save energy and communicate and manage risk.

Traditionally, energy supplier generation, transmission, consumer production and distribution systems, and building end use have been dealt with separately—an approach that has proven to be costly and inefficient. Rather than losing money and energy through the traditional approach, right now, we can build systems as integrated investments, save money, make money, and stop wasting energy.

Inherent to integrated energy investments is commitment to using a methodology and dynamic Web-based tool on which to plan, finance, implement, and sustain joint energy supplier and customer economic and environmental opportunities.

A Note on Sources

Energy gained discussions of energy infrastructure investment practices and solutions rely largely on experience and information drawn from publicly available sources: public-sector studies, Web sites, industry groups, professional associations, and U.S. government sources. The ISU data resulted from a study that my staff and I conducted with the help of the University staff. Extensive reference information can be found at the following Web sites: http://www.acee.org, http://www.aeecenter.org, http://www.appa.org, http://www.chpa.co.uk, http://www.cogeneration.net, http://www.eei.org, http://www.eia.doe.gov, http://www.ieadhc.org, http://www.epri.com, http://www.naruc.org, and http://www.naesco.org. Numerous other Web sites exist.

Addendum

Questions

It has been asked, "Would it be possible to give an estimation of how much energy could be saved from investment and use of integrated energy systems?" Putting a simple number to answer this question is not easy and is complicated by the many ways that experts define and measure energy. The answer varies based on two primary factors: 1) the age, location, pollution costs, and inefficiency of current energy systems and 2) our level of commitment to invest in and operate highly efficient, reliable, clean energy supply systems.

Our goals are to gain the greatest amount of energy output from every unit of energy mined, transported, and converted to electricity, heat, and cooling and to size production and distributions systems to meet reliable, efficient end-use facilities and equipment. (The complexity of this topic cannot be fully explained in this short narrative. Further elaboration and definition of terms can be found in my textbook, *Energy Efficiency: Real Time Energy Infrastructure Investment and Risk Management.*) The goal also includes how to dispatch and operate the energy commodities listed above to achieve efficient, reliable, and nonpolluting water and wastewater systems investments at the lowest production and distribution unit costs.

Although it is important to answer to "how much energy could be saved?," the more important questions are as follows:

- How do we implement and earn profits from integrated resource efficiency investments?
- How do we evaluate alternative fuels; technologies; operating and maintenance options; engineering, procurement, and construction progress; financing and ownership structures; life cycle operation and maintenance maximization; and regulatory and technology changes; and follow market demand changes and numerous other risks to close deals and earn the best returns on investments over time?

Savings Potential

In addition to the coal, natural gas, and petroleum used to produce electricity and heat, the U.S. Department of Energy, Energy Information Administration, reports in its World Consumption of Primary Energy by Energy Type and Selected Country Groups, Table 1, the "net" generation of electricity from numerous renewable fuels and nuclear. The efficiency or net output of useful electricity compared to the total energy value contained in the primary fuel during the 20th century is reported to have a sustained average in the United States of about 33%. The amount of energy consumed is embedded in the conversion factors to change the primary fuel to secondary commodities like electricity and heat. Each primary fuel has energy content. When a primary fuel is converted to electric energy in the United States, on average, two-thirds of the original energy content is thrown away.

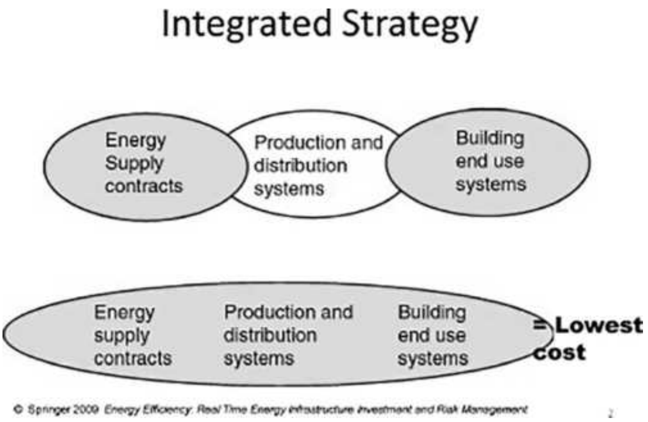

FIGURE A1 Integrated strategy.

Further energy losses also result from decisions about selection of sites to build electric, heat, and cooling production and transportation systems as well as energy use efficiencies, choices of equipment, time of use, fuel switching, storage, and other infrastructure investment efficiency options.

Investment in efficient energy systems requires a comprehensive, integrated approach solving for gaining the greatest output and reliability from every energy unit consumed at the lowest energy unit cost. Figure A1—Integrated Strategy (Solmes, Leslie, *Energy Efficiency: Real Time Energy Infrastructure Investment and Risk Management*, Springer, 2009, p. 20)—first reflects the traditional way of investing in energy systems as separate parts: primary fuels; production and distribution of electricity, heat, and cooling systems; and building end-use systems.

In order to create the greatest production and transmission/distribution efficiency, investment analyses begin with updating end-use facilities and equipment based on defined business goals and projections of end-use growth and cost escalation for primary fuels, labor, emissions, budgets, and other long-term cost considerations that will impact the returns of investment over its life cycle. An assessment of end-use efficiency and system upgrades will result in adjusting baselines for electricity, heat, and cooling requirements. Selection and sizing of new production and distribution equipment will be affected and often reduced.

Add up the energy and load savings that result from comprehensive, integrated energy systems' investments that include the following:

1. Updating of all aged, inefficient, unreliable, and polluting end-use facilities and equipment—*savings of 10%–50%*. A July 2009 McKinsey report on energy efficiency projects that there exists an investment opportunity of $520 billion that would save $1.5 trillion through 2020, reduce U.S. consumption by 23%, and more than offset U.S. expected growth in energy use (http://green.blogs.nytimes.com/2009/07/29/mckinsey-report-cites-12-trillion-in-potential-savings- from-energy-efficiency/). Success stories abound.
2. Sizing production and transmission/distribution systems to meet new, efficient end-use loads—*savings based on load reductions from end-use investments, often 20%–30%*. End-use efficiency will change the size and number of electric, heat, and cooling infrastructure, thus lowering the capital costs for replacement and/or new capacity additions and gaining greater optimization and efficiency of new production equipment and reducing the need for distribution systems expansions. For example, just one building retrofit at a major California university showed a 30% reduction in chilled water requirements due to end-use efficiency savings. The capital cost, even with 15% redundancy, was lowered by 22%.

3. Sizing on-site generation of electricity to meet the thermal load resulting in the greatest energy output from every unit burned—*savings from doubling energy output of primary fuel to produce electricity and dramatic reduction in consumption of primary fuels to produce heat energy could be 40%.* The U.S. Clean Heat and Power Association reports that combined heat and power investment get up to 2–3 times the useful energy products from the fuel and can effectively cut fuel costs by up to two-thirds (http://www.uschpa.org/14a/pages/index.cfm?pageid=3297).
4. Using recycled heat energy to provide heat and cooling also reduces the amount of new equipment needed—*same as above including reduction in new equipment needed to produce heat energy.*
5. Leveling the electrical load by using recycled heat energy for cooling—*savings in electric consumption and need for investments in electric peaking capacity.* Optimal equipment sizing for electricity production usually means that some purchase of electricity from the grid will be needed. However, use of waste heat for heating and air conditioning will result in flattening the electric load and reducing the need for building electric generation capacity to meet peak loads. It will also enable a high percentage of supplemental electricity to be purchased 24/7 thus improving the efficiency of the energy supplier's generation station. (Solmes 2009)
6. Incorporating multiple production equipment solutions to efficiently address shoulder months where heating and cooling vary greatest—*savings from turning off equipment operation during shoulder months and operating equipment at optimum efficiency.* For example, multiple small boilers can be run at full load during low heat demand compared to operating a large boiler for limited hours or partially loaded.
7. Incorporating district heating and cooling systems efficiencies—*it can result in as much as 50% energy savings in industrial, campus, military, hospital, dense city, and similar environments.* Placing boilers and chillers in each building means buying equipment sized to meet the higher heating and cooling loads for each building. Most of the year, this equipment runs partially loaded. A central plant with multiple generation units can run equipment to meet the aggregate load of multiple buildings, thus optimizing equipment performance efficiency and needing to invest in less equipment.
8. Increasing load and efficiency of electricity purchases from utilities, thus improving existing generation efficiency and capital utilization—*improved 24/7 use of electric generation capacity.* See (5).
9. Reducing investment requirements and losses associated with electricity transport systems—*savings from elimination of electric transportation losses and reduction in grid requirements.*
10. Improving load requirements on equipment and systems used to provide primary fuels—*savings from 12-month purchase and/or use of primary fuels.* Greater contracting cost leverage can result for longer-term contracts.

No doubt, more efficiency items can be listed as a part of integrated energy systems investments. Factor in the energy and capital efficiency that can be gained by the combination of all 10 items. Now, include the efficiency that results from financing a single larger project rather than numerous small ones. Add the savings that result from emissions reductions and reduced need to build new electricity generation and transmission systems. This cascading of energy and capital savings by integrating energy systems investments can fund the investment debt as well as earn significant returns on investment.

Thomas Casten in his book *Turning Off the Heat: Why America Must Double Energy Efficiency to Save Money and Reduce Global Warming* provides an answer to "how much could be saved from integrated energy systems investment?"—at least half of current consumption. The opportunity is that due to age and inefficiency, use of the integrated approach will result in funding investments, greater productivity, less pollution, more jobs, and a stronger economy.

New Energy Supply Systems Should Reduce Costs to Consumers

The savings reflected by McKinsey is appropriately titled "end-use" energy savings. Although some waste heat recovery is reflected in the table, the more than half a billion dollars in energy infrastructure investment does not address the investment opportunity that exists in investing in highly efficient, integrated electricity, heat, and cooling production and distribution systems. When Casten wrote about doubling our energy efficiency, he was citing the doubling effect of committing to supply-side resource efficiency—conversion of primary fuels to electricity, heat, and cooling production and distribution combined with efficient end use. This formula will result in meeting the goals of resource efficiency at the lowest cost to the consumer, doubling emissions reductions and tremendous opportunities to earn profits from value-added.

Tracking Investment Returns and Managing Risks

Numerous international measurement and verification guidelines and protocols have been developed and adopted to determine the energy savings from energy efficiency measures and renewable fuels. The oversight of this effort is now done by a non-profit organization called the Energy Valuation Organization or EVO. According to EVO's website, "EVO is the only non-profit organization in the world solely dedicated to creating measurement and verification (M&V) tools to allow efficiency to flourish. Our vision is a global market that properly values the efficiency resource, enabling and assisting the optimal investment in these opportunities."

The limitation to the work accomplished to date is that Web-based energy systems business investment plans, real time tracking, and calculation of electric, heat, and cooling unit costs as a means to achieve the lowest combined energy unit cost are not available. A software application that communicates, tracks, and reports all the assumptions that go into creating a baseline, comparing the benefits of a combination of efficient investment options and investment strategies, and automating the update of these assumptions over the term of the debt does not exist.

To gain the greatest value from integrated energy investments, stakeholders need to communicate and see the financial impact of market and business changes in real time. Even going through the investment stages of baseline development to preliminary assessment to detailed engineering, procurement, and construction entails very big financial risks if continuous automated tracking and data comparison using internet technology are not instituted to address critical time factors for decision making. An energy infrastructure investment and risk management software application that provides the answers to achieving resource efficiency is the means to successfully accomplish the efficiency investments described above and to encourage electric utilities, service companies, consumers, and investors to earn returns from integrated efficiency investments. An initiative to create this application standard is how to answer the question, "How much energy could be saved from investment and use of integrated energy systems?"

Bioreactors for Waste Gas Treatment

Sarina J. Ergas

- Low solubility compounds.
- Cometabolism of chlorinated organic compounds.
- Compounds requiring specialized microbial populations or conditions.
- Indoor air applications.

Introduction

Successful biofiltration applications have been limited to control of relatively soluble volatile organic compounds (VOCs) at low loading rates. Biofiltration is also of limited use for compounds that produce acidic or toxic metabolites or are degraded via cometabolism. To overcome the limitations described above, gas-phase biological treatment systems must be developed which (1) incorporate mass transfer of gas-phase pollutants across a media with high specific surface area and low diffusion length, (2) incorporate high biomass concentrations to maintain high biodegradation rates, (3) provide a method for wasting biomass to prevent clogging, and (4) provide a method for addition of pH buffers, nutrients, cometabolites, and/or other amendments to support the microbial population and neutralize acidic metabolites.

Hollow fiber membrane bioreactor (HFMB) systems have been under investigation which meet the above requirements and have been shown to achieve high VOC removal efficiencies in small reactor volumes. A schematic of a typical HFMB system is shown in Figure 1. The hollow fiber membranes serve as a support for the microbial population and provide a large surface area for VOC and oxygen mass transfer. Waste gases containing VOCs are passed through the lumen of the hollow fibers. Soluble compounds in the gas phase are transferred through the membrane pores and partition into

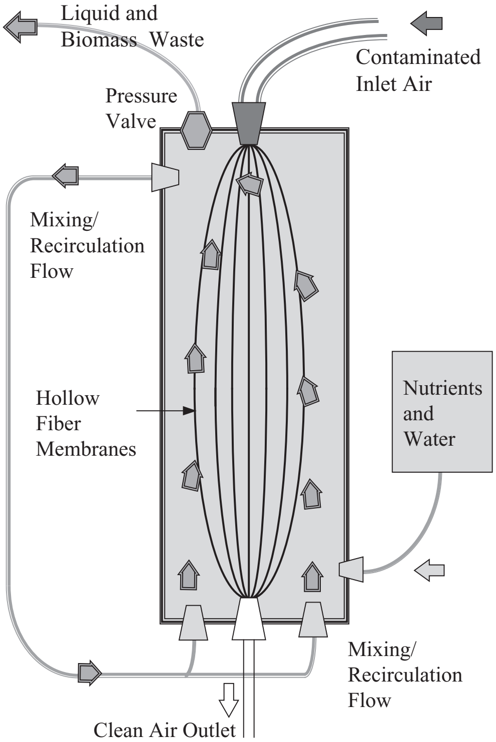

FIGURE 1 Schematic of a hollow fiber membrane bioreactor for biological air pollution control. (From Shumway, 1997.)

a VOC-degrading biofilm surrounded by a circulating nutrient media. Compounds in the biofilm are available for biodegradation. Potential advantages of HFMBs for waste gas treatment include

- Ability to continuously remove biomass to prevent clogging at high VOC loading rates.
- Ability to remove degradation by-products and add pH buffers, nutrients, and/or co-substrates to support the microbial population and neutralize acidic metabolites.
- Ability to treat low solubility compounds such as nitric oxide (NO) and methane.
- Separation of the microbial process from the gas being treated. This may be useful in indoor air applications where carryover of biomass into the ambient air is a concern.
- Optimal humidification of the gas stream.
- Low pressure drop.
- Gas and liquid flow rates can be varied independently without flooding or foaming.
- Modular design, no moving parts.

Disadvantages of HFMBs for waste gas treatment include high capital costs and that the technology has not been demonstrated at full scale.

Membrane Bioreactor Applications for Pollution Control

Hollow fiber membrane bioreactors have been used in a number of pollution control applications including

- Separation and retention of biosolids.
- Bubble-free aeration of bioreactors.

- Providing hydrogen and other low solubility gases to bioreactors.
- Extractive membrane bioreactors for controlled transfer of pollutants from industrial wastewaters.
- Biological air pollution control.

Membrane bioreactors are most often used for separation of biomass. The ultrafiltration of microfiltration membranes is used as a substitute for sedimentation. These systems are used to produce high-quality effluent and/or provide high solid retention times without washout of biomass. These applications are well documented in the literature and are outside the scope of this discussion (Stephenson et al., 2000).

Gas-to-liquid transfer membrane systems were first introduced for use in blood oxygenation and have been studied extensively for this application (Lund et al., 1996). Pollution control research into membrane aeration HFMBs has been focused on the enhancement of oxygen transfer for in high oxygen demanding applications such as the treatment of high-strength industrial wastewaters (Yamagiwa et al., 1998) and nitrification (Brindle and Stephenson, 1996; Brindle et al., 1998). These systems have also been used for bioreactors degrading VOCs, since the membranes allow for reactor aeration without stripping volatile compounds to the atmosphere (Pressman et al., 1999). Due to the low solubility of oxygen, oxygen transfer often limits aerobic degradation of high oxygen demanding wastewaters. Many facilities switch from atmospheric air to pure oxygen to enhance oxygen mass transfer; however, conventional oxygenation systems have high power requirements and are incompatible with attached growth reactors (Stephenson et al., 2000). Hollow fiber membranes provide a very high surface area for transfer of oxygen directly to the biofilm. Hydrophobic hollow fibers have been developed with sealed hydrophilic ends that enable 100% utilization efficiency in gas-to-liquid mass transfer applications (Ahmed and Semmens, 1992a,b).

A novel application of HFMB gas-transfer technology, hydrogenotrophic denitrification of drinking water, has been investigated by several researchers (Gantzer, 1995; Lee and Rittmann, 2000; Ergas and Reuss, 2001). A number of common genera of bacteria can use hydrogen as an electron donor and nitrate as an electron acceptor under anoxic conditions. These organisms have been shown to denitrify nitrate contaminated drinking water to acceptable levels. Disadvantages of hydrogenotrophic denitrification include lower denitrification rates and the difficulty in dissolving sufficient quantities of hydrogen into the water due to its low solubility. Use of HFMBs has been shown to support high biomass densities and improve hydrogen mass transfer rates while preventing the waste of excess hydrogen and avoiding accumulation of explosive gasses in a confined space.

Extractive membrane bioreactors have been used to biologically treat industrial wastewaters in the presence of high concentration of acids, bases, and salts that can inhibit degradation (Livingston, 1994; Livingston et al., 1998). Extractive membrane bioreactors utilize dense silicone membranes that selectively extract organic pollutants such as chloroethanes, chlorobenzenes, and toluene, from polar and ionic compounds. A VOC-degrading biofilm grows on the surface of the membranes creating a driving force for mass transfer. Due to the selectivity of the membranes, the biofilm is isolated from the harsh conditions in the wastewater to ensure high biodegradation rates.

Membrane Fundamentals

A membrane separates two distinct bulk phases of a system while allowing the transport of compounds from one phase to the other. In waste gas treatment applications, gases are most often blown through the lumen (inside) of tubes made from membrane materials. Pollutants from the gas phase diffuse through the membranes to a liquid phase on the shell side (outside) of the membranes. The membranes also serve as a support for the microbial population. Once in the liquid, compounds are biodegraded creating a concentration gradient, which serves as a driving force for mass transfer.

Membranes are available in a wide variety of materials, porosities, and pore sizes. For successful application, membrane materials must strike a balance between reasonable mechanical strength, high permeability, and high selectivity (Stephenson et al., 2000). For microporous membranes, high selectivity requires a membrane material with a narrow range of pore sizes, and high permeability requires a membrane material with a high porosity.

Dense and porous membranes are fundamentally different from each other. Dense membranes rely on physical–chemical interactions between the permeating compounds and the membrane materials. The mass transfer rate through a dense membrane depends on the solubility and the diffusivity of the permeating compound in the dense matrix (Reij et al., 1998). Dense membranes are limited to polymeric materials, such as latex and silicone, and they can be operated at high gas pressures, and are resistant to chemical and mechanical abrasion (Fitch et al., 2000; Stephenson et al., 2000). They have also been shown to be more resistant to biofouling than porous membranes (Coté et al., 1988, 1989), possibly because the hydrophobic nature of silicone resists attachment of microorganisms.

Microporous hydrophobic membranes are most often used in gas-transfer applications because they provide a high gas permeability, while not allowing transport of water across the membrane. The membrane pores remain gas filled and compounds transfer from the gas stream through the membrane pores by gaseous diffusion. At excess liquid side pressures above the critical pressure, ΔP_{cr}, water enters the pores of the membranes, dramatically decreasing mass transfer rates (Ergas and Reuss, 2001). Gas side pressures greater than the bubble point result in bubble formation in the liquid phase (Semmens et al., 1999). Thus, over the excess pressure range of 0 to ΔP_{cr}, the gas/liquid interface is immobilized at the mouth of the membrane pore on the liquid side.

Microporous hydrophobic membrane materials include polytetrafluorethylene (PTFE), polypropylene, Teflon™, Gore-Tex™ (PTFE/nylon), and other composites. Hydrophobic microporous membranes coated with an extremely thin layer of silicone have also been investigated (Sikar, 1992). The thin silicone layer increases mass transfer resistance but also decrease biofouling. Microporous hydrophobic membranes are available with pore diameters between 0.1 and 1.0 μm (Stephenson et al., 2000). The membranes are manufactured as small-diameter (200–400 μm ID) hollow fiber bundles that provide surface area-to-volume ratios as high as 30–100 cm^{-1} (Sirkar, 1992). This is an order of magnitude greater than equivalent sized packed towers.

Gas-to-liquid transfer can also be carried out using microporous hydrophilic membranes such as polysulfone and cellulose membranes. In these applications, gas pressure must be higher than liquid side pressures. The gas/liquid interface is thus immobilized at the pore mouth on the gas side of the membrane.

Control of biomass thickness has been shown to be a key operational consideration in continuously operated HFMBs for aeration of wastewaters (Stephenson et al., 2000) and biological waste gas treatment (Ergas and McGrath, 1997). Decreased HFMB performance has been observed in bioreactors after the development of a thick biofilm due to substrate mass transfer limitations, membrane fiber plugging, decreased biomass activity, and/or metabolite accumulation (Brindle and Stevenson, 1996; Freitas dos Santos et al., 1997). Hollow fiber bundles also tend to clump together when biofilm growth is high, resulting in fiber tangling and reduction of available membrane surface area. Several operational strategies have been used to maintain film thickness at an optimum level including the use of crossflow membrane configurations (Ahmed and Semmens, 1996) and periodic shearing of biomass from the membranes using high liquid velocities combined with scouring with gas bubbles (Pankhania et al., 1994; Dolasa and Ergas, 2000).

Research Overview

A summary of the laboratory-scale investigations of HFMBs for air pollution control is shown in Table 1. In an early study by Hartmans et al. (1992), a HFMB was used to control air emissions of toluene and dichloromethane. Mass transfer coefficients were determined for a number of different membrane materials. Using the experimentally determined mass transfer coefficients, dichloromethane removal was simulated. Results of simulations suggested that a significantly lower reactor volume would be required

TABLE 1 Summary of HFMB for Waste Gas Treatment Research

Reactor Type	Compound	Membrane Materials	Fiber ID (mm)	Pore Size (μm)	Membrane area (m^2)	References
–	Toluene, dichloromethane	Polypropylene	–	0.10	0.004	Hartmans et al., 1992
Flat sheet	Propene	Polypropylene	NA	0.1	0.0040	Reij et al., 1995
Hollow fiber	Propene	Polypropylene	1.8	0.2	0.10	Reij and Hartsmans, 1996
Hollow fiber	Toluene	Polysulfone	1.1	–	0.028	Parvatiyar et al., 1996a
Hollow fiber	Trichloroethene	Polysulfone	1.1	–	0.028	Parvatiyar et al., 1996b
Flat sheet	Propene	Polypropylene	NA	0.1	0.0040	Reij et al., 1997
Hollow fiber	Toluene	Polyethylene	0.28	–	0.23	Ergas and McGrath, 1997
Hollow fiber	Toluene	Polypropylene	0.20	0.05	0.37	Ergas et al., 1999
Hollow fiber	Toluene/TCE	Polypropylene	0.20	0.05	0.37	Dolasa and Ergas, 2000
Hollow fiber	Ammonia	Polyolefin multilayer	0.20	–	0.063	Keskiner and Ergas, 2001
Hollow fiber	Benzene	Latex rubber	9.5	NA	0.012	Fitch et al., 2000
Hollow fiber	Benzene	Silicone rubber	9.5	NA	0.012	Fitch et al., 2000
Hollow fiber	Benzene	Polypropylene	0.20	0.2	0.30	Fitch et al., 2000
Hollow fiber	Butanol	Polysulfone	1.1, 1.9, 2.7	0.05	0.030, 0.022, 0.013	Fitch et al., 2000
Hollow fiber	Trichloroethene	Polypropylene	0.24	0.03	0.70	Pressman et al., 2000

for a HFMB than for a biotrickling filter. Greater than 95% removal of toluene and dichloromethane were observed in experiments with a flat sheet membrane bioreactor.

Parvatiyar et al. (1996a) used a two module-in-series polysulfone HFMB to investigate toluene removal from a contaminated airstream. Toluene removal reached 84% with a 16-second gas residence time and an inlet concentration of 600 ppm. A similar experimental system was used by the authors to study degradation of trichloroethylene (TCE) (Parvatiyar et al., 1996b). The biofilm was initially acclimated to toluene and then gradually weaned from a toluene/TCE mixture to 100% TCE. A 30% TCE removal efficiency was achieved with a 36-second gas residence time.

Fitch et al. (2000) compared mass transfer and biodegradation rates for benzene and butanol contaminated gases in HFMBs that utilized dense (latex and silicone), microporous hydrophobic (polypropylene), and microporous hydrophilic (polysulfone) membranes. The highest overall pressure drops were observed with the polypropylene membranes due to the smaller diameter of these fibers compared with the other fibers. Significant sorption of benzene was observed in initial tests with the polysulfone membranes; therefore, butanol was used in subsequent experiments with these membranes. Removal efficiencies for butanol of up to 99% were obtained at an inlet concentration of 200 ppm. Dense high permeability latex and silicone membranes were found to have high benzene mass flux rates, possibly because the greater solubility of benzene in the polymers than in air creates a greater effective concentration gradient than observed in the air phase. The low total surface area of the dense membrane tubes limited overall removal; however, and the polypropylene membrane unit was the most effective on the basis of removal per total unit volume of reactor.

In my own laboratory, we have conducted a number of studies using toluene as a model VOC. In our first set of experiments (Ergas and McGrath, 1997), a laboratory-scale HFMB was constructed and operated with toluene at varying loading rates. The gasses passed from an inlet manifold to a membrane distributor made from 336 polypropylene hollow fibers (280 μm ID, 63% porosity, and an active fiber length of 1.1 m). A plot of removal efficiency vs. gas flow rate over the experimental period is shown in Figure 2. Toluene removal efficiencies of greater than 97% were achieved with an inlet toluene concentration of 100 ppm and gas flow rates less than 1.0 L/min (1.4 second residence time). When the gas flow rate was increased above 1.2 L/min (1.1-second residence time), a significant decrease in removal

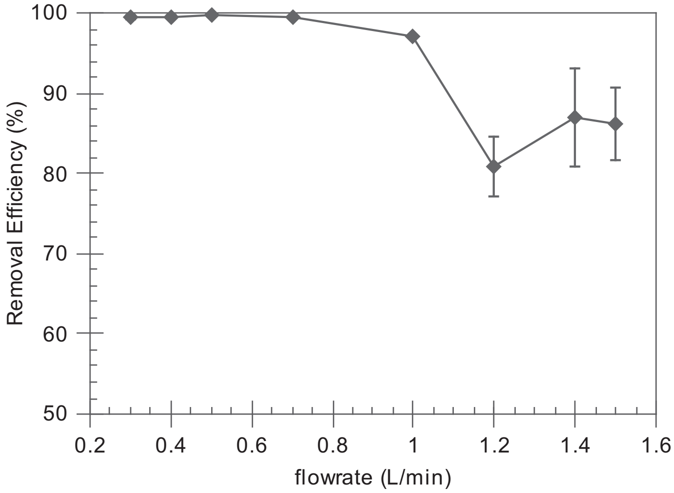

FIGURE 2 Removal efficiency in a HFMB gas flow rate. (From Ergas and McGrath, 1997.) Removal efficiency was determined after an acclimation period at each flow rate. The inlet toluene concentration was maintained at 100 ppm_v, and the liquid recirculation rate was 4 L/min.

efficiency was observed. Removal efficiency was found to decrease over the four-month operational period due to clogging of the bioreactor with microbial biomass, possibly due to the growth of nitrifying bacteria.

In subsequent experiments (Ergas et al., 1999), we investigated the effects of toluene loading rate, gas residence time, and liquid-phase turbulence on toluene removal in a laboratory-scale HFMB. Nitrate was used as a nitrogen source to discourage the growth of nitrifying bacteria. Initial acclimation of the microbial culture to toluene occurred over a period of nine days, after which a 70% removal efficiency was achieved at an inlet toluene concentration of 200 ppm and a gas residence time of 1.8 seconds (elimination capacity of 20 $\mathrm{g/m^3/min}$). At higher toluene loading rates, a maximum elimination capacity of 42 $\mathrm{g/m^3/min}$ was observed. Liquid-phase recirculation rate had no effect on toluene removal in the HFMB.

We have also investigated the use of a HFMB to control ammonia using nitrifying bacteria (Keskiner and Ergas, 2001). The reactor utilized polyolefin multilayer membrane bundles consisting of 200 fibers, with a length of 50 cm, an inner diameter of 200 μm, and a porosity of 42%. Greater than 92% removal efficiency was obtained at an inlet ammonia concentration of 60 ppm and a gas residence time of less than 0.4 seconds. Ammonia mass transfer rates were found to increase at higher recirculation rates. Biomass adhesion and accumulation was not a problem in this system, possibly due to the slow growth rates of nitrifying bacteria. Experiments are currently being conducted with this reactor using nitrifying bacteria to remove nitric oxide from combustion gas streams.

Treatment of Low Solubility Compounds

In biological air pollution control systems, compounds must partition from the gas phase into the moist biofilm before they can be degraded. Pollutant concentrations at the gas/biofilm interface can be described by Henry's law:

$$S_L = C_g / H \tag{1}$$

where H is the Henry's law coefficient, C_g is the gas-phase concentration, and S_L is the liquid phase concentration. Conventional biofilters have therefore been limited to the control of relatively soluble compounds. A number of environmentally relevant compounds such as nitric oxide (NO), hexane, and methane are biodegradable but have high Henry's law constants. For these compounds, mass transfer from the gas phase to the biofilm limits removal unless very large reactor volumes are used. Due to their higher mass transfer rates, HFMBs may make biological treatment of these compounds more economically feasible.

A number of studies have been carried out using propene as a model VOC because its low solubility makes it difficult to remove in conventional biofilters (air/water partition coefficient at 25°C of 8.6). A flat sheet microporous polypropylene HFMB inoculated with *Xanthobacter Py2* was investigated by Reij et al. (1995). After five days with an inlet propene concentration of 2,300 ppm, the biofilm acclimated and 58% propene removal was maintained for the duration of the 30-day test. Because of propene's poor solubility, all mass transfer resistance was found to be in the liquid phase. For more soluble compounds, the authors determined that membrane-phase resistance could approach the same order of magnitude as liquid-phase resistance. A similar reactor system and bacterial culture was investigated by Reij et al. (1997) to degrade propene at concentrations varying from 10 to 1,000 ppm. Once a biofilm was established, propene flux to the membranes was stable, even at low concentrations (9–30 ppm) when mass transfer limitations should be greatest.

Reij and Hartsmans (1996) investigated a HFMB that utilized 40 polypropylene hollow fibers with a length of 500 mm, an inner diameter of 1.8 mm and a pore size of 0.2 μm. Propene was again used as a model compound due to its low solubility. Maximum propene removal rates were 70–110 g/m^3/h. A gas residence time of 80 seconds was required for 95% removal at an inlet propene concentration of 480 ppm. The reactor was changed from ammonia as a nitrogen source to nitrate to discourage the growth of nitrifying bacteria. Increasing the shell side velocity was found to alleviate clogging of the fibers with biomass. A gradual decrease in propene degradation was observed, possibly due to aging of the biofilm.

Cometabolism

A number of chlorinated organic compounds, such as TCE, can only be degraded aerobically under cometabolic conditions. Cometabolism is defined as the transformation of a compound by a microorganism that is unable to use the substrate as a source of energy or as an essential nutrient element. A second substrate (primary substrate) is used to support growth and induce the enzymes necessary to cometabolize the target compound. The primary substrates often inhibit metabolism of the target compound due to enzyme competition (Alvarez-Cohen and McCarty, 1991). In plug-flow reactors, such as biofilters, the induced bacteria are located near the inlet of the bioreactor where the primary substrate is readily degraded. In these areas, competitive inhibition occurs between the two compounds. In the remaining sections, the bacteria do not get sufficiently induced with the low primary substrate concentrations remaining to cometabolize the target compound. Microbial activity can also be inhibited by the toxicity of the target compound or its metabolites. The result is low removal efficiencies for TCE in conventional biofilters (Speitel and McLay, 1993).

Several researchers have studied HFMBs for cometabolism in TCE in wastewaters. Aziz et al. (1995) investigated a HFMB with an external semi-batch reactor for TCE cometabolism. Wastewater contaminated with TCE flowed inside the hollow fibers, with a liquid media containing an active methanotrophic culture circulating around the fibers. At residence times of 5–9 minutes in the fiber lumen, TCE conversions of 80–95% were observed. Pressman et al. (1999) presented a follow-up study with a similar system and methanol as the primary substrate. Over 93% of the transferred TCE was biodegraded.

Pressman et al. (2000) used a HFMB for cometabolism of TCE-contaminated gases. A pure culture of *Methylosinus trichosporium* OB3b PP358 was grown in a continuous-flow chemostat and circulated through the fiber lumen of a HFMB, while TCE-contaminated air was circulated on the shell side of the reactor. *M. trichosporium* OB3b PP358 is a methanotrophic bacterium that has the ability to rapidly cometabolize chlorinated solvents when grown on either methane or methanol. Between 54% and 84% TCE transfer was observed, and 92–96% of the transferred TCE was cometabolized at gas residence times of 1.6–5.0 minutes. Biomass clogging did not occur in this system, possibly because the biomass was pumped through the lumen rather than the shell side of the fibers.

In my own laboratory, we have investigated TCE cometabolism in HFMBs using toluene as a primary substrate (Dolasa and Ergas, 2000). A TCE cometabolizing culture enriched from a wastewater seed was inoculated into the HFMB. Initially, toluene was supplied to the reactor to build a sufficient biomass density on the fibers. After steady-state toluene removal was achieved, TCE was added to gas phase of the reactor. Toluene was added in three different configurations: (1) as a mixture with TCE in the gas phase, (2) by pulsing into the gas phase, or (3) to the liquid phase. Addition of a toluene/TCE mixture through the fibers resulted in an initial decrease in toluene removal followed by complete recovery within 5 days and a maximum TCE removal efficiency of approximately 30%. Pulsing of toluene and TCE through the membranes did not result in significant TCE removal. Adding TCE in the gas phase and toluene in the liquid phase resulted in a maximum TCE removal efficiency of 23%; however, results were highly variable and appeared to be related to liquid-phase toluene utilization rates and biofilm thickness.

Theoretical Models

A number of researchers have presented mathematical models of mass transfer and biodegradation of substrates by biofilms growing on the surfaces of gas-transfer membranes (Livingston, 1993; Essila et al., 2000). The general biofilm model reported here was developed in collaboration with Dr. Mark W. Fitch of the University of Missouri, Rolla, and tested using experimental data from HFMB studies conducted using toluene as a model VOC (Ergas et al., 1999). The model uses an inert surface to establish a boundary condition, with substrate entering the biofilm from the gas/liquid interface. The model was derived for a single lumen and related to the total removal by the number of fibers. A conceptual model of this system is shown in Figure 3. Model assumptions include steady-state operation; Monod biodegradation kinetics; and constant biomass density, ρ_b. Because concentration varies both axially and radially, no analytical solution exists for a single lumen. Therefore, the lumen is divided along the axis into n sections, each with an axial length, Δz. The influent gas concentration to the nth section is the concentration exiting the previous section, C_{n-1}. The concentration exiting the nth section, C_n, is equal to the influent less the removal in the section due to the mass transfer and biodegradation.

Membrane Mass Transfer

The flux, J_n, of substrate through the membrane can be expressed as

$$J_n = k_m A_m \left(C_{n,m} - C_{n-1}\right) \tag{2}$$

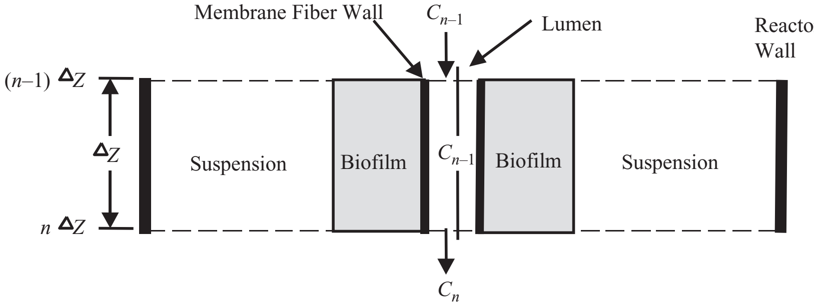

FIGURE 3 Conceptual model of the phases of the hollow fiber membrane reactor. (From Ergas et al., 1999.)

where k_m is the membrane mass transfer coefficient, A_m is the area of the membrane in the section, and $C_{n,m}$ is the gas-phase concentration on the outer face of the membrane. A number of authors have assumed that gas and membrane resistances are negligible compared to liquid-phase resistance (Ergas and McGrath, 1997; Yang and Cussler, 1986; Coté et al., 1989) and therefore $C_{n,m}$ is approximately equal to the concentration in the gas stream, C_{n-1}. Since the membrane is surrounded by biofilm, the liquid-phase concentration at the biofilm interface, $S_{n,0}$, can be related to C_{n-1} using Henry's law:

$$S_{n,0} = C_{n-1}/H \tag{3}$$

Equation 3 sets the inner surface (left-hand) boundary condition for the biofilm model.

Suspension Mass Transfer and Degradation

The suspension (liquid volume) was treated as a continuous-flow stirred tank reactor (CFSTR). The mass flux of the substrate, J_b, from the biofilm to the liquid can be described by

$$J_b = k_L A_B \left(S_{n,i} - S_L \right) \tag{4}$$

where k_L is the liquid mass transfer coefficient, A_b is the outer surface area of the biofilm, $S_{n,i}$ is the VOC concentration at the outer surface of the biofilm, and S_L is the bulk liquid VOC concentration. Assuming Monod biodegradation kinetics, a mass balance on the liquid volume yields:

$$\frac{\rho_L}{Y} \frac{\mu_{\max} S_L}{K_S + S_L} V = QS_o - QS_L + J_b \tag{5}$$

where V is the liquid volume, ρ_L is the biomass density in the liquid, $\mu_{\max}$ is the maximum specific growth rate, Y is the yield coefficient, K_S is the half saturation coefficient, Q is the liquid flow rate, and S_O is the influent VOC concentration to the suspension. Substituting Eq. (4) into Eq. (5) and solving for $S_{n,i}$ yields

$$S_{n,i} = \left(1 + \frac{V \rho_L \mu_{\max}}{Y k_L A_b (K_s + S_L)} \right) S - \frac{Q}{k_L A_b} (S_O - S_L) \tag{6}$$

This relationship sets the exterior surface (right-hand) boundary condition for the biofilm model.

Biofilm Mass Transfer and Degradation

Assuming no advection in the biofilm, steady-state ($\partial S/\partial t = 0$), no concentration gradient in the z direction, and Monod substrate utilization kinetics, the continuity equation for the biofilm in cylindrical coordinates (r, z, and θ) is

$$D_S \frac{1}{r} \left(\frac{1}{r} \frac{\partial^2 S}{\partial r^2} + \frac{\partial S}{\partial r} \right) = -\frac{\rho_b}{Y} \frac{\mu_{\max} S}{K_S + S} \tag{7}$$

where S is the substrate concentration in the biofilm and D_S is the VOC diffusion coefficient in the biofilm. There is no analytical solution for Eq. (7); therefore, a numerical solution was generated.

To fit the models, the biofilm density was varied until the predicted removal matched the observed removal (Ergas et al., 1999). The biofilm biomass density was calibrated at 29,000 mg/L, slightly higher than that reported by Characklis and Marshall (1990). The numerical model predicted the observed trend that shell side liquid flow rate had little effect on observed removal once a biofilm was established. The model slightly underpredicted the effect that substrate loading rate had on removal in the system.

The only case of poor prediction by the model was the effect of gas residence time on removal. Observed removals were higher than predicted removals for these runs. If the pore space of the membranes became water-filled during the course of experimentation, as discussed above, an added resistance to mass transfer would be expected, and mass transfer to the biofilm could become dependent upon the gas flow rate (gas-to-liquid transfer). Sensitivity analysis indicated that removal was a strong function of the biofilm phase biomass density and also of the biofilm diffusion coefficient, with diffusion rates below $(10)^{-9}\,m^2/s$ resulting in decreased removal rates.

Conclusions

Hollow fiber membrane bioreactors are a promising technology for the treatment of biodegradable gas phase pollutants. It has been shown to be effective for aerobic degradation of a range of compounds including ammonia, benzene, butanol, dichloromethane, propene, TCE, and toluene. Advantages of HFMBs include high mass transfer rates, low pressure drops, and small reactor volume requirements. In addition, the ability to separate the microbial population from the gases being treated allows for independent optimization of each phase of the system. In the opinion of this author, the most promising areas of air pollution research for HFMBs include

- Low solubility compounds.
- Cometabolism of chlorinated organic compounds.
- Compounds requiring specialized microbial populations or conditions.
- Indoor air applications.

The greatest disadvantages for the technology are high capital costs and that it has yet to be demonstrated at full scale. Due to their modular design; however, HFMBs should be relatively easy to scale up. EnviroGen, Inc. and the Medical University of South Carolina have developed a prototype with funding from the Department of Energy that they hope to field test in 2001 (Togna, 2000). Long-term studies have been conducted with membrane aeration bioreactors (Stephenson et al., 2000), which are similar in concept and operation. Membrane reactors have also been in use for several decades for blood oxygenation (Sikar, 1992) and separation and retention of biosolids (Brindle and Stephenson, 1996). In common with conventional biofilters, HFMBs have problems with excess biofilm growth and long-term stability of VOC-degrading biofilms. It is also unknown what effect long periods of association of membrane materials and biomass will have on mass transfer rates and mechanical strength in these systems.

Acknowledgments

I would like to thank my students Ayesha Dolasa, Carolyn Gendron, Yenner Keskiner, Michael McGrath, Fereshteh Mehmandoust, Andreas Reuss, and Leslee Shumway for their work on these projects. This material is based on work supported by the National Science Foundation (NSF). Review of Fine-Scale Air Quality Modeling for Carbon and Health Co-Benefits Assessments in Cities

Andrew Fang and
Anu Ramaswami

Introduction

Globally, cities exist as centers of population, economic activity, and innovation. Currently, cities around the world are grappling with serious air quality challenges that require action from local and national policymakers to protect the well-being of urban residents. Many cities around the world have annual air pollution levels exceeding the WHO standards (Health Effects Institute, 2019), and globally, this excess ambient air pollution contributed to 2.9 million premature mortalities in 2017 (Stanaway et al., 2018). As policymakers attempt to reduce urban air pollution exposure, they are challenged by air pollution emission sources which exist outside the city (and which they may not be able to manage) and inequities in intracity air pollution levels due to pollution "hotspots".

Cities are also important centers of climate change action as evidenced by the over 9,000 cities that have committed to the Global Covenant of Mayors for Climate and Energy and various organizations (e.g., ICLEI and C40) which support cities in their efforts to mitigate and adapt to climate change. Because cities are embedded within larger infrastructure and trade networks, various tools have been developed to assess current community-wide emissions, project future greenhouse gas (GHG) emissions, and assess the impact of climate mitigation policies.

Because cities are concurrently trying to manage carbon and air pollution emissions, urban environmental policies should take into account the co-benefits of carbon mitigation, particularly as they relate to reducing local air pollution levels. Recent literature (Mayrhofer and Gupta, 2016; Nemet, Holloway, and Meier, 2010) has documented the challenges of quantifying co-benefits, but the health benefits of reducing air pollution are too large to ignore. The health benefits of the reduction in air pollutants (PM2.5) from both clean energy and carbon mitigation policies may outweigh the costs of carbon mitigation in the United States (Fowlie, 2018) and globally (Markandya et al., 2018). Further, we know these benefits will be heterogeneous (Muller and Mendelsohn, 2009; Goodkind et al., 2019), and we know they will be concentrated in cities (West et al., 2013). The heterogeneity and size of these health benefits means that they also have significant equity implications (Anderson et al., 2018; Cushing et al., 2018). It is therefore important to develop accurate estimates of these benefits at the urban scale, so that the size and distribution of health co-benefits of carbon mitigation are accurately reflected in environmental policies.

For cities grappling with air quality challenges, the first question is how can we reduce annual average air pollution levels and the number of acute pollution episodes? The answer to this question varies from city-to-city depending on the economic structure of the city and various physical and meteorological characteristics. In particular, cities must identify which sectors (industrial, transportation, residential, agriculture, etc.) contribute to their local air quality challenges and whether the sources of pollution are located within or outside the city. Once policies are identified that will prove beneficial to reducing exposure to local air pollution, the next question becomes how do we make sure these benefits are distributed fairly? Potential approaches to distributing these health benefits equitably are complicated by economic (e.g., Where are marginal benefits highest? Where are marginal costs lowest?) and political concerns (e.g., Which neighborhoods historically have high levels of pollution? Does a given policy reduce this burden?). Policymakers seek to address both sets of questions as they develop strategies for urban air quality management; therefore, co-benefit models need to account for emissions inside and outside the city, while assessing changes in air quality within the city.

Separately, cities have also been developing carbon emission inventories for local climate action planning and for reporting to the Global Covenant of Mayors in Climate and Energy. Carbon accounting of community-wide emissions for cities has become more standardized over the past few years as cities have begun to report emissions through the Global Protocol for Community-Scale Greenhouse Gas Emission Inventories (GPC) (Fong et al., 2014). Community-wide carbon emissions are reported across multiple spatial scales grouped by three categories:

- Scope 1 emissions: Emissions that physically occur within the city
- Scope 2 emissions: Energy-related emissions from the use of electricity, steam, and/or heating/cooling supplied by grids which may or may not cross city boundaries
- Scope 3 emissions: Emissions that physically occur outside the city but are driven by activities taking place within the city's boundaries.

Historically, cities have used production-based approaches to quantify Scope 1 and 2 emissions. Production-based approaches have historically been ill-defined, but many have used the term in reference to territorial emissions or emissions that are occurring geographically within the city boundary (Chen et al., 2019). Recent studies (Lin et al., 2015) have re-defined the term to account for the goods and services imported into the city that are used by industries/manufacturers to better account for the impact of industrial symbiosis and other interventions improving the efficiency of urban-industrial supply chains. But cities may account for different Scope 3 emissions depending on the methodology they are following. For example, many cities have used a consumption-based approaches (C40, 2018; Lin et al., 2017) which account for Scope 1, 2, and 3 emissions due to the production of goods and services that are consumed by residents of the city, but exclude emissions from exported goods and services that are produced by the city and consumed elsewhere. The production-based approach likely underestimates emissions in cities with high consumption activity (such as cities with tourist-based economies), while the consumption-based approach has limited application in cities with high industrial or manufacturing activity (Chavez and Ramaswami, 2013). None of these approaches is perfect, but all seek to better account for carbon emissions associated with city activity that are outside the geographic boundary, and it is therefore critical that there is transparency in the methods used to quantify these emissions.

For cities using consumption-based approaches, there may be a spatial mismatch between the emissions accounted for in the carbon emissions inventory and the local/regional emissions required for air pollution modeling.

Many models and methods have been developed to manage urban air pollution and carbon emissions, but few models have been able to address the nexus of carbon, air pollution, and health co-benefits within cities. Assessing co-benefits at the city scale requires sophisticated models that are able to account for the transboundary nature of the supply chains supporting city activity and the potential for non-local emissions to impact local air quality, while also having the spatial resolution to accurately assess intracity air pollution concentrations. This review assesses the state-of-the-science tools that have been developed to assess co-benefits at the city scale.

Overview of City-Relevant Co-Benefit Models

Models which are able to assess carbon, air pollution, and health co-benefits are summarized below with a focus on nested models. This list is not meant to be exhaustive but illustrates how carbon and air pollution modeling methods can be coupled. Table 1 demonstrates how the authors' view the scope and spatial scale of models that have the ability to assess co-benefits of carbon and air pollution emission reductions. The first type of models develop carbon and air pollution co-pollutant inventories but assign air pollution/health benefits directly to each unit of emission without using air pollution and transport modeling to assess changes in air pollution concentration and exposure (e.g., UrbanFootprint, 2013). A second type of model (e.g., AERMOD) utilizes similar community-scale emission inventories to mechanistically estimate how changes in local emissions impact local air pollution concentration and exposure levels based upon non-linear dynamics of air pollution transport.

Nested models, a third type of model, are most applicable to addressing city-scale co-benefits because they acknowledge the fact that city activity induces emissions outside the territorial boundary of the city. While the location of carbon emissions is not as important due to its global impacts, the location of air pollution emissions is critical to determining to associated impacts on air quality and pollution exposure. For example, SIM-Air (Guttikunda, Nishadh, and Jawahar, 2019; Guttikunda and Jawahar, 2012), GAINS (Wagner et al., 2018), COBRA (USEPA, 2018), and AP3 (National Research Council, 2010) are well-known models which utilize gridded emission inventories and regional estimates of air pollution transport and formation to predict changes in air quality/pollution exposure resulting from changes in emissions. Models like the Carbon Footprinting and Air Pollution Dispersion (CFAD) (Ramaswami et al., 2017) utilize community-wide carbon and air pollution inventories coupled with air pollution models (e.g., AERMOD) to distinguish between how changes in local and regional emissions may impact urban air quality and exposure. Lastly, nested-reduced form models, such as InMap (Tessum et al., 2019; Hill et al., 2019), have the potential to couple carbon and air pollution inventories at multiple scales (national, state, city) with reduced form air pollution models in order to estimate changing air quality and exposure at multiple scales resulting from changes in consumption of goods and services.

Air Pollution Models

In order to assess carbon and air pollution co-benefits, air pollution models are required to connect spatially explicit carbon and air pollutant inventories with air pollution formation and transport in the atmosphere. This is critical because of the non-linear relationship between air pollution emissions and air pollution concentrations (e.g., each unit of air pollutant emission may have a varied effect on concentration). Air pollution concentrations then become the unit of analysis for air quality standards, public health, and exposure estimates. The relationship between emissions and concentration may be governed by physical characteristics of the pollution source (e.g., stack height and toxicity of pollutants), non-linear dynamics of physical processes governing pollution in the atmosphere (e.g., transport, reaction, and deposition), and geographic characteristics of the exposure site (e.g., topography and wind patterns).

TABLE 1 Boundary of Carbon Emission Accounting and Air Pollution Models for City-Relevant Co-Benefit Models

		Boundary of Carbon Emission Accounting		
		Geographic (community-wide, Scope 1+2)	Geographic (community-wide, Scope 1+2+3)	Consumption-based (Scope 1+2+3)
Boundary of Air Pollution Modeling	Air pollution emission inventories	Urban Footprint		
	Community-scale air quality models	AERMOD		
	Nested local-regional-national models (source–receptor)	GAINS, SIM-Air, COBRA, AP3		
	Nested local-regional-national models (dispersion)		CFAD	
	Nested local-regional-national models (reduced form)			InMap

Note: Co-benefit models with the ability to couple across spatial scales are organized based upon the geographic boundaries of the carbon emission accounting and air pollution exposure.

To accurately assess the impact of these factors, air pollution models are needed to determine the dynamics of each unit of emissions once they enter the atmosphere. For city-level co-benefits modeling, these tools need to have the potential utilize urban and regional emissions inventories while evaluating air pollution concentration at a fine-grained spatial resolution so that intercity and intracity air pollution/health benefits can be estimated. This means that the air pollution models that are most applicable at the city scale need to balance data availability and accessibility with the computational complexity necessary to model air pollution transport and formation.

Given the uncertainty in modeling and the need to estimate air quality across varying spatial and temporal resolution, various methods exist for estimating air quality. Monitors are generally used to track air quality over time and to ensure compliance with air quality regulations; they also provide data validation for modeling results. Land use regression techniques use the historical data from monitors in comparison with land use variables (e.g., density) to predict air pollution levels with high spatial resolution. Recently, aerosol optical dispersion techniques (Di et al., 2017; van Donkelaar et al., 2016) have advanced considerably, using satellite data with increasingly high spatial resolution to estimate air pollution concentrations over time in locations lacking monitoring data.

While these methods are extremely sophisticated, they do not connect emissions reductions directly to concentration reductions. Therefore, these techniques are not able to directly inform policy design and implementation but are useful for empirical and historical air quality studies; for example, many studies have explored how health outcomes change before and after a policy change (e.g., Ebenstein et al., 2017). The models described below estimate air pollution concentrations and changes in exposure based on spatially resolved emissions inventories. This is critical to developing prospective scenarios that determine a priori the benefits of policies and interventions which reduce air pollution.

The challenge for air pollution models is to balance the complexity of modeling atmospheric processes that induce primary and secondary formation of pollutants with the spatial and temporal resolution necessary to answer policy-relevant questions, for example, where are high air pollution concentrations located or how can cities improve region-wide air quality? Urban air pollution concentration will be a function of the emissions (local and non-local) and the meteorological conditions (wind speed, wind direction, mixing height, etc.) that govern pollution formation at any given time. In practice, modelers must make the choice between model processing time and spatial resolution (Gilmore et al., 2019; Tessum, Hill, and Marshall, 2017). This tradeoff is very important for determining which models can assess the benefits of policy-induced emissions reduction at the city scale.

Application of Fine-Scale Air Pollution Models to Co-Benefits in Cities

Air pollution and transport models are tailored to specific spatial and temporal scales, which means they can estimate air pollutant concentrations across multiple spatial scales ranging from global to between buildings. Figure 1 illustrates the spatial dimensions of carbon and air pollution emission inventories compared to the scale at which air pollution models operate. The discussion below will focus on those tools that have potential to be applied to urban-scale co-benefits evaluation and policy scenarios.

Models that are able to address co-benefits at the urban scale need to be designed to utilize emissions data that distinguishes between local and non-local emissions, estimate changes in air pollution exposure within cities, and be customizable to policies that are specific to the jurisdiction in question. Not all air pollution models will be well suited to evaluate co-benefits at the city-wide scale, because many may be designed for alternate purposes such as regulatory compliance. The air pollution models which are most relevant need to differentiate between in-boundary and transboundary emissions so that urban and non-urban pollution control strategies can be evaluated. They must also account for the variation of inter- and intra-city air pollution exposure, so that the distribution of air pollution and health benefits can be assessed to determine which areas and populations will benefit most from air pollution control policies being considered. To systematically evaluate the air pollution and transport models that have the ability to estimate city-scale co-benefits, the following air pollution model characteristics need to be considered:

1. Primary/Secondary PM2.5 formation – Primary PM2.5 drives the local emissions component of urban PM2.5 concentrations because it consists of the particles directly emitted during energy combustion, industrial, and agricultural processes. In contrast, secondary PM2.5 is formed in the atmosphere by reactions between SOx, NOx, NH_3, etc. that may occur over larger provincial and regional areas.

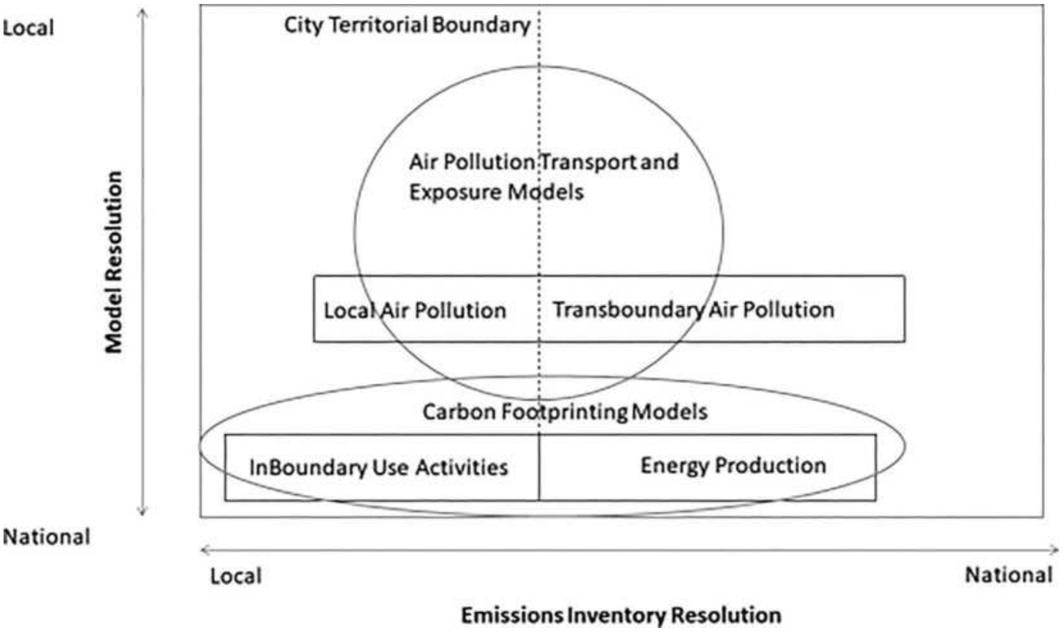

FIGURE 1 Spatial Resolution of Carbon Footprinting and Air Pollution Models – Geographic Scale of Carbon/Air Pollution Models shown as black ovals and geographic scale of emissions inventories shown as black boxes. Although carbon and air pollution emissions are aligned at the city scale, carbon and air pollution models evaluate outcomes at different scales because air pollution damages occur on a local-regional scale while climate damages occur on a global scale.

2. Spatial Resolution – Model inputs (emission inventories) and outputs (concentration estimates) will be set to a standardized or variable grid ranging from 0.1 to 50 km. The spatial resolution of these grids has implications for data availability and the model's ability to assess air pollution exposure within the city
3. Ground-Truthing and Relevance – Some models are comparable to real-time monitored air pollution levels, while others are intended to predict changes in air pollution levels based on changes in emissions. Recently, a number of reduced form tools (AP3, EASIUR, InMap) have been developed to quantify marginal benefits in pollution reduction. Critically, these reduced form tools do not claim to be more accurate than previous models, nor is their intention to be used for regulatory compliance. Instead, they focus on developing assessments of changes in pollution exposure due to policies that reduce local, regional, or national emissions.
4. Application – Certain air pollution models may be better suited for different policy-relevant questions. Models may be tailored to assess the health impacts of changes in emissions and exposure to air pollution, while others may be better suited for the identification of concentrated areas of pollution.

Although a variety of air pollution models exist, the following section is focused on the subset of models that can be readily applied to city-scale co-benefits. It is critical to note that the most state-of-the-art models may not be widely used by local policymakers due to data, computational, and technical capacity limitations. Reduced form models have been developed to make air pollution models more accessible and more policy-relevant by reducing computational effort and allowing for broader evaluation tailored to location-specific policies/interventions. The following three sections evaluate three types of air pollution models using the criteria above to determine which air pollution and transport models are best suited for different questions surrounding co-benefits at the urban scale.

Dispersion Models

- *Description*: Gaussian plume dispersion models (e.g., AERMOD) estimate air pollution levels that are downwind of individual sources or source groups. They are useful for predicting pollution impacts within cities due to nearby sources but are not recommended for predictions of long-range pollution transport (>50 km) (Cimorelli et al., 2005; USEPA, 2015).
- *PM2.5 Formation*: Primary PM2.5 only; assumes that increased concentration in cities is mainly due to local sources.
- *Spatial Resolution*: Fine-scale resolution (<1 km) enables assessment of intracity air pollution exposure.
- *Application*: Used for regulatory purposes to determine near-source impacts of large emitters, but generally cannot estimate secondary formation of PM2.5 or predict long-range pollution transport.
- *Co-Benefits Examples*: Applied at the local to regional scale, can be nested with carbon footprinting models (e.g., CFAD) (Ramaswami et al., 2017).

Chemical Transport Models

- *Description*: Chemical transport models (CTMs) are three-dimensional mechanistic models that predict ambient concentrations of pollutants using mass balance principles accounting for emissions, transport, dispersion by winds, chemical transformations, and atmospheric removal processes. CTMs are the most scientifically sophisticated and rigorous tools available for linking emissions to ambient concentrations (e.g., CMAQ, WRF-Chem) (Byun and Ching, 1999; Grell et al., 2005).
- *PM2.5 Formation*: Primary and Secondary PM2.5 including gridded emission inventory of all PM2.5 precursors.
- *Spatial Resolution*: Coarse (>4 km) due to model complexity, computational processing time, and availability of nationwide fine-scale emissions inventory data (US-based models utilize the triennial National Emissions Inventory).

TABLE 2 Summary of Air Pollution Models for Urban Application

	Increasing Complexity		
	Reduced Form Models	Air Pollution Dispersion	Chemical Transport Models
Example	InMap, AP3	AERMOD	CMAQ, WRF-Chem
Contribution	Less computationally intensive, predictions of marginal damages	High spatial resolution, intracity variability (identification of pollution hotspots)	State-of-the-art physical and chemical transport process model, most complete spatial/temporal coverage
Limitations	Limited temporal coverage, limited comparability to observed concentrations	Only primary PM2.5, not recommended for long-range transport	Computationally intensive, coarse spatial scale`

Note: In order of increasing computational complexity, this table provides examples, contribution, and limitations of air pollution models that can be applied to urban co-benefits.

- *Application*: Can be compared to real-time air pollution monitoring and used for regulatory impact assessment, but limited spatial and temporal resolution.
- *Co-Benefits Examples*: Applied at the National or Regional Scale (Thompson et al., 2016; Zhang et al., 2016).

Reduced Form Models

- *Description*: To improve the availability and accessibility of state-of-the-science CTM air quality modeling and cost estimates, the air quality research community has recently created a new set of simplified models, known as reduced form or reduced-complexity models, to estimate the marginal social costs of air pollution in terms of monetized health damages per pollutant (Gilmore et al., 2019). These models estimate marginal social costs with nested local-regional-national emission inventories.
- *PM2.5 Formation*: Variable – AP3 (Primary PM2.5 only), InMap (Primary and Secondary PM2.5 Formation).
- *Spatial Resolution*: InMap (1–48 km) but coarser than dispersion models.
- *Application*: Able to model prospective policy scenarios and sensitivity to model/scenario uncertainties due to lower computational intensity. These models are meant to estimate marginal air quality and health benefits based upon the changes in air quality that can be attributed to changes in emissions; may be limited in their comparability to real-time pollution data.
- *Co-Benefits Examples*: Applied at multiple scales – national (Markandya et al., 2018), regional (Muller and Mendelsohn, 2009), and local (Goodkind et al., 2019; Paolella et al., 2018) (Table 2).

In the US context, air pollution dispersion and CTMs have historically been used by state and national regulators to ensure regulatory compliance and perform regulatory impact assessments. These models on their own have robust applications to urban air quality management strategies, but are not necessarily aligned with local analyses that seek to address carbon, air pollution, and health co-benefits. Dispersion and reduced form models have already been integrated with city-scale carbon accounting methods due to their ability to incorporate nested emission inventories at multiple spatial scales. Local policymakers and practitioners should use these tools or tools with similar functionality to quantify the magnitude and distribution of carbon, air pollution, and health co-benefits

Conclusion

Reducing air pollution has significant benefits both globally and locally. Environmental policies that are designed and implemented at the local-regional scale must take into account both the magnitude and distribution of these health benefits because of their implications on cost-benefit analyses and developing political support for local environmental policies. Models developed to date have been limited in their ability to measure urban carbon and air pollution co-benefits. First, it has been challenging to acquire data on activity and emissions delineated between local sources and regional/national sources of pollution (>50 km from city). Second, the complexity of state-of-the-art models leads to limitations in terms of the software/equipment, computational time, and technical capacity needed to apply these tools towards the development of local air pollution and carbon policy. Further, these state-of-the-art models have been designed for state/national level assessments and may not have the spatial resolution necessary to estimate urban air pollution/health benefits.

A variety of commercially available models have been developed to assess how carbon emissions will respond to changes in land use, technology, and policy/behavior changes at the urban scale. Certain models also attempt to measure air pollution benefits of these changes using linear marginal benefits estimates (UrbanFootprint, 2013) or neural networks to predict air quality changes based on weather, traffic, and air pollution sensor data (Siemens, 2019). While these estimates may have some predictive value, these models have limited ability to inform the design and implementation of local policies that impact air pollution. Models that inform policy should estimate both the change in criteria air pollutant emissions *and* the changes in local air pollution concentrations due to the non-linear relationship between air pollution emissions reduction and air pollution exposure reduction. This is critical because of the heterogeneity that exists in the marginal benefits of reducing one unit of air pollution and because these benefits will be higher within cities but distributed unequally throughout the city. These marginal benefits need to be estimated at high spatial resolution (e.g., sub-county scale) because there may be an order of magnitude difference within counties (Goodkind et al., 2019).

The recent development of reduced-complexity models is a promising alternative, recognizing the importance of estimating the marginal benefits of reductions in air pollution with high spatial resolution and limited computational complexity (Gilmore et al., 2019). These models combine the ability to estimate the impact of both local/long-range pollution sources on air quality levels within cities with the granularity to estimate variations in air pollution exposure at the sub-county level. As these models develop and become used in discussions around equity (Tessum et al., 2019; Tessum, Hill, and Marshall, 2017), it is important to assess the relationship between mechanistic and empirical models.

The spatial resolution of relevant co-benefits models is a critical variable to assess, particularly when considering equity implications of the distribution of air pollution/health benefits (Paolella et al., 2018). Because carbon and air pollution emission inventories also take place across nested spatial scales (city, region, national), models addressing co-benefits must also have the ability to differentiate between urban and non-urban emission reductions. Models which can couple spatially explicit emission inventories with regional air pollution transport methods are best suited for assessing co-benefits at the city scale. If these models can combine regional air pollution transport with high spatial resolution at the sub-county scale, then they have the ability to inform environmental policy design so that the health benefits of reducing air pollution are both optimal and distributed more equitably.

Given the uncertainties in underlying local emissions, exposure, and demographic data, policymakers must acknowledge two key truths. First, not all emissions reductions are created equal; improving air quality across urban areas requires an understanding of the implications of emitter location and physical characteristics of local and non-local emitters. Second, the marginal health benefits of reducing local air pollution will not be distributed uniformly across the city, so policy needs to be designed to account for the presence of concentrated areas of pollution, particularly when addressing multi-pollutant policies (e.g., policies and interventions which reduce multiple pollutants, such as carbon and criteria air pollutant emissions). The complex nature of air pollution and atmospheric transport has resulted in multiple models that may be able to serve different co-benefits-related questions. Moving forward, it is critical that the modeling community develops tools that are suited to the questions that policymakers are asking so that environmental policy design is being informed by the best available science. These tools need to have the ability to utilize local and regional emissions data across multiple spatial scales spanning the city boundary, while also measuring air pollution exposure variation within the city. The existing suite of tools is not perfect but can be used to evaluate the magnitude and distribution of carbon, air pollution, and health co-benefits in cities. Policymakers can use these tools for prospective analyses to determine which carbon and air pollution policy options may have the most health benefits at the city scale and then utilize other empirical methods involving satellite-derived and air quality monitor data to evaluate how these policies change air quality and health outcomes over time.

Thermal Energy: Solar Technologies

Muhammad Asif
and Tariq Muneer

Introduction

The sun is a source of energy on Earth, and in a sense, it is a source of life, as energy is the most important commodity for life besides providing light and heat to the planet. The reaction between the sun's energy and Earth's atmosphere determines weather patterns and rainfall, and Earth's tilt towards the sun creates the seasons. Its role in photosynthesis helps plants to grow and in biodegradation complete the natural cycle of ecosystems. The sun also sources several other forms of energy on the planet: wind power depends on the sun's impact on atmospheric movement as it creates wind patterns; through photosynthesis, sun contributes to bioenergy (wood and other organic materials); and fossil fuels indirectly owe their creation millions of years ago to solar energy.[1]

Solar energy is one of the most promising renewable technologies. It is abundant, inexhaustible, environmentally friendly, and widely available. Solar energy has the potential not only to play a very important role in providing most of the heating, cooling, and electricity needs of the world, but also to solve global environmental problems. Solar energy can be exploited through solar thermal and solar photovoltaic (SPV) routes for various applications. While SPV technology enables direct conversion of sunlight into electricity through semiconductor devices called solar cells, solar thermal technologies utilize the heat energy from the sun for a wide range of purposes.

Solar thermal technologies are quite diverse in terms of their operational characteristics and applications—they include fairly simple technologies such as solar space heating and solar cooking as well as complex and sophisticated ones like solar air conditioning and solar thermal power generation. Solar thermal technologies have also a broad bandwidth in terms of their economical standing. Solar water heating and solar space heating, for example, are very cost-effective and are regarded among the most economical renewable energy technologies, while high-temperature technologies such as solar thermal power generation and solar air conditioning are on the higher economic bandwidth. Solar thermal technologies on the basis of their working temperature can be classified into the following three types:

- Low-temperature technologies (working temperature <70°C)—solar space heating, solar pond, solar water heating, and solar crop drying.
- Medium-temperature technologies (70°C< working temperature <200°C)—solar distillation, solar cooling, and solar cooking.
- High-temperature technologies (working temperature >200°C)—solar thermal power generation technologies such as parabolic trough, solar tower, and parabolic dish.

In the coming sections, this entry provides an overview of these technologies, briefly highlighting their technology fundamental and operating principles.

Solar Space Heating

Solar energy can be used to accomplish heat for comfort in buildings. The application, referred to as solar space heating, is used to optimize the reduction of auxiliary energy consumption in such a way that minimum overall cost is obtained. In combination with conventional heating equipment, solar heating provides the same levels of comfort, temperature stability, and reliability as conventional systems. A building that includes some arrangement to admit, absorb, store, and distribute solar energy as an integral part is also referred to as a solar house. A solar space-heating system can consist of a passive system, an active system, or a hybrid of the two.

Passive Space Heating

In passive space heating, the buildings are designed or modified so that they independently capture, store, and distribute solar heat throughout the building without using any electrical or mechanical equipment. Inherently flexible passive solar design principles typically accrue energy benefits with low maintenance risks over the life of the building. The design does not need to be complex, but it does involve knowledge of solar geometry, window technology, and local climate. Passive solar heating techniques generally fall into three categories: direct solar gain, indirect solar gain, and isolated solar gain, as shown in Figure 1.

Direct Solar Gain Design

Direct gain passive designs typically have large windows with predominately equatorial aspects. In this design, solar radiation directly penetrates and is stored in the building's inherent thermal mass, in materials such as concrete, stone floor slabs, or masonry partitions that hold and slowly release heat.

Indirect Solar Gain Design

In indirect solar passive design, a glazed heat collector, also referred to as Trombe wall, collects and stores solar radiation during the day. A Trombe wall consists of an 8–16″ thick masonry wall coated with a dark, heat-absorbing material and covered by a single or double layer of glass, placed from about

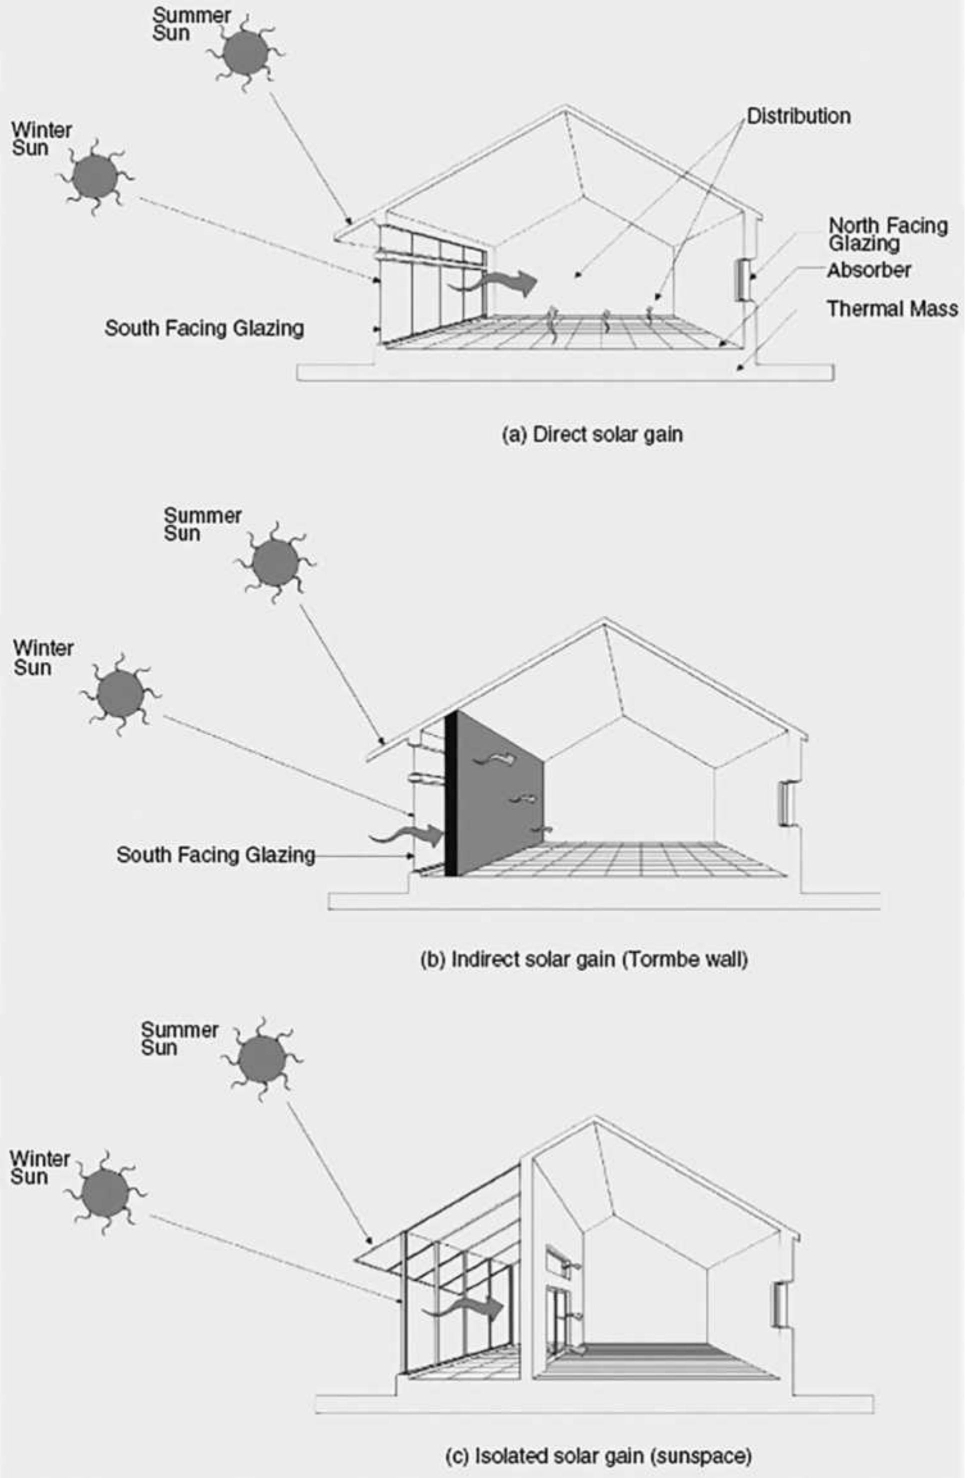

FIGURE 1 Passive solar space-heating principles. a-c captions adequately describe the relevant techniques, same is the case with Figure 6.

¾″ to 6″ away from the masonry wall. Heat from the sun is stored in the air space between the glass and the dark material, and conducted slowly to the interior of the building through the masonry through the conduction and convection mechanisms.

Isolated Solar Gain Design

In isolated solar passive systems, an extra highly glazed unheated room—a sun-space or conservatory—is added to the south side of the house. Solar gains always make sun-spaces warmer than the outside air, and this reduces heat losses from the house and warms any ventilation air that passes through the sun-space. When solar gains raise the sun-space above house temperature, the heat collected can be let into the house by opening communicating doors and windows.[2]

Active Space Heating

In active space heating of buildings, additional electrical and mechanical equipment is incorporated to circulate solar heated water or air. The main components of an active system are the heat collectors, storage tanks or pebble bed storage, heat exchangers, heat emitters, fans/pumps, connecting pipes or ducts, and controls. Active solar heating systems can be designed to provide the same levels of control of condition in the heated spaces as conventional systems. With indoor temperature essentially fixed at or little above a minimum, load estimations can be done by conventional methods. Passively heated buildings in many cases are not controlled within the same narrow temperature ranges.[3]

Hybrid Solar Space Heating

Solar space-heating system can also be of hybrid nature, combining both the passive and active modes. For example, in a hybrid system, a roof-space collector accomplishes passive collection of solar energy that can be actively distributed in the house using a fan and associated ductwork.

Solar Water Heating

Water heating is an essential feature of energy requirements in industrial and commercial sectors in general and in domestic sector in particular. A solar water heater consists of two main elements—the collector and the water storage tank, which, respectively, have the functions of absorbing solar radiation and transferring it to the water, and storing the water for usage. The collectors in solar water heaters can be broadly classified into two categories—flat plate and evacuated tube. A flat plate collector consists of an absorber plate that absorbs solar energy, while a glazing above it is used to reduce convective heat loss. An evacuated tube collector consists of tubes with vacuum maintained between the tubes and glazing for better protection against convective heat loss.

Solar water heaters come in three main types: thermosyphon, built-in-storage, and forced circulation. There are two operating principles for solar water heaters: passive system, which relies on natural circulation of water (such as thermosyphon, built-in-storage types); and active system, which uses an external element such as an electric pump to circulate the water (such as the forced circulation type). Another criterion that distinguishes solar water heaters is the way they transfer heat to water. Again, there are two types: direct system, in which the collector itself transfers heat to water; and indirect system, in which a heat-transfer fluid, circulating in collector in a closed loop, transfers heat to water through a heat exchanger. Figure 2 shows an indirect active solar water heater.

The efficiency of a solar water heater depends upon its design and the available solar radiation. In this entry, solar water heating has been classified as a low-temperature thermal technology because most of its application is in residential sector where it operates at a temperature of ≤70°C. Also, in industrial applications, solar water heaters are used as preheaters and to hold supply water at almost the

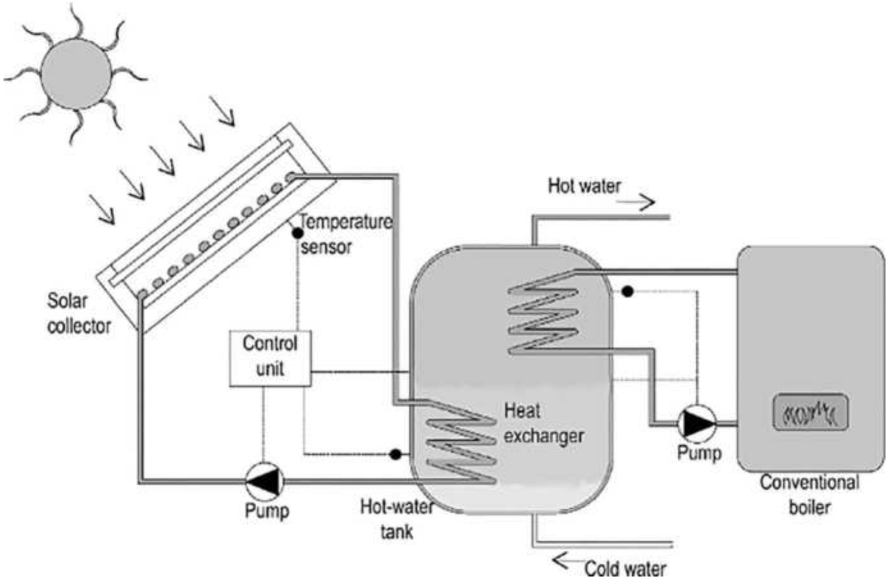

FIGURE 2 Indirect active solar water heating system.

same temperature for further heating by conventional means. Solar water heaters are a cost-effective technology—the payback period of solar water heaters can be as low as 3 years while having a service life of more than 20 years. Owing to its technical and economical viability across the world, solar water heating is one of the most established and efficient application of solar energy. Among solar thermal technologies, solar water heating holds the greatest market share and the highest market growth rate.

Solar Ponds

Solar ponds are naturally occurring salt gradient lakes that collect and store solar energy. A solar pond contains salt water with increasing concentrations of salt, hence the density of the solution. When solar radiation is absorbed, the density gradient prevents heat in the lower layers from moving upward by convection and leaving the pond. This results in an increased temperature at the bottom of the pond and a near atmospheric temperature at the top of the pond. The phenomenon of solar ponds was first discovered in 1902 by von Kalecsinsky, who reported that the Medve Lake in Transylvania, containing nearly saturated NaCl solution at a few meters depth with almost fresh water at its surface, had a bottom temperature of 70°C.

A solar pond has three distinctive zones. The top layer is the surface zone that has a low salt content and is at atmospheric temperature. It is also called the upper convective zone (UCZ), as shown in Figure 3. The bottom layer has a very high salt content and is at a high temperature, 70°C–90°C. This is the zone that collects and stores solar energy in the form of heat, and it is called the lower convective zone (LCZ). There is an intermediate insulating zone with a salt gradient. It establishes a density gradient that prevents heat exchange by natural convection, and hence, it is called the nonconvective zone (NCZ). In this zone, salt content increases with depth, creating salinity.

Solar ponds can be broadly classified into two main types: nonconvective and convective. In nonconvective solar ponds, the heat loss to environment is reduced by suppressing natural convection normally by using salt stratification. While in convective ponds, heat loss to environment is reduced by covering the pond surface with a transparent material. The heat trapped in the solar ponds can be used for many different purposes, such as industrial process heating, the heating of buildings, desalination, and to drive a turbine for generating electricity.

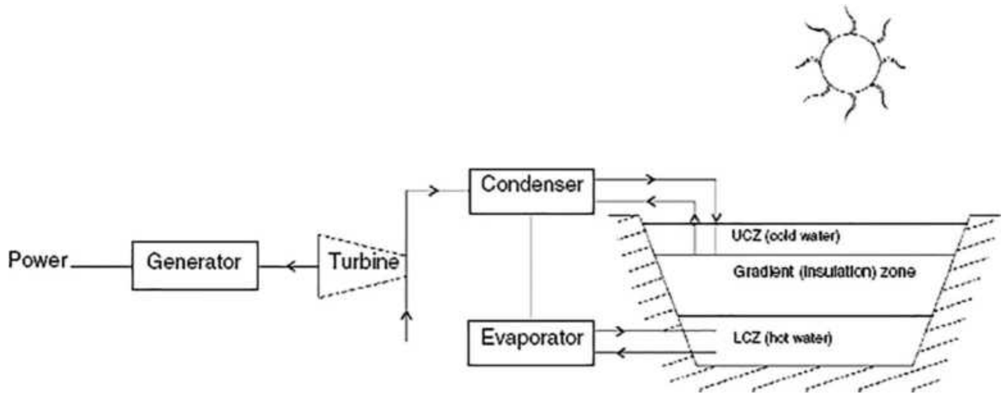

FIGURE 3 Schematic of solar pond power generation system.

The first artificial solar pond was developed in Israel in 1958. Since then, many countries such as Australia, the United States, China, India, Iran, Italy, and Mexico have constructed solar ponds, mostly for research and development purposes. During the last decade, significant success in operational practices and applications of solar pond technologies has been achieved.[4]

Solar Crop Drying

Drying is the oldest technique used to preserve food. Until around the end of the 18th century when canning was developed, drying was virtually the only method of food preservation. Solar energy is the main driving force that utilizes warm air to dry food. In drying, the moisture from the food is reduced to a certain level—as low as 5–25% depending on the type of food-to prevent decay and spoilage in an environment free of contaminations such as dust and insects. Successful drying depends on[5]

- Enough heat to draw out moisture, without cooking the food
- Dry air to absorb the released moisture
- Adequate air circulation to carry off the moisture.

Solar drying can be carried out in open air under the sun by simply spreading the material on a clean surface or in particularly designed solar dryers. Solar dryers, however, exhibit many advantages over open air drying. First, solar dryers are more efficient because they require lesser drying time and area. Second, the product is protected from rain, insects, animals, and dust, which may contain fecal material. Third, faster drying reduces the likelihood of mold growth. Fourth, higher drying temperatures mean that more complete drying is possible, and this may allow much longer storage times (only if rehumidification is prevented in storage). Finally, more complex types of solar driers allow some control over drying rates. Solar dryers can be made in many different designs depending upon various factors, i.e., the type of produce, scale of operation, and local economical and environmental conditions. In terms of their operational mode, solar dryers can be broadly classified into two main types, active and passive dryers, which can both be further subclassified into direct (in which the produce is directly heated from sun) and indirect types (in which the produce is not directly exposed to sun).

Almost all types of food—for example, vegetables, fruits, milk, herbs, spices, meat, and fish—can be dried by solar energy. The advantages of solar food drying are numerous. Dried foods, for example, are tasty, nutritious, lightweight, easy to prepare, and easy to store and use. The energy input is less than what is needed to freeze or can, and the storage space is minimal compared with that needed for canning jars and freezer containers.

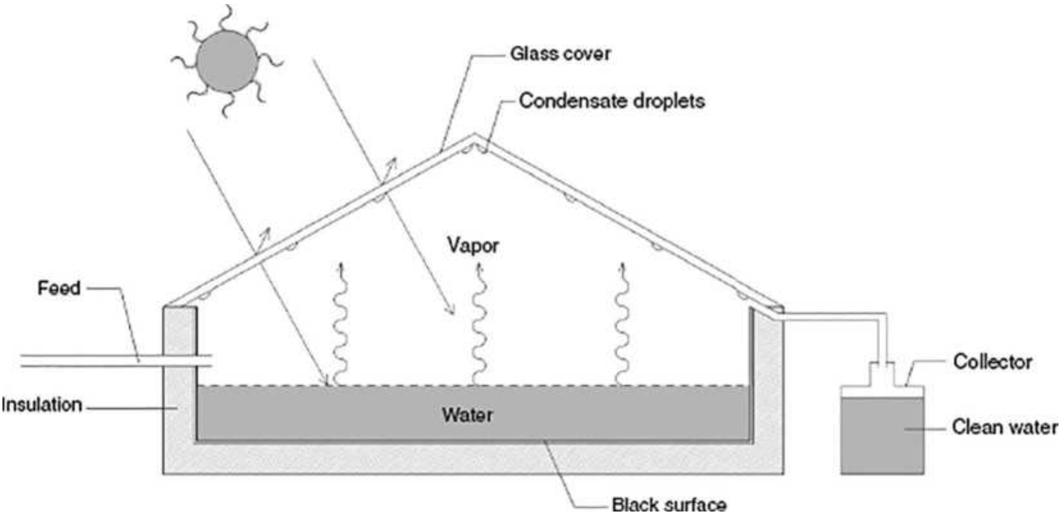

FIGURE 4 Schematic diagrams of a solar still.

Solar Distillation

Solar distillation is a process that utilizes solar energy to purify water through evaporation and condensation processes. The process is also referred to as water desalination when solar energy is used to purify water from saline water. Solar water distillation is a solar technology with a very long history. Installations were built over 2,000 years ago, although they were to produce salt rather than drinking water. Documented use of solar stills (the distillation unit) began in the 16th century. An early large-scale solar still was built in 1872 that spread over an area of 4,600 m^2 capable of producing 23,000 L of drinking water for a mining community in Chile. Mass production occurred for the first time during the World War II when 200,000 inflatable plastic stills were made to be kept in life-crafts for the US Navy.[6] In addition to their use in obtaining drinking water, solar stills are also suitable for the production of distilled water if there is appreciable demand for it in industry, laboratories, and medical facilities or to fill lead acid batteries.

Solar stills come in different designs; however, the main features of operation are the same for all of them. In its simple form, water can be placed in an airtight basin that has a sloped transparent cover normally made of glass or plastics, although glass is preferred for its high transparency. The basin is coated with a black lining to maximize absorption of solar radiation. The incident solar radiation is transmitted through the glass cover and is absorbed as heat by the black surface in contact with the water to be distilled. The water is thus heated and gives off water vapor. The vapor condenses on the glass cover, which is at a lower temperature because it is in contact with the ambient air, and runs down into a tray where it is fed to a storage tank, as shown in Figure 4. The economic viability of solar stills is determined to a critical degree by the design, the construction, the materials employed, and the local market conditions.

Solar Cooking

A solar cooker or solar oven harnesses solar energy to cook food. The solar cooker was first developed by a Swiss scientist Horace de Saussure in 1767.[7] Solar cookers are now being used in many countries across the world, especially in remote areas of poor countries. Solar cookers accomplish free cooking with environment friendliness as they only capitalize solar energy. Solar cooking can be very helpful in reducing the deforestation and pollution that originate from consumption of wood, and animal and agricultural residues for cooking in remote areas that lack access to electricity and gas. Solar cookers are capable of performing various types of cooking phenomena, i.e., frying, baking, and boiling. The maximum achievable temperature depends on the intensity of the available solar radiation and the design and size of the solar cooker. Solar cookers come in a wide range of designs, which can be categorized under the following three major types.

Solar Box Cookers

A solar box cooker consists of an insulated box with a transparent top and a reflective lid. It is designed to capture solar radiation and make use of the greenhouse effect to cause heat to accumulate inside. The top is removable to allow food pots to be placed inside. Temperatures in a typical box cooker can reach above 200°C, but the temperatures achieved obviously depend on the size and design parameters of the cooker and the location of use.

Solar Panel Cookers

The solar panel cooker is the simplest solar cooker, and it consists of multiple simple reflectors arranged to focus solar radiation onto a covered black pot enclosed in a clear heat-resistant plastic bag or other transparent enclosure, such as glass bowel.

Solar Parabolic Cookers

Parabolic solar cookers, also called concentrated cookers, consist of a concave disk that focuses the light onto the bottom of a pot that is arranged at the focal length of the disk, as shown in Figure 5. These are the most efficient types of solar cookers.

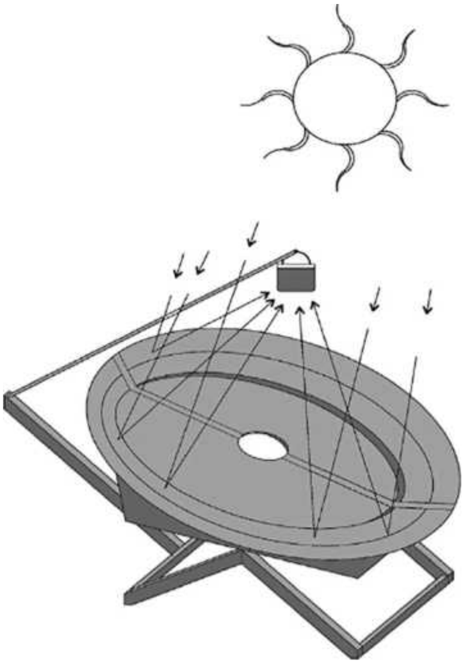

FIGURE 5 Parabolic type of solar cooker.

TABLE 1 Overview of Processes for Thermally Powered Cooling and Air Conditioning

Solar Thermal Cooling System Design	Adsorption Refrigeration	Absorption Refrigeration	Desiccant Air Conditioning
Solar collector	Vacuum tube collector, flat plate collector	Vacuum tube collector	Flat plate collector, solar air collector
Coolant circulation process	Closed refrigerant circulation systems	Closed refrigerant circulation systems	Open refrigerant circulation systems (in contact with the atmosphere)
Process basic principle	Cold water production	Cold water production	Air dehumidification and evaporative cooling
Sorbent type	Solid	Liquid	Solid
Refrigerant/sorbent	Water–silica gel ammonia–salt	Water–water–lithium bromide, ammonia–water	Water–silica gel water–lithium chloride–cellulose
Typical operating temp.	60°C–95°C	80°C–110°C (one step) 130°C–160°C (two step)	45°C–95°C

Solar Cooling/Air Conditioning

Solar thermal energy can be used for cooling and dehumidification. Collectors play a critical role in extracting the energy from solar radiation to operate the cooling device. The collectors used in solar thermal cooling could be of various types, such as low-temperature flat plates and high-temperature evacuated tubes and concentrators. The basic principle behind solar thermal cooling is the thermochemical process of sorption—a liquid or gaseous substance is either attached to a solid, porous material (adsorption) or taken in by a liquid or solid material (absorption). The heat-transfer fluid is heated in the solar collectors to a temperature well above ambient and used to power a cooling device—a type of heat-actuated pump. The heat-transfer fluid may be air, water, or another fluid; it can also be stored in a hot state for use during times of no sunshine. Heat extracted by the cooling device from the conditioned space and from the solar energy source is rejected to the environment using ambient air or water from a cooling tower.[8]

The solar thermal cooling process can be broadly classified under open cycle systems and closed cycle systems. Open cycle systems are those in which the refrigerant is in direct contact with atmosphere and is discarded from the system after providing the cooling effect and new refrigerant is supplied in an open-ended loop. In closed systems, on the other hand, the refrigerant is not in direct contact with the atmospheric air. Open and closed cycle systems can further be distinguished according to the type of sorbent used, which can be in a liquid or a solid form. The three main designs of solar thermal cooling technologies that have gained the most attraction include solar adsorption, solar absorption, and solar desiccant. The key features of these designs are provided in Table 1.[9]

Solar Thermal Power Generation

Solar thermal power generation systems start with capturing heat from solar radiation. Direct solar radiation can be concentrated and collected by a range of concentrating solar power technologies to provide medium- to high-temperature heat. This heat then operates a conventional power cycle—for example, through a steam turbine or a Stirling engine to generate electricity. Solar thermal power plants can be designed for solar-only or hybrid operation, where some fossil fuel is used in case of lower radiation intensity to secure reliable peak-load supply. Five distinct solar thermal power generation concepts are available:

- Solar pond
- Solar chimney

TABLE 2 Characteristics of Typical Concentrated Solar Collectors

Solar Collector Technology	Typical Operating Temperature (°C)	Concentration Ratio	Tracking	Maximum Conversion Efficiency (Carnot) (%)
Solar Fresnel reflector technology	260–400	8–80	One-axis	56
Parabolic trough collectors	260–400	8–80	One-axis	56
Heliostat field + central receiver	500–800	600–1000	Two-axis	73
Paraboloidal dish concentrators	500–1200	800–8000	Two-axis	80

- Solar parabolic trough
- Solar central receiver or solar tower
- Solar parabolic dish.

Solar pond and solar chimney are nonconcentrated types of technology. In this section, the three concentrated types of solar thermal technologies—solar parabolic trough, solar central receiver, and solar parabolic dish—are discussed, as they have received the greater degree of attention over the years due to their favorable technical and commercial characteristics. These technologies can be used to generate electricity for a variety of applications, ranging from remote power systems as small as a few kilowatts (kW) up to grid-connected applications of 200–350 megawatts (MW) or more.[10]

Solar thermal power generation systems have three essential elements needed to produce electricity: a concentrator (to collect and focus solar radiation), a receiver (to convert concentrated solar radiation into heat), and an engine cycle (to generate electricity). Some systems also involve a transport or storage system. Solar collectors have a crucial role to play in the whole system and can be mainly classified into two types: concentrating and nonconcentrating. They are further categorized on the basis of their concentrator optical properties and the operating temperature that can be obtained at the receiver. Most of the techniques for generating electricity from heat need high temperatures to achieve reasonable efficiencies. Concentrating systems are hence used to produce higher temperatures. Table 2 shows the operational characteristics of concentrated collectors.[11]

Parabolic Trough

The parabolic trough systems consist of large curved mirrors or troughs that concentrate sunlight by a factor of 80 or more onto thermally efficient receiver tubes placed in the trough's focal line, as shown in Figure 6a. A thermal transfer fluid, such as synthetic thermal oil, is circulated in the tubes at focal length. Heated to approximately 400°C by the concentrated sun's rays, this oil is then pumped through a series of heat exchangers to produce superheated steam.[12] The steam is converted to electrical energy in a conventional steam turbine generator, which can either be part of a conventional steam cycle or integrated into a combined steam and gas turbine cycle, as shown in Figure 7. Parabolic trough power plants are the only type of solar thermal power plant technology with existing commercial operating systems.

It is also possible to produce superheated steam directly using solar collectors. This makes the thermal oil unnecessary and also reduces costs because the relatively expensive thermo oil and the heat exchangers are no longer needed. However, direct solar steam generation is still in the prototype stage.

Central Receiver or Solar Tower

In solar thermal tower power plants, hundreds or even thousands of heliostats (large individually tracking mirrors) are used to concentrate sunlight onto a central receiver mounted at the top of a tower, as indicated in Figure 6b. A heat-transfer medium in this central receiver absorbs the highly concentrated radiation reflected by the heliostats and converts it into thermal energy to be used for the subsequent

(a) Parabolic trough

(b) Central receiver or solar tower

(c) Parabolic dish (Stirling engine)

FIGURE 6 Solar thermal power generation technologies.

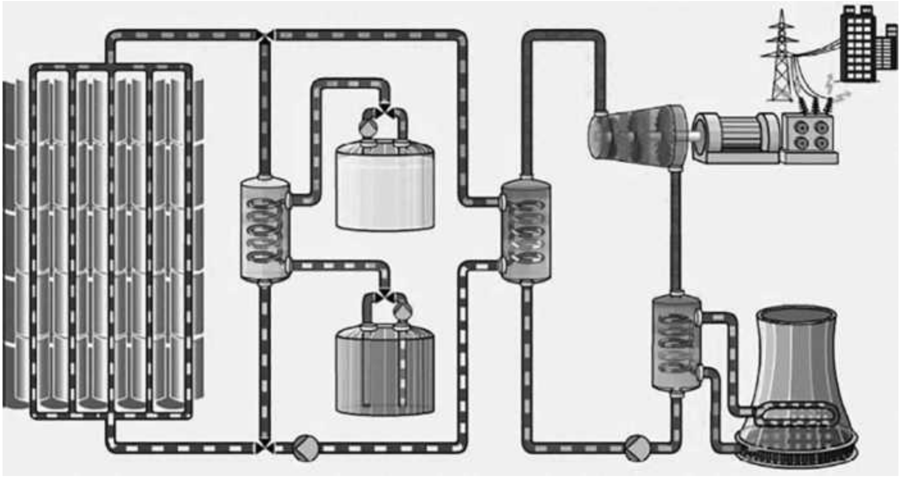

FIGURE 7 Schematic of solar parabolic trough power plant.

generation of superheated steam for turbine operation. To date, the heat-transfer media demonstrated include water or steam, molten salts, liquid sodium, and air. If pressurized gas or air is used at very high temperatures of about 1000°C or more as the heat-transfer medium, it can even be used to directly replace natural gas in a gas turbine, thus making use of the excellent cycle of modern gas and steam combined cycles.

Parabolic Dish

A parabolic dish system uses a parabolic concave mirror to concentrate sunlight onto a receiver located at the focal point of the mirror, as highlighted in Figure 6c. The concentrated beam radiation is absorbed into the receiver to heat a fluid or gas (air) to approximately 750°C. This fluid or gas is then used to generate electricity in a small piston, Stirling engine, or a microturbine attached to the receiver. These systems stand alone, and they are normally used to generate electricity in the kilowatts range.[13]

Solar Thermal Technologies—Market Growth and Trends

Solar thermal technologies, like other renewables, are experiencing a rapid growth. Between 2007 and 2017, for example, the global installed capacity of solar water heaters increased from 145 GW_{th} to 472 GW_{th}. The year 2017 saw an addition of 35 GW_{th}. China alone accounts for over 71% of the world's total solar water heating installed capacity. Other leading countries include Turkey, India, Brazil, the USA, and Germany. In terms of collector type, while glazed flat plate collectors are the preferred choice around the world, in China and India glazed evacuated tube collectors account for over two-thirds of the market. Of the new installations in 2017, vacuum tube collectors had a share of 73%. Flat plate collectors and unglazed collectors accounted for respective shares of 23% and with 4%.[14]

Over the past decade, concentrated solar power (CSP) has experienced a rapid growth —between 2007 and 2017 the global installed capacity increased from 0.45 to 4.9 GW, with around 2 GW of projects being under construction. Spain has emerged as the global leader over this period installing 2.3 GW of CSP projects. Over 80% of the world's total installed capacity is in Spain and the USA, the two countries having respective figures of 2.3 and 1.7 GW. In terms of the ongoing developments, China is having 20 projects—including parabolic trough, tower, and Fresnel facilities—at various stages of construction, with a combined capacity of 1 GW. The Middle East and North Africa (MENA) region, being rich in the direct solar radiation, has shown a significant interest in the technology. United Arab Emirates (UAE), having already installed 100 MW of CSP, has awarded tender for 700 MW (600 MW parabolic basin complex and a 100 MW solar tower) of projects. Morocco is having two projects with total capacity of 350 MW at advanced stages of completion. Projects are also underway in Kuwait, Israel, and Saudi Arabia with respective capacities of 50, 121, and 93 MW. Projects in Chile and Australia of respective capacity 110 and 100 MW are also under construction. Driven by factors like competition and technology cost reduction, the year 2017 has also witnessed record-low tariffs: AUD78/MWh in Australia, USD50/MWh in Chile, and USD73/MWh in UAE.[14]

Solar thermal technologies are regarded to be playing an important role in the future energy scenarios. A scenario of what could be achieved by the year 2025 was prepared by Greenpeace International, the European Solar Thermal Industry Association, and International Energy Agency (IEA) SolarPACES projects. It suggested that by 2025, the total installed capacity of solar thermal power around the world will reach over 36 GW. It is also projected that by 2040, more than 5% of the world's electricity demand may be satisfied by solar thermal power.[12]

Conclusions

Solar thermal technologies operate by converting solar radiation into heat, which can be either directly utilized in various applications such as solar space heating, solar water heating, and solar air conditioning, or can be transformed into electricity to serve any purpose similar to conventional electricity. The key element in all solar thermal technologies is the collector, whose function is to gather the heat of solar radiation. Collectors normally come in three different types: flat plate, evacuated tube, and concentrated, and they operate in a wide range of temperatures, i.e., from less than 50°C to more than 1200°C. Solar thermal technologies normally operate in passive or active modes. Different types of solar thermal technologies are gaining huge attention across the world depending upon their technical and economic viability. Solar thermal power generation is also expected to grow at a healthy rate in coming years, as it is projected that by 2040, more than 5% of the world's electricity demand could be satisfied by solar thermal power.

Acid Rain

Umesh Kulshrestha

Introduction

Any form of precipitation (rain, snow, or hail) having high acidity is known as acid rain. The term "acid rain" was first used by Robert Angus Smith in his book *Air and Rain: The Beginnings of a Chemical Climatology,* published in England in 1872.[1] He had chemically analyzed the rainwater near Manchester and observed three types of rain composition—"that with carbonate of ammonia in the fields of distance, that with sulfate of ammonia in the suburbs and that with sulfuric acid or acid sulfate, in the town."

In broader perspectives, acid rain refers to wet deposition (rain, snow, hail, cloud water, fog, dew, or sleet) and dry deposition (absorption of SO_2, NO_x, other acidic gases and particles) of acidic compounds. High acidity is generally caused by higher levels of sulfuric and nitric acids. These acids are contributed by their precursor gases (SO_2 and NO_2), which are emitted by natural as well as anthropogenic sources. Natural sources include volcanoes, vegetation decay, various biological processes on the land, and oceans, while major anthropogenic sources of these gases are fossil fuel combustion and smelting of metal ores. In regions of North America, the rates of anthropogenic emissions of these two gases have gone up to 100 times more than the natural rates, adding to higher atmospheric acidity.[2] Acid rain has caused severe damage in Europe, North America, parts of China and Japan through acidification of lakes and other water bodies, decline of forests, acidification of soils, and corrosion of building materials.

How Acid Rain Happens

Pure water (H_2O) is neutral in nature, having a pH value of 7. Any aqueous solution having a pH higher than 7 is said to be alkaline, while one having a pH lower than 7 is known as an acidic solution. Rainwater in remote and unpolluted atmospheres has a slightly acidic pH of around 5.6 due to the presence of carbonic acid formed at equilibrium due to dissolution of atmospheric carbon dioxide in cloud water:[3]

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \tag{1}$$

In water, carbonic acid is dissociated, forming bicarbonate ion:

$$H_2CO_3 \leftrightarrow HCO_3 - + H^+ \tag{2}$$

Rainwater pH is further depressed to about 5.2 in unpolluted regions by organic acids. However, anthropogenic acid rain arises due to oxidation of SO_2 and NO_2 in the atmosphere to form sulfuric and nitric acids. There are a number of probable reactions for the oxidation of these gases involving both homogeneous and heterogeneous oxidation.[4] The gas-phase oxidation of these gases is initiated by reaction with hydroxyl radicals:

$$SO_2 + OH \rightarrow HOSO_2 \tag{3}$$

$$HOSO_2 + O_2 \rightarrow HO_2 + SO_3 \tag{4}$$

$$SO_3 + H_2O \rightarrow H_2SO_4 \tag{5}$$

Homogeneous aqueous-phase oxidation of SO_2 takes place by its dissolution and dissociation in water, forming equilibrium similar to CO_2:

$$SO_2 + H_2O \leftrightarrow SO_2H_2O \tag{6}$$

$$SO_2.H_2O \leftrightarrow HSO_3 - + H^+ \tag{7}$$

$$HSO_3 - \leftrightarrow SO_3{}^{2-} + H^+ \tag{8}$$

Gas-phase oxidation of NO_2 is faster than SO_2 by one order of magnitude:

$$NO_2 + OH \rightarrow HNO_3 \tag{9}$$

In addition, significant formation of nitric acid takes place through ozone and NO_3 radical reactions.

During daytime, NO_3 radical is formed as follows:

$$NO_2 + O_3 \rightarrow NO_3 + O_2 \tag{10}$$

NO_3 radical so formed reacts with NO_2 at nighttime, finally resulting in the formation of HNO_3:

$$NO_3 + NO_2 \leftrightarrow N_2O_5 \tag{11}$$

$$N_2O_5 + H_2O \rightarrow 2HNO_3 \tag{12}$$

At ambient levels of NO, its aqueous-phase oxidation is very slow due to its low solubility in water and also the dependence on NO_2 concentrations. It can be faster at higher NO_2 levels. However, the reaction follows the path

$$2NO_2 + H_2O \leftrightarrow 2H^+ + NO_3 - + NO_2 - \qquad (13)$$

Heterogeneous oxidation of SO_2 and NO_2 involves gas- particle reactions. In the liquid phase, SO_2 is rapidly converted into sulfate by H_2O_2. SO_2 is also converted into sulfate on freshly emitted soot particles, but subsequently, the rate of oxidation is retarded due to saturation of soot particle surface. Preferable oxidation of SO_2 onto soil dust particles is reported in dusty regions where formation of calcium sulfate takes place instead of free sulfuric acid. NO_2 is also oxidized onto particles—for example, it reacts with NaCl of sea salt, forming $NaNO_3$ on the surface. However, over time, the surface is saturated, and the rate of oxidation becomes lower.

History of Acid Rain

The major cause of acid rain is the increased combustion of fossil fuels, which has been practiced at larger scale after the industrial revolution. The presence of sulfur compounds in the air of Sweden and England was realized in the 18th century. In fact, Robert Boyle, in 1692, mentioned in his book *A General History of the Air* the "nitrous and salino-sulphureous spirits" in the air.[4] The term "acid rain" was first used in 1872 by Robert Smith, who discovered acid rain in 1852 in the area surrounding Manchester. He referred to this term in a treatise on the chemistry of rain published in England in 1872. Robert Smith mentioned various factors such as coal combustion and the amount of rain affecting the precipitation. Unfortunately, this wonderful publication was overlooked until it was revisited and critiqued by Gorham in 1981.[1]

Acid rain attracted attention of the scientific community and society when Odén[6,7] reported that large-scale acidification of surface waters in Sweden could be attributed to pollution from the United Kingdom and central Europe. The worst-hit areas of acid rain were Scandinavia and Central and Southern Germany. In Europe, the rain pH was observed to be as low as 3.97 in Germany. Drastic loss of fish population was seen in lakes of Sweden and parts of southwest Norway. European data show that most of the acidity was intensified during 1955–1970, with a sudden increase in the mid-1960s. In parts of Germany and other European countries, forest damage and loss of needles from pine and spruce trees were noticed due to acid rain. Acid smog killed almost 4000 people in London in 1952.

Sources of Acidity

As mentioned earlier, in natural conditions, atmospheric CO_2 when dissolved in water forms carbonic acid (H_2CO_3), which brings down the pH of water. Other gases such as SO_2 and NO_2 also form acids, viz., sulfuric (H_2SO_4) and nitric acid (HNO3), respectively. The main cause of acid rain is excess contribution of H_2SO_4 and HNO_3 in precipitation due to anthropogenic sources, especially through combustion of coal and petroleum. Sulfur is present in significant amounts in fossil fuel (coal and petroleum), which is the major source of SO_2. Oxidation of SO_2 is accelerated by higher concentrations of H_2O_2 and O_3 found in polluted air. Martin and Barber[8] noticed that acidity of precipitation at several sites in England was the highest during spring, when O_3 concentrations were higher. During past century, huge consumption of fossil fuel in North America and Europe resulted in high SO_2 emissions.[9,10]

Natural Acidity Contributed by Organic Acids

Apart from sulfuric and nitric acids, acidity in rainwater is also contributed by organic acids. Formic acid (HCOOH) and acetic acid (CH3COOH) are the major species reported in rainwater, contributing around two-thirds of the total acidity at remote sites.[11] Generally, formic acid is found to dominate over acetic acid. A relatively higher contribution of organic acids is observed at tropical sites than at temperate ones. These organic acids are produced in gas phase by the oxidation of isoprene and terpenes emitted by the vegetation,[12,13] which are then scavenged by the rain. These are also formed through aqueous-phase oxidation of aldehydes. Sometimes, these acids are emitted by soils.[14] It is to be noted that organic acids may be important for pH in cloud and rainwater in some areas, but their contribution to acidification of soils and surface waters is small because these are quickly consumed by microorganisms.

Spread and Monitoring of Acid Rain

Considering the degree of damage caused by acid rain, several efforts are made by European countries to monitor and control it. The European Air Chemistry Network was started in the early 1950s by Stockholm University in collaboration with the Swedish University of Agricultural Sciences. Both institutes served as centers for the network for the chemical analysis of samples. Originally, the purpose of this network was to study the depositions of plant nutrients to forest and agriculture systems. Under this network, continuous data related to chemical composition of precipitation have been available since 1955.[15] Later on, this network became part of the Swedish National Monitoring Programme. A Norwegian program called SNSF, "Acid Precipitation: Effects on Forests and Fish" was run up to 1980.[16] Immediately after the Stockholm conference in 1972, the European Organization for Economic Cooperation and Development (OECD), in 1978, established a network to monitor long-distance transport of pollutants and the impacts of European countries on their neighbors, known as the Cooperative Program for Monitoring and Evaluation of Long-Range Transmission of Air Pollutants in Europe (EMEP). Further, in 1983, the Convention on Long-Range Transboundary Air Pollution (CLRTAP) was signed by more than 30 countries, including the United States, Canada, and the European Union, to deal with transboundary air pollution.

The discovery of acid rain in Europe attracted attention of scientific community in North America too. Odén's study was followed up by the United Nations (UN).[17] This also led to the first international conference on acid rain in Columbus, Ohio, United States, in 1975. Later on, under the Acid Precipitation Act of 1980, U.S. Congress formed a national network called National Acid Precipitation Assessment Program (NAPAP), which supported the expansion of National Atmospheric Deposition Program (NADP) to monitor the trends in long-term precipitation chemistry and deposition. Further, the NADP was changed to the NADP National Trends Network, which has around 250 monitoring sites.

Similar to Europe and United States, Canada also experienced acid rains. Environment Canada has developed its program called the Canadian Air and Precipitation Monitoring Network (CAPMoN) to monitor the regional patterns and trends of atmospheric pollutants. including acid rain, smog, particulate matter, etc., Canada started the Canadian Network for Sampling Precipitation in 1978, which was renamed as the Air and Precipitation Network (APN). CAP- MoN is the new name of APN (changed in 1983).

Later on, the spread of acid rain was also noticed in East Asia. After successful implementation of CLRTAP in Europe, the UN Conference on Environmental Development adopted to continue and share the experience gained from acid rain programs in Europe and North America and established the Acid Deposition Monitoring Network in East Asia (EANET) in 1993. This network includes Japan, Russia, China, the Republic of Korea, Mongolia, Thailand, Singapore, Cambodia, Lao People's Democratic Republic, Myanmar, Vietnam, the Philippines, Malaysia, and Indonesia.

Measurements through the long-term acid rain network have not been carried out extensively in other parts of the world such as India, Africa, and Latin America. However, programs such as the Composition of Atmospheric Aerosols and Precipitation in India and Nepal and the Composition of Asian Deposition (CAD), as part of the Regional Air Pollution in Developing Countries (RAPIDC) program funded by the Swedish International Development Cooperation Agency), were very effective in providing a summarized picture of the acid rain scenario in the Indian region.[18,19] The RAPIDC program was coordinated by the Stockholm Environment Institute, which facilitated international cooperation on air pollution issues to develop relevant knowledge to support decision making in Asia and Africa. The CAD program was a part of the International Global Atmospheric Chemistry/Deposition of Biogeochemically Important Trace Species (IGAC/DEBITS) activities of the International Geosphere-Biosphere Programme, which focused on good-quality measurements at rural sites in Asia to produce high-quality data so as to understand the Asian wet deposition scenario. In the African region, the IGAC/DEBITS-Africa program has its network of 10 stations for the measurement of wet and dry depositions at selected sites.

In Australia, acid rain studies have been carried out under the Commonwealth Scientific and Industrial Research Organisation (CSIRO) network of sites.[20] Globally, the 1989 initiative of the World Meteorological Organization, under the Global Atmospheric Watch (GAW), is carrying out precipitation measurements at around 80 stations in different countries. Earlier, GAW used to be known as the Background Air Pollution Monitoring Network (BAPMoN).

Regional Acidity of Precipitation

United States

As described by Gibson,[10] northeastern United States and southeastern Canada were the most affected areas by acid rain. Likens[21] was the first who evaluated the 1955–1956 and 1972–1973 data and found a significant increase in acidity in northeastern United States and southeastern Canada during the two decades. He also noticed a significant increase in the spread of acid rain in the areas of southeastern and Midwestern United States.[22]

Canada

Long-term measurements of acid deposition in Canada showed that other than local sources, acidity was also contributed by the long-range transport of oxides of sulfur and nitrogen from sources located southerly in the United States. According to Environment Canada, more than half of the acid deposition in eastern Canada is originated from the United States. Studies by the APN showed higher acidity in southern Ontario, having a pH of around 4.2.[23] Regionally representative sites Long Point and Chalk River experienced that, most of the time, wind parcels came from southerly source areas. These sites are the receptor sites to the major sources in Ontario and the lower Great Lakes region. Estimates of the year 1995 showed that 3.5–4.2 Tg per year of SO_2 was transported from the United States to Canada. Acid deposition in Canada can be reduced by the joint measures of the United States and Canada. Collaborative efforts in this direction are already in progress.

Europe

Areas affected by acid rain in Europe include northern and western Europe, southeast England, Germany, the Netherlands, and parts of Denmark. Table 1 shows a drastic decrease of precipitation pH in western Europe during the 1950s and 1970s.[24]

TABLE 1 Change in pH of Precipitation in Western Europe during the 1950s and 1970s

Country	pH in 1950s	pH in 1970s
Southern Norway	5.0–5.5	4.7
Northern Sweden	5.5–6.0	4.3
Southern Sweden	5.5–6.0	4.3
Southeast England	4.5–5.0	4.2

Source: Environmental Resources Ltd. Pearce.[24]

OECD 1977 estimates indicate that anthropogenic emissions of sulfur in Europe increased by 50% during 1955–1970. However, later on (1972–1982), many European countries, viz., the United Kingdom, West Germany, the Netherlands, Sweden, Norway, and Denmark reduced their sulfur emissions. These reduction measures improved the situation in Europe.[15]

Asia

In the Asian region, much of the acid rain problem prevails in East Asia, covering China, Japan, North Korea, and Thailand. Among these, China is the biggest polluter. According to estimates, China's sulfur emissions will triple between 1990 and 2020.[25] After the United States and Europe, China is the biggest consumer of fossil fuel. Rapid increase in SO_2 and NO_x emissions from 2000 onward is a major reason for the spread of acid rain in China.[26] The area most affected by acid rain in China is south of the Yangtze River, where average pH is recorded to be less than 4.5.

Acidity levels in precipitation in Japan show seasonality. During the summer season, most of the acidity is observed to be due to local sources of sulfur oxides, whereas during the winter season, increased level of acidity is due to long-range transport from the Asian continent, which results in higher acidity of precipitation at the sites in western Japan.[27] Similarly, Thailand also experiences acid rain. Around 50% of rain events are reported acidic due to high concentration of sulfate and nitrate. Of these oxides, 70%–80% are contributed by Thai sources.[28]

In the Indian subcontinent, precipitation is reported to have relatively higher pH (>5.6).[19,29] The pH of rainwater at some of the continental sites in India is as high as 8.3 (Table 2) due to interference of soil dust (rich in calcium carbonate) suspended in the atmosphere. Abundance of soil dust in air is a

common feature of the Indian atmospheric environment. The pH of most soils of India is very high as compared with the pH of soils in acidified regions of the world. Generally, in India, the pH of rainwater is the mirror image of the pH of soil in the region. The acidity generated by the oxidation of gases like SO_2 and NO_x is buffered by soil-derived particles. Acidity of SO_2 is buffered by $CaCO_3$ of soil dust forming calcium sulfate, which is removed by below-cloud scavenging (Figure 1). Due to this, the spread of acid rain at continental sites in India is controlled by the continuous suspension of loose soil during prevailing dry weather conditions. However, a bigger number of hot spots of higher wet deposition of non-sea salt sulfate (nss SO_4) are reported in urban and industrial areas than in rural areas. Several of these larger hot spots lie in the Indo-Gangetic region (Figure 2).

Although rainwater pH higher than 5.6 is more frequently recorded in India, sometimes, occurrence of acid rain (pH <5.6) is also reported. Figure 3 shows the frequency of acid rain reported from various sites in India.[46] Rainwater is noticed to be acidic in India if any of following applies:

1. Rain continues for a long time, washing off soil dust from the atmosphere. A similar situation prevails over the Indian Ocean, where soil dust interference is at a minimum.
2. In the areas where a large part of ground is covered with vegetation.
3. In the areas where soil itself is acidic (northeast, east, and southwest India).
4. Near heavy sources of SO_2 (e.g., thermal power plants).

In the African region, the pH of precipitation is reported to be nearly similar to that in the Indian region. Longterm data (1994–2005) showed that the acidity of precipitation at Banizaumbou, a regional

representative site in the semiarid savanna region, has high interference of soil dust, resulting in higher pH.[47] In addition, neutralization by ammonium ion is also partly responsible for elevated pH in Africa.

At a glance, the model based global distribution of pH of rain water is shown in Figure 4.[48] The distribution of pH shows high acidity in Europe, eastern North America, and East Asia. To some extent, acidity is seen in the west coast of South America and Africa also. High acidity in these areas is due to free acidity

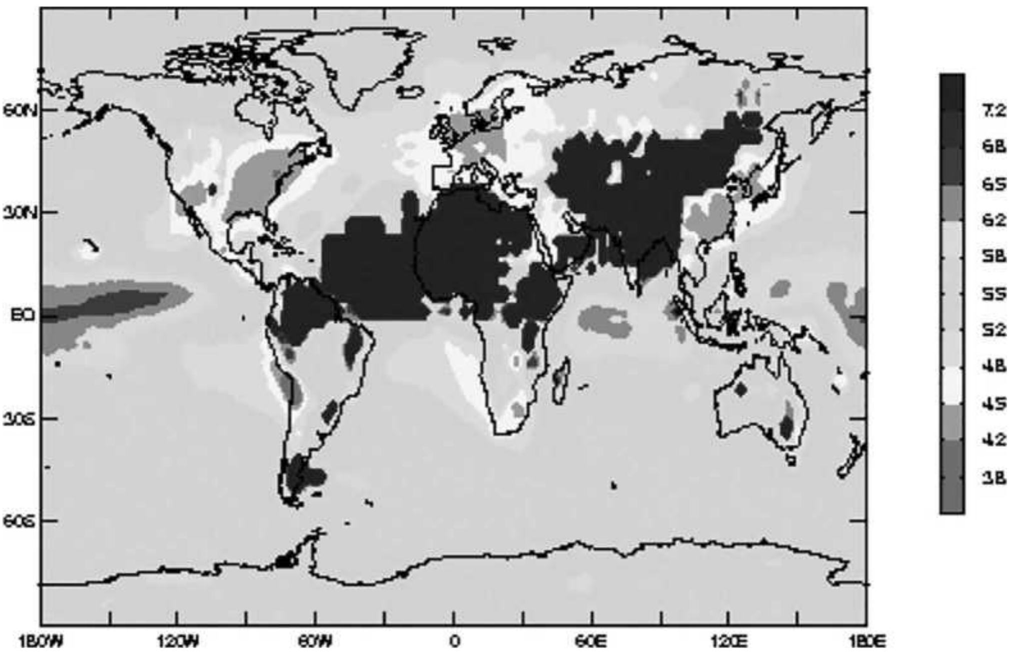

FIGURE 4 Estimated global distribution of pH of precipitation.
Source: Rodhe et al.[48]

contributed by sulfuric acid. However, in areas such as north of South America, northern Africa, South Asia, and part of China, the acidity is lower which is due to neutralization by ammonia and soil dust.

Trends in Acidity

United States and Europe

After 1980, significant reduction in SO_2 emissions has improved the situation of acidity in Europe.[49] Similarly, in Canada and the United States, effective steps of reduction in SO_2 emissions have contributed to improved acidity levels. In the United States, the average reduction in SO_2 emissions from 1980 to 2008 was around 54%, as shown in Figure 5. Overall, the reduction measures have resulted in a decrease in H^+ in precipitation over these regions. Trends of acidity in the United States show a significant improvement after implementation of the 1995 Clean Air Act Amendment, which forced them to reduce SO2 emissions. Figure 6 is an example of trends of acidity of precipitation in North Carolina during 1985–2005,[52] which shows around 50% reduction in H^+ during two decades. In Europe, sulfate concentrations increased by approximately 50% between the 1950s and the late 1960s but have been declining since the mid-1970s. In Sweden and Norway, an average of 20% reduction in SO_4 levels has been achieved since the 1970s,[15] followed by higher reductions in more recent decades.

Asia

China

In the developed countries, efforts have been made to control SO_2 emissions, but in the developing countries, SO_2 emissions continue to be high. In Asia, China is the biggest SO_2 emitter. Total Chinese SO_2 emission increased from 21.7 Tg to 33.2 Tg (53% increase) from 2000 to 2006, showing an annual growth rate of 7.3% per year.[53]

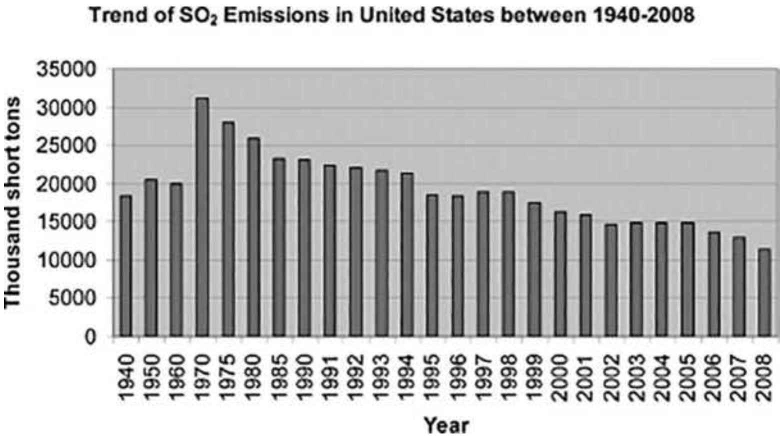

FIGURE 5 Trend of SO_2 Emissions in the United States from 1940 to 2008.

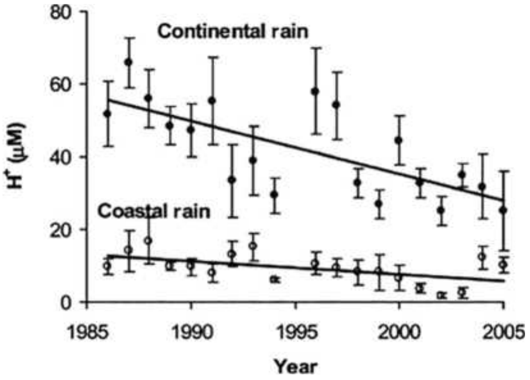

FIGURE 6 Annual volume-weighted average H^+ concentration in Wilmington, North Carolina, continental (filled circles) and coastal (open circles) precipitation from 1985 to 2005.
Source: Willey et al.[52]

Long-term acid precipitation observations show that the temporal and spatial distribution of rain acidity in China has changed remarkably since 2000.[26] Future estimates of acidification potential, using a dynamic soil acidification model, indicate that sensitive soils in south China and Southeast Asia may reach a critical threshold within a few decades.[54] Model-based estimates (Figures 7a and b) indicate higher levels of total depositions of S-SO_x and N-N_r in East Asia.

India

SO_2 emissions in India are relatively less, but the rate of increase is almost doubled from 1985 to 2005. In 2000, Indian SO_2 emission was estimated to be 4.26 Mt.[53] Precipitation studies in India lack long-term measurements. Most of the studies were carried out by individual scientists/groups. A few sites under the GAW network are in operation. In addition, one study from Pune[56] reports that during 1984–2002, there was significant increase in SO_4 and NO_3 concentrations (Figure 8), which resulted in decrease in pH of rainwater from 6.9 in 1982 to 6.5 in 2002. These changes are due to increase in industrial and vehicular activities in the region. Another long-term network study in a rural area of Nandankanan (Orissa state in east India) reported 57% frequency of acid rain events during 1997–1998,[57] which was reduced

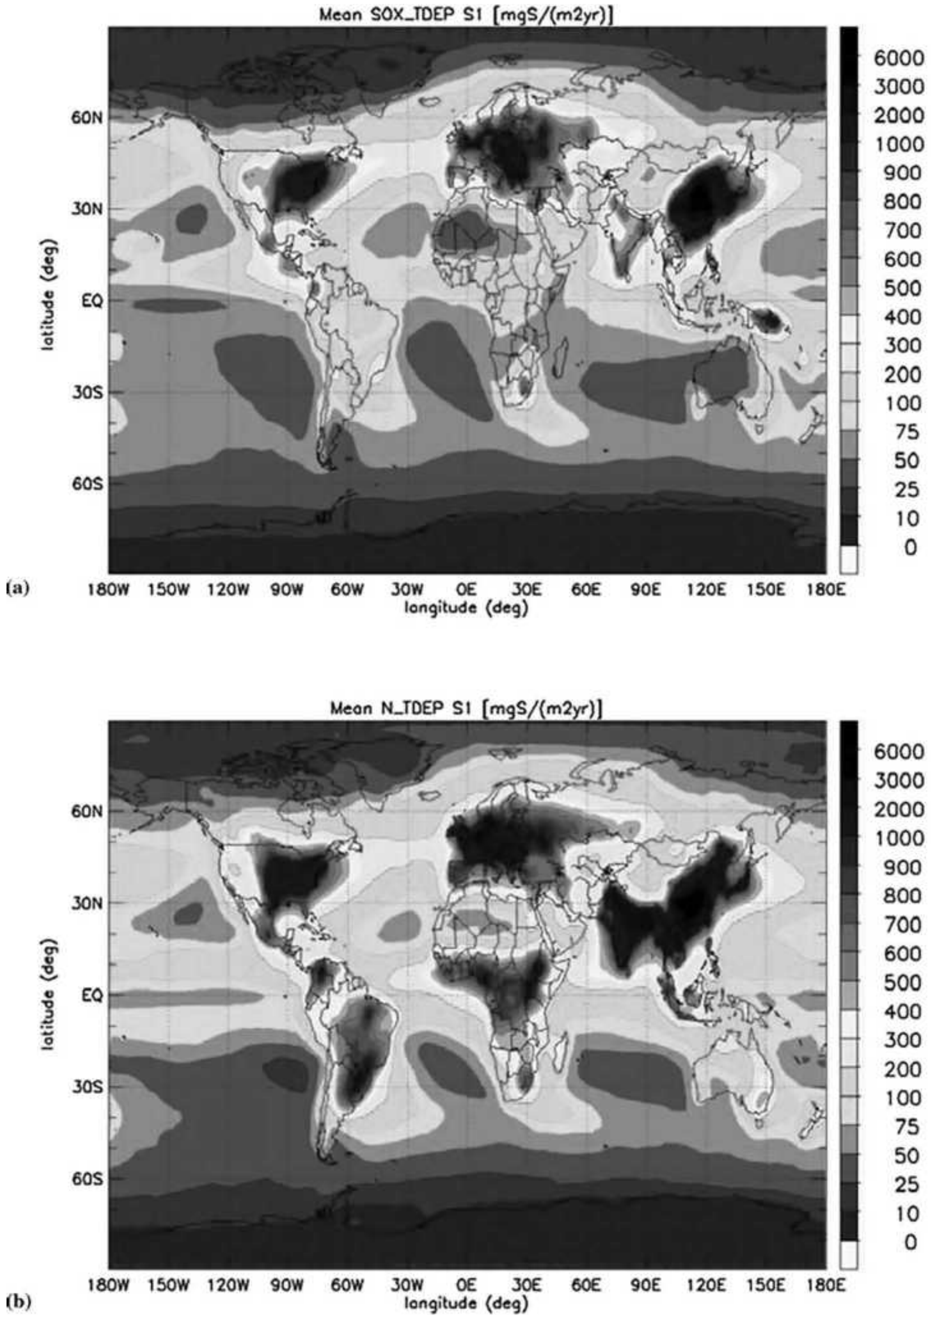

FIGURE 7 Estimated total deposition of (a) S (mg m^{-2} yr^{-1}) of SO_x and (b) N (mg m^{-2} yr^{-1}) of reactive nitrogen for year 2000.
Source: Dentener et al.[55]

to 40% during 2005–2007.[58] SO_4/Na ratios were also reduced drastically from 1.58 in 1997–1998 to 0.519 during 2005–2007. In a review compiled by Kulshrestha and coworkers,[19] it is reported that most of the Indian precipitation measurements lack quality assurance (QA) and quality control (QC) in sampling, storage, and analysis of samples. Hence, this region really needs quality-controlled measurements of

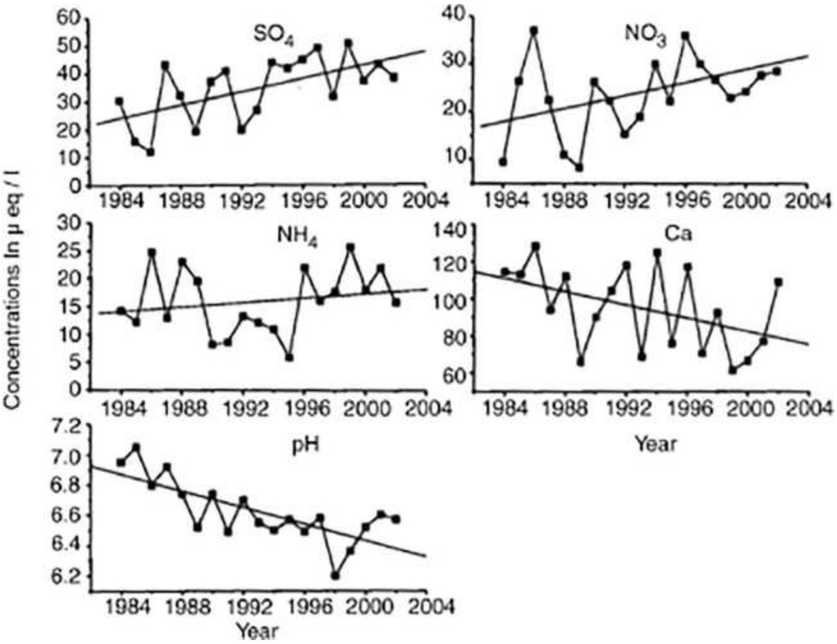

FIGURE 8 Trends of pH, SO_4, NO_3, Ca, and NH_4 in rainwater at Pune during 1984–2000.
Source: Rao et al.[56]

wet and dry depositions at a few selected sites in order to get an idea about the trends of acidity with the growing emissions of oxides of S and N.

Acidification of Oceans

Oceans are the biggest sinks for atmospheric CO_2. Increasing emissions of CO_2 due to anthropogenic sources will lead to ocean acidification through excess dissolution of CO_2 in seawater. Since the industrial revolution, the acidity of the ocean has increased by 30% (from a pH of 8.2 to 8.1). Future projections show that under a business-as-usual scenario, surface ocean pH will be lowered by 0.4 pH units by the end of the century. Acidification of the ocean affects the nitrification process, which further affects marine biota. Apart from CO_2 rise, acid deposition can add to the acidification of oceans. Precipitation having very low pH contributes a significant amount of hydrogen ions in seawater, which in the long term may alter the pH of seawater. Results from Indian Ocean Experiment showed the pH of rainwater to be between 3.8 and 5.6 over the Indian Ocean.[45] The acidic nature of rainwater over the Indian ocean is due to insignificant influence of soil dust and the dominance of anthropogenic sulfate contributed by long-range transport.[59,60] This aspect needs to be investigated in the future in order to protect the marine ecosystem.

Global Sensitivity toward Acidification

Global precipitation acidity and mapping of soil sensitivity to acid deposition suggests three main problematic areas. These are North America, Europe, and southern China (Figure 9), where acid rain control is necessary. Already, in North America and Europe, steps have been taken to reduce SO_2 emissions. Other parts of the world also need to take appropriate steps to reduce sulfur emissions.[62]

FIGURE 9 Global sensitivity toward acidification.
Source: Kuylenstierna et al.[63]

Global Scenario: Future Projections through Modeling

Recently, the Regional Air Pollution Information and Simulation model has been developed by International Institute for Applied Systems Analysis (IIASA) as a tool for the integrated assessment of alternative strategies to reduce acid deposition in Europe and Asia.[63] Dentener and coworkers[55] have attempted simulation of the global future scenario (up to 2030) of deposition of oxides of nitrogen and sulfur by using 23 atmospheric chemistry transport models. The stud focused mainly upon three emission scenarios: 1) current legislation (CLE); 2) case of the maximum emission reductions (MFR); and 3) pessimistic IPCC SRES A2 scenario. The model output showed a good agreement with observations in Europe and North America primarily because of quality-controlled measurements reported from these regions. The study suggested that in the future, deposition fluxes are going to be controlled mainly by the changes in emissions, with atmospheric chemistry and climate having a very limited role.

Regional Comparison of Precipitation Scenario

Sulfate in the Atmosphere

Normally, free acidity is contributed by the acids of SO_2 and NO_2. In case of free acidity of H_2SO_4, pH value decreases with increasing concentration of SO_4 ions. A comparison of pH and SO4 in rainwater at different sites in the United States, Sweden, and India is shown in Figs. 10–12. The United States and Sweden are examples of developed and acidified countries, whereas India is a developing country having high pH of rainwater. From Figures. 10 and 11, pH decreases with increase of SO_4 concentration, while at Indian sites (Figure 12), even at higher SO_4 levels, higher pH of rainwater is observed. This indicates that in the United States and Sweden, the SO_4 is present as H_2SO_4, which gives free H^+ in rain, but in India, it is present in a different form that does not contribute free H^+ in rainwater. The Indian dusty atmosphere is rich in $CaCO_3$, which allows SO_2 to form calcium sulfate, due to which pH of rainwater in India and other dusty regions is observed to be higher. In the Indian region, the possible

Source: Granat.[65]

mechanism of SO_2 removal is the adsorption of SO_2 onto the $CaCO_3$-dominated dust particles forming calcium sulfate.[62]

$$CaCO_3 + SO_2 + 1/2O_2 + 2H_2O \rightarrow CaSO_4.2H_2O + CO_2 \quad (14)$$

A comparison of typical composition of precipitation in an acidified region and a dusty region has been reported by Rodhe and coworkers,[48] establishing such differences very clearly.

Control of Acid Rain

Acid Rain Control Policy of the United States

Due to pressure from the public, the federal government of the United States adopted the Clean Air Act in 1970. Under this act, emission standards were set for SO_2 and NO_x, and states were directed to compliance with the National Ambient Air Quality Standards. Congress formed a 10 years program, the NAPAP, and mandated it to conduct scientific, technological, and economic study of the acid rain.

In 1990, under Clean Air Act Amendments, the National Deposition Control Program was implemented. This legislation was to control adverse effects of acidic deposition through reductions in emissions of SO_2 and NO_x. It was targeted to achieve a 50% reduction in annual SO_2 emissions by the year 2000. In 2001, SO_2 emissions from utilities subject to the provisions of the acid rain program were 39% below their 1980 levels, and total emissions from all sources were 50% less than their 1980 levels.[67] These implementation steps will help in environment protection, in particular, to check deterioration of historic buildings, to reduce fine particulate matter (sulfates, nitrates) and ground-level ozone (smog), and to improve public health.[68]

Since Canada is affected by transboundary pollution, an air quality accord was signed between the United States and Canada in 1991 under the framework of the UN Economic Commission for Europe. This bilateral accord facilitates the United States' and Canada's meeting their emissions targets for SO_2 and NO_x and putting coordinated efforts into atmospheric modeling and monitoring the effects of transboundary air pollution.[69]

European Policy to Control Acid Rain

Among European countries, most of the scientific research on acid rain effects was conducted in Norway and Sweden. In the beginning, acidification of lakes through transboundary pollution was the primary issue in Scandinavian countries. In 1972, at the UN Conference on the Human Environment in Stockholm, Sweden's case study on the effects of long-range transport of sulfur compounds was presented, which emphasized the need for international agreement to reduce damage from acid deposition. Soon after the Stockholm conference, in 1978, OECD initiated EMEP to monitor long-range pollution.

The 1985 Helsinki Protocol was the first binding commitment on the reduction of sulfur emissions or their transboundary fluxes by at least 30%. Later, a group of 12 countries decided to sign a declaration to reduce by 30% NO_x emissions by 1998 as compared with 1986 (base year). The latest agreement is the 1999 Gothenburg Protocol, which deals with SO_2, NO_x, NH_3, and non-methane volatile organic compounds (VOCs), aiming to mitigate the problem of acidification, eutrophication, and ground-level ozone. The Gothenburg Protocol targets the reduction of Europe's sulfur emissions by at least 63%, NO_x emissions by 41%, VOC emissions by 40%, and NH_3 emissions by 17%by the year 2010 from their 1990 levels.[70]

Effects of Acid Rain

Acid rain is very harmful to the environment as it damages many living and non-living things over a period of time. Acid rain affects both terrestrial as well as aquatic life. There are many inevitable impacts of acid rain, which affect natural as well as anthropogenic environments.

Effects on Aquatic Ecosystem

The aquatic ecosystem is visibly affected by acid rain as it directly falls into water bodies like lakes, streams, and rivers. Also, the extra acidic rainwater from other terrestrial places like forests and roads flows into nearby water bodies. Although the acidic effect of the rain may get diluted after it is mixed into the water bodies, it may lower the average pH of the aquatic system over the period, and in case the water body has low base cation supply or buffering capacity, it can become acidic faster. Charles and Norton[71] have reviewed the situation in lakes in United States and Canada and found that around the 1920s–1950s onward, weakly buffered lakes in some regions became more acidic. There are estimated to be around 50,000 lakes in the United States and Canada with a pH below 5.3. Out of these, hundreds of lakes have very low pH and are unable to support aquatic life, eliminating many existing insect and fish species. At pH lower than 5, the life of aquatic animals is threatened as they are unable to absorb oxygen from water. At pH lower than 4.8, fishes, frogs, and aquatic insects experience increased mortality. However, constructive steps, such as SO_2 emission reduction and liming of lakes, have significant potential for reversibility.[72,73]

Effects on Vegetation and Soil

In addition to the aquatic ecosystem, acid rain significantly affects trees, plants, forests, and other vegetation. Acid rain can damage the leaves and stems of the trees and affect their growth by getting absorbed through roots via soil. Acid rain reacts with leaves and stem wax coatings and allows acidic water to enter the leaves, thereby damaging the trees and plants. Experimental studies have established that acidic deposition causes some physiological effects in plants.[74] Especially at high altitude, the forests are surrounded by clouds carrying acidic water. The moisture of the clouds passing through the forests leads to severe damaging effects on the forests. In addition to individual effects on trees and forests, there are also effects on the soil, which contains the necessary nutrients and microorganisms for the healthy growth of the trees, plants, forests, and other vegetation. Virtual effects of acids rain have been observed all over the world, especially in Europe and eastern North America.[75,76] Hedin and coworkers[77] have reported evidence of steep decline of base cations in precipitation, which is based on long-term quality-controlled measurements, in Europe and North America. These measurements support that decline in base cations in precipitation might have resulted in increased sensitivity of a weakly buffered ecosystem, affecting forests and vegetation. Nitrification of ammonia (NH_3) and ammonium (NH_4^+) leads to the acidification of soil, which also adds to nutrient leaching:

$$NH_3 + O_2 \rightarrow NO_2 - +3H^+ + 2e- \tag{15}$$

$$NO_2 - +H_2O \rightarrow NO_3 - +2H^+ + 2e- \tag{16}$$

Effects on Buildings and Monuments

Acid rain can damage buildings and historic monuments as well by reacting with their paints and construction material. The damaged walls of the buildings and monuments leave a rough surface along with the moisture, which is a favorable place for the growth of microorganisms. Acid rain can affect sculpture and architecture adversely by corrosion. Acid rain can even corrode railway tracks, paints of cars, and joints of bridges and flyovers. A BERG report[78] gives more details of evidence of damage to stone and other materials by acid deposition. Under CLRTAP, the International Cooperative Programme on Effects on Materials, Including Historic and Cultural Monuments, has been set up, with 39 test sites, three of which are in the United States and Canada. According to a report, the corrosion rates of carbon steel, paint on steel, limestone, and bronze have decreased to about 60% from 1987 values in Europe due to decrease in SO_2 levels.[79]

Conclusion

Acid rain, which was a problem of North America and Europe, is now spreading in East Asia due to increased emissions of SO_2 from fossil fuel combustion. Experiences of the global community show that acid rain is spread through transboundary pollution. Scandinavia, Canada, and Japan are such examples. Acid rain damages water bodies, forests, vegetation, buildings, human health, etc., costing a huge loss to the economy. Although appreciable steps are taken by the United States, Canada, and Europe to control SO_2 and NO_x emissions, the considerable increase in SO_2 emission rates in China is of concern in the Asian region. During the past two decades, Chinese SO_2 emissions increased tremendously. Data show that spread of acid rain is very much controlled by suspended atmospheric soil dust in Indian and African regions. At a glance, the following are concluded:

1. Decreasing trends of SO_2 emissions in Europe and North America will be helpful in improving the pH of precipitation in coming decades.
2. Increasing trends of acidity in China in Asia may result in more acid rains in the region.
3. Systematic monitoring networks are established in North America, Europe, and East Asia to monitor acid deposition.
4. There is a strong need for long-term studies on acid deposition, including wet and dry depositions at selected sites in South Asia, Africa, and South America, through extensive networking.

Acid Rain: Nitrogen Deposition

George F. Vance

Introduction

Air pollution has occurred naturally since the formation of the Earth's atmosphere; however, the industrial era has resulted in human activities greatly contributing to global atmospheric pollution.[1,2] One of the more highly publicized and controversial aspects of atmospheric pollution is that of acidic deposition. Acidic deposition includes rainfall, acidic fogs, mists, snowmelt, gases, and dry particulate matter.[3] The primary origin of acidic deposition is the emission of sulfur dioxide (SO_2) and nitrogen oxides (NO_x) from fossil fuel combustion; electric power generating plants contribute approximately two-thirds of the SO_2 emissions and one-third of the NO_x emissions.[4]

Acidic materials can be transported long distances, some as much as hundreds of kilometers. For example, 30%–40% of the S deposition in the northeastern U.S. originates in industrial midwestern U.S. states.[5] After years of debate, U.S. and Canada have agreed to develop strategies that reduce acidic compounds originating from their countries.[5,6] In Europe, the small size of many countries means that emissions in one industrialized area can readily affect forests, lakes, and cities in another country. For example, approximately 17%of the acidic deposition falling on Norway originated in Britain and 20% in Sweden came from eastern Europe.[5]

The U.S. EPA National Acid Precipitation Assessment Program (NAPAP) conducted intensive research during the 1980s and 1990s that resulted in the "Acidic Deposition: State of the Science and Technology" that was mandated by the Acid Precipitation Act of 1980.[6] NAPAP Reports to Congress have been developed in accordance with the 1990 amendment to the 1970 Clean Air Act and present the expected benefits of the Acid Deposition Control Program,[6,7] http://www.nnic.noaa.gov/CENR/NAPAP/. Mandates include an annual 10 million ton or approximately 40% reduction in point-source SO_2 emissions below 1980 levels, with national emissions limit caps of 8.95 million tons from electric utility and 5.6 million tons from point-source industrial emissions. A reduction in NO_x of about 2 million tons from 1980 levels has also been set as a goal; however, while NO_x has been on the decline since 1980, projections estimate a rise in NO_x emissions after the year 2000. In 1980, the U.S. levels of SO_2 and NO_x emissions were 25.7 and 23.0 million tons, respectively.

Acidic deposition can impact buildings, sculptures, and monuments that are constructed using weatherable materials like limestone, marble, bronze, and galvanized steel,[7,8] http://www.nnic.noaa.gov/CENR/NAPAP/. While acid soil conditions are known to influence the growth of plants, agricultural impacts related to acidic deposition are of less concern due to the buffering capacity of these types of ecosystems.[2,5] When acidic substances are deposited in natural ecosystems, a number of adverse environmental effects are believed to occur, including damage to vegetation, particularly forests, and changes in soil and surface water chemistry.[9,10]

Sources and Distribution

Typical sources of acidic deposition include coal- and oil-burning electric power plants, automobiles, and large industrial operations (e.g., smelters). Once S and N gases enter the earth's atmosphere they react very rapidly with moisture in the air to form sulfuric (H_2SO_4) and nitric (HNO_3) acids.[2,3] The pH of natural rainfall in equilibrium with atmospheric CO2 is about 5.6; however, the pH of rainfall is less than 4.5 in many industrialized areas. The nature of acidic deposition is controlled largely by the geographic distribution of the sources of SO_2 and NO_x (Figure 1). In the midwestern and northeastern U.S., H_2SO_4 is the main source of acidity in precipitation because of the coal-burning electric utilities.[2] In the western U.S., HNO_3 is of more concern because utilities and industry burn coal with low S contents and populated areas are high sources of NO_x.[2]

Emissions of SO_2 and NO_x increased in the 20th century due to the accelerated industrialization in developed countries and antiquated processing practices in some undeveloped countries. However, there is some uncertainty as to the actual means by which acidic deposition affects our environment,[11,12] http://nadp.sws.uiuc.edu/isopleths/maps1999/. Chemical and biological evidence, however, indicates that atmospheric deposition of H_2SO_4 caused some New England lakes to decrease in alkalinity.[13,14] Many scientists are reluctant to over-generalize cause and effect relationships in an extremely complex environmental problem. Although, the National Acid Deposition Assessment Program has concluded there were definite consequences due to acidic deposition that warrant

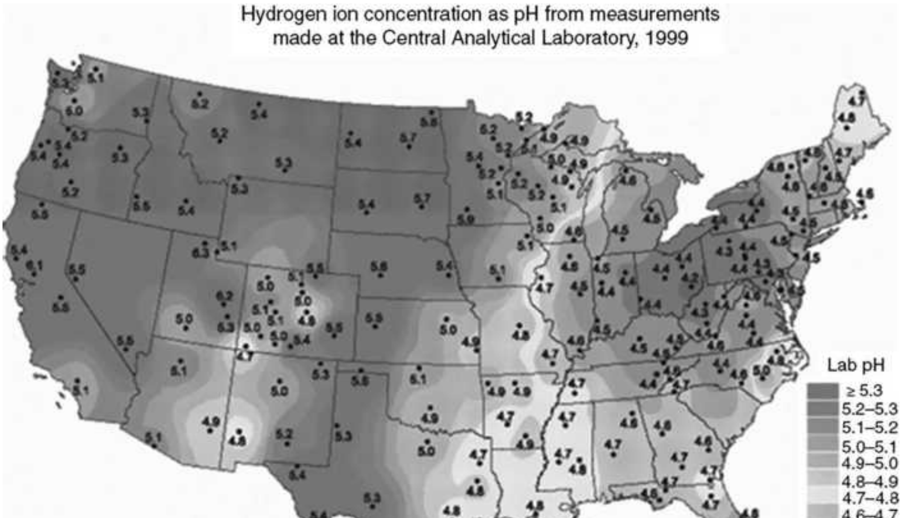

FIGURE 1 Acidic deposition across the U.S. during 1999.
Source: National Atmospheric Deposition Program/National Trends Network http://nadp.sw.uluc.edu.[11]

remediation[6,7] http://www.nnic.noaa.gov/CENR/NAPAP/. Since 1995, when the 1990 Clean Air Act Amendment's Title IV reduction in acidic deposition was implemented, SO_2 and NO_x emissions have, respectively, decreased and remained constant during the late 1990s.[4]

Both H_2SO_4 and HNO_3 are important components of acidic deposition, with volatile organic compounds and inorganic carbon also components of acidic deposition- related emissions. Pure water has a pH of 7.0, natural rainfall about 5.6, and severely acidic deposition less than 4.0. Uncontaminated rainwater should be pH 5.6 due to CO_2 chemistry and the formation of carbonic acid. The pH of most soils ranges from 3.0 to 8.0.[2] When acids are added to soils or waters, the decrease in pH that occurs depends greatly on the system's buffering capacity, the ability of a system to maintain its present pH by neutralizing added acidity. Clays, organic matter, oxides of Al and Fe, and Ca and Mg carbonates (limestones) are the components responsible for pH buffering in most soils. Acidic deposition, therefore, will have a greater impact on sandy, low organic matter soils than those higher in clay, organic matter, and carbonates. In fresh waters, the primary buffering mechanism is the reaction of dissolved bicarbonate ions with H^+ according to the following equation:

$$H^+ + HCO_3^- = H_2O + CO_2 \tag{1}$$

Human Health Effects

Few direct human health problems have been attributed to acidic deposition. Long-term exposure to acidic deposition precursor pollutants such as ozone (O_3) and NO_x, which are respiratory irritants, can cause pulmonary edema.[5,6] Sulfur dioxide (SO_2) is also a known respiratory irritant, but is generally absorbed high in the respiratory tract.

Indirect human health effects due to acidic deposition are more important. Concerns center around contaminated drinking water supplies and consumption of fish that contain potential toxic metal levels. With increasing acidity (e.g., lower pH levels), metals such as mercury, aluminum, cadmium, lead, zinc, and copper become more bioavailable.[2] The greatest human health impact is due to the consumption of fish that bioaccumulate mercury; freshwater pike and trout have been shown to contain the highest average concentrations of mercury.[5,15] Therefore, the most susceptible individuals are those who live in an industrial area, have respiratory problems, drink water from a cistern, and consume a significant amount of freshwater fish.

A long-term urban concern is the possible impact of acidic deposition on surface-derived drinking water. Many municipalities make extensive use of lead and copper piping, which raises the question concerning human health effects related to the slow dissolution of some metals (lead, copper, zinc) from older plumbing materials when exposed to more acidic waters. Although metal toxicities due to acidic deposition impacts on drinking waters are rare, reductions in S and N fine particles expected by 2010 based on Clean Air Act Amendments will result in annual public health benefits valued at $50 billion with reduced mortality, hospital admissions and emergency room visits.[16]

Structural Impacts

Different types of materials and cultural resources can be impacted by air pollutants. Although the actual corrosion rates for most metals have decreased since the 1930s, data from three U.S. sites indicate that acidic deposition may account for 31%–78% of the dissolution of galvanized steel and copper,[7,8] http://www.nnic.noaa.gov/CENR/NAPAP/. In urban or industrial settings, increases in atmospheric acidity can dissolve carbonates (e.g., limestone, marble) in buildings and other structures. Deterioration of stone products by acidic deposition is caused by: 1) erosion and dissolution of materials and surface details; 2) alterations (blackening of stone surfaces); and 3) spalling (cracking and spalling of stone surfaces due to accumulations of alternation crusts.[8] Painted surfaces can be discolored or etched, and there may also be degradation of organic binders in paints.[8]

Ecosystem Impacts

It is important to examine the nature of acidity in soil, vegetation, and aquatic environments. Damage from acidification is often not directly due to the presence of excessive H^+, but is caused by changes in other elements. Examples include increased solubilization of metal ions such as Al^{3+} and some trace elements (e.g., Mn^{2+}, Pb^{2+}) that can be toxic to plants and animals, more rapid losses of basic cations (e.g., Ca^{2+}, Mg^{2+}), and the creation of unfavorable soil and aquatic environments for different fauna and flora.

Soils

Soil acidification is a natural process that occurs when precipitation exceeds evapotranspiration.[2] "Natural" rainfall is acidic (pH of ~ 5.6) and continuously adds a weak acid (H_2CO_3) to soils. This acidification results in a gradual leaching of basic cations (Ca^{2+} and Mg^{2+}) from the uppermost soil horizons, leaving Al^{3+} as the dominant cation that can react with water to produce H^+. Most of the acidity in soils between pH 4.0 and 7.5 is due to the hydrolysis of Al^{3+},[17,18] http://www.epa.gov/airmarkets/acidrain/effects/index.html. Other acidifying processes include plant and microbial respiration that produces CO_2, mineralization and nitrification of organic N, and the oxidation of FeS_2 in soils disturbed by mining or drainage.[2] In extremely acidic soils ($pH < 4.0$), strong acids such as H_2SO_4 are a major component.

The degree of accelerated acidification depends both upon the buffering capacity of the soil and the use of the soil. Many of the areas subjected to the greatest amount of acidic deposition are also areas where considerable natural acidification occurs.[19] Forested soils in the northeastern U.S. are developed on highly acidic, sandy parent materials that have undergone tremendous changes in land use in the past 200 years. However, clear-cutting and burning by the first European settlers have been almost completely reversed and many areas are now totally reforested.[5] Soil organic matter that accumulated over time represents a natural source of acidity and buffering. Similarly, greater leaching or depletion of basic cations by plant uptake in increasingly reforested areas balances the significant inputs of these same cations in precipitation.[20,21] Acidic deposition affects forest soils more than agricultural or urban soils because the latter are routinely limed to neutralize acidity. Although it is possible to lime forest soils, which is done frequently in some European countries, the logistics and cost often preclude this except in areas severely impacted by acidic deposition.[5]

Excessively acidic soils are undesirable for several reasons. Direct phytotoxicity from soluble Al^{3+} or Mn^{2+} can occur and seriously injure plant roots, reduce plant growth, and increase plant susceptibility to pathogens.[21] The relationship between Al^{3+} toxicity and soil pH is complicated by the fact that in certain situations organic matter can form complexes with Al^{3+} that reduce its harmful effects on plants.[18] Acid soils are usually less fertile because of a lack of important basic cations such as K^+, Ca^{2+}, and Mg^{2+}. Leguminous plants may fix less N_2 under very acidic conditions due to reduced rhizobial activity and greater soil adsorption of Mo by clays and Al and Fe oxides.[2] Mineralization of N, P, and S can also be reduced because of the lower metabolic activity of bacteria. Many plants and microorganisms have adapted to very acidic conditions (e.g., $pH < 5.0$). Examples include ornamentals such as azaleas and rhododendrons and food crops such as cassava, tea, blueberries, and potatoes.[5,22] In fact, considerable efforts in plant breeding and biotechnology are directed towards developing Al- and Mn-tolerant plants that can survive in highly acidic soils.

Agricultural Ecosystems

Acidic deposition contains N and S that are important plant nutrients. Therefore, foliar applications of acidic deposition at critical growth stages can be beneficial to plant development and reproduction. Generally, controlled experiments require the simulated acid rain to be pH 3.5 or less in order to produce injury to certain plants.[22] The amount of acidity needed to damage some plants is 100 times greater than natural rainfall. Crops that respond negatively in simulated acid rain studies include garden beets, broccoli, carrots, mustard greens, radishes, and pinto beans, with different effects for some cultivars. Positive responses to acid rain have been identified with alfalfa, tomato, green pepper, strawberry, corn, lettuce, and some pasture grass crops.

Agricultural lands are maintained at pH levels that are optimal for crop production. In most cases the ideal pH is around pH 6.0–7.0; however, pH levels of organic soils are usually maintained at closer to pH 5.0. Because agricultural soils are generally well buffered, the amount of acidity derived from atmospheric inputs is not sufficient to significantly alter the overall soil pH.[2] Nitrogen and S soil inputs from acidic deposition are beneficial, and with the reduction in S atmospheric levels mandated by 1990 amendments to the Clean Air Act, the S fertilizer market has grown. The amount of N added to agricultural ecosystems as acidic deposition is rather insignificant in relation to the 100–300 kg N/ha/yr required of most agricultural crops.

Forest Ecosystems

Perhaps the most publicized issue related to acidic deposition has been widespread forest decline. For example, in Europe estimates suggest that as much as 35% of all forests have been affected.[23] Similarly, in the U.S. many important forest ranges such as the Adirondacks of New York, the Green Mountains of Vermont, and the Great Smoky Mountains in North Carolina have experienced sustained decreases in tree growth for several decades.[6] Conclusive evidence that forest decline or dieback is caused solely be acidic deposition is lacking and complicated by interactions with other environmental or biotic factors. However, NAPAP research[6] has confirmed that acidic deposition has contributed to a decline in high-elevation red spruce in the northeastern U.S. In addition, nitrogen saturation of forest ecosystems from atmospheric N deposition is believed to result in increased plant growth, which in turn increases water and nutrient use followed by deficiencies that can cause chlorosis and premature needle-drop as well as increased leaching of base cations from the soil.[24]

Acidic deposition on leaves may enter directly through plant stomates.[1,22] If the deposition is sufficiently acidic (pH ~ 3.0), damage can also occur to the waxy cuticle, increasing the potential for direct injury of exposed leaf mesophyll cells. Foliar lesions are one of the most common symptoms. Gaseous compounds such as SO_2 and SO_3 present in acidic mists or fogs can also enter leaves through the stomates, form H_2SO_4 upon reaction with H_2O in the cytoplasm, and disrupt many metabolic processes. Leaf and needle necrosis occurs when plants are exposed to high levels of SO_2 gas, possibly due to collapsed epidermal cells, eroded cuticles, loss of chloroplast integrity and decreased chlorophyll content, loosening of fibers in cell walls and reduced cell membrane integrity, and changes in osmotic potential that cause a decrease in cell turgor.

Root diseases may also increase in excessively acidic soils. In addition to the damages caused by exposure to H_2SO_4 and HNO_3, roots can be directly injured or their growth rates impaired by increased concentrations of soluble Al^{3+} and Mn^{2+} in the rhizosphere,[2,25] http://nadp.sws.uiuc.edu. Changes in the amount and composition of these exudates can then alter the activity and population diversity of soil-borne pathogens. The general tendency associated with increased root exudation is an enhancement in microbial populations due to an additional supply of carbon (energy). Chronic acidification can also alter nutrient availability and uptake patterns.[8,22]

Long-term studies in New England suggest acidic deposition has caused significant plant and soil leaching of base cations,[1,21] resulting in decreased growth of red spruce trees in the White Mountains.[6] With reduction in about 80% of the airborne base cations, mainly Ca^{2+} but also Mg^{2+}, from 1950 levels, researchers suggest forest growth has slowed because soils are not capable of weathering at a rate that can replenish essential nutrients. In Germany, acidic deposition was implicated in the loss of soil Mg^{2+} as an accompanying cation associated with the downward leaching of SO_4^{2-}, which ultimately resulted in forest decline.[2] Several European countries have used helicopters to fertilize and lime forests.

Aquatic Ecosystems

Ecological damage to aquatic systems has occurred from acidic deposition. As with forests, a number of interrelated factors associated with acidic deposition are responsible for undesirable changes. Acidification of aquatic ecosystems is not new. Studies of lake sediments suggest that increased acidification began in the mid-1800s, although the process has clearly accelerated since the 1940s.[15] Current studies indicate there is significant S mineralization in forest soils impacted by acidic deposition and that the SO_4^{2-} levels in adjacent streams remain high, even though there has been a decrease in the amount of atmospheric-S deposition.[24]

Geology, soil properties, and land use are the main determinants of the effect of acidic deposition on aquatic chemistry and biota. Lakes and streams located in areas with calcareous geology resist acidification more than those in granitic and gneiss materials.[16] Soils developed from calcareous parent materials are generally deeper and more buffered than thin, acidic soils common to granitic areas.[2] Land management decisions also affect freshwater acidity. Forested watersheds tend to contribute more acidity than those dominated by meadows, pastures, and agronomic ecosystems.[8,14,20] Trees and other vegetation in forests are known to "scavenge" acidic compounds in fogs, mists, and atmospheric particulates. These acidic compounds are later deposited in forest soils when rainfall leaches forest vegetation surfaces. Rainfall below forest canopies (e.g., throughfall) is usually more acidic than ambient precipitation. Silvicultural operations that disturb soils in forests can increase acidity by stimulating the oxidization of organic N and S, and reduced S compounds such as FeS_2.[2]

A number of ecological problems arise when aquatic ecosystems are acidified below pH 5.0, and particularly below pH 4.0. Decreases in biodiversity and primary productivity of phytoplankton, zooplankton, and benthic invertebrates commonly occur.[15,16] Decreased rates of biological decomposition of organic matter have occasionally been reported, which can then lead to a reduced supply of nutrients.[20] Microbial communities may also change, with fungi predominating over bacteria. Proposed mechanisms to explain these ecological changes center around physiological stresses caused by exposure of biota to higher concentrations of Al^{3+}, Mn^{2+}, and H^+ and lower amounts of available Ca^{2+}.[15] One specific mechanism suggested involves the disruption of ion uptake and the ability of aquatic plants to regulate Na^+, K^+, and Ca^{2+} export and import from cells.

Acidic deposition is associated with declining aquatic vertebrate populations in acidified lakes and, under conditions of extreme acidity, of fish kills. In general, if the water pH remains above 5.0, few problems are observed; from pH 4.0 to 5.0 many fish are affected, and below pH 3.5 few fish can survive.[23] The major cause of fish kill is due to the direct toxic effect of Al^{3+}, which interferes with the role Ca^{2+} plays in maintaining gill permeability and respiration. Calcium has been shown to mitigate the effects of Al^{3+}, but in many acidic lakes the Ca^{2+} levels are inadequate to overcome Al^{3+} toxicity. Low pH values also disrupt the Na^+ status of blood plasma in fish. Under very acidic conditions, H^+ influx into gill membrane cells both stimulates excessive efflux of Na^+ and reduces influx of Na^+ into the cells. Excessive loss of Na^+ can cause mortality. Other indirect effects include reduced rates of reproduction, high rates of mortality early in life or in reproductive phases of adults, and migration of adults away from acidic areas.[16] Amphibians are affected in much the same manner as fish, although they are somewhat less sensitive to Al^{3+} toxicity. Birds and small mammals often have lower populations and lower reproductive rates in areas adjacent to acidified aquatic ecosystems. This may be due to a shortage of food due to smaller fish and insect populations or to physiological stresses caused by consuming organisms with high Al^{3+} concentrations.

Reducing Acidic Deposition Effects

Damage caused by acidic deposition will be difficult and extremely expensive to correct, which will depend on our ability to reduce S and N emissions. For example, society may have to burn less fossil fuel, use cleaner energy sources and/or design more efficient "scrubbers" to reduce S and N gas entering our atmosphere. Despite the firm conviction of most nations to reduce acidic deposition, it appears that the staggering costs of such actions will delay implementation of this approach for many years. The 1990 amendments to the Clean Air Act are expected to reduce acid-producing air pollutants from electric power plants. The 1990 amendments established emission allowances based on a utilities' historical fuel use and SO_2 emissions, with each allowance representing 1 ton of SO_2 that can bought, sold or banked for future use,[4,6,7] http://www.nnic.noaa.gov/CENR/NAPAP/. Short-term remedial actions for acidic deposition are available and have been successful in some ecosystems. Liming of lakes and some forests (also fertilization with trace elements and Mg^{2+}) has been practiced in European counties for over 50 years.[16,23] Hundreds of Swedish and Norwegian lakes have been successfully limed in the past 25 years. Lakes with short mean residence times for water retention may need annual or biannual liming; others may need to be limed every 5–10 years. Because vegetation in some forested ecosystems has adapted to acidic soils, liming (or over-liming) may result in an unpredictable and undesirable redistribution of plant species.

Carbon Sequestration

Nathan E. Hultman

Introduction

The increasing likelihood of human-caused changes in climate could lead to undesirable impacts on ecosystems, economies, and human health and well-being. These potential impacts have prompted extensive assessment of options to reduce the magnitude and rate of future climate changes. Since climate changes are derived ultimately from increases in the concentrations of greenhouse gases (GHGs) in the atmosphere, such options must target either (a) reductions in the rate of inflow of GHGs to the atmosphere or (b) the removal of GHGs from the atmosphere once they have been emitted. Carbon sequestration refers to techniques from both categories that result in the storage of carbon that would otherwise be in the atmosphere as CO_2.

CO_2 is often targeted among the other GHGs because it constitutes the vast majority of GHG emissions by mass and accounts for three-fifths of the total anthropogenic contribution to climate change. Human emissions of CO_2 come primarily from fossil fuel combustion and cement production (80%), and land-use change (20%) that results in the loss of carbon from biomass or soil.

The rate of inflow of GHGs to the atmosphere can be reduced by a number of complementary options. For CO_2, mitigation options aim to displace carbon emissions by preventing the oxidation of biological or fossil carbon. These options include switching to lower-carbon fossil fuels, renewable energy, or nuclear power; using energy more efficiently; and reducing the rate of deforestation and land-use change. On the other hand, sequestration options that reduce emissions involve the capture and storage of carbon before it is released into the atmosphere.

CO_2 can also be removed directly from the atmosphere. While the idea of a large-scale, economically competitive method of technologically "scrubbing" CO_2 from the atmosphere is enticing, such technology currently does not exist. Policy has therefore focused on the biological process of carbon absorption through photosynthesis, either through expanding forested lands or, perhaps, enhancing photosynthesis in the oceans. This entry describes both the technological and biological approaches to carbon sequestration.

Technological Sequestration: Carbon Capture and Storage

The technological process of sequestering CO_2 requires two steps: first, the CO_2 must be separated from the industrial process that would otherwise emit it into the atmosphere; and second, the CO_2 must be stored in a reservoir that will contain it for a reasonable length of time. This process is therefore often referred to as carbon capture and storage (CCS) to distinguish it from the biological carbon sequestration that is described later.

Sources of Carbon

The best sites for CCS are defined by the efficiency of the capture technique, the cost of transport and sequestration, and the quantity of carbon available. The large capital requirements for CCS also dictate that large, fixed industrial sites provide the best opportunities. Therefore, although fossil-fueled transportation represents about 20% of current global CO_2 emissions, this sector presents no direct options for CCS at this time. The industrial sector, on the other hand, produces approximately 60% of current CO_2 emissions; most of these emissions come from large point sources which are ideal for CCS, such as power stations, oil refineries, petrochemical and gas reprocessing plants, and steel and cement works.[1]

Separation and Capture

Carbon capture requires an industrial source of CO_2; different industrial processes create streams with different CO2 concentrations. The technologies applied to capture the CO_2 will therefore vary according to the specific capture process.[2–4] Capture techniques can target one of three sources:

- Post-combustion flue gases
- Pre-combustion capture from gasification from power generation
- Streams of highly pure CO_2 from various industrial processes

Post-Combustion Capture

Conventional combustion of fossil fuels in air produces CO_2 streams with concentrations ranging from about 4 to 14% by volume. The low concentration of CO_2 in flue gas means that compressing and storing it would be uneconomical; therefore, the CO_2 needs to be concentrated before storage. Currently, the favored process for this task is chemical absorption, also known as chemical solvent scrubbing. Cooled and filtered flue gas is fed into an absorption vessel with a chemical solvent that absorbs the CO_2. The most common solvent for this process is monoethanolamine (MEA). The CO_2-rich solvent is then passed to another reaction vessel called a stripper column. It is then heated with steam to reverse the process, thus regenerating the solvent and releasing a stream of CO_2 with a purity greater than 90%.

Scrubbing with MEA and other amine solvents imposes large costs in energy consumption in the regeneration process; it requires large amounts of solvents since they degrade rapidly; and it imposes high equipment costs since the solvents are corrosive in the presence of O_2. Thus, until solvents are improved in these areas, flue gas separation by this method will remain relatively costly: just the steam and electric load from a coal power plant can increase coal consumption by 40% per net kWh_e. Estimates of the financial and efficiency costs from current technology vary. Plant efficiency is estimated to drop from over 40% to a range between 24 and 37%.[2,5,6] For the least efficient systems, carbon would cost up to \$70/t CO_2 and result in an 80% increase in the cost of electricity.[5] Other studies estimate an increase in the cost of electricity of 25%–75% for natural gas combined cycle and Integrated Gasification Combined Cycle (IGCC), and of 60%–115% for pulverized coal.[4] A small number of facilities currently practice flue gas separation with chemical absorption, using the captured CO_2 for urea production, foam blowing, carbonated beverages, and dry ice production.

In addition, several developments may improve the efficiency of chemical absorption.

Several other processes have been proposed for flue-gas separation. Adsorption techniques use solids with high surface areas, such as activated carbon and zeolites, to capture CO_2. When the materials become saturated, they can be regenerated (releasing CO_2) by lowering pressure, raising temperature, or applying a low-voltage electric current. A membrane can be used to concentrate CO_2, but since a single pass through a membrane cannot achieve a great change in concentration, this process requires multiple passes or multiple membranes. An alternative use for membranes is to use them to increase the efficiency of the chemical absorption. In this case, a membrane separating the flue gas from the absorption solvent allows a greater surface area for the reaction, thus reducing the size and energy requirements of the absorption and stripper columns. *Cryogenic* techniques separate CO_2 from other gases by condensing or freezing it. This process requires significant energy inputs and the removal of water vapor before freezing.

One of the main limitations to flue-gas separation is the low pressure and concentration of CO_2 in the exhaust. An entirely different approach to post-combustion capture is to dramatically increase the concentration of CO_2 in the stream by burning the fuel in highly enriched oxygen rather than air. This process, called oxyfuel combustion, produces streams of CO_2 with a purity greater than 90%. The resulting flue gas will also contain some H_2O that can be condensed and removed, and the remaining high-purity CO_2 can be compressed for storage. Though significantly simpler on the exhaust side, this approach requires a high concentration of oxygen for the intake air. While this process alone may consume 15% of a plant's electric output, the separated N_2, Ar, and other trace gases also can be sold to offset some of the cost. Oxyfuel systems can be retrofitted onto existing boilers and furnaces.

Pre-Combustion Capture

Another approach involves removing the carbon from fossil fuels before combustion. First, the fuel is decomposed in the absence of oxygen to form a hydrogen-rich fuel called synthesis gas. Currently, this process of gasification is already in use in ammonia production and several commercial power plants fed by coal and petroleum byproducts; these plants can use lower-purity fuels and the energy costs of generating synthesis gas are offset by the higher combustion efficiencies of gas turbines; such plants are called IGCC plants. Natural gas can be transformed directly by reacting it with steam, producing H_2 and CO_2. While the principle of gasification is the same for all carbonaceous fuels, oil and coal require intermediate steps to purify the synthesis fuel and convert the byproduct CO into CO_2.

Gasification results in synthesis gas that contains 35%–60% CO_2 (by volume) at high pressure (over 20 bar). While current installations feed this resulting mixture into the gas turbines, the CO_2 can also be separated from the gas before combustion. The higher pressure and concentration give a CO_2 partial pressure of up to 50 times greater than in the post-combustion capture of flue gases, which enables another type of separation technique of physical solvent scrubbing. This technique is well known from ammonia production and involves the binding of CO_2 to solvents that release CO_2 in the stripper under lower pressure. Solvents in this category include cold methanol, polyethelene glycol, propylene carbonate, and sulpholane. The resulting separated CO_2 is, however, near atmospheric pressure and requires compression before storage (some CO_2 can be recovered at elevated pressures, which reduces the compression requirement). With current technologies, the total cost of capture for IGCC is estimated to be greater than \$25 per ton of CO_2; plant efficiency is reduced from 43 to 37%, which raises the cost of electricity by over 25%.[5]

Pre-combustion capture techniques are noteworthy not only for their ability to remove CO_2 from fossil fuels for combustion in turbines, but also because the resulting synthesis gas is primarily H_2. They therefore could be an important element of a hydrogen-mediated energy system that favors the higher efficiency reactions of fuel cells over traditional combustion.[7]

Industrial CO_2 Capture

Many industrial processes release streams of CO_2 that are currently vented into the atmosphere. These streams, currently viewed as simple waste in an economically viable process, could therefore provide capture opportunities. Depending on the purity of the waste stream, these could be among the most economical options for CCS. In particular, natural gas processing, ethanol and hydrogen production, and cement manufacturing produce highly concentrated streams of CO_2. Not surprisingly, the first large-scale carbon sequestration program was run from a previously vented stream of CO_2 from the Sleipner gas-processing platform off the Norwegian coast.

Storage of Captured CO_2

Relatively small amounts of captured CO_2 might be re-used in other industrial processes such as beverage carbonation, mineral carbonates, or commodity materials such as ethanol or paraffins. Yet most captured CO_2 will not be re-used and must be stored in a reservoir. The two main routes for storing captured CO_2 are to inject it into geologic formations or into the ocean. However, all reservoirs have some rate of leakage and this rate is often not well known in advance. While the expected length of storage time is important (with targets usually in the 100–1000 year range), we must therefore also be reasonably confident that the reservoir will not leak more quickly than expected, and have appropriate measures to monitor the reservoir over time. Moreover, transporting CO_2 between the point of capture and the point of storage adds to the overall cost of CCS, so the selection of a storage site must account for this distance as well.

Geologic Sequestration

Geologic reservoirs—in the form of depleted oil and gas reservoirs, unmineable coal seams, and saline formations— comprise one of the primary sinks for captured CO_2. Estimates of total storage capacity in geologic reservoirs could be up to 500% of total emissions to 2050 (Table 1).

Captured CO_2 can be injected into depleted oil and gas reservoirs, or can be used as a means to enhance oil recovery from reservoirs nearing depletion. Because they held their deposits for millions of years before extraction, these reservoirs are expected to provide reliable storage for CO_2. Storage in depleted reservoirs has been practiced for years for a mixture of petroleum mining waste gases called "acid gas."

A petroleum reservoir is never emptied of all its oil; rather, extracting additional oil just becomes too costly to justify at market rates. An economically attractive possibility is therefore using captured

TABLE 1 CO_2 Reservoirs. Carbon Dioxide Storage Capacity Estimates. *E* Is Defined as the Total Global CO_2 Emissions from the Years 2000–2050 in IPCC's Business-as-Usual Scenario IS92A. Capacity Estimates Such as These Are Rough Guidelines Only and Actual Utilization Will Depend on Carbon Economics

	Storage Capacity	
Reservoir Type	Billion Tonnes CO_2	% of E
Coal basins	170	8%
Depleted oil reservoirs	120	6%
Gas basins	700	37%
Saline formations		
Terrestrial		276%
Off-shore		192%
Total	10.490	517%

Source: Dooley and Friedman.[8]

CO_2 to simultaneously increase the yield from a reservoir as it is pumped into the reservoir for storage. This process is called enhanced oil recovery. Standard oil recovery yields only about 30%–40% of the original petroleum stock. Drilling companies have years of experience with using compressed CO_2, a hydrocarbon solvent, to obtain an additional 10%–15% of the petroleum stock. Thus, captured CO_2 can be used to provide a direct economic benefit along with its placement in a reservoir. This benefit can be used to offset capture costs.

Coal deposits that are not economically viable because of their geologic characteristics provide another storage option. CO_2 pumped into these unmineable coal seams will adsorb onto the coal surface. Moreover, since the coal surface prefers to adsorb CO_2 to methane, injecting CO_2 into coal seams will liberate any coal bed methane (CBM) that can then be extracted and sold. This enhanced methane recovery is currently used in U.S. methane production, accounting for about 8% in 2002. Such recovery can be used to offset capture costs. One potential problem with this method is that the coal, as it adsorbs CO_2, tends to swell slightly. This swelling closes pore spaces and thus decreases rock permeability, which restricts both the reservoir for incoming CO_2 and the ability to extract additional CBM.

Saline formations are layers of porous sedimentary rock (e.g., sandstone) saturated with saltwater, and exist both under land and under the ocean. These layers offer potentially large storage capacity representing several hundred years' worth of CO_2 storage. However, experience with such formations is much more limited and thus the uncertainty about their long-term viability remains high. Moreover, unlike EOR or CBM recovery with CO_2, injecting CO_2 into saline formations produces no other commodity or benefit that can offset the cost. On the other hand, their high capacity and relative ubiquity makes them attractive options in some cases. Statoil's Sleipner project, for example, uses a saline aquifer for storage.

Research and experimentation with saline formations is still in early stages. To achieve the largest storage capacities, CO_2 must be injected below 800 m depth, where it will remain in a liquid or supercritical dense phase (supercritical point at 31°C, 71 bar). At these conditions, CO_2 will be buoyant (a density of approximately 600–800 kg/m^3) and will tend to move upward. The saline formations must therefore either be capped by a less porous layer or geologic trap to prevent leakage of the CO_2 and eventual decompression.[9] Over time, the injected CO_2 will dissolve into the brine and this mixture will tend to sink within the aquifer. Also, some saline formations exist in rock that contains Ca-, Mg-, and Fe-containing silicates that can form solid carbonates with the injected CO_2. The resulting storage as rock is highly reliable, though it may also hinder further injection by closing pore spaces. Legal questions may arise when saline formations, which are often geographically extensive, cross national boundaries or onto marine commons.

Ocean Direct Injection

As an alternative to geologic storage, captured CO_2 could be injected directly into the ocean at either intermediate or deep levels. The oceans have a very large potential for storing CO_2, equivalent to that of saline aquifers (~10^3 Gt). While the ocean's surface is close to equilibrium with atmospheric carbon dioxide concentrations, the deep ocean is not because the turnover time of the oceans is much slower (~5000 years) than the observed increases in atmospheric CO_2. Since the ocean will eventually absorb much of the atmospheric perturbation, injecting captured CO_2 into the oceans can therefore be seen as simply bypassing the atmospheric step and avoiding the associated climate consequences. Yet little is known about the process or effects—either ecological or geophysical—of introducing large quantities of CO_2 into oceanic water.

At intermediate depths (between 500 and 3000 m), CO_2 exists as a slightly buoyant liquid. At these depths, a stream of CO_2 could be injected via a pipe affixed either to ship or shore. The CO_2 would form a droplet plume, and these droplets would slowly dissolve into the seawater, disappearing completely before reaching the surface. Depressed pH values are expected to exist for tens of km downcurrent of

TABLE 2 Additional Costs to Power Generation from CCS. Approximate Capture and Storage Costs for Different Approaches to Power Plant Sequestration

Fossil Type	Cost of CCS ¢ per kWh
Natural gas combined cycle	1–2
Pulverized coal	2–3
Coal IGCC	2–4

Source: Herzog and Golomb,[4] National Energy Technology Laboratory,[5] Dooley et al.,[11] and Freund and Davison.[12]

the injection site, though changing the rate of injection can moderate the degree of perturbation. In addition, pulverized limestone could be added to the injected CO_2 to buffer the acidity.

Below 3000 m, CO_2 becomes denser than seawater and would descend to the seafloor and pool there. Unlike intermediate injection, therefore, this method does not lead to immediate CO_2 dissolution in oceanic water; rather, the CO_2 is expected to dissolve into the ocean at a rate of about 0.1 m/y. Deep injection thus minimizes the rate of leakage to the surface, but could still have severe impacts on bottom-dwelling sea life.

The primary obstacles to oceanic sequestration are not technical but relate rather to this question of environmental impacts.[10] Oceanic carbon storage might affect marine ecosystems through the direct effects of a lower environmental pH; dissolution of carbonates on fauna with calcareous structures and microflora in calcareous sediments; impurities such as sulfur oxides, nitrogen oxides, and metals in the captured CO_2; smothering effects (deep injection only); and changes in speciation of metals and ammonia due to changes in pH. Few of these possibilities have been studied in sufficient detail to allow an informed risk assessment. In addition, the legality of dumping large quantities of CO_2 into the open ocean remains murky.

Overall Costs of CCS

The costs of CCS can be measured either as a cost per tonne of CO_2, or, for power generation, a change in the cost of electricity (Table 2). The total cost depends on the cost of capture, transport, and storage. Capture cost is mainly a function of parasitic energy losses and the capital cost of equipment. Transport cost depends on distance and terrain. Storage costs vary depending on the reservoir but are currently a few dollars per tonne of CO_2. The variety of approaches to CCS and the early stages of development make precise estimates of cost difficult, but current technology spans about \$25–\$85/t CO_2.

Biological Sequestration: Enhancing Natural Carbon Sinks

The previous sections have described processes by which CO_2 could be technologically captured and then stored. Photosynthesis provides an alternate route to capture and store carbon. Enhancing this biological process is therefore an alternative method of achieving lower atmospheric CO_2 concentrations by absorbing it directly from the air.

Terrestrial Carbon Sinks

Carbon sequestration in terrestrial ecosystems involves enhancing the natural sinks for carbon fixed in photosynthesis. This occurs by expanding the extent of ecosystems with a higher steady-state density of carbon per unit of land area. For example, because mature forest ecosystems contain more carbon per hectare than grasslands, expanding forested areas will result in higher terrestrial carbon storage.

Another approach is to encourage the additional storage of carbon in agricultural soils. The essential element in any successful sink enhancement program is to ensure that the fixed carbon remains in pools with long lives.

Afforestation involves planting trees on unforested or deforested land.[13,14] The most likely regions for forest carbon sequestration are Central and South America and Southeast Asia because of relatively high forest growth rates, available land, and inexpensive labor. However, the translation of forestry activities into a policy framework is complex. Monitoring the carbon changes in a forest is difficult over large areas, as it requires not only a survey of the canopy and understory, but also an estimate of the below-ground biomass and soil carbon. Some groups have voiced concern over the potential for disruption of social structures in targeted regions.

Soil carbon sequestration involves increasing soil carbon stocks through changes in agriculture, forestry, and other land use practices. These practices include mulch farming, conservation tillage, agroforestry and diverse cropping, cover crops, and nutrient management that integrates manure, compost, and improved grazing. Such practices, which offer the lowest-cost carbon sequestration, can have other positive effects such as soil and water conservation, improved soil structure, and enhanced soil fauna diversity. Rates of soil carbon sequestration depend on the soil type and local climate, and can be up to 1000 kg of carbon per hectare per year. Management practices can enhance sequestration for 20–50 years, and sequestration rates taper off toward maturity as the soil carbon pool becomes saturated. Widespread application of recommended management practices could offset 0.4 to 1.2 GtC/y, or 5%–15% of current global emissions.[15]

If sinks projects are to receive carbon credits under emissions trading schemes like that in the Kyoto Protocol, they must demonstrate that the project sequestered more carbon than a hypothetical baseline or business-as-usual case. They must also ensure that the carbon will remain in place for a reasonable length of time, and guard against simply displacing the baseline activity to a new location.

Ocean Fertilization

Vast regions of the open ocean have very little photosynthetic activity, though sunlight and major nutrients are abundant. In these regions, phytoplankton are often deprived of trace nutrients such as iron. Seeding the ocean surface with iron, therefore, might produce large phytoplankton blooms that absorb CO_2. As the plankton die, they will slowly sink to the bottom of the ocean, acting to transport the fixed carbon to a permanent burial in the seafloor. While some experimental evidence indicates this process may work on a limited scale, little is known about the ecosystem effects and potential size of the reservoir.[16]

Prospects for Carbon Sequestration

Carbon sequestration techniques—both technological and biological—are elements of a portfolio of options for addressing climate change. Current approaches hold some promise for tapping into the geologic, biologic, and oceanic potential for storing carbon. The costs of some approaches, especially the improved management of agricultural and forest lands, are moderate (Table 3). Yet these opportunities are not infinite and additional options will be necessary to address rising global emissions. Thus, the higher costs of current technological approaches are likely to drop with increasing deployment and changing market rates for carbon.

Possible developments include advanced CO_2 capture techniques focusing on membranes, ionic (organic salt) liquids, and microporous metal organic frameworks. Several alternative, but still experimental, sequestration approaches have also been suggested. Mineralization could convert CO_2 to stable minerals. This approach seeks, therefore, to hasten what in nature is a slow but exothermic weathering process that operates on common minerals like olivine, forsterite, or serpentines (e.g., through selected sonic frequencies). It is possible that CO_2 could be injected in sub-seafloor carbonates. Chemical looping

TABLE 3 Costs of Carbon Sequestration. Estimates for Sequestration Costs Vary Widely. Future Costs Will Depend on Rates of Technological Change

	Cost
Sequestration Technique	\$ per T CO_2
Carbon capture and storage	26–84
Tree planting and agroforestry	10–210
Soil carbon sequestration	6–24

describes a method for combusting fuels with oxygen delivered by a redox agent instead of by air or purified oxygen; it promises high efficiencies of energy conversion and a highly enriched CO_2 exhaust stream. Research also continues on microbial CO_2 conversion in which strains of microbes might be created to metabolize CO_2 to produce saleable commodities (succinic, malic, and fumeric acids). In addition, the nascent science of monitoring and verifying the storage of CO_2 will be an important element toward improving technical performance and public acceptance of sequestration techniques.

Energy Conservation

Ibrahim Dincer
and Adnan Midili

Introduction

Civilization began when people found out how to use fire extensively. They burned wood and obtained sufficiently high temperatures for melting metals, extracting chemicals, and converting heat into mechanical power, as well as for cooking and heating. During burning, the carbon in wood combines with O_2 to form carbon dioxide (CO_2), which then is absorbed by plants and converted back to carbon for use as a fuel again. Because wood was unable to meet the fuel demand, the Industrial Revolution began with the use of fossil fuels (e.g., oil, coal, and gas). Using such fuels has increased the CO_2 concentration in the air, leading to the beginning of global warming. Despite several warnings in the past about the risks of greenhouse- gas emissions, significant actions to reduce environmental pollution were not taken, and now many researchers have concluded that global warming is occurring. During the past two decades, the public has became more aware, and researchers and policymakers have focused on this and related issues by considering energy, the environment, and sustainable development.

Energy is considered to be a key catalyst in the generation of wealth and also a significant component in social, industrial, technological, economic, and sustainable development. This makes energy resources and their use extremely significant for every country. In fact, abundant and affordable energy is one of the great boons of modern industrial civilization and the basis of our living standard. It makes people's lives brighter, safer, more comfortable, and more mobile, depending on their energy demand and consumption. In recent years, however, energy use and associated greenhouse-gas emissions and their potential effects on the global climate change have been of worldwide concern.

Problems with energy utilization are related not only to global warming, but also to such environmental concerns as air pollution, acid rain, and stratospheric ozone depletion. These issues must be taken into consideration simultaneously if humanity is to achieve a bright energy future with minimal environmental impact. Because all energy resources lead to some environmental impact, it is reasonable to suggest that some (not all) of these concerns can be overcome in part through energy conservation efforts.

Energy conservation is a key element of energy policy and appears to be one of the most effective ways to improve end-use energy efficiency, and to reduce energy consumption and greenhouse-gas emissions in various sectors (industrial, residential, transportation, etc.). This is why many countries have recently started developing aggressive energy conservation programs to reduce the energy intensity of the their infrastructures, make businesses more competitive, and allow consumers to save money and to live more comfortably. In general, energy conservation programs aim to reduce the need for new generation or transmission capacity, to save energy, and to improve the environment. Furthermore, energy conservation is vital for sustainable development and should be implemented by all possible means, despite the fact that it has its own limitations. This is required not only for us, but for the next generation as well.

Considering these important contributions, the energy conservation phenomenon should be discussed in a comprehensive perspective. Therefore, the main objective of this entry is to present and discuss the world's primary energy consumption and production; major environmental problems; potential solutions to these issues; practical energy conservation aspects; research and development (R&D) in energy conservation, energy conservation, and sustainable development; energy conservation implementation plans; energy conservation measurements; and life-cycle costing (LCC) as an excellent tool in energy conservation. In this regard, this contribution aims to:

- Help explain main concepts and issues about energy conservation
- Develop relations between energy conservation and sustainability
- Encourage energy conservation strategies and policies
- Provide energy conservation methodologies
- Discuss relations between energy conservation and environmental impact
- Present some illustrative examples to state the importance of energy conservation and its practical benefits

In summary, this book contribution highlights the current environmental issues and potential solutions to these issues; identifies the main steps for implementing energy conservation programs and the main barriers to such implementations; and provides assessments for energy conservation potentials for countries, as well as various practical and environmental aspects of energy conservation.

World Energy Resources: Production and Consumption

World energy consumption and production are very important for energy conservation in the future. Economic activity and investment patterns in the global energy sector are still centered on fossil fuels, and fossil-fuel industries and energy-intensive industries generally have been skeptical about warnings of global warming and, in particular, about policies to combat it. The increase of energy consumption and energy demand indicates our dependence on fossil fuels. If the increase of fossil-fuel utilization continues in this manner, it is likely that the world will be affected by many problems due to fossil fuels. It follows from basic scientific laws that increasing amounts of CO_2 and other greenhouse gases will affect the global climate. The informed debate is not about the existence of such effects, but about their magnitudes and seriousness. At present, the concentration of CO_2 is approximately 30% higher than its preindustrial level, and scientists have already been able to observe a discernible human influence on the global climate.[1]

In the past, fossil fuels were a major alternative for overcoming world energy problems. Fossil fuels cannot continue indefinitely as the principal energy sources, however, due to the rapid increase of world energy demand and energy consumption. The utilization distribution of fossil-fuel types has changed significantly over the past 80 years. In 1925, 80% of the required energy was supplied from coal, whereas in the past few decades, 45% came from petroleum, 25% from natural gas, and 30% from coal. Due to world population growth and the advance of technologies that depend on fossil fuels, reserves of those fuels eventually will not be able to meet energy demand. Energy experts point out that reserves are less than 40 years for petroleum, 60 years for natural gas, and 250 years for coal.[2] Thus, fossil-fuel costs are likely to increase in the near future. This will allow the use of renewable energy sources such as solar, wind, and hydrogen. As an example, the actual data[3,4] and projections of world energy production and consumption from 1980 to 2030 are displayed in the following figures, and the curve equations for world energy production and consumption are derived as shown Table 1.

As presented in Figures 1 and 2, and in Table 2, the quantities of world primary energy production and consumption are expected to reach 14,499.2 and 13,466.5 Mtoe, respectively, by 2030. World population is now over six billion, double that of 40 years ago, and it is likely to double again by the middle of

TABLE 1 World Energy Production and Consumption Models through Statistical Analysis

the 21st century. The world's population is expected to rise to about seven billion by 2010. Even if birth rates fall so that the world population becomes stable by 2030, the population still would be about ten billion. The data presented in Figures 1 and 2 are expected to cover current energy needs provided that the population remains constant. Because the population is expected to increase dramatically, however, conventional energy resource shortages are likely to occur, due to insufficient fossil-fuel resources. Therefore, energy conservation will become increasingly important to compensate for shortages of conventional resources.

Major Environmental Problems

One of the most important targets of modern industrial civilizations is to supply sustainable energy sources and to develop the basis of living standards based on these energy sources, as well as implementing energy conservation measures. In fact, affordable and abundant sustainable energy makes our lives brighter, safer, more comfortable, and more mobile because most industrialized and developing societies use various types of energy. Billions of people in undeveloped countries, however, still have limited access to energy. India's per-capita consumption of electricity, for example, is one-twentieth that of the United States. Hundreds of millions of Indians live "off the grid"- that is, without electricity-and cow dung is still a major fuel for household cooking. This continuing reliance on such preindustrial energy sources is also one of the major causes of environmental degradation.[5]

After many decades of using fossil fuels as a main energy source, significant environmental effects of fossil fuels became apparent. The essential pollutants were from greenhouse gases (e.g., CO_2, SO_2, and NO_2). Fossil fuels are used for many applications, including industry, residential, and commercial sectors. Increasing fossil-fuel utilization in transportation vehicles such as automobiles, ships, aircrafts, and spacecrafts has led to increasing pollution. Gas, particulate matter, and dust clouds in the atmosphere absorb a significant portion of the solar radiation directed at Earth and cause a decrease in the oxygen available for the living things. The threat of global warming has been attributed to fossil fuels.[2] In addition, the risk and reality of environmental degradation have become more apparent. Growing evidence of environmental problems is due to a combination of factors.

During the past two decades, environmental degradation has grown dramatically because of the sheer increase of world population, energy consumption, and industrial activities. Throughout the 1970s, most environmental analysis and legal control instruments concentrated on conventional pollutants such as SO_2, NO_x, particulates, and CO. Recently, environmental concern has extended to the control of micro or hazardous air pollutants, which are usually toxic chemical substances and harmful in small doses, as well as to that of globally significant pollutants such as CO_2. Aside from advances in environmental engineering science, developments in industrial processes and structures have led to new environmental problems.[6,7] In the energy sector, for example, major shifts to the road transport of industrial goods and to individual travel by cars has led to an increase in road traffic and, hence, to a shift in attention paid to the effects and sources of NO_x and to the emissions of volatile organic compounds (VOC). In fact, problems with energy supply and use are related not only to global warming, but also to such environmental concerns as air pollution, ozone depletion, forest destruction, and emission of radioactive substances. These issues must be taken into consideration simultaneously if humanity is to achieve a bright energy future with minimal environmental impact. Much evidence exists to suggest that the future will be negatively impacted if humans keep degrading the environment. Therefore, there is an intimate connection among energy conservation, the environment, and sustainable development. A society seeking sustainable development ideally must utilize only energy resources that cause no environmental impact (e.g., that release no emissions to the environment). Because all energy resources lead to some environmental impact, however, it is reasonable to suggest that some (not all) of the concerns regarding the limitations imposed on sustainable development by environmental emissions and their negative impacts can be overcome in part through energy conservation. A strong relation clearly exists between energy conservation and environmental impact, because for the same services or products, less resource utilization and pollution normally are associated with higher-efficiency processes.[8]

Table 3 summarizes the major environmental problems such as acid rain, stratospheric ozone depletion, and global climate change (greenhouse effect)-and their main sources and effects.

As shown in Figure 3, the world total CO_2 production is estimated to be 18,313.13 million tons in 1980, 25,586.7 million tons in 2006, 27,356.43 million tons in 2012, and 29,716.1 million tons in 2020 whereas fossil-fuel consumption is found to be 6092.2 million tons in 1980, 8754.5 million tons in 2006,

TABLE 3 Major Environmental Issues and Their Consequences

Issues	Description	Main Sources	Main Effects
Acid precipitation	Transportation and deposition of acids produced by fossil-fuel combustion (e.g., industrial boilers, transportation vehicles) over great distances through the atmosphere via precipitation on the earth on ecosystems	Emissions of SO_2, NO_x and volatile organic compounds (VOCs) (e.g., residential heating and industrial energy use account for 80% of SO_2 emissions)	Acidification of lakes, streams and ground waters, resulting in damage to fish and aquatic life; damage to forests and agricultural crops; and deterioration of materials, e.g., buildings, structures
Stratospheric ozone depletion	Distortion and regional depletion of stratospheric ozone layer though energy activities (e.g., refrigeration, fertilizers)	Emissions of CFCs, halons (chlorinated and brominated organic compounds) and N_2O (e.g. fossil fuel and biomass combustion account for 65%–75% of N_2O emissions)	Increased levels of damaging ultraviolet radiation reaching the ground, causing increased rates of skin cancer, eye damage and other harm to many biological species
Greenhouse effect	A rise in the earth's temperature as a result of the greenhouse gases	Emissions of carbon dioxide (CO_2), CH_4, CFCs, halons, N_2O, ozone and peroxyacetylnitrate (e.g., CO_2 releases from fossil fuel combustion (w50% from CO_2), CH_4 emissions from increased human activity)	Increased the earth's surface temperature about 0.68C over the last century and as a consequence risen sea level about 20 cm (in the next century by another 28C–48C and a rise between 30 and 60 cm); resulting in flooding of coastal settlements, a displacement of fertile zones for agriculture and food production toward higher latitudes, and a decreasing availability of fresh water for irrigation and other essential uses

Source: Dincer,[9] Dincer,[10] and Dincer.[11]

9424.3 million tons in 2012, and 10,317.2 million tons in 2020. These values show that the CO_2 production will probably increase if we continue utilizing fossil fuel. Therefore, it is suggested that certain energy conversion strategies and technologies should be put into practice immediately to reduce future environmental problems.

The climate technology initiative (CTI) is a cooperative effort by 23 Organization for Economic Cooperation and Development (OECD)/International Energy Agency (IEA) member countries and the European Commission to support the objectives of the united nations framework convention on climate change (UNFCCC). The CTI was launched at the 1995 Berlin Conference of the Parties to the UNFCCC. The CTI seeks to ensure that technologies to address climate change are available and can be deployed efficiently. The CTI includes activities directed at the achievement of seven broad objectives:

- To facilitate cooperative and voluntary actions among governments, quasigovernments, and private entities to help cost-effective technology diffusion and reduce the barriers to an enhanced use of climate-friendly technologies
- To promote the development of technology aspects of national plans and programs prepared under the UNFCCC
- To establish and strengthen the networks among renewable and energy efficiency centers in different regions
- To improve access to and enhance markets for emerging technologies
- To provide appropriate recognition of climate-friendly technologies through the creation of international technology awards

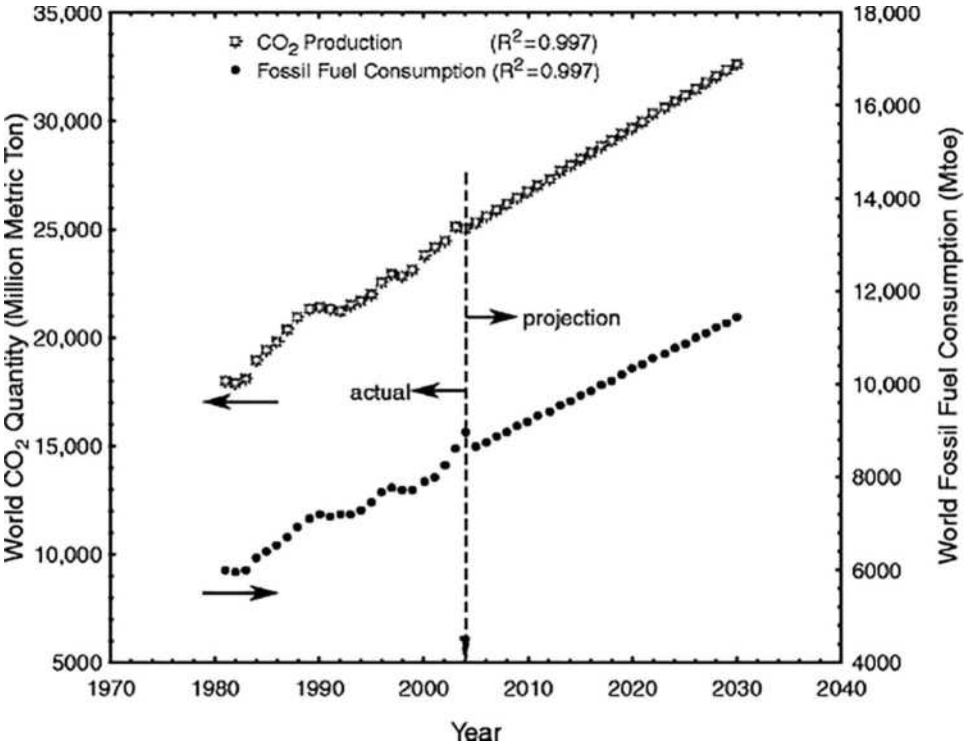

FIGURE 3 Variation of world total fossil-fuel consumption and CO_2 production; actual data from BP[3] and projections. Mtoe, million tons of oil equivalent.
Source: BP.[3]

- To strengthen international collaboration on short-, medium-, and long-term research; development and demonstration; and systematic evaluation of technology options
- To assess the feasibility of developing longer-term technologies to capture, remove, or dispose of greenhouse gases; to produce hydrogen from fossil fuels; and to strengthen relevant basic and applied research

Potential Solutions to Environmental Issues

Although there are a large number of practical solutions to environmental problems, three potential solutions are given priority, as follows[11]:

- Energy conservation technologies (efficient energy utilization)
- Renewable energy technologies
- Cleaner technologies

In these technologies, we pay special attention to energy conservation technologies and their practical aspects and environmental impacts. Each of these technologies is of great importance, and requires careful treatment and program development. In this work, we deal with energy conservation technologies and strategies in depth. Considering the above priorities to environmental solutions, the important technologies shown in Figure 4 should be put into practice.

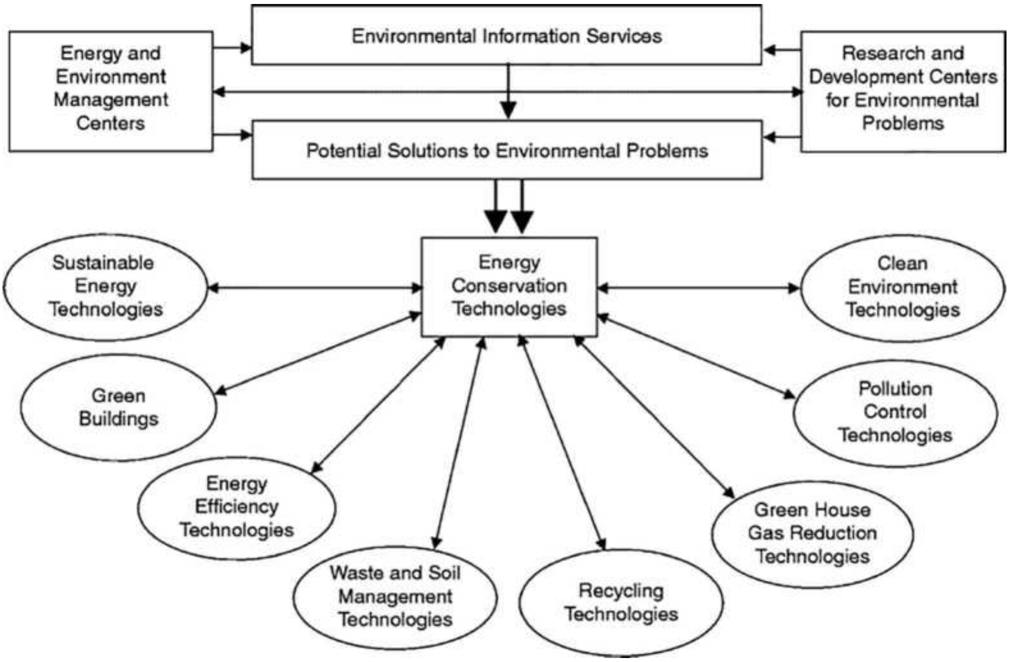

FIGURE 4 Linkages between possible environmental and energy conservation technologies.

Practical Energy Conservation Aspects

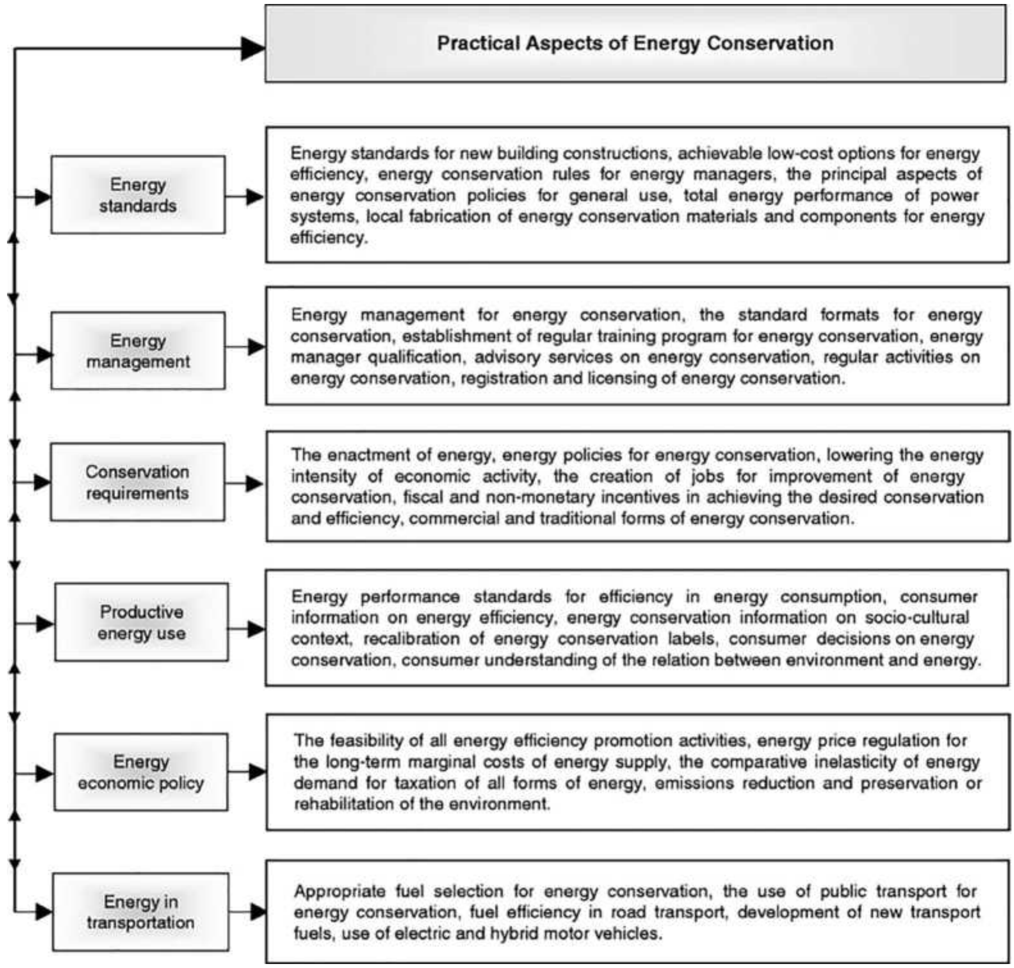
The energy-saving result of efficiency improvements is often called energy conservation. The terms efficiency and conservation contrast with curtailment, which decreases output (e.g., turning down the thermostat) or services (e.g., driving less) to curb energy use. That is, energy curtailment occurs when saving energy causes a reduction in services or sacrifice of comfort. Curtailment is often employed as an emergency measure. Energy efficiency is increased when an energy conversion device-such as a household appliance, automobile engine, or steam turbine-undergoes a technical change that enables it to provide the same service (lighting, heating, motor drive, etc.) while using less energy. Energy efficiency is often viewed as a resource option like coal, oil, or natural gas. In contrast to supply options, however, the downward pressure on energy prices created by energy efficiency comes from demand reductions instead of increased supply. As a result, energy efficiency can reduce resource use and environmental impacts;[12]

The quality of a country's energy supply and demand systems is increasingly evaluated today in terms of its environmental sustainability. Fossil-fuel resources will not last indefinitely, and the most convenient, versatile, and inexpensive of them have substantially been used up. The future role of nuclear energy is uncertain, and global environmental concerns call for immediate action. OECD countries account for almost 50% of total world energy consumption: Current use of oil per person averages 4.5 bbl a year worldwide, ranging from 24 bbl in the United States and 12 bbl in western Europe to less than 1 bbl in sub-Saharan Africa. More than 80% of worldwide CO_2 emissions originate in the OECD area. It is clear, then, that OECD countries should play a crucial role in indicating a sustainable pattern and in implementing innovative strategies.[11]

From an economic as well as an environmental perspective, energy conservation holds even greater promise than renewable energy, at least in the near-term future. Energy conservation is indisputably beneficial to the environment, as a unit of energy not consumed equates to a unit of resources saved and a unit of pollution not generated.

Furthermore, some technical limitations on energy conservation are associated with the laws of physics and thermodynamics. Other technical limitations are imposed by practical technical constraints related to the real-world devices that are used. The minimum amount of fuel theoretically needed to produce a specified quantity of electricity, for example, could be determined by considering a Carnot (ideal) heat engine. However, more than this theoretical minimum fuel may be needed due to practical technical matters such as the maximum temperatures and pressures that structures and materials in the power plant can withstand.

As environmental concerns such as pollution, ozone depletion, and global climate change became major issues in the 1980s, interest developed in the link between energy utilization and the environment. Since then, there has been increasing attention to this linkage. Many scientists and engineers suggest that the impact of energy-resource utilization on the environment is best addressed by considering exergy. The exergy of a quantity of energy or a substance is a measure of the usefulness or quality of the energy or substance, or a measure of its potential to cause change. Exergy appears to be an effective measure of the potential of a substance to impact the environment. In practice, the authors feel that a thorough understanding of exergy and of how exergy analysis can provide insights into the efficiency and performance of energy systems is required for the engineer or scientist working in the area of energy systems and the environment.[8] Considering the above explanations, the general aspects of energy conservation can be summarized as shown in Figure 5.



Energy standards for new building constructions, achievable low-cost options for energy efficiency, energy conservation rules for energy managers, the principal aspects of energy conservation policies for general use, total energy performance of power systems, local fabrication of energy conservation materials and components for energy efficiency.

Energy management for energy conservation, the standard formats for energy conservation, establishment of regular training program for energy conservation, energy manager qualification, advisory services on energy conservation, regular activities on energy conservation, registration and licensing of energy conservation.

The enactment of energy, energy policies for energy conservation, lowering the energy intensity of economic activity, the creation of jobs for improvement of energy conservation, fiscal and non-monetary incentives in achieving the desired conservation and efficiency, commercial and traditional forms of energy conservation.

Energy performance standards for efficiency in energy consumption, consumer information on energy efficiency, energy conservation information on socio-cultural context, recalibration of energy conservation labels, consumer decisions on energy conservation, consumer understanding of the relation between environment and energy.

The feasibility of all energy efficiency promotion activities, energy price regulation for the long-term marginal costs of energy supply, the comparative inelasticity of energy demand for taxation of all forms of energy, emissions reduction and preservation or rehabilitation of the environment.

Appropriate fuel selection for energy conservation, the use of public transport for energy conservation, fuel efficiency in road transport, development of new transport fuels, use of electric and hybrid motor vehicles.

FIGURE 5 A flow chart of practical energy conservation aspects.

Research and Development Status on Energy Conservation

Now we look at R&D expenditures in energy conservation to assess the importance attached to energy conservation in the long range. The share of energy R&D expenditures going into energy conservation, for example, has grown greatly since 1976, from 5.1% in 1976 to 40.1% in 1990 and 68.5% in 2002.[11] This indicates that within energy R&D, research on energy conservation is increasing in importance. When R&D expenditures on energy conservation are compared with expenditures for research leading to protection of the environment in the 2000s, the largest share was spent on environment research. In fact, it is not easy to interpret the current trends in R&D expenditures, because energy conservation is now part of every discipline from engineering to economics. A marked trend has been observed since the mid-1970s, in that expenditures for energy conservation research have grown significantly, both in absolute terms and as a share of total energy R&D. These expenditures also grew more rapidly than those for environmental protection research, surpassing it in the early 1980s. Therefore, if R&D expenditures reflect long-term concern, there seems to be relatively more importance attached to energy conservation as compared with environmental protection.

In addition to the general trends discussed above, consider the industrial sector and how it has tackled energy conservation.

The private sector clearly has an important role to play in providing finance that could be used for energy efficiency investments. In fact, governments can adjust their spending priorities in aid plans and through official support provided to their exporters, but they can influence the vast potential pool of private-sector finance only indirectly. Many of the most important measures to attract foreign investors include reforming macroeconomic policy frameworks, energy market structures and pricing, and banking; creating debt recovery programs; strengthening the commercial and legal framework for investment; and setting up judicial institutions and enforcement mechanisms. These are difficult tasks that often involve lengthy political processes.

Thus, the following important factors, which are adopted from a literature work[13] can contribute to improving energy conservation in real life. Figure 6 presents the improvement factors of energy conservation.

Energy Conservation and Sustainable Development

Energy conservation is vital for sustainable development and should be implemented by all possible means, despite the fact that it has its own limitations. This is required not only for us, but for the next generation as well.

A secure supply of energy resources is generally considered a necessity but not a sufficient requirement for development within a society. Furthermore, sustainable development demands a sustainable supply of energy resources that, in the long term, is readily and sustainably available at reasonable cost and can be utilized for all required tasks without causing negative societal impact. Supplies of such energy resources as fossil fuels (coal, oil, and natural gas) and uranium are generally acknowledged to be finite. Other energy sources (such as sunlight, wind, and falling water) are generally considered to be renewable and, therefore, sustainable over the relatively long term. Wastes (convertible to useful energy forms through, for example, waste- to-energy incineration facilities) and biomass fuels usually also are viewed as being sustainable energy sources. In general, the implications of these statements are numerous and depend on how the term *sustainable* is defined.[14]

Energy resources and their utilization are intimately related to sustainable development. For societies to attain or try to attain sustainable development, much effort must be devoted not only to discovering sustainable energy resources, but also to increasing the energy efficiencies of processes utilizing these resources. Under these circumstances, increasing the efficiency of energy-utilizing devices is important. Due to increased awareness of the benefits of efficiency improvements, many institutes and agencies have started working along these lines. Many energy conservation and efficiency improvement programs have been developed and are being developed to reduce present levels of energy consumption.

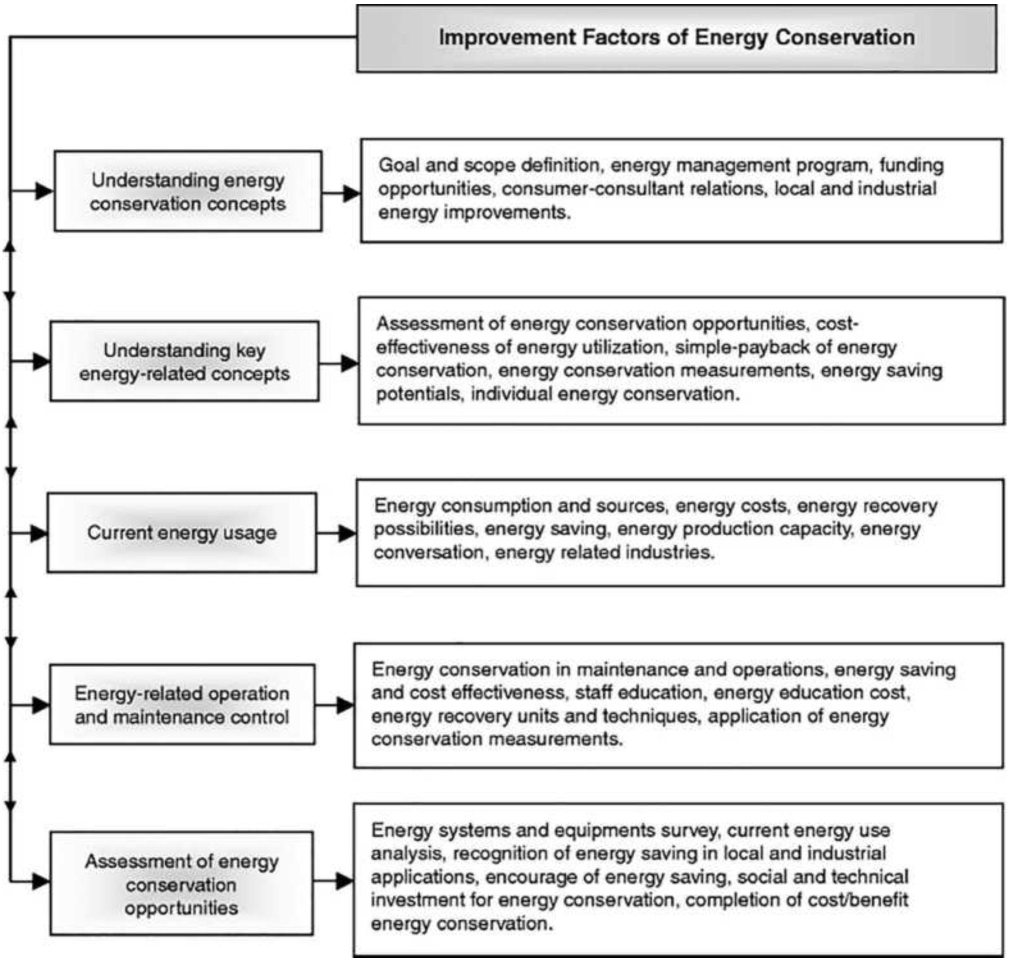


FIGURE 6 Improvement factors of energy conservation.

To implement these programs in a beneficial manner, an understanding is required of the patterns of "energy carrier" consumption-for example, the type of energy carrier used, factors that influence consumption, and types of end uses.[15]

Environmental concerns are an important factor in sustainable development. For a variety of reasons, activities that continually degrade the environment are not sustainable over time-that is, the cumulative impact on the environment of such activities often leads over time to a variety of health, ecological, and other problems. A large portion of the environmental impact in a society is associated with its utilization of energy resources. Ideally, a society seeking sustainable development utilizes only energy resources that cause no environmental impact (e.g., that release no emissions to the environment). Because all energy resources lead to some environmental impact, however, it is reasonable to suggest that some (not all) of the concerns regarding the limitations imposed on sustainable development by environmental emissions and their negative impacts can be overcome in part through increased energy efficiency. Clearly, a strong relationship exists between energy efficiency and environmental impact, because for the same services or products, less resource utilization and pollution normally are associated with increased energy efficiency.

Here, we look at renewable energy resources and compare them with energy conservation. Although not all renewable energy resources are inherently clean, there is such a diversity of choices that a shift to renewables carried out in the context of sustainable development could provide a far cleaner system than would be feasible by tightening controls on conventional energy. Furthermore, being by nature site-specific, they favor power system decentralization and locally applicable solutions more or less independently of the national network. It enables citizens to perceive positive and negative externalities of energy consumption. Consequently, the small scale of the equipment often makes the time required from initial design to operation short, providing greater adaptability in responding to unpredictable growth and/or changes in energy demand.

The exploitation of renewable energy resources and technologies is a key component of sustainable development.[11] There are three significant reasons for it:

- They have much less environmental impact compared with other sources of energy, because there are no energy sources with zero environmental impact. Such a variety of choices is available in practice that a shift to renewables could provide a far cleaner energy system than would be feasible by tightening controls on conventional energy.
- Renewable energy resources cannot be depleted, unlike fossil-fuel and uranium resources. If used wisely in appropriate and efficient applications, they can provide reliable and sustainable supply energy almost indefinitely. By contrast, fossil-fuel and uranium resources are finite and can be diminished by extraction and consumption.
- They favor power system decentralization and locally applicable solutions more or less independently of the national network, thus enhancing the flexibility of the system and the economic power supply to small, isolated settlements. That is why many different renewable energy technologies are potentially available for use in urban areas.

Taking into consideration these important reasons, the relationship between energy conservation and sustainability is finally presented as shown in Figure 7.

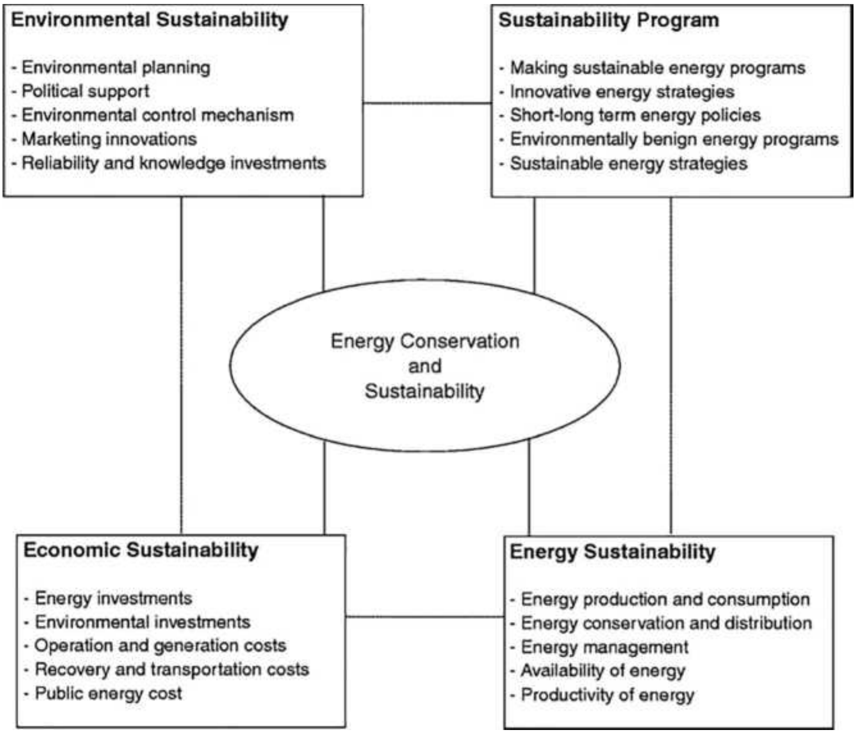

FIGURE 7 Linkages between energy conservation and sustainable development.

Energy Conservation Implementation Plan

The following basic steps are the key points in implementing an energy conservation strategy plan[11]:

1. *Defining the main goals.* It is a systematic way to identify clear goals, leading to a simple goal-setting process. It is one of the crucial concerns and follows an organized framework to define goals, decide priorities, and identify the resources needed to meet those goals.
2. *Identifying the community goals.* It is a significant step to identify priorities and links among energy, energy conservation, the environment, and other primary local issues. Here, it is also important to identify the institutional and financial instruments.
3. *Performing an environmental scan.* The main objective in this step is to develop a clear picture of the community to identify the critical energy-use areas, the size and shape of the resource-related problems facing the city and its electrical and gas utilities, the organizational mechanisms, and the base data for evaluating the program's progress.
4. *Increasing public awareness.* Governments can increase other customers' awareness and acceptance of energy conservation programs by entering into performance contracts for government activities. They can also publicize the results of these programs and projects. In this regard, international workshops to share experiences on the operation would help overcome the initial barrier of unfamiliarity in countries.
5. *Performing information analysis.* This step carries out a wide range of telephone, fax, email, and Internet interviews with local and international financial institutions, project developers, and bilateral aid agencies to capture new initiatives, lessons learned, and viewpoints on problems and potential solutions.
6. *Building community support.* This step covers the participation and support of local industries and communities, and the understanding the nature of conflicts and barriers between given goals and local actors; improving information flows; activating education and advice surfaces; identifying institutional barriers; and involving a broad spectrum of citizen and government agencies, referring to the participation and support of local industrial and public communities.
7. *Analyzing information.* This step includes defining available options and comparing the possible options with various factors (e.g., program implementation costs, funding availability, utility capital deferral, potential for energy efficiency, compatibility with community goals, and environmental benefits).
8. *Adopting policies and strategies.* Priority projects need to be identified through a number of approaches that are best for the community. The decision-making process should evaluate the cost of the options in terms of savings in energy costs; generation of business and tax revenue; and the number of jobs created, as well as their contribution to energy sustainability and their benefit to other community and environmental goals.
9. *Developing the plan.* When a draft plan has been adopted, it is important for the community to review it and comment on it. The public consultation process may vary, but the aim should be a high level of agreement.
10. *Implementing new action programs.* This step involves deciding which programs to concentrate on, with long-term aims being preferred over short-term aims. The option that has the greatest impact should be focused on, and all details should be defined, no matter how difficult the task seems. Financial resources needed to implement the program should be identified.
11. *Evaluating the success.* The final stage is evaluating and assessing how well the plan performed, which helps identify its strengths and weaknesses and to determine who is benefiting from it.

Energy Conservation Measures

For energy conservation measures, the information about the measure's applicability, cost range, maintenance issues, and additional points should be presented. Energy conservation involves efficiency improvements, formulation of pricing policies, good "housekeeping practices," and load management strategies, among other measures. A significant reduction in consumer energy costs can occur if conservation measures are adopted appropriately. The payback period for many conservation programs is less than 2 years.

In spite of the potentially significant benefits of such programs to the economy and their proven successes in several countries, conservation programs have not yet been undertaken on a significant scale in many developed and developing countries. Some reasons for this lack of energy conservation programs relate to the following factors:

- Technical (e.g., lack of availability, reliability, and knowledge of efficient technologies)
- Institutional (e.g., lack of appropriate technical input, financial support, and proper program design and monitoring expertise)
- Financial (e.g., lack of explicit financing mechanisms)
- Managerial (e.g., inappropriate program management practices and staff training)
- Pricing policy (e.g., inappropriate pricing of electricity and other energy commodities)
- Information diffusion (e.g., lack of appropriate information)

Reduced energy consumption through conservation programs can benefit not only consumers and utilities, but society as well. In particular, reduced energy consumption generally leads to reduced emissions of greenhouse gases and other pollutants into the environment.

Accelerated gains in energy efficiency in energy production and use, including those in the transportation sector, can help reduce emissions and promote energy security. Although there is a large technical potential for increased energy efficiency, there exist significant social and economic barriers to its achievement. Priority should be given to market forces in effecting efficiency gains. Reliance on market forces alone, however, is unlikely to overcome these barriers. For this reason, innovative and bold approaches are required by governments, in cooperation with industry, to realize the opportunities for energy efficiency improvements, and to accelerate the deployment of new and more efficient technologies.

Here, we look at energy conservation measures, which may be classified in six elements:

- Sectoral measures
- Energy conservation through systematic use of unused energy
- Energy conservation by changing social behavior
- International cooperation to promote energy conservation to counteract global warming
- Enhancing international and government-industry- university cooperation in developing technologies for energy conservation
- Promoting diffusion of information through publicity and education

The emphasis is on sectoral energy conservation. Table 4 presents some examples of such sectoral energy conservation measures. After determining which energy conservation measures are applicable, you should read the description of each of the applicable energy conservation measures. Information about the savings that can be expected from the measure, maintenance issues related to the measure, and other items to consider is provided for each energy conservation measure.

To evaluate the energy conservation measures, the following parameters should be taken into consideration[13]:

- *Cost estimation*. The first step is to estimate the cost of purchasing and installing the energy conservation measure. Cost estimates should be made for the entire development rather than for a single piece of equipment (e.g., obtain the cost for installing storm windows for an entire

TABLE 4 Sectoral Energy Conservation Measures

Sector	Measures
Industrial	Strengthening of financial and tax measures to enhance adoption and improvement of energy saving technologies through energy conservation equipment investments Re-use of waste energy in factories and/or in surrounding areas Enhancing recycling that reduces primary energy inputs such are iron scraps and used papers, and devising measures to facilitate recycling of manufactured products Retraining of energy managers and diffusion of new energy saving technologies through them Creating database on energy conservation technologies to facilitate diffusion of information
Residential and Commercial	Revising insulation standards provided in the energy conservation law, and introducing financial measures to enhance adoption of better insulation Development of better insulation materials and techniques Developing' energy conservation' model homes and total energy use systems for homes Revising or adopting energy conservation standards for home and office appliances Developing more energy saving appliances Revising guidelines for managing energy use in buildings, and strengthening advisory services to improve energy management in buildings
Transportation	Because 80% of energy consumption of the sector is by automobiles, further improvement in reducing fuel consumption by automobiles is necessary together with improvement in transportation system to facilitate and reduce traffic flow Diffusion of information about energy efficient driving Adopting financial measures to enhance the use of energy saving transportation equipment such as wind powered boats

Source: Adapted from Energy Conservation Policies and Technologies in Japan: A Survey.[16]

development or building, rather than the cost of one storm window). If you are planning to implement the energy conservation measure without the help of an outside contractor, you can obtain cost estimates by calling a vendor or distributor of the product. If, on the other hand, you will be using a contractor to install or implement the energy conservation measure, the contractor should provide estimates that include all labor costs and contract margins.

- *Data survey.* In this step, the questions on fuel consumption and cost should be listed for more than one possible fuel type (e.g., gas, oil, electric, or propane). The appropriate data for each fuel type should be selected and used accordingly for the cost estimation of each fuel.
- *Energy savings.* The amount of energy or fuel used should be estimated.
- *Cost savings.* This step determines the level of savings.
- *Payback period.* The last step in the cost/benefit analysis estimates the simple payback period. The payback period is found by dividing the cost of the measure by the annual cost savings.

Life-Cycle Costing

The term LCC for a project or product is quite broad and encompasses all those techniques that take into account both initial costs and future costs and benefits (savings) of a system or product over some period of time. The techniques differ, however, in their applications, which depend on various purposes of systems or products. Life-cycle costing is sometimes called a cradle-to-grave analysis. A life-cycle cost analysis calculates the cost of a system or product over its entire life span. Life-cycle costing is a process to determine the sum of all the costs associated with an asset or part thereof, including acquisition, installation, operation, maintenance, refurbishment, and disposal costs. Therefore, it is pivotal to the asset management process.

From the energy conservation point of view, LCC appears to be a potential tool in deciding which system or product is more cost effective and more energy efficient. It can provide information about how to evaluate options concerning design, sites, materials, etc., how to select the best energy conservation feature among various options; how much investment should be made in a single energy conservation feature; and which is the most desirable combination of various energy conservation features.

A choice can be made among various options of the energy conservation measure that produces maximum savings in the form of reduction in the life-cycle costs. A choice can be made between double-glazed and triple-glazed windows, for example. Similarly, a life-cycle cost comparison can be made

TABLE 5 An Example of Life-Cycle Costing (LCC) Analysis

Cost of Purchasing Bulbs	Incandescent	Compact Fluorescent
Lifetime of one bulb (hours)	1,000	10,000
Bulb price ($)	0.5	6.0
Number of bulbs for lighting 10,000 h	10	1
Cost for bulbs ($)	$10 \times 05 = 5.0$	$1 \times 6 = 6$
Energy cost		
Equivalent wattage (W)	75	12
Watt-hours (Wh) required for lighting for 10,000 h	$75 \times 10{,}000 = 750{,}000$ Wh = 750 kWh	$12 \times 10{,}000 = 120{,}000$ Wh = 120 kWh
Cost at 0.05 per kWh	750 kWh × \$0.05 = \$37.5	120 kWh × \$0.05 = \$6
Total cost ($)	$5 + 37.5 = 42.5$	$6 + 6 = 12$

between a solar heating system and a conventional heating system. The one that maximizes the life-cycle costs of providing a given level of comfort should be chosen. The application of such techniques to energy conservation is related to determining the optimum level of the chosen energy conservation measure. Sometimes, energy conservation measures involve the combination of several features. The best combination can be determined by evaluating the net LCC effects associated with successively increasing amounts of other energy conservation measures. The best combination is found by substituting the choices until each is used to the level at which its additional contribution to energy cost reduction per additional dollar is equal to that for all the other options.

Illustrative Example

Here, we present an illustrative example on LCC to highlight its importance from the energy conservation point of view. This example is a simple LCC analysis of lighting for both incandescent bulbs and compact fluorescent bulbs, comparing their life-cycle costs as detailed in Table 5. We know that incandescents are less expensive (95% to heat and 5% to usable light) and that compact fluorescent bulbs are more expensive but much more energy efficient. So the question is which type of lighting comes out on top in an LCC analysis.

This example clearly shows that LCC analysis helps in energy conservation and that we should make it part of our daily lives.

Conclusion

Energy conservation is a key element in sectoral (e.g., residential, industrial, and commercial) energy utilization and is vital for sustainable development. It should be implemented by all possible means, despite the fact that it sometime has its own limitations. This is required not only for us, but for the next generation as well. A secure supply of energy resources is generally considered a necessary but not a sufficient requirement for development within a society. Furthermore, sustainable development demands a sustainable supply of energy resources that, in the long term, is readily and sustainably available at reasonable cost and can be utilized for all required tasks without causing negative societal impact.

An enhanced understanding of the environmental problems relating to energy conservation presents a high-priority need and an urgent challenge, both to allow the problems to be addressed and to ensure that the solutions are beneficial for the economy and the energy systems.

All policies should be sound and make sense in global terms-that is, become an integral part of the international process of energy system adaptation that will recognize the very strong linkage existing between energy requirements and emissions of pollutants (environmental impact).

In summary this study discusses the current environmental issues and potential solutions to these issues; identifies the main steps for implementing energy conservation programs and the main barriers to such implementations; and provides assessments for energy conservation potentials for countries, as well as various practical and environmental aspects of energy conservation.

Energy Conservation: Lean Manufacturing

Bohdan W. Oppenheim

Introduction

At the time of this writing (2005), the world is experiencing strong contradictory global trends of diminishing conventional energy resources and rapidly increasing global demands for these resources, resulting in substantial upwards pressures in energy prices. Because the energy used by industry represents a significant fraction of the overall national energy use, equal to 33% in the United States in the year 2005, a major national effort is underway to conserve industrial energy.[1] The rising energy prices place escalating demands on industrial plants to reduce energy consumption without reducing production or sales, but by increasing energy density.

Optimization of industrial hardware and its uses, including motors and drives, lights, heating, ventilation and cooling equipment, fuel-burning equipment, and buildings, are well understood, have been practiced for years,[2] and are important in practice. However, they offer only limited energy conservation opportunities, rarely exceeding a few percent of the preoptimization levels. In contrast, the impact of productivity on energy use and energy density offers dramatically higher savings opportunities in energy and in other costs. In the extreme case, when transforming a factory from the traditional "process village" batch-and- queue system to the state-of-the-art, so-called Lean system, the savings in energy can reach 50% or more.

The best organization of production known at this time is called Lean, developed at Toyota in Japan.[3] It is the flow of value-added work through all processes required to convert raw materials to the finished products with minimum waste. Major elements of Lean organization include: steady single-piece flow with minimum inventories and no idle states or backflow; flexible production with flexible equipment and operators and flexible floor layouts ready to execute the order of any size profitably and just-in-time; reliable and robust supplies of raw materials; minimized downtime due to excellent preventive maintenance and quick setups; first-pass quality; clean, uncluttered, and well-organized work space; optimized work procedures; and, most importantly, an excellent workforce–well trained, motivated, team-based and unified for the common goals of having market success, communicating efficiently, and being well-managed. The Lean organization of production is now well understood among productivity professionals, but it is not yet popular among the lower tier suppliers in the United States. Its implementation would save energy and benefit the suppliers in becoming more competitive.

The engineering knowledge of energy conservation by equipment improvements is well understood and can be quantified with engineering accuracy for practically any type of industrial equipment.[2] In contrast, industrial productivity is strongly influenced by intangible and complex human factors such as management, work organization, learning and training, communications, culture, and motivation. These work aspects are difficult to quantify in factory environments. For this reason, the accuracy of productivity gains and the related energy savings are typically much less accurate than the energy savings computed from equipment optimization. Simple quantitative models with a conservative bias are therefore recommended as tools for energy management in plants. This entry includes some examples. They are presented in the form of energy savings or energy cost savings that would result from implementing a given productivity improvement, or eliminating a given productivity waste, or as simple metrics measuring energy density.

It is remarkable that in most cases, these types of energy savings occur as a natural byproduct of productivity improvements, without the need for a direct effort centered on energy. Thus, the management should focus on productivity improvements. In a traditional non-Lean plant intending to transform to Lean production, the first step should be to acquire the knowledge of the Lean system. It is easily available from industrial courses and workshops, books,[3,4] and video training materials.[6] The next step should be the actual transformation of production to Lean. Most of the related energy savings will then occur automatically. Implementation of individual productivity elements such as machine setup time reduction will yield some energy savings, but the result will not be as comprehensive as those yielded by the comprehensive implementation of Lean production.

Traditional vs. Lean Production

The traditional organization of production still used frequently in most factories tends to suffer from the following characteristics:

- Supplier selection is based on minimum cost, resulting in a poor level of mutual trust and partnership, the need for receiving inspection, and often large inventories of raw materials (RM).
- Work-in-progress (WIP) is moving in large batches from process village to process village and staged in idle status in queues in front of each machine, while the machine moves one piece at a time. This work organization is given the nickname "batch-and-queue" (BAQ).[3]
- Finished goods (FG) are scheduled to complex forecasts rather than customer orders, resulting in large inventories.
- The floor is divided into "process villages" populated with large, complex, and fast similar machines selected for minimum unit cost.
- Minimum or no information is displayed at workstations, and the workers produce quotas.
- Work leveling is lacking, which results in a random mix of bottlenecks and idle processes.
- Unscheduled downtime of equipment occurs frequently.
- Quality problems with defects, rework, returns, and customer complaints are frequent.
- Quality assurance in the form of 100% final inspections attempts to compensate for poor production quality.
- The floor space is cluttered, which makes moving around and finding items difficult.
- The workforce has minimum or no training and single skills.
- The management tends to be authoritarian.
- A language barrier exists between the workers and management.
- There is a culture of high-stress troubleshooting rather than creative trouble prevention.

In such plants, the waste of materials, labor, time, space, and energy can be as much as 50%–90%.[3]

The Lean production method developed primarily at Toyota in Japan under the name Just-In-Time (JIT), and generalized in the seminal work[3] is the opposite of the traditional production in almost all respects, as follows:

- Raw materials are bought from reliable supplier– partners and delivered JIT in the amount needed, at the price agreed, and with the consistently perfect quality that obviates incoming inspection.
- Single-piece flow (SPF) of WIP is steadily moving at a common takt time (Takt time is the common rhythm time of the pieces moving from workstation to workstation on the production line. It is the amount of time spent on EACH operation. It precisely synchronizes the rate of all production operations to the rate of sales JIT.), from the first to the last process.
- The FG are produced to actual customer orders JIT resulting in minimum inventories.
- The floor is divided into flexible production lines with small simple machines on casters that can be pushed into position and setup in minutes.
- The labor is multiskilled, well motivated and well trained in optimized procedures.
- Quality and production status are displayed on large visible boards at each workstation, making the entire production transparent for all to see.
- Preventive maintenance assures no unscheduled downtime of equipment.
- All process operators are trained in in-line quality checks and variability reduction.
- No final inspection is needed, except for occasional sampled checks of FG.
- Defects, rework, returns, and customer complaints are practically eliminated.
- The floor space is clean and uncluttered.
- The workforce is trained in company culture and commonality of the plant mission, customer needs, workmanship, and quality.
- The culture promotes teamwork, multiple job skills, supportive mentoring management, and company loyalty.
- The management promotes trouble prevention and “stopping the line” at the first sign of imperfection so that no bad pieces flow downstream.

According to Womack et al. the transformation from traditional to Lean production can reduce overall cost, inventory, defects, lead times by 90%, and space by 50%, and vastly increase plant competitiveness, customer satisfaction, and workforce morale. The resultant energy savings can be equally dramatic. Liker,[4] contains interviews with industry leaders who have succeeded in this transformation.

Impact on Energy

The impact of productivity on plant energy falls into the following two broad categories:

1. Productivity improvements that save infrastructure energy. These improvements reduce the energy consumed by all plant support systems, which tend to be energized regardless of the actual production activities, such as lights, space cooling and heating devices, cooling towers, combustion equipment (boilers, molten metal furnaces), air compressors, forklift battery chargers, conveyors, etc. To the first approximation, the infrastructure energy is reduced in proportion to the production time reductions, which can be huge in the Lean system. In order to perform more detailed estimates of the infrastructure energy savings, the management would have to conduct detailed energy accounting and understand how much energy is used by each support system under different production conditions. This knowledge is rarely available; therefore the former simplistic approach, combined with conservative estimates, offer useful tools.
2. Process energy savings. In this category, the energy savings of process equipment are obtained by improving the process productivity. Examples include the reduction of unscheduled machine downtime or setup time and the elimination of process variability, defects, rework, scrap, excessive labor time, etc.

Single Piece Flow (SPF)

Changing the traditional BAQ production to Lean production is by far the most effective productivity transformation a plant can undertake, creating dramatic savings in the overall throughput time, cost, quality, and energy. The example shown in Figure 1 compares just one aspect of the transformation—a reduction of batch size from five to one, i.e., the SPF. In both cases, four processes of equal one-minute takt time are assumed. The benefits of the SPF alone are dramatic, as follows:

1. In BAQ, the batch is completed in 20 min and in SPF in only 8 min, a 60% reduction.
2. In BAQ, only one machine at a time produces value, while three others are idle. If the idle machines remain energized, as is the case, e.g., with injection molding, three of the four machines (75%) would be wasting energy, and doing it for 16 min each, adding up to 64 min of machine energy

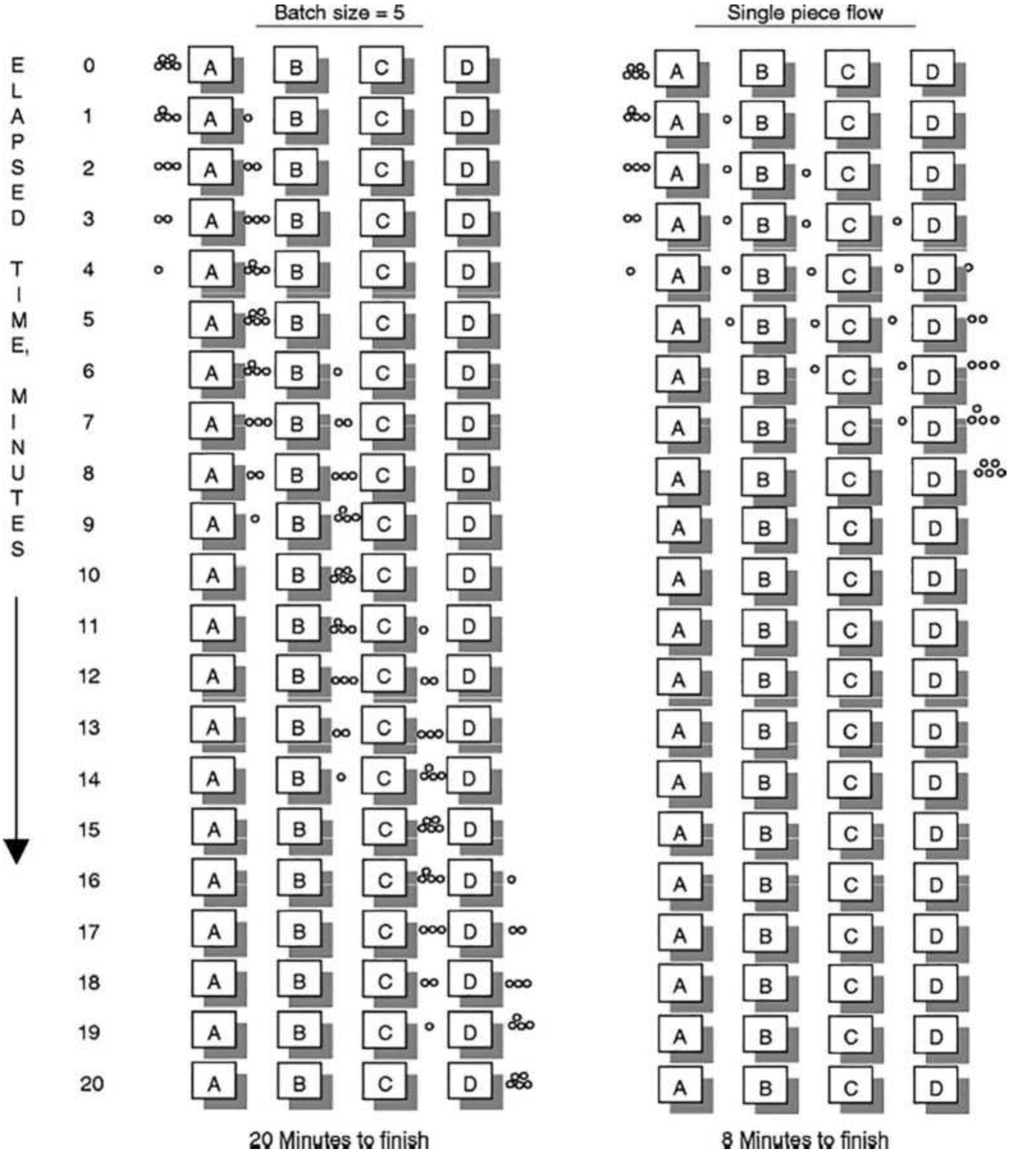

FIGURE 1 BAQ with batch size of five vs SPF.

wasted. In the SPF system, no machine energy is wasted as no machine would be idle, except for the lead and tail of each process of 4 min, adding up to 16 min of machine energy wasted, a savings of 75% from BAQ.

3. Reducing the batch throughput time by 60% reduces the infrastructure energy by the same amount, assuming the production is completed faster and the plant is de-energized. Alternatively, the freed 60% time and energy could be used for additional production and profits.
4. An important additional benefit is that in SPF, a defect can be detected on the first specimen–as soon as it reaches the next process, while in the BAQ, the entire batch may be wasted before the defect is discovered and a corrective action undertaken, with the energy used for making the batch wasted.

This simple example clearly illustrates the dramatic impact of SPF on both overall productivity and energy consumption. Typically, as the factories transform to the Lean system, their sales, production, and profits increase simultaneously and the energy used decreases. A convenient metric to track the overall benefit is the gross energy density, ED_1 or ED_2:

$$\mathrm{ED}_1 = \frac{\mathrm{EC}_\mathrm{T}}{P} \tag{1a}$$

$$\mathrm{ED}_2 = \frac{\mathrm{EC}_\mathrm{T}}{\mathrm{AC}} \tag{1b}$$

where EC_T is the overall annual cost of energy in the plant, P is the number of products produced per year and AC is the total annual costs (sales minus net profit). ED_1 should be used if similar products are made most of the time, and ED_2 should be used if the plant has a wide menu of dissimilar products. The ED ratios will decrease as progress is made from BAQ to SPF. If the volume of production remains constant during the transformation, energy savings and energy cost savings alone may be more convenient metrics to track plant energy efficiency.

Inventory Reduction

All inventories, whether in RM, WIP, or FG, beyond the immediate safety buffers, are detrimental. Inventory means that company capital is “frozen” on the floor; cutting into the cash flow; wasting labor for inventory control, storage, and security; wasting infrastructure energy for lights, forklift energy, and possible cooling or heating of the inventory spaces if the goods require temperature or humidity control; wasting space and the associated lease/mortgage fees and taxes; and becoming scrap if not sold (a frequent waste in large inventories). Inventory and inventory space reductions lead to infrastructure energy savings. Process energy can also be saved by not making the FG that end up in inventory, cannot be sold, and become scrap. Womack and Jones[3] and Liker[4] contain case studies for, among others, inventory reductions. A convenient nondimensional metric to track the overall impact of all inventories on energy savings is

$$\mathrm{EC}_T \times \frac{I_T}{AC} \tag{2}$$

where I_T is the number of inventory turns per year.

Workmanship, Training, and Quality Assurance

In the ideal Lean system, the processes, equipment, procedures, and training are perfected to the degree that guarantees consistent and robust production with predictable effort, timing, quality, and cost; with no variability, defects, or rework, and with maximum ergonomics and safety. This is accomplished by a

TABLE 1 Energy Waste from Poor Workmanship

A plant with \$20,000,000 in sales and \$2,000,000 in profits spends \$1,000,000 on energy per year. The typical order requires 10 processes of roughly equal energy consumption. The production equipment consumes 60% and the supportive infrastructure consumes 40% of the plant energy. Sequential process #5 has the defect rate of 10%. In order to compensate for the defects, the first 5 processes must produce 10% extra pieces. The annual waste of energy cost (and the energy cost savings, if the defective process is fixed) is then:

(\$1,000,000/yr)(5/10 processes) (60% process energy) (10% defect rate) = \$30,000/yr (3)

The additional production time of 10% waste not only the cost of the process energy computed in (3) but also the infrastructure energy cost of:

(\$1,000,000/yr) (40% infrastructure energy) (10% defects) = \$40,000/yr (4)

Such delays also extend the promised delivery time and reduce customer satisfaction and factory competitiveness. Adding (1) and (2) together. (not counting the direct productivity losses), the wasted energy cost alone of \$70,000/yr represents 3.5% of the annual profits and 7% in annual energy costs. Based on the author's experience,[5] these numbers are not infrequent in industry. Fixing the productivity of process #5 would eliminate these wastes.

consistent long-term strategy of continuous improvement of all the above elements, including intensive initial training of the workforce and subsequent retraining in new procedures. A procedure must be developed for each process until it is robust and predictable and optimized for minimum overall cost, required quality, maximum ergonomics, and safety. Process operators must be trained in the procedures as well as in the process quality assurance, and they must be empowered to stop the process and take corrective action or call for help if unable to avoid a defect. Management culture must be supportive for such activities. Any departure from this ideal leads to costly penalties in quality, rework, delays, overtime or contract penalties, crew frustrations, and customer dissatisfaction. These, in turn, have negative impacts on energy as follows:

1. Defects require rework, which requires additional energy to remake or repair the part. The best metric to use here is the energy or energy cost per part used in the given defective process multiplied by the number of bad parts produced per year.
2. Variability in the process time or delays caused by defects mean that the production takes more time and more infrastructure and process energy for the same amount of value work and profits when compared with the ideal nonvariable process. Table 1 illustrates cases (1) and (2).
3. Defective processes usually require a massive final inspection to sort out the good products. Finding the finished goods defective is the most inefficient means of quality assurance because often the entire batch must then be remade, consuming the associated energy. The inspection space, labor, and energy represent a direct waste and should be replaced with in-line quality assurance (ILQA) that detects the first bad piece (Governmental, medical, etc., orders usually require a 100% final inspection. In the Lean system, this is performed as a formality because everybody in the plant knows that all pieces will be perfect because all imperfections have been removed in real time before the inspection process.) and immediately undertakes a corrective action. Typically, the ILQA can be implemented in few days of operators' training and has the simple payback period measured in days or weeks.[5]

Overage Reduction

Many a plant compensates for its notorious defects by routinely scheduling production in excess of what the customer orders. Some minimum overage is usually justified for machine setups, adjustments, and QA samples. In a Lean plant this rarely exceeds a fraction of one percent. In a traditional plant, the value of 5%–15% is not infrequent. A 5% overage means that the plant spends 105% of the necessary costs. If the profit margin is 5%, the overage alone may consume the entire profit. The overall energy waste (and the opportunity to save energy) is simply proportional to the overage amount. Overage is one of the most wasteful ways of compensating for defective processes. The best remedy is to simply identify the defective process with ILQA, find the root cause (typically the lack of training, excessive work quotas, or bad process or material), and repair it.

Unintentional overage can also be destructive to profits and energy use. Example: A worker is asked to cut only a few small pieces from a large sheet of metal, but instead he cuts the entire sheet, thinking, "my machine is already setup and soon they will ask me to cut the rest of the sheet anyway, so I may as well do it now." The excessive pieces then move through all processes, unknowingly to the management, consuming energy, labor and fixed costs, to end up as excessive FG inventory and, in the worst case, find no buyer and end up as scrap. Uncontrolled and careless overage can easily consume all profits, and, of course, waste energy proportionately to the overage amount.

Downtime

Equipment downtime and idleness may occur due to scheduled maintenance, unscheduled breakdowns, machine setups, and poor process scheduling. The downtime may cause proportional loss of both profits and energy. The downtime may have fourfold impact on energy use, as follows:

1. When a process stops for whatever reason during an active production shift, the plant infrastructure continues to use energy and loosing money, as in Equation 4. A good plant manager should understand what fraction of the infrastructure energy is wasted during the specific equipment downtime. With this knowledge, the energy waste can be estimated as being proportional to the downtime.
2. Some machines continue using energy during maintenance, repair, or setup in proportion to the downtime (e.g., the crucible holding molten metal for a die casting machine remains heated by natural gas while the machine is being setup or repaired). Reducing the setup time or eliminating the repair time saves the gas energy in direct proportion to the downtime saved. In order to calculate energy savings in such situations, it is necessary to understand the energy consumption by the equipment per unit of time multiplied by the downtime reduction.
3. When a particular machine is down, additional equipment upstream or downstream of that machine may also be forced into an idle status but remain energized, thus wasting energy. In an ideal single-piece flow, the entire production line (As in the saying "In Lean either everything works or nothing works") will stop. In order to estimate the energy-saving opportunity from reducing this cumulative downtime, the energy manager must understand which equipment is idled by the downtime of a given machine and how much energy it uses per unit time while being idle.
4. Lastly, energized equipment should be well managed. A high-powered machine may be left energized for hours at a time when not scheduled for production. A good practice is to assign each of these machines to an operator who will have the duty of turning the machine off when not needed for a longer time, if practical, and to turn it back on just in time to be ready for production exactly when it is needed.

Preventive maintenance and setup time reduction have a particularly critical impact on both productivity and related energy use, as follows:

Preventive Maintenance

Practical and routine preventive maintenance should be done during the hours free of scheduled production (e.g., during night shifts, on weekends, or during layover periods). The maintenance should be preventive rather than reactive (The term "preventive" tends to be replaced with "productive" in modern industrial parlance). Well-managed "total" preventive[6] maintenance involves not only oiling and checking the machines per schedule but also ongoing training of the mechanics; developing a comprehensive database containing information on the particular use and needs of various machines; preparing a schedule of part replacement and keeping inventory of frequently used spare parts; and a

TABLE 2 Energy Savings from Setup Time Reduction

A plant operates on two shifts, 260 days per year, performing on average of 20 two-hour setups per day on their electrically heated injection molding machines. Each machine consumes 20 kW when idle bur energized. By a focused continuous improvement system and training, the crew reduces the routine setup time 0.5 h, with few, if any expenses for additional hardware, thus saving:

(260 days/yr) (20 setups/day) (1.5 h saved/setup) = 7800 machine h/yr.

The resultant process energy saved will be:

(7800 h/yr) (20 kW) = 156,000 kWh/yr (5)

In addition, infrastructure energy will be saved because of the reduced downtime. Using the data from Example 1, if the work is done in two shifts for 260 days per year (4160 h/yr.), the plant infrastructure uses 40% of the plant energy, and each machine consumes 2% of the plant infrastructure energy during the set up, the additional energy cost savings due to the setup time reduction will be:

(7,800 hr/yr) (0.02) (0.04) ($1,000,000)/(4160 h/yr) = #15,000 (6)

well-managed ordering system for other parts, including vendor data so that when a part is needed it can be ordered immediately and shipped using the fastest possible means. Industry leaders have demonstrated that affordable preventive maintenance can reduce the unscheduled downtime and associated energy waste to zero. This should be the practical goal of well-run factories.

Setups

Modern market trends push industry towards shorter series and smaller orders, requiring, in turn, more and shorter setups. Industry leaders have perfected routine setups to take no more than a few minutes. In poorly managed plants, routine setups can take as long as several hours. In all competitive modern plants, serious efforts should be devoted to setup time reductions. The effort includes both training and hardware improvements. The training alone, with only minimal additional equipment (such as carts), can yield dramatic setup time reductions (i.e., from hours to minutes). Further gains may require a change of the mounting and adjustment hardware and instrumentation. Some companies organize competitions between teams for developing robust procedures for the setup time reductions. In a plant performing many setups, the opportunity for energy savings may be significant, both in the process and infrastructure energy, as shown in Table 2.

Flexibility

Production flexibility, also called agility, is an important characteristic of competitive plants. A flexible plant prefers small machines (if possible, on casters) that are easy to roll into position and plug into adjustable quick-connect electrical and air lines and that are easy to setup and maintain over the large fixed machines selected with large batches and small unit costs in mind (such machines are called "monuments" in Womack and Jones[3]). Such an ideal plant will also have trained a flexible workforce in multiple skills, including quality assurance skills. This flexibility allows for the setup of new production lines in hours or even minutes, optimizing the flow and floor layout in response to short orders, and delivers the orders JIT. The energy may be saved in two important ways, as follows:

- Small machines processing one piece at a time use only as much energy as needed. In contrast, when excessively large automated machines are used, the typical management choice is between using small batches JIT, thus wasting the large machine energy, or staging the batches for the large machine, which optimizes machine utilization at the expense of throughput time, production flow, production planning effort, and the related infrastructure energy.
- Small machines are conducive to flexible cellular work layout, where 2–4 machines involved in the sequential processing of WIP are arranged into a U-shaped cell with 1–3 workers serving all processes in the cell in sequence, and the last process being quality assurance. This layout can be made very compact—occupying a much smaller footprint in the plant compared to traditional

"process village" plants, roughly a reduction of 50%[3,4]—and is strongly preferred by workers because it saves walking and integrates well the work steps. Such a layout also saves forklift effort and energy and infrastructure energy due to the reduction of the footprint.

Other Productivity Elements

The complete list of productivity elements is beyond the scope of this entry, and all elements have some leverage on energy use and conservation. In the remaining space, only the few most important remaining aspects are mentioned, with their leverage on energy. Descriptive details can be found in Ohno[7] and numerous other texts on Lean production.

- *Visual factory:* Modern factories place an increasing importance on making the entire production as transparent as possible in order to make any problem visible to all, which is motivational for immediate corrective actions and continuous improvements. Ideally, each process should have a white board displaying the short-term data, such as the current production status (quantity completed vs required); the rate of defects or rejects and their causes; control charts and information about the machine condition or maintenance needs; and a brief list and explanation of any issues, all frequently updated. The board should also display long-term information such as process capability history, quality trends, operator training, etc. Such information is most helpful in the optimization of, among other things, process time and quality, which leads to energy savings, as discussed above.
- "*Andon*" *signals:* The term refers to the visual signals (lights, flags, markers, etc.,) displaying the process condition, as follows: "green=all OK," "yellow=minor problem being corrected," and "red=high alarm, stopped production, and immediate assistance needed." The signals are very useful in identifying the trouble-free and troubled processes, which is conducive to focusing the aid resources to the right places in real time, fixing problems immediately and not allowing defects to flow downstream on the line. These features, in turn, reduce defects, rework, delays, and wasted costs, which improve overall productivity and save energy, as described above. It is also useful to display the estimated downtime (Toyota and other modern plants have large centrally located Andon boards that display the Andon signal, the workstation number, and the estimated downtime.). Knowing the forecasted downtime frees other workers to perform their pending tasks which have waited for such an opportunity rather than wait idle. This leads to better utilization of the plant resources, including infrastructure energy.
- "*5Ss*": The term comes from five Japanese words that begin with the "s" sound and loosely translate into English as: sorting, simplification, sweeping, standardization, and self-discipline (many other translations of the words are popular in industry); and describes a simple but powerful workplace organization method.[8] The underlying principle of the method is that only the items needed for the immediate task (parts, containers, tools, instructions, materials) are kept at hand where they are needed at the moment, and everything else is kept in easily accessible and well-organized storage in perfect order, easy to locate without searching, and in just the right quantities. All items have their designated place, clearly labeled with signs, labels, part numbers, and possibly bar codes. The minimum and maximum levels of inventory of small parts are predefined and are based on actual consumption rather than the "just-in-case" philosophy. The parts, tools, and materials needed for the next shift of production are prepared by a person in charge of the storage during the previous shift and delivered to the workstation before the shift starts. The floor is uncluttered and marked with designated spaces for all equipment. The entire factory is spotlessly clean and uncluttered. Walls are empty except for the visual boards. In consequence of these changes, the searching for parts, tools, and instructions which can represent a significant waste of labor and time is reduced, and this, in turn, saves energy. Secondary effects are also important. In a well-organized place, fewer mistakes are made; fewer wrong parts are used; less inspection is

FIGURE 2 In this messy plant, the workers waste close to 20% of their time looking for items and scavenging for parts and tools, also wasting the plant energy.

needed; quality, throughput time, and customer satisfaction are increased; and costs and energy are decreased. Figure 2 illustrates a fragment of a messy factory, where the average worker was estimated to waste 20% of his shift time looking for and scavenging for parts and tools. This percentage multiplied by the number of workers yields a significant amount of wasted production time, also wasting plant energy in the same proportion. Sorting, cleaning, and organizing the workplace is one of the simplest and most powerful starting points on the way to improved productivity and energy savings.

Conclusion

Large savings in energy are possible as an inherent byproduct of improving productivity. The state-of-the-art Lean productivity method can yield dramatic improvements in productivity. In the extreme case of converting from the traditional batch-and-queue and "process village" manufacturing system to Lean production, overall costs, lead times, and inventories can be reduced by as much as 50%–90%, floor space and energy by 50%, and energy density can be improved by 50%. The amount of energy that can be saved by productivity improvements often radically exceeds the savings from equipment optimization alone, thus providing a strong incentive to include productivity improvements in energy-reduction efforts.

Productivity strongly depends on human factors such as management, learning, and training, communications, culture, teamwork, etc., which are difficult to quantify, making accurate estimates of the cost, schedule, and quality benefits from various productivity improvements and the related energy savings difficult to estimate with engineering accuracy. For this reason, simple metrics and models are recommended, and some examples have been presented. If applied conservatively, they can become useful tools for energy management in a plant. The prerequisite knowledge includes an understanding of Lean Flow and its various productivity elements and a good accounting of energy use in the plant, including the knowledge of the energy used by individual machines and processes both when in productive use and in the idle but energized state, as well as the energy elements used by the infrastructure (various light combinations, air- compressors, cooling and heating devices, combusting systems, conveyers, forklifts, etc.). In the times of ferocious global competition and rising energy prices, every industrial plant should make every effort to improve both productivity and energy use.

Acknowledgments

This work is a result of the studies of energy conservation using the Lean productivity method performed by the Industrial Assessment Center funded by the U.S. Department of Energy at Loyola Marymount University. The author is grateful to Mr. Rudolf Marloth, Assistant Director of the Center, for his help with various energy estimates included herein and his insightful comments, to the Center students for their enthusiastic work, and to his son Peter W. Oppenheim for his diligent editing.

Global Climate Change: Carbon Sequestration

Sherwood Idso
and Keith E. Idso

Introduction

Concomitant with mankind's growing numbers and the progression of the Industrial Revolution, there has been a significant increase in the burning of fossil fuels (coal, gas, and oil) over the past 200 years, the carbon dioxide emissions from which have led to ever-increasing concentrations of atmospheric CO_2. This "large-scale geophysical experiment," to borrow the words of two of the phenomenon's early investigators,[1] is still ongoing and expected to continue throughout the current century. Furthermore, this enriching of the air with CO_2 is looked upon with great concern, because CO_2 is an important greenhouse gas, the augmentation of which is believed by many to have the potential to produce significant global warming. Therefore, and because of perceived serious consequences, such as the melting of polar ice, rising sea levels, coastal flooding, and more frequent and intense droughts, floods, and storms,[2] a concerted effort is underway to slow the rate at which CO_2 accumulates in the atmosphere, with the goal of stabilizing its concentration at a level that would prevent dangerous anthropogenic interference with the planet's climate system.

Removing Carbon from the Air

Role of Man

There are only two ways to significantly increase the natural flux of carbon from the atmosphere to the biosphere within the time frame required for effective ameliorative action if the ongoing rise in the air's CO_2 content is indeed a bona fide global warming threat: 1) increase the rate of vegetative CO_2 assimilation (photosynthesis) per unit leaf area and/or 2) increase the total plant population of the globe, i.e., leaf area per unit land area. Additionally, these things must be done without increasing the rate at which carbon is lost from the soil.

Man can do certain things to promote both of these phenomena while meeting the latter requirement as well. He can, for example, increase the rate of CO_2 assimilation per unit leaf area in agro-ecosystems by supplying additional nutrients and water to his crops. As has recently been noted, however, there are significant carbon costs associated with the production and application of fertilizers, as well as the transport of irrigation water; and factoring the CO_2 emissions of these activities into the equation often results in little net CO_2 removal from the atmosphere via these intensified agricultural interventions.[3]

Man can also draw more CO_2 out of the air by increasing the acreage of land devoted to growing crops, but this approach simultaneously releases great stores of soil carbon built up over prior centuries. When the plow exposes buried organic matter and it is oxidized, for example, prodigious amounts of CO_2 are produced and released to the atmosphere. But if a transition to less intensive tillage is made on fields that have a long history of conventional management and have thus been largely depleted of carbon, there is a good opportunity for nature to rebuild previously lost stores of soil organic matter.[4]

This approach to carbon sequestration is doubly beneficial for it results in a net removal of CO_2 from the atmosphere at the same time that it enhances a whole host of beneficial soil properties.[4,5] Also, abandoned farmlands will gradually replenish their carbon stores, both above- and below-ground, as native vegetation gradually reestablishes itself upon them. And, of course, the process can be hastened and made even more effective if trees are planted on such lands. Even without trees, it has been estimated that agricultural "best management practices" that employ conservation tillage techniques have the potential to boost the current U.S. farm and rangeland soil carbon sequestration rate of 20 million metric tons of carbon per year to fully 200 million metric tons per year,[6] which is approximately 13% of the country's yearly carbon emissions.[7]

Commercial forests also offer excellent opportunities for CO_2 removal from the air for considerable periods of time, especially when harvested wood is used to produce products that have long lifetimes. In addition, since some species of trees, such as many of those found in tropical rainforests,[8] can live in excess of a thousand years, CO_2 can be removed from the atmosphere and sequestered within their tissues—if man protects the trees from logging—until either long after the Age of Fossil Fuels has run its course or until significant changes in energy systems have reduced our dependence on fossil fuels and the CO_2 content of the air has returned to a level no longer considered problematic. Furthermore, carbon transferred to the soil beneath the trees via root exudation and turnover has the potential to remain sequestered even longer.

Role of Nature

The fact that the biosphere has maintained itself over the eons in the face of a vast array of environmental perturbations (albeit with significant modifications) suggests that earth's plant life has great resiliency and may even be able to exert a restraining influence on climate change.

A particularly important negative feedback of this type is the biosphere's ability to intensify its rate of carbon sequestration in the face of rising atmospheric CO_2 concentrations, as this phenomenon slows the rate of rise of the air's CO_2 content and thereby reduces the degree of intensification of the atmosphere's greenhouse effect. This particular climate-moderating influence of atmospheric CO_2 enrichment was first described in quantitative terms by Idso.[9,10] It begins when the aerial fertilization effect produced by the rising CO_2 content of the atmosphere elicits an increase in plant CO_2 assimilation rate per unit leaf area and when the concomitant plant water use efficiency-enhancing effect of the elevated CO_2 leads to an increase in the total plant population of the globe, due to the ability of more water-use-efficient plants to live and successfully reproduce in areas where it was formerly too dry for them to survive. In fact, these two effects are so powerful, they may actually be able to stabilize the CO_2 content of the atmosphere sometime during the current century, but only if anthropogenic CO_2 emission rates do not rise by an inordinate amount in the interim.[9,10] At the very least, together with the things man can do, they have the potential to "buy time" until other less-CO_2-emitting technologies become available.[11]

Keeping Carbon in the Soil

As more carbon is added to soils via CO_2-enhanced root growth, turnover and exudation, as well as from CO_2- induced increases in leaf litter and other decaying plant parts, the trick of significantly augmenting soil carbon sequestration is to keep at least the same percentage of this carbon in the soil as has historically been the case and to do so in the face of potential global warming.

A number of studies have addressed various aspects of this subject in recent years, with most of them finding that atmospheric CO_2 enrichment has little to no significant effect on plant litter decomposition rates. Furthermore, in nearly all of the cases where elevated CO_2 was observed to impact this phenomenon, the extra CO_2 was found to actually slow the rate of plant decomposition.[12] Much the same results have been obtained when analogous studies have used temperature as the independent variable. Warming has had either no effect on CO_2 evolution from the soil, or it has led to an actual decrease in CO_2 loss to the atmosphere.[13] Hence, the balance of evidence obtained from these studies suggests that the same—or a greater—percentage of plant material produced in a world of elevated atmospheric CO_2 concentration (and possibly higher mean air temperature) would indeed be retained in the soils of the terrestrial biosphere.

Even more compelling are the results of experiments where scientists have made direct measurements of changes in soil carbon storage under conditions of elevated atmospheric CO_2. Nearly every such study has observed increases in soil organic matter. In a Free-Air CO_2 Enrichment (FACE) experiment where portions of a cotton field were exposed to a 50% increase in atmospheric CO_2, for example, Leavitt et al.[14] found that 10% of the organic carbon present in the soil below the CO_2-enriched plants at the conclusion of the three-year experiment came from the extra CO_2 supplied to the FACE plants. In addition, some of the stored carbon had made its way into a very recalcitrant portion of the soil organic matter that had an average soil residence time of 2200 years.

Here, too, most experiments indicate that concomitant increases in temperature do not negate the increased carbon storage produced by atmospheric CO_2 enrichment. In a two-year study of perennial ryegrass grown at ambient and twice-ambient atmospheric CO_2 concentrations, as well as ambient and ambient+3°C temperature levels, for example, Casella and Soussana[15] determined that the elevated CO_2 increased soil carbon storage by 32% and 96% at low and high levels of soil nitrogen supply, respectively, "with no significant increased temperature effect." Hence, as in the case of studies of plant decomposition rates, the balance of evidence obtained from these studies also suggests that the same—or a greater—percentage of plant material produced in a world of elevated atmospheric CO_2 concentration (and possibly higher mean air temperature) would indeed be retained in the soils of the terrestrial biosphere.

Conclusions

As the air's CO_2 content continues to rise, there will almost certainly be a significant upward trend in the yearly production of terrestrial vegetative biomass, due to the growth-enhancing aerial fertilization effect of atmospheric CO_2 enrichment and the concomitant CO_2-induced increase in plant water use efficiency that enables plants to grow where it is currently too dry for them. Experimental evidence further suggests that at least the same percent- age—but in all likelihood more—of this yearly-increasing mass of plant tissue will be sequestered in earth's soils. Consequently, it is almost impossible to conclude that the carbon sequestering prowess of the planet will not be greatly enhanced in the years ahead, even without any overt actions on the part of man. Hence, if the nations of the earth were to implement even a modicum of carbon- conserving measures—such as 1)using minimum tillage techniques wherever possible in agricultural settings; 2) allowing abandoned agricultural land to revert to its natural vegetative state; 3) allowing stands of trees that can grow to very old age to actually do so; and 4) employing wise forestry practices to produce wood for making products that have long lifetimes—it is possible that

TABLE 1 Potential Rates of Carbon Sequestration (Kilograms Carbon per Hectare per Year) due to Land Management Practices That Could Be Employed for This Purpose

Improved rangeland management	50 to 150
Improved pastureland management	
Commercial fertilizer applications	100 to 200
Manure applications	200 to 500
Use of improved plant species	100 to 300
Improved grazing management	300 to 1300
Nitrogen fertilization of mountain meadows	100 to 200
Restoration of eroded soils	50 to 200
Restoration of mined lands	1000 to 3000
Conversion of cropland to pasture	400 to 1200
Conversion of cropland to natural vegetation	600 to 900
Conversion from conventional to conservation tillage	
No till	500
Mulch till	500
Ridge till	500

Global Climate Change: Earth System Response

Amanda Staudt and
Nathan E. Hultman

Introduction

For the past century, Earth's climate has been changing due to human activities. Observations show that Earth's surface warmed by approximately 0.6°C (1.1°F) on average in the 20th century. Much of this warming has been attributed to increasing abundances of greenhouse gases emitted to the atmosphere by human activities, although it is difficult to quantify this contribution against the backdrop of natural variability and climate-forcing uncertainties. Atmospheric abundances of the major anthropogenic greenhouse gases (carbon dioxide; methane; nitrous oxide; halocarbons manufactured by humans, such as chlorofluorocarbons; and tropospheric ozone) reached their highest recorded levels at the end of the 20th century, and all but methane have continued to rise. Major causes of this rise have been fossil fuel use, agriculture, and land-use change.

The emerging impacts of climate change on natural systems include melting glaciers and ice caps, the rising sea level, extended growing seasons, changes in precipitation regimes, and changes in the geographical distributions of plant and animal species. Additional impacts, to which it may be difficult for human and natural systems to adapt, could arise from events whose triggers are poorly understood. Human-induced global warming will continue during the 21st century and beyond, because many parts of the Earth's system respond slowly to changes in greenhouse gas levels and because altering established energy-use practices is difficult. Uncertainties remain about the magnitude and the impacts of future climate change, largely due to gaps in understanding of climate science and the socioeconomic drivers of climate change.

The Climate System and the Natural Greenhouse Effect

While climate conventionally has been defined as the long-term statistics of the weather (e.g., temperature, cloudiness, precipitation), improved understanding of the atmosphere's interactions with the oceans, the cryosphere (ice-covered regions of the world), and the terrestrial and marine biospheres has led scientists to expand the definition of climate to encompass the oceanic and terrestrial spheres as well as chemical components of the atmosphere (Figure 1). Physical processes within the atmosphere are influenced by ocean circulation, the reflectivity of Earth's surface, the chemical composition of the atmosphere, and vegetation patterns, among other factors.

The Sun provides almost all of Earth's energy. Solar radiation intercepted by Earth first encounters the atmosphere, which allows most of it to pass to Earth's surface. The intensity of radiation at the surface depends on the amount of incident radiation and on the orientation of the surface with respect to that radiation. The surface either reflects or absorbs this incoming radiation. Different surfaces reflect different amounts of sunlight. The fraction of solar energy reflected is defined as a surface's albedo. Albedos range from about 10% for open water, dark soil, and asphalt to about 80% for fresh snow.[1] Earth's average albedo is about 31%.

Although we do not normally think of it as a radiative body, Earth—like all bodies with a nonzero temperature—emits electromagnetic radiation. For Earth's temperature, most of this radiation is in the form of infrared light. In the absence of an atmosphere, all the radiation emitted by Earth would escape to space. The balance of incoming solar radiation and outgoing infrared radiation would result in a global-mean temperature for Earth of 255 K (–18°C/0°F). However, some molecules in Earth's atmosphere absorb some of this outgoing infrared light, thereby increasing their temperature. These greenhouse gases in the atmosphere emit some energy back toward Earth, warming Earth's surface. This natural

greenhouse effect, which is present in the absence of human activities, raises the global-mean surface temperature from 255 K to a comfortable 288 K (or about 15°C/59°F).[2]

Greenhouse gases that are present naturally in the atmosphere include water vapor (H_2O), carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), and ozone (O_3). The most common greenhouse gas by quantity and the one exerting the greatest influence on the climate is water vapor; however, because water has a very short lifetime in the atmosphere (~1 week), any human perturbation will dissipate quickly. In most cases, the "greenhouse effect" or "climate change" refers not to this natural phenomenon but to additional, anthropogenic enhancements to the atmosphere's capacity to trap heat. Much higher concentrations of CO_2, CH_4, and N_2O have been observed in the past century than were naturally present for the past 1000 years (Figure 2) and likely much longer.[3] Earth's surface is warmer now on average than it was at any time during the past 400 years, and it is likely warmer now than it was at any time in the past 2000 years.[4]

Climate Forcings and Feedbacks

Factors that affect climate change are usefully separated into forcings and feedbacks. Climate forcings are energy imbalances imposed on the climate system either externally or by human activities.[5] Examples include human- caused emissions of greenhouse gases, as discussed in the preceding section, as well as changes in solar energy input; volcanic emissions; deliberate land modification; or anthropogenic emissions of aerosols, which can absorb and scatter radiation. Climate forcings can be either direct or indirect. Direct radiative forcings are simple changes to the drivers of Earth's radiative balance. For

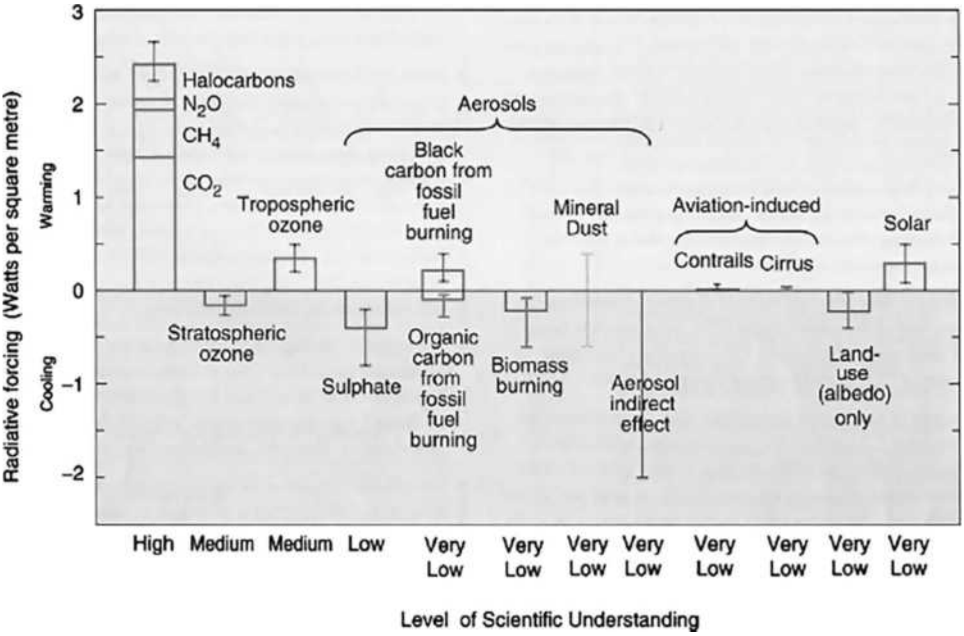

FIGURE 3 Estimated radiative forcings since preindustrial times for Earth and the troposphere system. The height of the rectangular bar denotes a central or best estimate of the forcing, while each vertical line is an estimate of the uncertainty range associated with the forcing, guided by the spread in the published record and physical understanding, and with no statistical connotation. Each forcing agent is associated with a level of scientific understanding, which is based on an assessment of the nature of assumptions involved, the uncertainties prevailing about the processes that govern the forcing, and the resulting confidence in the numerical values of the estimate. On the vertical axis, the direction of expected surface temperature change due to each radiative forcing is indicated by the labels "warming" and "cooling."
Source: Intergovernmental Panel on Climate Change (see IPCC[10]).

example, added CO_2 absorbs and emits infrared radiation. Indirect radiative forcings create a radiative imbalance by first altering climate system components that lead to consequent changes in radiative fluxes; an example is the effect of aerosols on the precipitation efficiency of clouds. Figure 3 provides a summary of the estimated contribution from major climate forcings. Additional information about specific climate forcings is provided in the discussion below.

Climate feedbacks are internal climate processes that amplify or dampen the climate response to an initial forcing.[6] An example is the increase in atmospheric water vapor that is triggered by an initial warming due to rising CO_2 concentrations, which then acts to amplify the warming through the greenhouse properties of water vapor (Figure 4). Other climate feedbacks involve snow and ice cover, biogeochemistry, clouds, and ocean circulation. Some of the uncertainty about how the climate will change in the future stems from unresolved research questions on climate change feedbacks.

Natural Climate Forcings: Solar and Volcanic Variability

Variations in the Sun's activity and in Earth's orbital parameters cause natural forcing of climate. Radiometers on various spacecraft have been measuring the total solar irradiance since the late 1970s. There is an 11-year cycle in total solar irradiance of peak-to-peak amplitude ~1 W m^{-2} (0.1%) in the past three cycles. Allowing for reflection of 30% of this incident energy (Earth's albedo) and

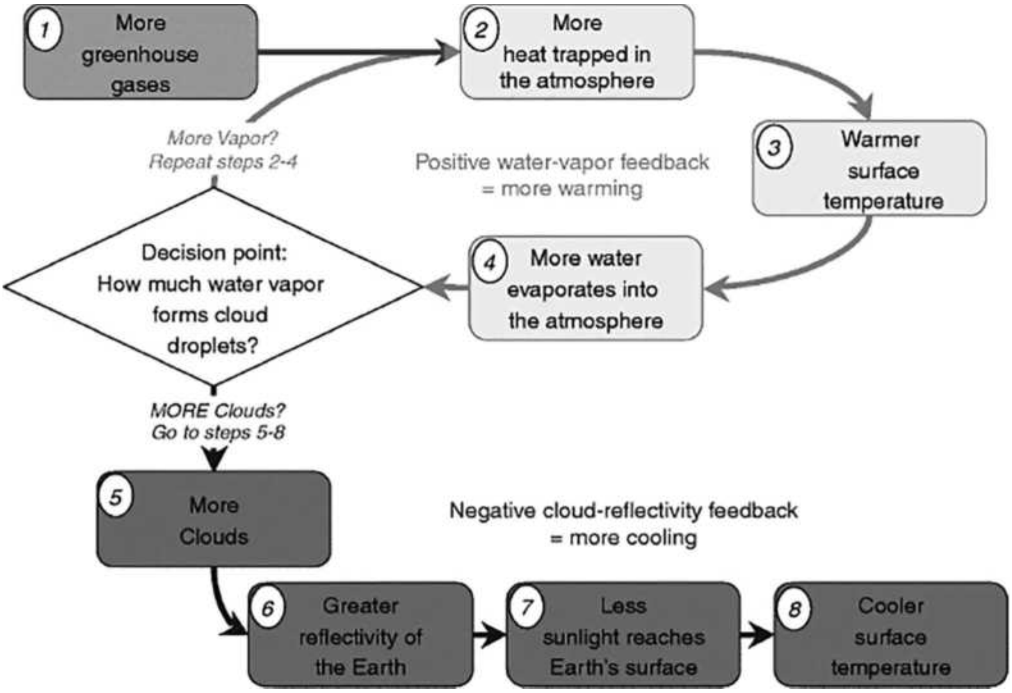

FIGURE 4 This schematic illustrates just two out of the dozens of climate feedbacks identified by scientists. The warming created by emitting more greenhouse gases leads to evaporation of water into the atmosphere. But water itself is a greenhouse gas and can cause even more warming via positive water-vapor feedback. On the other hand, if the water vapor leads to more clouds, the result could be to counteract some of the warming because clouds can reflect incoming sunlight back to space. This chain of events is negative cloud- reflectivity feedback. Trying to understand whether water vapor will create more clouds and what kinds of clouds water vapor will create is a major research objective right now. The answer depends on weather patterns, where the evaporation takes place, and the amount of small soot particles suspended in the air.

averaging over the globe, the corresponding climate forcing is of order 0.2 W m^{-2}, although recent analyses have found little secular trend in solar irradiance over the past 30 years.[7] Knowledge of solar irradiance variations prior to 1979 is less certain, as it relies upon models of how sunspot and facular influences relate to solar irradiance observed since then. These models are used to extrapolate variations back to about 1610, when telescopes were first used to monitor sunspots. The amount of energy Earth receives from the Sun also depends on Earth's distance from the Sun, which does not remain constant. The eccentricity of Earth's orbit (currently 0.0167) and the tilt of its axis relative to the orbital plane result in continual changes to the amount and distribution of energy Earth receives. In modern times, this variation is ±3.5% during the year, with maximum energy and minimum distance in January.

Volcanic forcing has been the dominant source of natural global radiative forcing over the past millennium. Emissions from volcanic eruptions have multiple effects on climate, as listed in Table 1.[8] The greater prevalence of explosive volcanic activity during both the early and the late 20th century and the dearth of eruptions from 1915 to 1960 represent a significant natural radiative forcing of 20th century climate.[9] Similarly, longer-term volcanic radiative forcing has been associated with a significant long-term forced cooling from 1000 to 1900, resulting from a general increase in explosive volcanic activity in later centuries.

TABLE 1 Effects of Large Explosive Volcanoes on Weather and Climate

Effect and Mechanism	Begins	Duration
Reduction of diurnal cycle	Immediately	1–4 days
	Blockage of shortwave and emission of longwave radiation	
Reduced tropical precipitation	1–3 months	3–6 months
	Blockage of shortwave radiation, reduced evaporation	
Summer cooling of Northern Hemisphere tropics and subtropics	1–3 months	1–2 years
	Blockage of shortwave radiation	
Reduced Sahel precipitation	1–3 months	1–2 years
	Blockage of shortwave radiation, reduced land temperature, reduced evaporation	
Stratospheric warming	1–3 months	1–2 years
	Stratospheric absorption of shortwave and longwave radiation	
Winter warming of Northern Hemisphere continents	6–18 months	1 or 2 winters
	Stratospheric absorption of shortwave and longwave radiation, dynamics	
Global cooling	Immediately	1–3 years
	Blockage of shortwave radiation	
Global cooling from multiple eruptions	Immediately	Up to decades
	Blockage of shortwave radiation	
Ozone depletion, enhanced UV radiation	1 day	1–2 years
	Dilution, heterogeneous chemistry on aerosols

Greenhouse Gas Forcing

The role of greenhouse gases in the climate system is well understood by scientists because instruments can accurately measure the abundances of these gases in the atmosphere and their radiative properties. The concentrations of CO_2, CH_4, $N_2$0, various halocarbons, and O_3 have increased substantially since preindustrial times, and they are the greatest contributors to total anthropogenic radiative forcing.[10] Many of these greenhouse gases are emitted primarily as a byproduct of fossil fuel combustion.

For a given gas, the total amount of heat-trapping ability depends on the efficiency of heat trapping for a given unit of gas (i.e., radiative forcing), the number of units present in the atmosphere, and the average length of time a given unit spends in the atmosphere. While these three components are enough to characterize a single gas, the large number of gases has prompted the development of an index called the global warming potential (GWP), which represents the relative impact of a particular greenhouse gas on the atmosphere's radiative balance.[10] See Table 2 for some GWP calculations. As the standard reference gas, CO_2 has a GWP of 1, by definition. Over a time horizon of 100 years, CH_4 and N_2O have GWPs of 23 and 296, respectively. In other words, 1 additional kg of CH_4 in the atmosphere absorbs as much radiation as 23 additional kg of CO_2. However, these numbers change if the time horizon shifts.[10] By allowing greenhouse gases to be compared directly, GWPs enable policies that can reduce total climate impact by addressing the least-cost abatement options first.[11,12]

TABLE 2 Radiative Forcing Characteristics of Some Major Greenhouse Gases

	Contribution to Direct Radiative Forcing				Global Warming Potential (GWP) for Different Time Horizons		
	Wm2	%	Concentration in 1998	Lifetime (Years)	20 Years	100 Years	500 Years
Carbon dioxide (CO_2)	1.46	60	365 ppm	5–200a	1	1	1
Methane (CH_4)	0.48	20	1745 ppb	12.0	62	23	7
Nitrous oxide (N_2O)	0.15	6	314 ppb	114	275	296	156
Halocarbons and related compounds	0.34	14	—	0.3–3200	40–15100	12–22200	4–16300

Source: Intergovernmental Panel on Climate Change (see IPCC[10]).

Total direct radiative forcing uncertainty is approximately 10%. The abbreviations parts per million (ppm) and parts per billion (ppb) refer to the ratio of greenhouse gas molecules to molecules of dry air.

[a] No single lifetime can be defined for CO2 because it is affected by multiple removal processes with different uptake rates.

Atmospheric Aerosol Forcing

Aerosols are small particles or liquid droplets suspended in the atmosphere. Aerosols both scatter and absorb radiation, representing a direct radiative forcing. Scattering generally dominates (except for black carbon particles) so that the net effect is of cooling. The average global mean of aerosol-direct forcing from fossil fuel combustion and biomass burning is in the range of -0.2 to -2.0 W m^{-2}.[10] This large range results from uncertainties in aerosol sources, composition, and properties used in different models. Recent advances in modeling and measurements have provided important constraints on the direct effect of aerosols on radiation.[13–15] Aerosols have several indirect effects on climate, all arising from their interaction with clouds— particularly from their roles as cloud condensation nuclei (CCN) and ice nuclei (Table 3).

TABLE 3 Overview of the Different Aerosol Indirect Effects Associated with Clouds

Effect	Cloud Type	Description	Sign of Top of the Atmosphere Radiative Forcing
First indirect aerosol effect (cloud albedo or Twomey effect)	All clouds	For the same cloud water or ice content more but smaller cloud particles reflect more solar radiation	Negative
Second indirect aerosol effect (cloud lifetime or Albrecht effect)	All clouds	Smaller cloud particles decrease the precipitation efficiency, thereby prolonging cloud lifetime	Negative
Semidirect effect	All clouds	Absorption of solar radiation by soot leads to evaporation of cloud particles	Positive
Glaciation indirect effect	Mixed-phase clouds	An increase in ice nuclei increases the precipitation efficiency	Positive
Thermodynamic effect	Mixed-phase clouds	Smaller cloud droplets inhibit freezing, causing super cooled droplets to extend to colder temperatures	Unknown
Surface energy budget effect	All clouds	The aerosol-induced increase in cloud optical thickness decreases the amount of solar radiation reaching the surface, changing the surface energy budget	Negative

Source: National Academies Press (see NRC[5]).

Land-Use Change Forcing

Land-use changes include irrigation, urbanization, deforestation, desertification, reforestation, the grazing of domestic animals, and dryland farming. Each of these alterations in landscape produces changes in radiative forcing, both directly and indirectly.[16,17] Direct effects include the change of albedo and emissivity resulting from the different types of land covers. For example, the development of agriculture in tropical regions typically results in an increase of albedo from a low value of forest canopies (0.05–0.15) to a higher value of agricultural fields, such as pasture (0.15–0.20). The Intergovernmental Panel on Climate Change (IPCC)[10] reports the globally averaged forcing due to albedo change alone as -0.25 ± 0.25 W m^{-2}. Significant uncertainties remain in estimating the effect of land-use change on albedo because of the complexity of land surfaces (e.g., the type of vegetation, phenology, density of coverage, soil color).

Indirect effects of land-cover change on the net radiation include a variety of processes related to (1) the ability of the land cover to use the radiation absorbed at the ground surface for evaporation, transpiration, and sensible heat fluxes (the impact on these heat fluxes caused by changes in land cover is sometimes referred to as thermodynamic forcing); (2) the exchange of greenhouse and other trace gases between the surface and the atmosphere; (3) the emission of aerosols (e.g., from dust); and (4) the distribution and melting of snow and ice.[5] These effects are not yet well characterized or quantified.

Evidence of Human-Induced Climate Change

Because we do not have a “control Earth” against which to compare the effects of our current changing atmosphere, incontrovertibly linking human activities and observed climate change is difficult. Scientists therefore rely on multiple, overlapping evidence of changes and then compare observed patterns of change with what our scientific understanding indicates should happen under anthropogenic climate change. This two-stage concept of discovering changes in climate and linking them to human activity is called detection and attribution. Evidence used to detect climate change is summarized in this section, and the use of climate models for attribution is discussed in the following section.

One piece of evidence of global warming is an increase in surface temperature since the 1900s, with particularly rapid increases since the late 1970s (Figure 5). This dataset caused some controversy when researchers discovered that readings taken near the surface of Earth with thermometers appeared to be higher than readings of the lower atmosphere taken by satellites from above. Subsequent studies concluded that the warming trend in global-mean surface temperature observations during the past 30 years is undoubtedly real and is substantially greater than the average rate of warming during the 20th century.[18] Satellite-and balloon-based observations of middle-troposphere temperatures, after several revisions of the data, now compare reasonably with one another and with observations from surface stations, although some uncertainties remain.[19,20]

The ocean, which represents the largest reservoir of heat in the climate system, has warmed by about 0.118°C (0.212°F), averaged over the layer extending from the surface down to 700 m, from 1955 to 2003 (Figure 6).[21] Approximately 84% of the total heating of Earth’s system (oceans, atmosphere, continents, and cryosphere) over the past 40 years has gone into warming the oceans. Recent studies have shown that the observed heat storage in the oceans is what would be expected by a human-enhanced greenhouse effect. Indeed, increased ocean heat content accounts for most of the planetary energy imbalance (i.e., when Earth absorbs more energy from the Sun than it emits back to space) simulated by climate models.[22]

Changes in several other climate indicators have been observed over the past decades, providing a growing body of evidence consistent with a human impact on the climate. For example, reductions

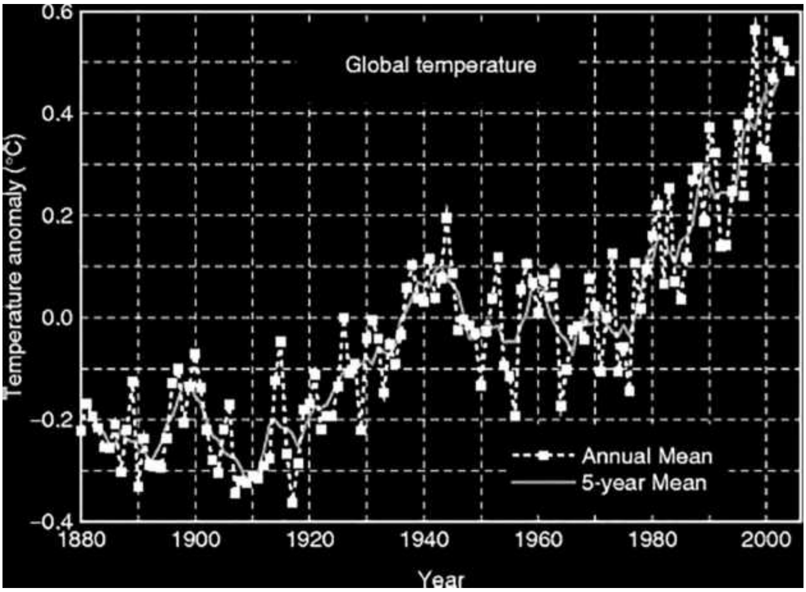

FIGURE 5 Global annual-mean surface air temperature change derived from the meteorological station network. Data and plots are available from the Goddard Institute for Space Sciences (GISS) at http://data.giss.nasa.gov/gistemp/graphs.

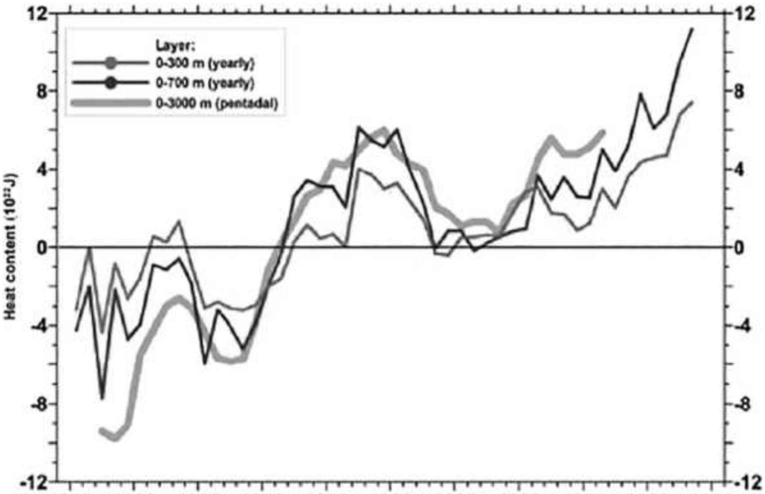

FIGURE 6 Time series of (i) yearly ocean heat content (10^{22} J) for the 0–300 m and 0–700 m layers and (ii) 5-year running averages for 1955–1959 through 1994–1998 for the 0–3000 m layer.
Source: Reproduced/modified by permission of the American Geophysical Union (see Levitus[21])).

in snow and ice cover are one important indicator.[10] Satellite observations indicate that snow cover has decreased by about 10% since the 1960s, while spring and summer sea-ice extent in the Northern Hemisphere has decreased by about 10%–15% since the 1950s. The shrinking of mountain glaciers in many nonpolar regions has also been observed during the 20th century.

Attribution of Observed Climate Change to Human Influence

An important question in global climate change is to what extent the observed changes are caused by the emissions of greenhouse gases and other human activities. Climate models are used to study how the climate operates today, how it may have functioned differently in the past, and how it may evolve in response to forcings. Built using our best scientific knowledge of atmospheric, oceanic, terrestrial, and cryospheric processes, climate models and their components are extensively tested against the full suite of observations of current and past climate to verify that they simulate a realistic version of the climate. Discrepancies between models and observations provide indications that we need to improve understanding of physical processes, model representations of the processes, or in some cases the observations themselves. Hence, climate models contain our accumulated wisdom about the underlying scientific processes and can be no better than our observations of the system and our understanding of the climate.

Figure 7 shows how scientists have used climate models to make the case that human activities have perturbed the climate since preindustrial times. In this experiment, the model is run with three different sets of climate forcings: (a) natural only, (b) anthropogenic only, and (c) natural and anthropogenic. When the natural or anthropogenic forcings are employed separately, the model is unable to reproduce the global-mean variation of temperature anomalies over the simulated time period. Only when both sets of forcings are used does the model capture the nature of the variations, providing evidence that human activities have caused a significant fraction of warming in the past 150 years.[10]

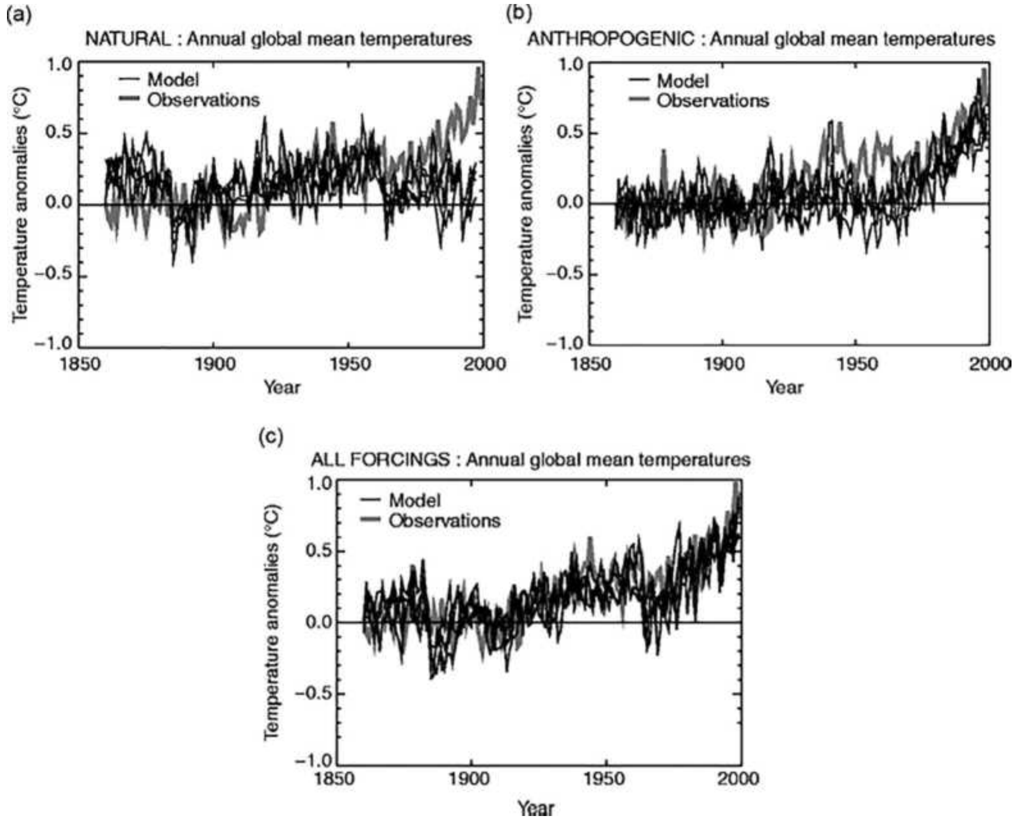

FIGURE 7 Climate model results with (a) solar and volcanic forcings only; (b) anthropogenic forcings only; and (c) all forcings, both natural and anthropogenic.

Projections for Future Climate Change

The IPCC has concluded that by 2100, global surface temperatures will likely be from 1.4 to 5.8°C (2.5°F–10.4°F) above 1990 levels (Figure 8) and that the combined effects of ice melting and seawater expansion from ocean warming will cause the global-mean sea level to rise by between 0.1 and 0.9 m.[10] Uncertainties remain about the magnitude and impacts of future climate change, largely due to gaps in understanding of climate science and the difficulty of predicting societal choices.

Climate changes in the coming century will not be uniformly distributed; some regions will experience more warming than others. There will be winners and losers from the impacts of climate change, even within a single region, but globally, the losses are expected to far outweigh the benefits. A changed climate will increase the likelihood of extreme heat and drought events.[23] High latitudes and polar regions are expected to see comparatively greater increases in average temperatures than lower latitudes, resulting in melting of permafrost and sea ice, which will result in additional costs for residents and in disruption to wildlife and ecosystems.[24] Precipitation changes, which are of great importance to agriculture, may have even more regional variability that is hard to predict.

Finally, several elements of Earth's system seem to be vulnerable to rapid destabilization. For example, the West Antarctic ice sheet and the Greenland ice sheet may be more prone to rapid melting than

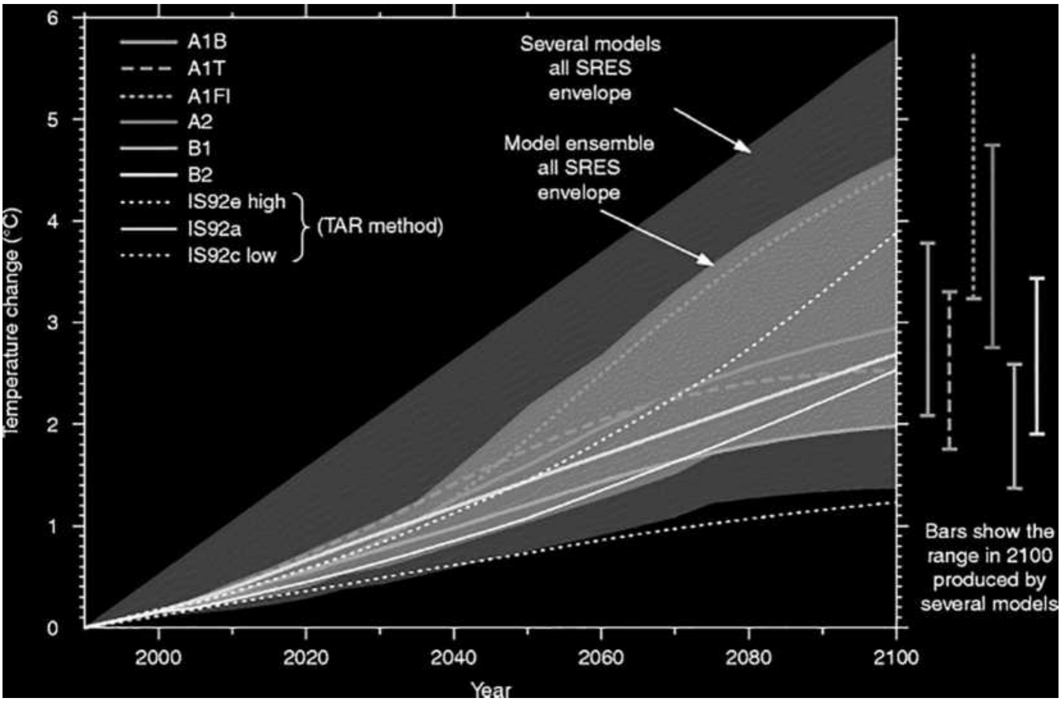

FIGURE 8 Climate models are often used to simulate possible future climates to help inform decisions about policy responses to potential climate changes. This figure shows the range of plausible global-mean temperature change over the next 100 years, simulated by a collection of models. The spread in 2100 temperatures from 1.4 to 5.8°C reflects two factors: (1) Each model was run multiple times using different scenarios (indicated by different line textures) for future climate forcings, and (2) each model makes different assumptions about how the climate responds to those forcings. The scenarios range from those that assume continued acceleration of greenhouse gas emissions to those that assume more moderate growth or leveling off of emissions rates. SRES refers to the collection of scenarios presented in the Special Report on Emissions Scenarios. TAR refers to the IPCC Third Assessment Report.

Source: Intergovernmental Panel on Climate Change (see IPCC[10]).

previously thought, and the loss of either of these would result in a large sea-level rise greater than 5 m. Moreover, the stability of the oceanic circulation that brings heat to Northern Europe has also been questioned. Because of feedback processes and the large uncertainty in system sensitivity, these outcomes are not easy to model and are usually not included in the gradual climate change projections quoted above. Nevertheless, they are nontrivial threats and represent active areas of current research.

Unfortunately, the regions that will be most severely affected are often the regions that are the least able to adapt. Bangladesh, one of the poorest nations in the world, is projected to lose 17.5% of its land if sea level rises about 1 m (40 in.), displacing tens of thousands of people.[10] Several islands throughout the South Pacific and Indian Oceans will be at similar risk for increased flooding and vulnerability to storm surges. Although wetland and coastal areas of many developed nations—including the United States—are also threatened, wealthy countries may be more able to adapt to sea-level rise and threats to agriculture. Solutions could include limiting or changing construction codes in coastal zones and developing new agricultural technologies.

Conclusion

Research conducted to understand how the climate system may be changing—and in turn affecting other natural systems and human society—has led to significant advancement in scientific understanding, but many questions remain. Society faces increasing pressure to decide how best to respond to a changing climate and associated global and regional changes.

One way to address global climate change is to take steps to reduce the amount of greenhouse gases in the atmosphere. Because CO_2 and other greenhouse gases can remain in the atmosphere for many decades, the climate-change impacts from concentrations today will likely continue throughout the 21st century and beyond. Failure to implement significant reductions in net greenhouse gas emissions now will make the job much harder in the future—both in terms of stabilizing CO_2 concentrations and in terms of experiencing more significant impacts. While no single solution can eliminate all future warming, many potentially cost-effective technological options could contribute to stabilizing greenhouse gas concentrations. These options range from personal choices such as driving less to national choices such as regulating emissions or seeking technologies to remove greenhouse gases from the atmosphere to international choices such as sharing energy technologies.

At the same time, it will be necessary to seek ways to adapt to the potential impacts of climate change. Climate is becoming increasingly important to public and private decision-making in various fields such as emergency management, water-quality assurance, insurance, irrigation and power production, and construction. For example, developing practical, “no regrets” strategies that could be used to reduce economic and ecological systems’ vulnerabilities to change could provide benefits whether a significant climate change ultimately occurs or not. No-regrets measures could include low-cost steps to improve climate forecasting; to slow biodiversity loss; to improve water, land, and air quality; and to make institutions—such as the health care enterprise, financial markets, and transportation systems—more resilient to major disruptions.

Global Climate Change: Gas Fluxes

Pascal Boeckx
and Oswald Van
Cleemput

Sampling Techniques, Sample Handling, and Analysis

Chamber Techniques

Flux chambers are simple inverted containers, which form an enclosure for gases emitted from the soil surface.[1] Both closed (static) and open (dynamic) chambers can be used. Advantages and disadvantages of chamber techniques are listed in Table 1.

TABLE 1 Advantages and Disadvantages of the Closed Chamber, Open Chamber, and Micrometeorological Methods to Measure Gas Fluxes from Soils

Method	Advantage	Disadvantage
Closed chamber	Simple and low cost	Labor intensive
	Multiple gases can be sampled	Small area is covered
	Small fluxes can be measured	Only a short-term emission event is monitored (1–2 h)
	Manual and automated gas sampling can be used	Disturbance of the emitting surface upon installation
		Altered conditions of temperature and soil atmosphere exchange
		Different functioning of plants in the chamber
Open chamber	Relatively simple	Small area is covered
	Environmental condition close to uncovered field	Disturbance of the emitting surface upon installation

(*Continued*)

TABLE 1 (*Continued*) Advantages and Disadvantages of the Closed Chamber, Open Chamber, and Micrometeorological Methods to Measure Gas Fluxes from Soils

Method	Advantage	Disadvantage
	Continuous long-term monitoring possible	Pressure deficits can cause artificially high fluxes
		Automated sampling is required
Micrometeorological	Useful for diurnal and seasonal variations	Expensive and sophisticated instrumentation needed
	Large areas can be monitored (aggregate flux)	Dependence on a uniform, large surface and constant atmospheric conditions
	Minimal disturbance of the emitting surface	

Closed and Open Chambers

Emissions of CO_2, CH_4, and N_2O are very variable, both spatially and temporally. It has not been determined whether the size of the flux chambers has an influence on this variability. Nevertheless, at least six chambers should be used per campaign. Flux chambers (cylindrical, or square or rectangular and box-like) can either be installed as a complete assembly, eventually for a short period and then removed until the next sampling occasion (Figure 1a), or they can exist out of a basal part, which is installed for the entire duration of the experiment with a gas-tight chamber attached to it for short periods (Figure 1b). This last variant is often used in flooded systems (e.g., paddy soils). The normal procedure for installation is to make a slit in the soil with a metal cutting edge, the same size and shape as the collar of the chamber, and to insert the chamber collar for about 3 cm into the slit.

When a closed chamber is fixed in place, gas samples can be taken from the headspace at different time intervals. The change in concentration in the chamber over time is used to calculate the gas flux. The calculation of the flux goes through a linear regression analysis of the gas concentration increase with time (corrected for eventual temperature changes) and a calculation of the chamber volume and area. Typical expressions of fluxes are g GHG $ha^{-1}d^{-1}$. A minimum of three measurements should be made to check the linearity of concentration increase in the chamber. A non-linear increase could indicate an inadequate sealing of the chamber or an important increase of pressure in the chamber due to temperature increases.[2] However, venting of the closed chambers can create large errors. The chamber cover should be removed once the final sample has been taken to minimize disturbance of the environmental conditions of the area covered by the chamber.

Open chambers can be used as well (Figure 2). In open chambers outside air flows into the chamber via an inlet and is forced to flow over the enclosed soil surface before leaving the chamber via an outlet. The concentration of the respective gas is measured at the in- and outlet sides. The gas flux from the soil surface can be calculated from the concentration difference between the in- and outlet, gas flow rate, and volume and area covered by the chamber.

Manual or Automated Sampling and Analysis

Using closed chambers, the headspace can be sampled by syringe. The gas samples are transferred to the laboratory into sealed containers (evacuated vials fitted with rubber septa) for analysis. To obtain a representative sample of the headspace, a diffusive mixing over 30 min is adequate, unless a mixing fan is used. Gas samples should be taken from the headspace immediately after sealing and at equal time intervals, thereafter, during which, gas concentrations increase linearly.

With automatic sampling, manual gas sampling from the chamber is replaced by a gas flow system providing a periodic sample transfer to a detector. The basic elements of an automatic system consist of closed chambers (equipped with lids that open and close automatically) or open chambers, gas flow

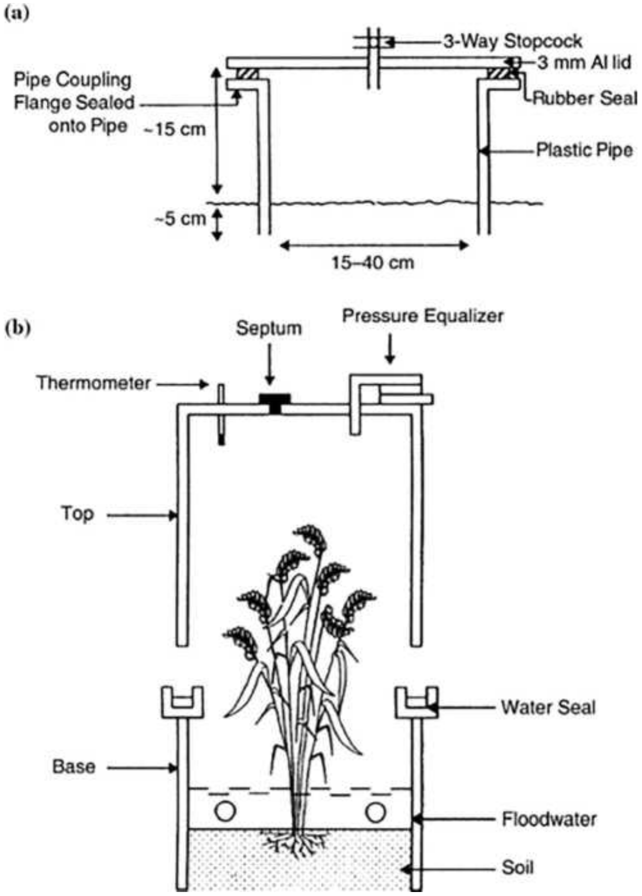

FIGURE 1 (a) Typical closed chamber used for greenhouse gas flux measurements from aerobic soils. **Source:** Adapted from Manual on Measurement of Methane and Nitrous Oxide Emissions from Agriculture.[2] (b) Schematic drawing of closed chamber used for greenhouse gas flux measurements in flooded soil.

systems (tubing and pump); a sampling unit; an analytical unit (detector); a time controller; and a data acquisition system. Automatic sampling is more expensive and it needs to be done in the vicinity of the analysis device. However, this technique is helpful when extensive data sets need to be collected over longer periods of time. It increases the reliability of the emission data obtained, because the number of manipulations is reduced. In most cases open chambers are sampled automatically.

Analytical Aspects

Gas Chromatography

Gas samples are injected into the gas chromatograph (GC) either manually or through the use of a sample loop (automated). Depending on the type of gas to be analyzed, specific GC settings and columns are used. Carbon dioxide is detected using a thermal conductivity detector (TCD). Methane is detected using a flame ionization detector (FID). Nitrous oxide is detected using a ^{63}Ni electron capture detector (ECD). For analysis of N_2O, care must be taken to remove both CO_2 and water vapor. In experiments with acetylene, to block the last step in the denitrification process, one may need to bypass the ECD with the acetylene in the sample after it exits from the chromatographic column. Acetylene alters both the sensitivity and stability of some ECDs.[2]

Photo-Acoustic-Infrared Detector (PAID)

The measuring principle is based on photo-acoustic detection of the absorption of infrared light. This means that any gas that absorbs infrared light of a specific wavelength can be measured. The most common PAID is the *Brüel and Kjær multi-gas monitor.* The PAID is equipped with a pump, which draws air from the flux chamber into an analysis cell inside the gas monitor. This cell can be sealed hermetically. Light from an infrared source is pulsated by a mechanical chopper and then passes through one of the optical filters of the filter carousel. The filter produces an infrared wavelength, which is selectively absorbed by the gas being monitored. Absorption of infrared light by the gas in the closed analysis cell causes the temperature to increase. Because the infrared light is pulsating, the gas temperature increases and decreases. In the closed cell this results in an increase and decrease of the pressure, which can be measured via 2 microphones. This acoustic signal is proportional to the concentration of the gas monitored. The *Brüel and Kjær multi-gas monitor* allows the analysis of 5 different gases and water vapor from 1 sample in approximately 120 sec. The device has the ability to compensate for temperature fluctuations and water vapor interference. Using an automated sampling system, careful calibration of the multi-gas monitor and the sampling unit is required.[4]

Micrometeorological Methods

The basic concept of micrometeorological methods for measuring trace gas fluxes to or from the soil surface is that gas transport is accomplished by the eddying motion of the atmosphere which displaces parcels of air from one level to another. Transport of a gas through the free atmosphere is provided by turbulent diffusion and convection in which the displacement of individual eddies is the basic transport process. Micrometeorological methods are based on the assumption that the flux to or from the soil surface is identical to the vertical flux measured at the reference level some distance above the surface. Therefore, a flat and homogeneous terrain is needed. The flux measured at the reference level provides than the average flux over the upwind area (fetch), provided that sampling point at the reference level is in the height range in which the vertical flux is constant with height (fetch$\approx$100H, where H$=$height of the sampling point). In the simplest of the micrometeorological methods, the flux may be measured by sensing the concentrations and velocities of components of the turbulence. [5,6]

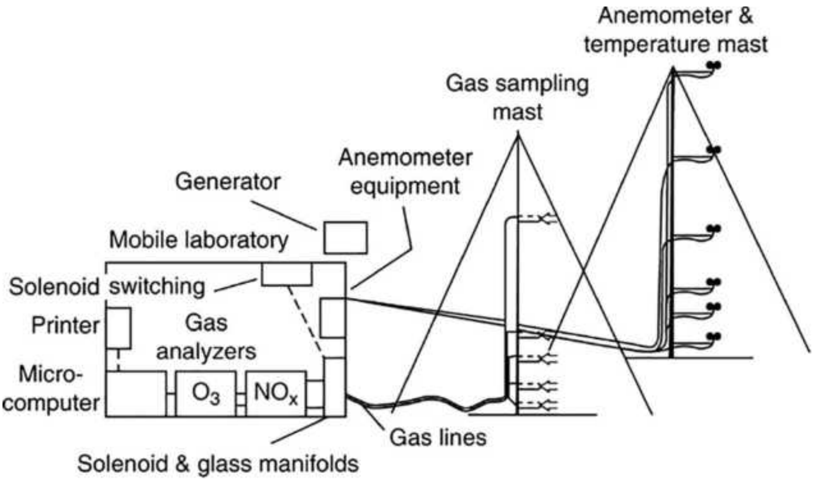

FIGURE 3 Typical instrument for flux gradient measurements of greenhouse gas fluxes in the field.
Source: Adapted from Denmead.[5]

Two general micrometeorological techniques are used to measure trace gas fluxes: the eddy correlation and flux- gradient technique (Figure 3). Application of both approaches is limited to situations in which the air analyzed has passed over a homogeneous exchange surface for a long distance so that profiles of gas concentration in the air are in equilibrium with the local rates of exchange. These methods also require that horizontal concentration gradients are negligible. Eddy correlation methods require a fast response detector. The tuneable diode laser (TDL) technique is based on infrared absorption spectrometry, whereby the absorption depends upon path length, line strength, and absorber concentration. Liquid nitrogen temperature diodes are commercially available to cover the infrared spectrum from about 2–10 μm, the region where most trace gases have absorption spectra.[5,6] Advantages and disadvantages of micrometeorological methods are listed in Table 1.

Nonisotopic Tracer Methods

Tracer methods involve the release of an inert tracer gas, most commonly sulphur hexafluoride (SF_6), from an emitting surface. The tracer gas is released at a known rate in a pattern similar to the release pattern of the GHG, perpendicular to the direction of the prevailing wind. This method can be applied when a definite plume of the GHG can be readily detected in the ambient environment. Under these conditions the plume of the dispersed emission is located based on analyses of upwind and downwind air samples. The flux rate is computed, using the ratio of the plume concentration of the tracer and the GHG and the known release rate of the tracer. The advantage of this technique is that aggregate gas emissions can be collected from heterogeneous areas, such as landfills, circumventing the problem of spatial heterogeneity. However, the high costs, dependence on meteorological conditions, and the potential for interfering sources limit its application.[2]

Ultra-Large Chambers with Long-Path Infrared Spectrometers

Infrared absorption spectrometers are available that can give an average value for the gas concentration over distances of tens or hundreds of meters. They are useful for measurements of average emissions from a whole experimental plot, by covering the plot temporarily with a large canopy to act as a chamber and retain the gas emitted from the soil. Two systems are available: 1) the Fourier Transform Infrared (FTIR) spectrometer with a mirror system, which allows multiple reflections and thus a total path of up to 1km that is capable of measuring GHG concentration changes down to a fraction of 1 ppb; and 2) a simpler, less-sensitive IR spectrometer with the capacity to detect a concentration change of about 25 ppbv of N_2O and 10 ppbv of CH_4.[2]

Contents

SECTION I APC: Anthropogenic Chemicals and Activities

SECTION II COV: Comparative Overviews of Important Topics for Environmental Management

SECTION III CSS: Case Studies of Environmental Management

SECTION IV DIA: Diagnostic Tools: Monitoring, Ecological Modeling, Ecological Indicators, and Ecological Services

SECTION V ELE: Focuses on the Use of Legislation or Policy to Address Environmental Problems

SECTION VI ENT: Environmental Management Using Environmental Technologies

SECTION VII PRO: Basic Environmental Processes

Preface

Given the current state of the world as compiled in the massive Millennium Ecosystem Assessment Report, humans have changed ecosystems more rapidly and extensively during the past 50 years than in any other time in human history. These are unprecedented changes that need certain action. As a result, it is imperative that we have a good scientific understanding of how these systems function and good strategies on how to manage them.

In a very practical way, this multivolume *Environmental Management Handbook* provides a comprehensive reference to demonstrate the key processes and provisions for enhancing environmental management. The experience, evidence, methods, and models relevant for studying environmental management are presented here in six stand-alone thematic volumes, as follows:

VOLUME 1 – Managing Global Resources and Universal Processes
VOLUME 2 – Managing Biological and Ecological Systems
VOLUME 3 – Managing Soils and Terrestrial Systems
VOLUME 4 – Managing Water Resources and Hydrological Systems
VOLUME 5 – Managing Air Quality and Energy Systems
VOLUME 6 – Managing Human and Social Systems

In this manner, the handbook introduces in the first volume the general concepts and processes used in environmental management. The next four volumes deal with each of the four spheres of nature (biosphere, geosphere, hydrosphere, and atmosphere). The last volume ties the material together in its application to human and social systems. These are very important chapters for a wide spectrum of students and professionals to understand and implement environmental management. In particular, the features include the following:

- The first handbook that demonstrates the key processes and provisions for enhancing environmental management.
- Addresses new and cutting-edge topics on ecosystem services, resilience, sustainability, food–energy–water nexus, socio-ecological systems, etc.
- Provides an excellent basic knowledge on environmental systems, explains how these systems function, and gives strategies on how to manage them.
- Written by an outstanding group of environmental experts.

Since the handbook covers such a wide range of materials from basic processes, to tools, technologies, case studies, and legislative actions, each handbook entry is further classified into the following categories:

APC: Anthropogenic chemicals: The chapters cover human-manufactured chemicals and activities
COV: Indicates that the chapters give comparative overviews of important topics for environmental management

CSS: The chapters give a case study of a particular environmental management example
DIA: Means that the chapters are about diagnostic tools: monitoring, ecological modeling, ecological indicators, and ecological services
ELE: Focuses on the use of legislation or policy to address environmental problems
ENT: Addresses environmental management using environmental technologies
NEC: Natural elements and chemicals: The chapters cover basic elements and chemicals found in nature
PRO: The chapters cover basic environmental processes.

Volume 6, *Managing Human and Social Systems*, applies the cumulative knowledge of environmental science and systems specifically into managing human and social systems. There are over 50 entries covering a wide area from environmental legislation and policy to human health, economics, sustainable development, and green technologies. New entries are included to cover environmental accounting, limits to growth, and urban agriculture. Case studies investigate the impact of cell tower placement, health consequences of pesticides in developing countries, and the promise of community-based monitoring. This culminating volume gives guidance for effective environmental management and a glimpse into future challenges and opportunities.

Editors

Brian D. Fath is Professor in the Department of Biological Sciences at Towson University (Maryland, USA) and Senior Research Scholar at the International Institute for Applied Systems Analysis (Laxenburg, Austria). He has published over 180 research papers, reports, and book chapters on environmental systems modeling, specifically in the areas of network analysis, urban metabolism, and sustainability. He has co-authored the books *A New Ecology: Systems Perspective* (2020), *Foundations for Sustainability: A Coherent Framework of Life–Environment Relations* (2019), and *Flourishing within Limits to Growth: Following Nature's Way* (2015). He is also Editor-in-Chief for the journal Ecological Modelling and Co-Editor-in-Chief for *Current Research in Environmental Sustainability*. He was the 2016 recipient of the Prigogine Medal for outstanding work in systems ecology and twice a Fulbright Distinguished Chair (Parthenope University, Naples, Italy in 2012 and Masaryk University, Czech Republic in 2019). In addition, he has served as Secretary General of the International Society for Ecological Modelling, Co-Chair of the Ecosystem Dynamics Focus Research Group in the Community Surface Modeling Dynamics System, and member and past Chair of Baltimore County Commission on Environmental Quality.

Sven E. Jørgensen (1934–2016) was Professor of environmental chemistry at Copenhagen University. He received a doctorate of engineering in environmental technology and a doctorate of science in ecological modeling. He was an honorable doctor of science at Coimbra University (Portugal) and Dar es Salaam (Tanzania). He was Editor-in-Chief of *Ecological Modelling* from the journal inception in 1975 until 2009. He was Editor-in-Chief for the *Encyclopedia of Environmental Management* (2013) and *Encyclopedia of Ecology* (2008). In 2004, he was awarded the Stockholm Water Prize and the Prigogine Medal. He was awarded the Einstein Professorship by the Chinese Academy of Sciences in 2005. In 2007, he received the Pascal Medal and was elected a member of the European Academy of Sciences. He has published over 350 papers and has edited or written over 70 books. He gave popular and well-received lectures and courses in ecological modeling, ecosystem theory, and ecological engineering worldwide.

APC: Anthropogenic Chemicals and Activities

1

Food: Pesticide Contamination

Denis Hamilton

Introduction

How much pesticide residue did I eat today?

No more than necessary, and less than would be detrimental to your health.

Government authorities must be able to support the answer to the consumer's question with scientific data and valid scientific studies.[1] The "no more residues than necessary" concept originates from the principle of good agricultural practice, which implies that the desired effect (pest control) will be achieved without leaving more residues than necessary in the food.

Before Registration

Pesticide residue evaluation and risk assessment prior to registration are summarized in Figure 1.[2,3]

Risks to the environment and to the user are also evaluated but are not considered further under the present topic—*food contamination with pesticide residues.*

Metabolism studies on a pesticide in crops and farm animals identify the nature of the residue. The residue may consist of a parent compound or metabolites or a mixture. In some cases, different pesticides produce the same metabolites; in other cases, the metabolite of one pesticide is another pesticide. Some crops genetically modified for herbicide resistance achieve their resistance by metabolizing the herbicide to a derivative with no herbicidal activity.

The acceptable daily intake (ADI) of a chemical is the daily intake, expressed on a body-weight basis, which, during an entire lifetime, appears to be without appreciable risk to the health of the consumer on the basis of all the known facts at the time. The ADI is based on animal feeding studies that find the daily dose over a lifetime resulting in no observable adverse effect on the most sensitive animal species tested. Then, a margin of safety (safety factor, commonly 100) is applied to allow for extrapolation from animals to humans and the variability in responses between average and highly sensitive humans.

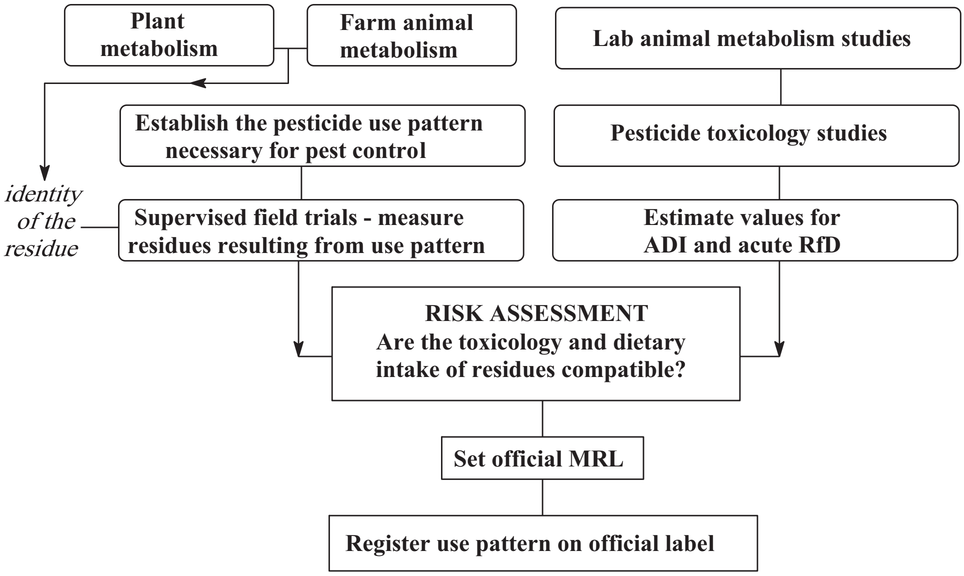

FIGURE 1 Risk assessment process before registration for pesticide residues in food. ADI: acceptable daily intake; Acute RfD: acute reference dose; MRL: maximum residue limit or tolerance.
Source: Hamilton DJ, Food contamination with pesticide residues, in *Encyclopedia of Pest Management*, 2002, p 287.

The acute reference dose (acute RfD or ARfD) of a chemical is an estimate of the amount normally expressed on a body-weight basis, which can be ingested in a period of 24 hours or less without appreciable health risk to the consumer on the basis of all known facts at the time of the evaluation. The acute RfD is also based on the results of animal dosing studies with a suitable safety factor.

The maximum residue limit (MRL), synonymous with "tolerance," is the maximum concentration of pesticide residue legally permitted in or on food commodities. The MRL usually applies to the commodity of trade, which may or may not be the same as the edible portion. For a fruit such as apples, it is the same, while for bananas, the MRL applies to the whole banana, but only the pulp is eaten. An MRL provides a division between food that is legally acceptable or unacceptable. Foods derived from commodities complying with the relevant MRLs are intended to be toxicologically acceptable, but the MRL is not a dividing line between safe and unsafe.

Supervised residue trials on animal feed commodities and livestock feeding studies with pesticide residues generate the information required to support MRLs for meat, milk, and eggs.

Risk assessment tells us whether or not the amounts of residue are likely to be safe for consumers.[4,5] We estimate dietary intake (also referred to as "dietary exposure") of pesticide residues by multiplying the level of residue in the food ready for consumption by the amount of the food consumed. For chronic risk assessment, we compare the sum for all foods of expected long-term average intake with the ADI for the pesticide. For acute risk assessment, we compare possible intake from high consumption of a food, in a period of 24 hours or less, with the acute RfD.

After Registration

The design of monitoring studies for residues in food commodities depends on the purpose: random survey of food consignments (surveillance), targeted enforcement sampling where a residue problem is suspected, export monitoring to meet trade requirements, and total diet studies.

Government authorities regularly survey agricultural and animal products for levels of pesticide residues. If the label directions were based on reliable and representative field trials and if users are faithfully following label directions, then residues will be within the legal MRLs. Most surveys have demonstrated a high level of compliance.

Total diet studies identify which pesticides and measure in what quantities people are actually consuming. Food purchased in the marketplace is prepared by peeling and cooking as in the normal household and is then subjected to residue analysis. Amounts of foods consumed are known from specially designed food surveys for subpopulations such as adult males and females, children, toddlers, and infants, as well as for ethnic groups and regions or localities. Dietary intakes for populations and subpopulations are calculated from the diets and the residue levels found by analysis. Commonly, total diet studies demonstrate intakes much less than the ADI.

Food Processing

Food processing usually reduces pesticide residue levels because of the washing or cleaning, peeling, milling, juicing, cooking, or baking. Residue levels may increase in some processed commodities because the residue tends more to one fraction than another.[6] For example, residues on the surface of a wheat grain will find their way into the bran fraction with little in the flour. Residues of oil-soluble pesticides will find their way mainly into the vegetable oil fraction from an oilseed such as soybean.

In particular cases, a food process can change the nature of the residue. For example, ethylenebisdithiocarbamate fungicides are converted, on cooking, to ethylenethiourea, which is more toxic than the parent pesticide. Fortunately, ethylenebisdithiocarbamates are essentially surface residues, and their levels can substantially be reduced by thorough washing before a cooking or blanching step.

Trade Issues

MRL values derived from good agricultural practice are, by their nature, local. A pesticide is used in the best way within local cultural practices to control a specific pest, and the rate of pesticide disappearance depends on local environmental conditions. Comparisons among countries of national MRLs and tolerances will frequently reveal substantial differences. Table 1 shows the range of MRLs for ethephon in 17 countries for each of four commodities.

TABLE 1 National Ethephon MRLs and Tolerances (mg/kg) in 1999[7]

	Peppers	Tomatoes	Pineapples	Grapes
Argentina	2	2		
Australia		2	2	10
Brazil		1.5	0.5	
Canada		2		
France				0.05
India		2	2	
Ireland	3	3		
Italy		3		0.05 Wine grapes 3 Table grapes
Korea		3	1	2
Netherlands	3	3		
New Zealand		1		
Poland		3		
Portugal	3	3		
South Africa			1	5
Taiwan		2	2	2
United Kingdom	3	3		
United States	30	2	2	2

The differences pose problems for international trade in food commodities. The importing country may reject shipments of food that do not comply with its national MRLs. It is attractive for some lobby groups and some governments to use national differences in MRLs as a barrier to trade.

Where no MRL or tolerance has been set for a pesticide on a food, some national governments apply a "zero tolerance," that is, the MRL is assumed to be zero unless otherwise stated. The reason no MRL is set could simply be that the pest problem does not occur or that the crop is not produced locally; for example, cold temperate countries do not produce pineapples, so there will be no local uses or local MRLs.

The Codex Alimentarius Commission was established in 1961 to implement the FAO/WHO Food Standards Program. A purpose of the program is to protect the health of consumers and to ensure fair practices in the food trade. The Codex Committee on Pesticide Residues (CCPR) has the responsibility to establish Codex MRLs for food commodities in international trade.

CCPR relies on the data supplied by member governments and has established many MRLs. The methods of data evaluation in Codex are very similar to the methods in countries with regulatory control of pesticide use; Codex draws on the expertise of scientists from such countries around the world. Member government acceptance of Codex MRLs for food commodities in international trade is reducing the incidence of trade barriers based on national MRLs.

Developing countries have sometimes suffered pesticide residue trade difficulties because a lack of resources has made it difficult for them to monitor their exports effectively to ensure compliance with the importing country MRL requirements.

Analytical Methods for Pesticide Residues

Analytical methods for pesticide residues in food typically rely on gas-liquid chromatography (GLC) or high-performance liquid chromatography (HPLC) in the final measurement step following extraction from the sample and a sequence of clean-up steps.[2,8] Multiresidue methods include many residues in one procedure for the sake of economy. Monitoring usually requires the detection and quantitative measurement of residue levels down to concentrations of around 0.01–0.05 mg/kg. Laboratories must validate their procedures down to the required level, that is, prove that the procedures can identify and measure with a specified precision residues down to a required "limit of quantification" (LOQ).

The LOQ is important in the interpretation of monitoring data. An analytical result reported as "less than LOQ" or sometimes as "no detectable residue" could possibly mean no residue or a residue at a level too low for the method.

Not all pesticide residues are amenable to inclusion in multiresidue methods; they may need separate analysis, which becomes expensive. Reports of monitoring data should state explicitly which residues would have been detected if present above stated LOQs.

Reliable high-quality data are essential for correct interpretation during registration, investigation, and control of residues in food. Highly skilled analysts using good laboratory practices, standard procedures, and other measures are generating valid data to support those requirements.

Future

The science of risk assessment will be further developed. Food safety and food security will continue to be important for consumer, government, and industry.[9] Trade issues will continue to be problematic with specific incidents of residues in foods arising from time to time. National governments will develop strategic approaches to deal with trade issues related to pesticide residues. Knowledgeable people in government and industry and experienced workers in functioning laboratories will be needed to support those strategic approaches. Exporters will need to monitor residues in a high percentage of their exports to meet the requirements of their customers. We might expect more developments with biopesticides. Relevant impurities in biopesticides are more likely to be biological than chemical, posing new challenges for analytical and test methods.

Human Health: Consumer Concerns to Pesticides

George Ekström and
Margareta Palmborg

Introduction

A recent European survey of risk perception and food safety showed, in line with previous research findings, that consumers tend to worry most about risks caused by external factors over which they have little or no control. Consequently, consumers appear to be less worried about risks possibly associated with their own behavior or practices. Physicians and scientists are the most trusted information sources with regard to serious food risks, followed by public authorities and mass media. Economic operators (food manufacturers, farmers, and retailers) are cited as being among the least trusted.[1]

Interviews conducted with over 1,000 consumers in a survey done in 2001 by the British Co-op Group showed that consumers were concerned about the effects of pesticides. Consumers who took part in this survey, when prompted with a series of questions, were concerned that pesticides are harmful to wildlife, leave residues in food, pollute water courses, are harmful to growing children, are harmful to the respondents themselves, and damage the health of farm workers.[2,3] According to a personal communication with David Pimentel, in the United States, the Food and Drug Administration has reported that 97% of people prefer foods without pesticides.

Particular causes of consumer concern are the potential for 'cocktail' effects from multiple residues (see Table 1),[4–6] and the fact that children may exceed health- related acute reference doses even at legally acceptable residue levels (see Table 2).[6] In Australia, the Food Standards code contains provisions for an additional, overall limit for pesticides belonging to the same chemical group (see Table 3).[7]

TABLE 1 Multiple Residues Found in a Single Sample of Pears 2004

Pesticides Found	Residue Level (mg/kg)	Maximum Residue Limit (mg/kg)	Residue Level in % of Maximum Residue Limit
Dithiocarbamates	0.305	3	10
Chlorpropham	0.155	0.05	310
Azinphosmethyl	0.084	0.5	17
Procymidone	0.071	1	7
Dichlofluanid	0.060	5	1
Chlorpyriphos	0.059	0.5	12
Bromopropylate	0.055	0.05	110
Cyprodinil	0.022	—	—
		Combined total residues	466

Source: Maximum residue limits—Chemical groups[7] and The Co-operative Group.[11]

[a] ISO common name is malathion.

[b] WHO INN, no ISO common name available.

Pests and Pesticide Safety in Homes and Gardens

Consumers use a range of pesticides in their homes and gardens:

- *Herbicides* against weeds in vegetables, moss in turf, brush, etc.
- *Fungicides* against mold, mildew, etc.

- *Insecticides* against aphids, greenflies, ants, wasps, pests on potted plants, moths, pantry pests, cockroaches, flies, etc.
- *Rodenticides* against moles, rats, mice, voles, etc.
- *Repellents* against mosquitoes, black flies, ticks, game, and pests on dogs, cats, and horses
- *Wood preservatives* against rot on timber or furniture

For the general public, ingestion is the most common route of pesticide exposure. Accidental, single, high- level exposures can lead to acute pesticide poisoning, often in children, and may result from mistakenly swallowed pesticides stored in unlocked cabinets or in unmarked bottles or containers. With regard to long-term, low-level exposure of the general public, the main route of exposure, ingestion through food and drinking water, is followed by inhalation through air or dust. This exposure results in an unknown number of people with diverse chronic health effects.[8]

A comparison of pesticide poisoning cases in 1984, 1994, and 2004, performed by the Swedish Poisons Information Centre, showed that there was an increase in the overall number of human cases related to pesticide exposure—from 493 in 1984, and 774 in 1994, to 1,071 in 2004.

The proportion of pesticide-related inquiries, however, remained constant at 3%.

Most incidents were due to accidental exposure at home. Ingestion was the most frequent route of exposure, followed by inhalation. Data from Swedish hospitals reported to the Poisons Information Centre showed the same pattern, that is, an increase in the proportion of cases related to accidental exposure at home. Children were involved in about 60% of all cases in 1984 as well as in 1994 and 2004. With the exception of 'superwarfarins' found in some rodenticides, most pesticides involved in incidents at home were of low toxicity and present at low concentrations in the formulated products. The few severe cases are mainly intentional poisonings.[9]

Thirty percent of the total number of inquiries to the Centre in 2004 was due to children's ingestion of insecticides intended for control of ants, containing low concentrations of borax, organophosphorus compounds or pyrethroids. No symptoms were recorded. Therefore, the considerable number of inquiries may reflect anxiety about pesticide exposure among the Swedish population.

Food Residues

Pesticide Residues in Foods from Organic, Integrated and Conventional Production[6]

In the Swedish monitoring program for 2004, no residues were detectable in 57% of the samples. Residues at or below maximum residue limits (MRLs) were found in 39% of the samples. 3.5% of all samples contained residues above the MRLs. Of foods from organic production, 4%–5% (import and domestic, respectively) contained detectable residues. Foods from integrated production were free from detectable residues in 91% of domestic produce and 50% of imported product. Foods from conventional production contained no detectable residues in 83% of domestic foods and 46% of imported foods. Residues below the MRLs were found in foods from all three production categories. Residues above the MRLs were found only in imported products from conventional production. No residues were found in any of the 92 samples of foods intended for infants and young children.

Although produced without pesticides, organically produced foods sometimes contain residues. The reason for this may be unintentional mix-up of foods from different sources (organic and conventional), environmental contamination of soils and plants, or fraud. The organic foods that contained pesticides in the United States have been shown to come mostly from soils treated many years ago with DDT or arsenical compounds, according to a personal communication with David Pimentel.

In 11 food commodities (22 samples) from ten countries, residues of ten different pesticides were found at levels 10–37 times the MRL. Multiple residues were found in 492 samples of which 279 samples with two residues, 127 samples with three residues, 54 samples with four residues, 25 samples with five residues, five samples with six residues, and two samples with eight residues (see Table 1 and Figure 1).

FIGURE 1 European Union organic logo. (Available at http://europa.eu.int/comm/agriculture/qual/organic/logo/index_en.htm.)

Towards Residue-Reduced Food Crops

Government Action Plans

The British Food Standards Agency has recognized that while levels of pesticide residues typically found in food are not normally a food safety concern, consumer preference is for food that does not contain residues. Sixty-eight percent of consumers consider that reducing residue levels further than the current level is important. As a result, the Agency has developed an action plan for pesticide residue minimization with a goal of enabling consumers to make informed choices, and promoting best practice within the food industry. The overall action plan includes, among other things, development of crop specific action plans to achieve pesticide residue minimization for five priority crops: apples, pears, potatoes, tomatoes, and cereal grains.[10]

Retailer Initiatives[11,12]

Retailers may employ a range of strategies to reduce pesticide use and residues in the foods they produce and put on the market:

- Monitoring pesticide usage and residues
- Consulting with growers, including advice on integrated pest management and on alternative pest control systems
- Designing and providing decision tools, including crop-specific advisory sheets and frameworks for pesticide selection
- Prohibiting or restricting the use of certain pesticides
- Publishing monitoring results, for example, on corporate websites
- Promoting organically grown foods

NGO Initiatives—Ranking Residue Contents

In the United States, the Environmental Working Group has designed a report card to score pesticide residues in food products.[13] The report card, which is based on government agency monitoring and published monitoring data, shows scores for each analyzed commodity based on a number of residue characteristics, and a combined (or total) score in these categories:

- Percentage of samples with detectable residues
- Percentage of samples with two or more pesticides
- Average number of pesticides found on each sample
- Average total concentration of pesticides found
- Maximum number of pesticides found on a single sample
- Total number of pesticides found on a single commodity

In the Netherlands, Natuur and Milieu (a Dutch NGO), has designed and used a ranking system based on the following components, and a calculated total score[14]:

- For any residue not exceeding an MRL: 1 penalty point
- For each residue of a pesticide with neurotoxic effects: 2 penalty points
- For each residue exceeding an MRL or resulting from the use of a pesticide not authorized for use in the Netherlands (applicable also to imported foods): 4 penalty points
- For each residue exceeding an MRL and resulting from the use of a pesticide not authorized for use in the Netherlands (applicable also to imported foods): 8 penalty points

Conclusions

Polls have shown repeatedly that consumers are concerned about pesticide residues in food. Maximum residue limits are trading standards, which prescribe the maximum amount of particular pesticides legally permitted. These limits (MRLs) are generally based on the level of pesticides expected if good agricultural practice is followed.[10] Other MRLs may reflect only that a pesticide is no longer authorized for use, leading to zero tolerance, and to potential problems for food exporters overseas. Since many consumers feel that current good agricultural practice is not good enough for their own or their childrens' safety, governments, retailers and NGOs have initiated actions to reduce residues. Strategies focus on production methods (integrated, organic) as well as product quality (residue-reduced or residue-free foods).

Human Health: Endocrine Disruption

Evamarie Straube
and Sebastian
Straube

Introduction

In general, endocrine disruption in humans can result from genetic disorders,[1] diseases,[2] medical treatments, mental and physical[3] stress, and chemical exposures. Endocrine disruption through chemical agents forms the focus of the present chapter.

Substances relevant for such endocrine-disrupting chemical exposures include pesticides (organochlorines such as DDT,[4] other organohalogens such as dibromochloropropane,[5] some organophosphates, carbamates, dithiocarbamates, phthalates), polychlorinated biphenyls,[6] some solvents,[7] metals such as cadmium, lead, and manganese,[8] phytoestrogens, and isoflavonoids.[9] Furthermore, endocrine disruption can be caused by smoking and alcohol use,[3] and by certain drugs, for example, glucocorticoids, hypnotics, antihypertensives, neuroleptics, and H_2-antihistaminies.[2]

Endocrine disruption can affect various endocrine systems. For example, thyroid hormone inhibition has been reported in humans after occupational exposure to amitrol and mancozeb.[10] Insulin levels can be affected by streptozotocin, which is toxic to pancreatic beta cells.[11]

Arguably the most extensive knowledge exists for chemical exposure affecting the reproductive system, which is discussed in further detail below.

Of note, for some endocrine-disrupting chemicals, non-monotonic dose–response relationships have been described with hormonal disruption occurring at relatively low levels of exposure.[12]

Mechanisms of Endocrine Disruption

Diverse mechanisms of endocrine disruption by chemical agents have been described. Endocrine disruption can be caused by xenohormones. Xenoestrogens, such as endosulfan, toxaphene, dieldrin, DDT, bisphenol A, nonylphenols, and dibutylphthalates,[7] mimic the physiological effects of estrogens. Xenoantiestrogens have effects opposite to those of xenoestrogens. For example, dioxin exerts its inhibitory effect by enhancing the expression of enzymes that degrade the estrogen receptors.[13] Antiandrogenic effects may result from competitive antagonism at androgen receptors. This was demonstrated for vinclozolin and DDE, the stable metabolite of the DDT.[7] Sometimes a xenobiotic and its metabolite (such as DDT and DDE) can exert their effects at different targets in the organism.

Pesticide-induced enzymes such as UDP-glucuronyl transferase and monooxygenases can degrade hormones (e.g., testosterone). Furthermore, the pesticides endosulfan, mirex, and DDT can increase the elimination of androgens by stimulating cytochrome P450.[14,15] Pesticide exposure can also disrupt hormonal status by inhibiting enzymes. For example, inhibition of the aromatase system can lead to an increase in testosterone levels and a decrease in the formation of estradiol from testosterone.[16] Inhibitors of the aromatase system include prochloraz, imazalil, propiconazole, fenarimol, triadimenol, triadimefon, and dicofol.[17]

Endocrine disruption can furthermore involve hormone transport proteins: for example, polychlorinated biphenyl can induce thyroid disruption, and this may involve its sulfated metabolites which bind to the thyroid hormone transport protein transthyretin with high affinity.[18]

Moreover, recent research demonstrates that endocrine disruption can involve epigenetic alterations, which may be preserved into the third generation, as has been shown for DNA methylation changes that are associated with lead exposure.[19]

Endocrine Disruption with Occupational Exposure in Women

Pesticide exposure has been linked with reproductive difficulties and menstrual abnormalities. For example, prolonged time to pregnancy, reduced fecundability, reduced fertility as well as infertility have been described for pesticide-exposed women and for women working in agriculture and greenhouses, presumably related to pesticide exposure.[20–24] Furthermore, pesticide exposure has been associated with long cycles, missed periods, and intermenstrual bleeding.[25]

Endocrine Disruption with Occupational Exposure in Men

In men, pesticides may adversely affect sperm count and quality as well as impacting the levels of testosterone, follicle-stimulating hormone, and luteinizing hormone.[26]

We have found changes in sex hormone concentrations after low-dose occupational exposure to pesticides (mainly pyrethroids, carbamates, and organophosphates). With chronic occupational pesticide exposure, we found a higher level of testosterone in comparison to control persons. There also was a reduction in estradiol levels during and after the application season in pesticide applicators.[16] Another study[27], however, found an increase in estradiol concentration in pesticide-exposed men; it may be that variations in the nature and timing of the exposure can account for these differences.

Endocrine Disruption with *In Utero* Exposure

Historically, diethylstilbestrol (DES) was the first recognized example of a xenobiotic eliciting a hormonal effect. This now very well-described paradigm serves to illustrate the potential consequences of *in utero* exposure to endocrine-disrupting chemicals. The treatment of pregnant women with DES leads to an increase in the incidence of adenocarcinoma of the vagina in their daughters[28] and malformations of the external genitals in their sons[29] and grandsons.[30] The risk of breast cancer after age 40 was also increased in women with prenatal DES exposure, as were the risks for spontaneous abortions, premature births, and ectopic pregnancies in later pregnancies of women exposed *in utero*.[31–33] Treatment with DES has, furthermore, been reported to have an effect on sexual orientation[34] and handedness.[35]

Acknowledgment

We acknowledge the contribution of our previous co-author, Wolfgang Straube, to whose memory this chapter is dedicated.

Human Health: Pesticides

Kelsey Hart and
David Pimentel

Introduction

Since the first use of DDT for crop protection in 1945, the total amount of pesticides used in agriculture worldwide has been staggering. In 1945, about 50 million kg of pesticides were applied worldwide. Today, global usage is currently at about 2.5 billion kg/yr, an approximate 50-fold increase since 1945.[1] Unfortunately, the toxicity of most modern pesticides is more than 10-fold greater than those used in the early 1950s,[1] so the potential hazards have increased as well. In fact, studies have linked exposure to pesticides with a variety of human health problems, from asthma to cancer.[2] High levels of exposure to toxic pesticides can even result in fatal poisonings. In addition, we are discovering that we can be unknowingly exposed to pesticides and pesticide residues through the food we eat, water we drink, and air we breathe,[3] and that both short- and long-term exposure to pesticides can lead to chronic health effects. Based on the available data, estimates are that human pesticide poisonings and related illnesses in the United States cost about $933 million each year.[3]

Exposure to Pesticides

While farmers and pesticide applicators typically are exposed to higher levels and more kinds of pesticides, the general public is also exposed—often unwittingly—to pesticides and pesticides residues in their daily lives. For example, about 35% of the foods purchased by American consumers have detectable levels of pesticide residues.[4] This estimate is, in fact, conservative because we currently test for only about one-third of the pesticides in use.

In addition to food contamination, the public can also be exposed to pesticides in other ways. The principle exposure of the general public in the United States occurs in the home; about 90% of all U.S. households use pesticides on their lawn, garden, and/or the inside of the home.[5] Drinking water can also contain significant chemical and pesticide residues; at present, more than 10% of U.S. rivers and 5% of U.S. lakes are measurably polluted with pesticides.[5] Groundwater supplies can also be polluted when pesticides seep into aquifers or wells.[6] Finally, public exposure to pesticides can occur through accidents or spills, or even through the air during application, when pesticides drift from the target area into more populated towns and cities. In fact, only 25%–50% of pesticides applied by aircraft under ideal weather conditions actually reach the target area.[1]

Acute Effects: Pesticide Poisonings

In 1945, when synthetic pesticides were first used, few pesticide poisonings were reported. But by the late 1960s, both pesticide usage and toxicity had increased so dramatically that the number of human pesticide poisonings was substantial.[1] Unfortunately, this trend continued into the year 2000 (Figure 1). Just in the last decade, the total number of pesticide poisonings in the United States has increased from 67,000 in 1989, to the current level of 110,000 per year.[2] Worldwide, the increased use of pesticides results in approximately 26.5 million cases of occupational pesticide poisonings each year, and an unknown number of non-occupational pesticide poisonings.[7] Of all these estimated poisoning episodes, about 3 million cases are hospitalized, resulting in approximately 220,000 fatalities and about 750,000 cases of chronic illness every year.[8]

Poisonings can occur when pesticides contact the skin or eyes, are inhaled, or are ingested. Typically, pesticides can have acute local effects on the area they directly contact—skin, eye, or respiratory tract irritation—in addition to acute systemic effects. Different pesticides act on different systems in the body in a variety of ways, but most common insecticides—organophosphates and organo-chlorines (i.e., Parathion)—have acute neurotoxic effects. This means that they impair normal functioning of the brain and/or the spinal cord, which can result in tremors, paralysis, seizures, and other systemic effects. Large degrees of exposure or exposure to highly toxic pesticides can be fatal.

Chronic Effects: Cancer and Other Health Concerns

Exposure to pesticides, though, does not always occur at a level sufficient to produce these acute symptoms. Many people are exposed to low levels of pesticides over a long period of time through their occupations or in the food they eat or water they drink. If no overt symptoms occur close to the time of exposure, we often assume that no damage is being done. However, pesticides have been associated with numerous chronic illnesses and health problems, especially in some highly sensitive individuals.

Chronic effects of pesticides are diverse and can affect most systems of the human body. The major types of chronic health effects that pesticides can have are neurological effects, respiratory and

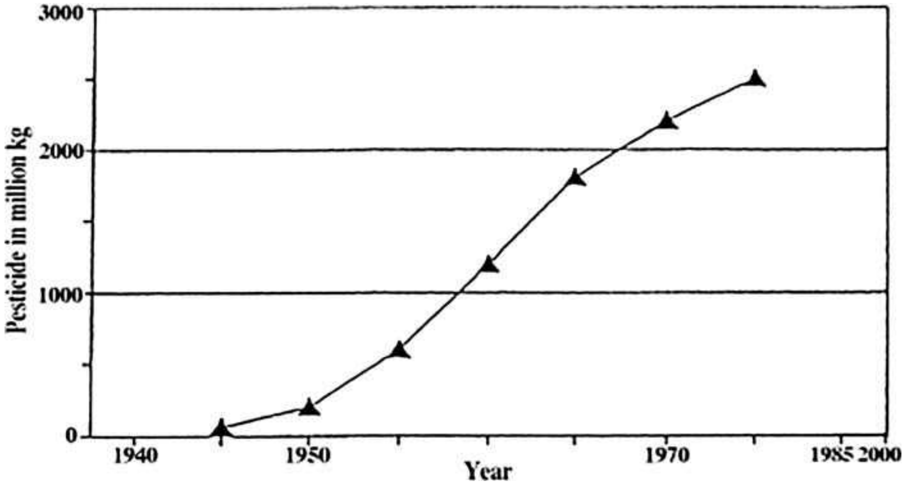

FIGURE 1 Trend in annual world pesticide use.[2]

reproductive effects, and carcinogenic effects. The chronic neurotoxic effects of pesticide exposure are not well understood, but there is some evidence linking pesticide exposure with symptoms like fatigue, muscle weakness, and sensory disturbances as well as cognitive effects such as memory loss, language problems, and learning impairment. The malady organophosphate-induced delayed poly-neuropathy (OPIDP) is well documented and includes irreversible neurological effects.

In addition to their neurotoxic effects, pesticides can have adverse effects on the respiratory and reproductive systems. For example, 15% of a group of professional pesticide applicators suffered asthma, chronic sinusitis, or chronic bronchitis as compared with 2% of people who used pesticides infrequently.[9] Studies have also linked pesticides with reproductive effects such as infertility and fetal deformities, but the data are still inconclusive.[10] Some pesticides have been shown to cause testicular dysfunction or sterility in animals, and similar effects are suspected in humans, but are less well understood at present.[10] Sperm counts in males in Europe and the United States, for example, declined by about 50% between 1938 and 1990[11]—a time period during which the use of synthetic pesticides increased about 30-fold and toxicity per pound increased about 10-fold.[1] At present, there is evidence that human sperm counts continue to decrease by about 2% per year.[3]

U.S. data indicate that 18% of all insecticides, and about 90% of all fungicides, are carcinogenic,[12] and many studies have shown that risks for certain types of cancers are higher in people—such as farmworkers and pesticide applicators—who are more frequently exposed to certain pesticides. Certain pesticides have been shown to induce tumors in lab animals; there is some evidence to suggest that they may have similar effects in humans.[10]

Many pesticides are also estrogenic—they mimic or interact with the hormone estrogen—linking them to the increased breast cancer rate among some groups of women in the United States. The breast cancer rate rose from 1 in 20 in 1960 to 1 in 8 in 1995.[13] There was a concurrent increase in pesticide use during that time period, and, although it has not been concretely linked to the increase in breast cancer rates, some studies suggest that exposure to pesticides is related to breast cancer incidence. Pesticides that interfere with the body's endocrine—hormonal—system can also have reproductive, immulogic, or developmental effects; these effects are well documented in animals and just starting to be understood in humans.[10] While endocrine disrupting chemicals may appear less dangerous at first glance—hormonal effects rarely result in acute poisonings or sudden death—their effects on reproductive and developmental processes may prove to have far-reaching and even more sinister consequences.[10]

Effects on Children

The negative health effects that pesticides can have—both acute and chronic—can be more significant in children than in adults, for several important reasons. First, children have much higher metabolic rates than adults, and their ability to activate, detoxify, and excrete toxic compounds is different from that of adults. Also, because of their smaller physical size, children are exposed to higher levels of pesticides per unit of body weight. In addition, certain types of pesticides are inherently more dangerous for children than for adults.[2,10] For example, the organophosphate and carbamate classes of pesticides adversely affect the nervous system by inhibiting cholinesterase, a critical enzyme, and can produce difficulty breathing, partial or total paralysis, convulsions, coma, or death. This problem is particularly significant for children since their brains are more than five times larger in proportion to their body weight than an adult's brain, making cholinesterase even more vital. In a California study, 40% of the children working in agricultural fields had blood cholinesterase levels below normal, a strong indication of organophosphate and carbamate pesticide poisoning.[14] In addition, a study in England and Wales has shown that 50% of all pesticide poisoning incidents in those countries involved children less than 10 years of age.[15] Use of pesticides in the home is also linked to childhood cancer.[16]

Because these studies and others have demonstrated that children's increased sensitivities to toxicants is a significant concern, some pesticide regulations have recently been reevaluated to provide special protections for children and infants. The Food Quality Protection Act of 1996 requires the EPA to specifically address risks that pesticides pose to infants and children and provides for an additional safety factors to take into account the potentially greater exposure and/ or sensitivity to pesticide effects on infants and children.

Economic Costs and Conclusions

Although no one can place a precise monetary value on a human life, the economic "costs" of human pesticide poisonings have been estimated. For our assessment, we use the conservative estimate of $2.2 million per human life—the average value that the surviving spouse of a slain New York City policeman receives.[17] Available estimates suggest that human pesticide poisonings and related illnesses in the United States cost about $933 million per year.[3] Pesticide use, though, provides a substantial net agricultural return of $12 billion per year.[2] Are the public health risks associated with pesticide use a great enough concern to warrant a reduction in pesticide use?

Given the known—and suspected—adverse effects of pesticide use on public health discussed in previous sections, it seems fairly clear that our present levels and methods of pesticide use present significant public health dangers and concerns. However, the abrupt and complete cessation of synthetic pesticide use is not without substantial costs of its own. Termination of pesticide use would result in huge crop losses—the food supply would be severely reduced and a huge number of people would starve in a short time,[18] an especially dire consequence given the 3 billion people—half the world's population—currently malnourished worldwide.[19]

Clearly, it is essential that all the costs and benefits—economic, environmental, and social/health—of pesticide use be considered when current and future pest control programs are being developed and evaluated. A recent study estimated that the environmental and social costs related to U.S. pesticide use—crop losses, public health effects, pesticide resistance, water pollution, and other environmental effects—total $8.3 billion each year.[3] Furthermore, another study has shown that U.S. pesticide use can be reduced up to one-half without any reduction in crop yields and cosmetic standards, and only a minimal 0.6% increase in food costs.[20] Therefore, it is clear that our current methods of chemical pesticide use need to be reconsidered and evaluated with the above-outlined public health effects and the related economic costs in mind, toward the goal of the development of sound, sustainable pest management practices that maximize the benefits of pesticide use while at the same time minimizing the adverse effects that pesticides can have on human health.

Nanoparticles

Alexandra
Navrotsky

Introduction

Nanoparticles have no exact definition, but they are aggregates of atoms bridging the continuum between small molecular clusters of a few atoms and dimensions of 0.2–1 nm and chunks of solid containing millions of atoms and having the properties of macroscopic bulk material. In water, nanoparticles include colloids; in air, they include aerosols. Nanoparticles are ubiquitous. We pay to have them. We pay more to not have them. They occur as dust in the air, as suspended particles that make river water slightly murky, in soil, in volcanic ash, in our bodies, and in technological applications ranging from ultratough ceramics to microelectronics. They both pollute our environment and help keep it clean. Microbes feast on, manufacture, and excrete nanoparticles.

Understanding nanoparticle formation and properties requires sophisticated physics, chemistry, and materials science. Tailoring nanomaterials to specific applications requires both science and Edisonian inventiveness. Applying them to technology is state-of-the-art engineering. Tracing their transport and fate in the environment invokes geology, hydrology, and atmospheric science. Applying them to improving soil fertility and water retention links soil science and agriculture to surface chemistry. Understanding their biological interactions brings in fields ranging from microbiology to medicine. Probing the impact of nanoparticles on humans and of human behavior on the production and control of nanoparticles requires the behavioral and social sciences, e.g., in dealing with issues of automotive pollution. The purpose of this review is to describe some of the unique features of nanoparticles and to discuss their occurrence and importance in the natural environment.

Although we often think of the natural environment as that part of the planet which we can see, a somewhat broader definition includes the "critical zone": the atmosphere, hydrosphere, and shallow portion of the solid earth that exchange matter on a geologically short time scale, on the order of tens to thousands of years. This critical zone affects us directly, and our activities influence it. Because of the active chemical reactions continuously taking place in the critical zone, and because its temperatures and pressures are relatively low and it is dominated by water, solids are constantly being formed and decomposed. Many of these solids start out as nanoparticles; many remain so. In a yet broader sense, our entire planet from crust to core, the solar system, and the galaxy are part of our environment.

Physical Chemistry of Nanoparticles

A major feature of nanoparticles is their high surface-to-volume ratio. Figure 1 shows the volume fraction within 0.5 nm of the surface for a spherical particle of radius *r*. One can think of this fraction either as the fraction of atoms likely to be influenced by processes at the surface, or as the fraction of the volume of a material that could be taken up by a 0.5-nm coating of another material. In the first case, because the surface dominates chemical reactivity, the increased surface to volume ratio means that nanoparticles dominate chemical reactions. In the second case, the ability to carry a substantial coating offers a mechanism for the transport of nutrients or pollutants.

Many oxides are *polymorphic,* exhibiting several crystal structures as a function of pressure and temperature. Often, nanosized oxide particles crystallize in structures different from that of large crystals of the same composition.[1] Examples are γ-Al_2O_3, a defect spinel rather than α-Al_2O_3, corundum, γ-Fe_2O_3, the defect spinel maghemite rather than α-Fe_2O_3, hematite, and the anatase and brookite forms of TiO_2 rather than rutile. From arguments based on transformation sequences and the occurrence of phases, it was long argued that there may be a crossover in phase stability at the nanoscale if the structure which is metastable for large particles has a significantly lower surface energy.[2] This has been proven for alumina and titania in recent calorimetric studies (Figure 2).[3,4] The resulting transformation enthalpies and surface energies, and those of other related systems are shown in Table 1. Another interesting feature is that the hydrous phases AlOOH boehmite and FeOOH goethite have significantly lower surface energies than their anhydrous counterparts, Al_2O_3 and Fe_2O_3.[5,6] Whether this is a general feature of hydrous minerals with hydroxylated surfaces is not yet known.

As particles become less than about 10 nm in size, their x-ray diffraction patterns are broadened sufficiently that they begin to appear "x-ray amorphous" (Figure 3). This term lacks exact definition. High-resolution electron microscopy may still detect periodicity, and short-range order is certainly present.[7] The identification of structure in 1–10 nm particles is very difficult, and phases are empirically described as, for example, "two line ferrihydrite," based on x-ray diffraction patterns.[8]

Nanoparticles in Soil and Water

Soil is a complex aggregate of inorganic, organic, and biological material.[9] Its constituents of largest size are rocks and gravel, small animals, plant roots, and other debris. Smaller mineral grains, clumps of organic matter, and microorganisms make up an intermediate size fraction. The smallest particles, ranging into the nanoscale, are clays, iron oxides, and other minerals. These are often heterogeneous and coated by other minerals and organic matter. The entire composite is porous and hydrated. The percolation of water in soil transports both nanoparticles and dissolved organic and inorganic species. The texture and porosity, as well as the chemical composition and pH, are crucial to biological productivity. The surfaces of nanoparticles provide much of the chemical reactivity for both biological and abiotic processes.

Major aluminosilicate minerals in soils include clays, zeolites, and poorly crystalline phases (Table 2). These can change their water content in response to ambient conditions, often swelling in wet seasons, and shrinking in dry seasons. These nanophase materials are major controllers of soil moisture and permeability. Iron and manganese oxides are another class of major sol minerals. Their extensive polymorphism at the nanoscale makes them highly variable. They sequester and/or transport and make available the essential plant nutrient iron, as well as other essential transition metals (cobalt, copper, zinc, etc.). They frequently carry coatings of other metal oxides and oxyhydroxides, including toxic metals such as lead and chromium. They also frequently have organic coatings. Sulfates, including the jarosite–alunite family of hydrated [(K, Na), (Al, Fe)] sulfates, are another important constituent. In alkaline and arid environments, other sulfates and halides form, and their formation, dissolution, and transport is a major issue in heavily irrigated regions. How much these processes are controlled by nanoscale phenomena is not known.

Groundwater is constantly in touch with soil and rock, and minerals are dissolving and precipitating as it flows. The load of fine sediments in streams and groundwater can be substantial, especially during

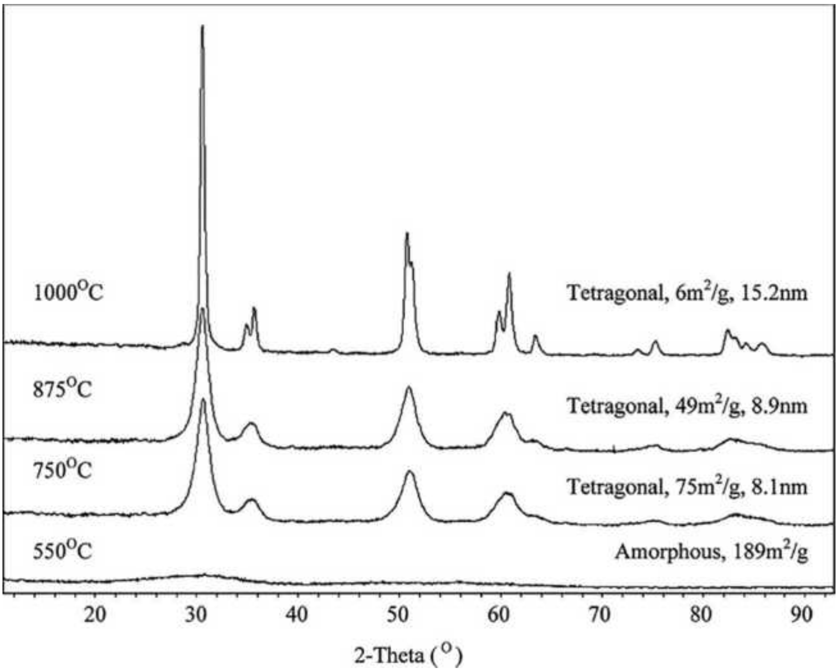

FIGURE 3 Powder x-ray diffraction patterns of sol–gel zirconia heated at various temperatures. The structure and average particle diameters are indicated.

TABLE 2 Major Soil Minerals and Constituents

Type	Composition	Structures
Clay	Hydrated aluminosilicate	Layered
Zeolite	Hydrated aluminosilicate	Three-dimensional porous
Salts	NaCl, Na_2SO_4, $CaSO_4$	Ionic crystals
Carbonates	$CaCO_3$–$MgCO_3$–$FeCO_3$	Calcite, dolomite, others
Allophane	Hydrous aluminosilicate gel	Amorphous
Iron oxides	$Fe2O_3$, FeOOH	Various polymorphs
Aluminum oxides	AlOOH, $Al(OH)_3$	Various polymorphs
Quartz	SiO_2	Quartz
Manganese oxides	Mn_2O_3, MnOOH, MnO_2	Various polymorphs
H_2O	H_2O	Water, ice, vapor
Organics	C–H–N–O	Large surface area amorphous colloids
Jarosite-alunite	Alkali (Fe, Al) sulfates	Ionic double salts

spring floods. The Missouri River is called “the Big Muddy” because of its load of particulate matter, a large fraction of which is of nanoscale dimensions. The yearly flooding of the Nile, depositing fertile soil with its large nanoparticle content, made ancient Egyptian civilization flourish. Today, one of the major concerns of our system of dams, especially in the arid western United States, is interference with the normal cycle of sediment transport and “silting up” of the lakes behind the dams. Silt is partly nanoparticles.

Contaminants and pollutants in water can be transported as aqueous ions (dimensions < 0.5 nm), as molecular clusters (0.5–2 nm), as nanoparticles (2–100 nm), as larger colloids (100–1000 nm), and as macroscopic particles (>1 μm). These size range distinctions are rather arbitrary and serve to illustrate the continuity between the dissolved and the solid state. Several examples illustrate this complexity. Aluminum oxyhydroxide particles can transport transition metals such as nickel, cobalt, and zinc, seemingly as adsorbed coatings. Initially thought to be loosely bound metal complexes at the surface of the aluminum oxyhydroxide mineral grain, these are now realized to be precipitates, only a few atomic layers thick, of mixed double hydroxides of the hydrotalcite family, in which anions such as carbonate play an essential role.[10] The transport of plutonium through groundwater is a concern in old plutonium processing facilities such as the Hanford, WA atomic energy reservation, in the Nevada nuclear test site, and in the planned nuclear waste repository at Yucca Mountain, Nevada. There remain questions of permeability and the adhesion of particles to the rock and engineered barrier walls, of colloid transport, of biological transport, and of mineral precipitation which can change the rate of progress of a contamination plume. Linking laboratory scale, field scale, and simulation studies of nanoparticle transport is an essential area of research for understanding radioactive and chemical contamination and geologic processes involving uranium and other actinides.[11]

When particles are below 5 nm in size, several other effects must be considered. Whereas for larger particles, most of the atoms are in specific planes or faces, for smaller ones, an increasing number of surface atoms must sit at the intersection of facets, in presumably even higher energy sites. An alternate, more macroscopic way of describing this is to consider the surface as curved, rather than as a series of planes. Then the surface energy per unit area is no longer a constant, but potentially increases quite rapidly with decreasing particle size. This unfavorable energy may be relaxed by the adsorption of various molecules on the surface, and there is evidence that the adsorption coefficient of organics rises steeply at very small particle size.[12]

The flocculation of colloids depends on the surface charge; the pH of which the surface is neutral is the “point of zero charge.”[13] Does this depend on particle size? This is an area of active research.

How do nanocrystals form from solution? The classical picture of nucleation and growth by addition of single atoms or ions is probably inadequate.[14] There is increasing evidence for clusters of atoms or

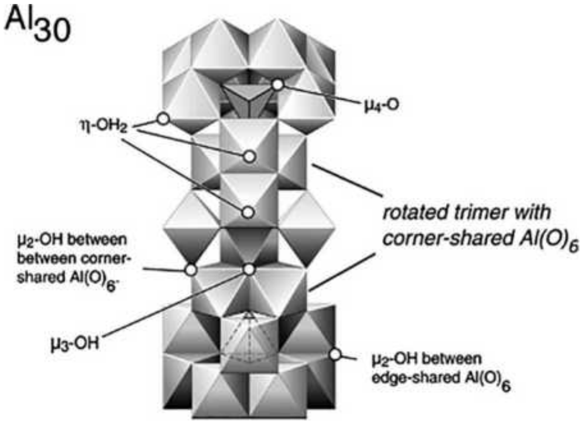

FIGURE 4 $Al_2O_8Al_{28}(OH)_{56}(H_2O)_{24}{}^{18+}(aq)$ (often called Al_{30}) cluster of 2 nm dimensions, which is intermediate in structure and properties between isolated ions and solid aluminum.
Source: W.H. Casey, personal communications. From Rowsell and Nazar.[15]

ions in solution which contain 5–50 atoms and clearly show some of the structural features of the solid. An example is the Keggin-molecular cluster containing 13 aluminum atoms shown in Figure 4.[16] It appears stable over a wide range of neutral to basic pH, and is probably a major precursor to and a dissolution product of aluminum oxyhydroxides.[17] The growth of TiO_2 anatase may occur by the oriented attachment of ~3-nm particles.[18] The growth of zeolites templated by organics may involve 3-nm cuboctahedral clusters.[19] Nanoclusters have been invoked in the growth of sulfides in ore-forming solutions.[20] Characterization of such nanoscale precursors in aqueous solutions remains a major challenge.

The coarsening and phase transformation of nanoscale precipitates upon heating is equally important to the sol–gel synthesis of ceramics and the geologic compaction and diagenesis of buried sediments. Loss of water, loss of surface area, and phase transformations to the stable bulk polymorph are closely interlinked.[14] A nanoparticle with dimensions below 5 nm probably cannot maintain defects or dislocations; they can migrate to the surface and be annihilated.[21] An aggregate of such single domain nanocrystals, with disorder and impurities at their surfaces, may be a common morphology in nature. Such aggregates give smaller average particle size from x-ray peak broadening than from gas adsorption [Brunauer–Emmett–Teller (BET)] measurements.

Magnetic nanoparticles cannot hold a direction of magnetization for a long time because of thermal fluctuations.[22] The magnetic iron oxides found in magnetotactic bacteria, which are single domain particles, neither too large nor too small, provide orientation in the Earth's magnetic field (see below). On a geologic time scale (millions of years), magnetization of largely nanophase iron oxides provides a record of the variation of the Earth's magnetic field through time, including periodic reversals of north and south poles. Thus the ability or inability of nanoparticle oxides to retain magnetization is of critical importance.

Nanoparticles in the Atmosphere

Atmospheric particles include dust (rock and soil), sea salt, acids including sulfuric, organics (especially carbon), inorganics, and, of course, water and ice (Table 3). The atmosphere can carry particles of spherical equivalent diameters from 1 to 10^5 nm. Often, a trimodal distribution of particle sizes, with peaks in number density near 5, 50, and 300 nm, is seen.[23] The smaller particles account for most of the reactive surface area but little of the total mass.

Atmospheric particles affect the environment in many ways.[23,24] They reduce visibility (smog, haze) primarily through light scattering. They act as nuclei for water vapor condensation and cloud formation.

Many particles have core–shell structures and coatings

They are involved in radiative forcing, changing the ratio of absorbed sunlight to reflected sunlight. Thus they are implicated in global climate change. Their effect on radiative forcing can be positive (more energy adsorbed) or negative (more energy reflected), leading to warming or cooling, respectively.[23,24] Their net effect is a subject of vigorous research and controversy.

Anthropogenic particles contribute disproportionately to the fine particle fractions.[23] These may have very significant effects on climate and (see below) health. Soot (carbon) from burning coal and oil and from automobile (especially diesel) emissions contributes greatly to the atmospheric load of nanoparticles.

Particles in the atmosphere travel a long way. Dust from Africa is seen in Florida; industrial emissions from China are detected in North America. Particles are removed from the atmosphere by diffusion and gravitational settling (aided by small particles coalescing into larger ones) and by rain. The residence time of nanoparticles in the atmosphere ranges from minutes to days.[23]

Atmospheric nanoparticles are more involved in gas phase reactions than particles in soil and water.[24] Their formation may involve combustion synthesis, as in industrial or automobile emission. Mineral nanoparticle surfaces may catalyze the oxidation of SO_2 and NO_2, leading to sulfuric and nitric acid. These acids can exist as gaseous species, liquids, or solid hydrates at low temperature. Nanoparticles are invoked in the depletion of atmospheric ozone by catalytic production of reactive chlorine compounds. Changes of phase (liquid to solid) are critical to the chemistry of sodium chloride and sodium nitrate particles, with their water content being controlled by available humidity.

Mineral dust particles may provide critical nutrients (e.g., iron) to the surface of the ocean far from land. The ocean's biological productivity is often limited by the availability of these nutrients; thus such inorganic nanoparticles may significantly influence the global cycling of carbon through ocean biomass.[25]

Nanoparticles in Sediments, Rocks, and the Deep Earth

The debris of rock weathering is brought down river to the ocean in sediments consisting of nanoscale particles of clay, small quartz grains, and other minerals. Indeed, the terms "clay" and "silt" have a classic connotation of size fraction, although the former also implies a structural group of minerals, the layered aluminosilicates. In the ocean, carbonates precipitate, dissolve, and reprecipitate as a complex function of depth.[26] Both silica and various polymorphs of calcium carbonate (calcite, aragonite, vaterite) are produced by organisms such as diatoms, foraminifera, and corals. Their debris rains down on the ocean bottom, forming sediments which often show annual cycles in composition and texture and which bear records of climate change, shifts in ecosystems, and catastrophic events such as meteor impacts.[27] These sediments start off largely nanoscale. They coarsen and dehydrate with time and depth of burial. The evolution of their organic matter leads to petroleum. The evolution of their minerals, involving coarsening and compaction, called diagenesis, leads to rocks such as limestones and shales. The nanoscale processes that take place (dehydration and organic loss, phase transformation, coarsening and densification) are natural analogs of ceramic processing which starts with nanoscale precipitates or gels.

Natural processes involving changes in temperature, pressure, acidity, and oxygen fugacity cause the concentration of trace metals into ore deposits. These often occur in hydrothermal systems, spatially contained circulations of hot, pressurized, metal-rich aqueous solutions. Our ability to mine low-grade deposits by chemical leaching techniques brings us into the world of nanoparticles and reactions at mineral surfaces. There is increasing evidence that microorganisms play an active role in ore deposition.[28,29] Hot springs at the surface produce deposits of nanoscale amorphous silica and other minerals, which may also be closely linked to microbial activity.[30]

At temperatures above a few hundred degrees Centigrade and pressures above a few kilobars, coarse-grained metamorphic and igneous rocks predominate. The interior of the Earth is layered, with seismic discontinuities delineating the crust, upper mantle, transition zone, lower mantle, and core. These discontinuities represent regions of rapidly changing density, mineralogy, and chemistry.[31] Ongoing phase transitions and chemical reactions can decrease the grain size of a material and render it easier to deform.[32] Thus nanoscale phenomena, occurring at specific locations, may play a disproportionate role in processes such as subduction, plate tectonics, earthquake generation, and volcanism. Shock processes, (e.g., meteor impact, nuclear detonation) also produce nanoparticles.

When a volcano erupts explosively, a plume of dust particle is sent into the atmosphere, sometimes reaching the stratosphere. These particles make beautiful sunsets but they also exert a significant cooling effect on climate for several years and pose a significant aviation hazard. Combining sedimentation, coarsening, subduction, volcanism, and weathering, there is an ongoing global geochemical cycle of nanoparticles, analogous in some ways to global geochemical cycles of elements such as carbon. However, the mass balances, or imbalances, in global nanoparticle production and consumption through time have not been characterized.

Nanoparticles beyond the Earth

In the early stages of planet formation, dilute and more or less uniform gas condensed to form a series of mineral particles, with the order of condensation described by thermodynamic calculations based on the volatility and stability of these phases.[37] The more refractory oxides condensed earlier than those with higher volatility. These particles accreted, under the influence of gravity, to form our solar system. What was the nature of these initial particles? What was their size distribution? Were they crystalline or amorphous? Were metastable polymorphs formed? While the initial high temperatures might argue against such metastability, the low pressures and condensation from a vapor argue for it. In technological processes, chemical vapor deposition produces nanoscale amorphous silica "snow," and combustion produces soot and inorganic nanoparticles. The role of nanoparticles in planetary accretion has not yet been explored. The change in stability at the nanoscale, which will be different for various compositions and polymorphs, may alter the sequence of condensation of phases. Are the particles now present in space as interplanetary dust partly or mostly nanoparticles?

The surfaces of the Moon and Mars, subject to "space weathering" by bombardment with meteorites of all sizes, contain an extensive fine grained dust or soil layer.[32] Samples of lunar soil, brought back by the Apollo missions, contain a distribution of particle sizes of spherules and irregular shards. Their particle size distribution appears not to have been a subject of active interest, but clearly a significant number are in the nanoregime. The red surface of Mars appears to be dominated by various fine-grained or nanophase iron oxides. Until Martian sample return missions, planned to occur in the next decade or two, bring some of this material to Earth, we must rely on remote sensing technology (spectroscopic techniques) and instrumentation on Martian landers (possibly Mossbauer spectroscopy, x-ray fluorescence, and x-ray diffraction) to obtain information on the composition and structure of Martian soil. Considering the difficulty of characterizing iron oxide nanoparticles in the best laboratories on Earth, definitive conclusions about the nature of Martian soil are unlikely until we have some samples in hand. Meteorites believed to be from Mars contain micron-sized spherules, which were proposed to be biological in origin. This sparked much recent controversy and it is by no means settled whether these structures are fossil microorganisms or the product of inorganic nanoscale crystal growth processes.[33,34]

Nanoparticles and Life

Microbial communities are rich in the production and utilization of nanoparticles.[35] Table 4 lists some examples. In addition to aerobic respiration (the enzymatic oxidation of carbohydrates and other organics with molecular oxygen to produce water, carbon dioxide, and energy stored as high-energy phosphate linkages) organisms use many other strategies to extract energy from the environment. The following biological reactions produce or consume nanoparticles. Dissolved Mn(II) or Fe(II) can be oxidized by oxygen, producing Mn(III), Mn(IV), or Fe(III) oxide nanoparticles, while organics can be oxidized by manganese or iron oxides, producing soluble Mn(II) and Fe(II) species. Some bacteria can also utilize the U(IV)–U(VI) couple as an energy source. Because hexavalent uranium is much more soluble than tetravalent, biological processes that accelerate its production are of concern in modeling nuclear waste leaching. The sum of these two groups of redox processes is the oxidation of organics by oxygen, akin to respiration. The important difference is that the organic food source and the oxygen source can be spatially separated in the sharp gradients in oxygen and organic contents that frequently occur in sediments, and different communities of organisms participate in the two processes. In marine sediments, sulfate is the dominant biological electron acceptor and is more important than oxygen. Bacterial sulfate reduction produces sulfide which often precipitates as nanophase metal sulfide minerals. Sulfide and sulfur oxidizing bacteria typically live in specialized environments where there is enough oxygen to oxidize sulfur but not so much that chemical oxidation swamps biological oxidation. This oxidation consumes solid sulfur and sulfides, and produces soluble sulfate.

TABLE 4 Example of Interaction of Microorganisms and Nanoparticles

Class of Organisms	Example	Nanoparticle Interaction
Iron and manganese oxidizing bacteria	*Thiobacillus*	Oxidize soluble Mn^{2+} and Fe^{2+} to insoluble higher oxides
Iron and manganese reducing bacteria	*Shewenella*	Reduce insoluble Mn and Fe oxides to soluble forms oxidize sulfide to sulfate to sulfide precipitate
Sulfur reducing bacteria	*Thiobacillus*	Reduce sulfate to sulfur in sulfide
Magnetotactic bacteria	*Aquaspirillum magnetotacticum*	Nanoparticles of Fe_2O_3, Fe_3O_4, and/or iron sulfides
Uranium reducing bacteria	*Geobacter, shewenella*	Soluble $U^{6+} \rightarrow$ insoluble U^{4+}
Fungi	Specific strains unknown	Oxidize Mn^{2+}, precipitate MnO_2
Diatoms	Various	Precipitate silica
Foraminifera	Various	Precipitate $CaCO_3$ calcite and aragonite

Organisms utilize nanoparticles in processes other than respiration. Bacterial precipitation of sulfide minerals, e.g., ZnS and UO_2, may also be a mechanism of detoxification.[36] Similar detox processes may occur in plants. Magnetotactic bacteria synthesize and align single domain magnetic iron oxide and iron sulfide particles in structures called magnetosomes.[37] Such bacteria align themselves both north–south and vertically in the Earth's magnetic field. The navigational (homing) capabilities of bees, pigeons, and probably other higher organisms utilize magnetic field orientation sensed by magnetic iron oxide particles in their brains. Similar particles, although at lower abundance, occur in many mammals, including *Homo sapiens*.[38] There has been a debate in the public sector whether the magnetic fields produced by high-voltage power lines are potentially dangerous to human health. In contrast, the use of magnets in alternative medicine, and the market for magnetic pillows, back supports, etc., suggests, or at least hopes for, a beneficial effect of the interaction of magnetic fields with animals. Key to either harmful or helpful biological effects is a mechanism for the magnetic field to interact with living cells. Interaction with biological magnetic nanoparticles may provide such a mechanism, but very little is known at present.

Nanoparticles have other documented health effects.[39] When inhaled into the lungs, particles cause an inflammatory response, which contributes to allergies, asthma, and cancer.[48] The detailed mechanism of this response, and how it depends on surface area, particle size, or specific particle chemistry, is not clear. The harmful effects of inhaled particles may be enhanced by other pollutants, particularly ozone, typically present in smog. Nanoparticles penetrate deep into the lungs. Many are returned with exhaled air, some stick to the surfaces of the alveoli, and some may even penetrate into general blood circulation and be transported to other organs. Studies linking detailed nanoparticle characterization, biochemical and physiological processes, and health effects are just beginning to be carried out. It is likely that not all particles have comparable effects, and understanding which are the most dangerous could lead to rational, rather than arbitrary, emission standards for automotive and industrial particulates.

In the early Earth, prebiotic processes culminated in the origin of life.[40] Because the synthesis of complex organic molecules competes with their destruction by hydrolysis and other degradation, it is possible that the most successful synthesis could have occurred in sheltered and catalytic environments, such as those provided by mineral surfaces, nanoparticle surfaces, and pores within mineral grains. Present-day organisms utilize a wide variety of elements (e.g., Fe, Co, Ni, Cr, Zn, Se) in specific enzymes. Although large amounts of such elements are toxic, trace amounts are essential. The active centers in enzymes utilizing these trace elements often consist of clusters of metal atoms, sometimes associated with sulfide. Are these fine-tuned by evolution from earlier simpler metal clusters and nanoparticles existing in the environment? Thus nanoparticles may play a role not just in the sustenance of life but in its origin.

Conclusions

Nanoparticles play diverse roles in the environment and are involved in both abiotic and biologically mediated chemical and physical processes. Their high surface area, chemical reactivity, polymorphism, and unique properties involve nanoparticles in a disproportionately large fraction of the chemical reactions occurring on and in the Earth and other planets. Understanding this involvement is itself evolving into a new field of study in the environmental and Earth sciences, which is beginning to be called "nanogeoscience." Nanogeoscience will take its place alongside other new areas such as astrobiology and biogeochemitry, fields that link physical, chemical, and biological processes viewed in the context of the long time and distance scales natural to the Geosciences.

Pharmaceuticals: Treatment

Diana Aga and
Seungyun Baik

Introduction

The presence of pharmaceutical chemicals and their byproducts in soil, wastewater effluents, surface water, and drinking water sources has become a growing concern over the past two decades. Improvements in analytical methods coupled with large-scale surveys have revealed the broad range of persistent pharmaceuticals that are cycling through our wastewater-to-drinking water cycle. Non-metabolized active ingredients and transformation products of veterinary and human pharmaceuticals are introduced into the environment through the effluents of municipal wastewater treatment plants (WWTPs), pharmaceutical formulation facilities, and through the land application of animal waste and sewage sludge. Approximately 10 million tons of sewage sludge and manure containing residues of pharmaceuticals are used to fertilize croplands each year. Public awareness of the potential problems related to pharmaceutical pollution, widely known as "emerging contaminants," has brought this issue to the forefront in the water and wastewater treatment industries. Hence, advanced water treatment systems are being evaluated to potentially eliminate these emerging contaminants from effluents of WWTPs and from drinking water sources. This entry aims to provide an overview on the occurrence of pharmaceuticals in the environment and recent studies that investigate promising treatment technologies to eliminate emerging contaminants from wastewater and drinking water systems.

Although the human risk associated with chronic exposure to pharmaceuticals in the environment remains unclear, evidence of detrimental ecological impacts is growing. The environmental contamination by pharmaceutical residues, especially antibiotics, may have profound environmental effects at several levels. While the promotion of antibiotic resistance in pathogenic microorganisms has been the major concern associated with the presence of antibiotics in the environment, other issues such as endocrine disruption in fish and wildlife, plant uptake, and phytotoxicity are also significant and warrant discussion. Therefore, the second goal of this entry is to summarize current knowledge on the ecological impacts of pharmaceutical pollution.

Occurrence and Impacts of Pharmaceuticals in the Environment

The presence of pharmaceutical residues in terrestrial and aquatic systems, resulting largely from discharges of municipal WWTPs and the land application of animal wastes, is now well documented in the literature.[1–3] As depicted in Figure 1, residues of human pharmaceuticals and their metabolites may eventually enter surface water, groundwater, and drinking water systems after passing through WWTPs. While most active ingredients of drugs are metabolized in the body, or removed during wastewater treatment, others remain intact and persist in the environment. Low levels of persistent pharmaceuticals can eventually end up in finished drinking water and distribution system (tap) water, when using source waters that have been affected by effluents from WWTPs.[4]

Veterinary pharmaceuticals, particularly antibiotics used for therapeutic purposes and for growth promotion, are also finding their ways into the environment. While some antibiotics used in animal production are decomposed quickly after being excreted, others remain stable during manure storage and end up in agricultural fields upon manure application. Additionally, antibiotics are widely used in fish farms and may enter the aquatic environment via direct discharge. For example, the antibiotic oxytetracycline has been detected in groundwater that has been affected by fish farming at sub-parts-per-billion concentrations.[5]Highly polar pharmaceuticals are susceptible to leaching and may therefore reach the groundwater aquifer. For example, the high frequency of detection of sulfonamide antibiotics in groundwater from various sites in the United States can be attributed to the relatively high water solubility and poor biodegradability of these drugs.[6,7] The detection of sulfonamides in groundwater from wells deeper than 50 ft, located downgradient from an animal feeding operation in the United States, indicates the persistence and mobility of this class of antibiotics.[8] Similar results were observed in Germany where sulfonamides were detected in groundwater located downgradient from an agricultural field where sewage sludge was used for irrigation.[9] The concentrations of pharmaceuticals in groundwater are typically lower than in surface water because infiltration through the soil profile removes some

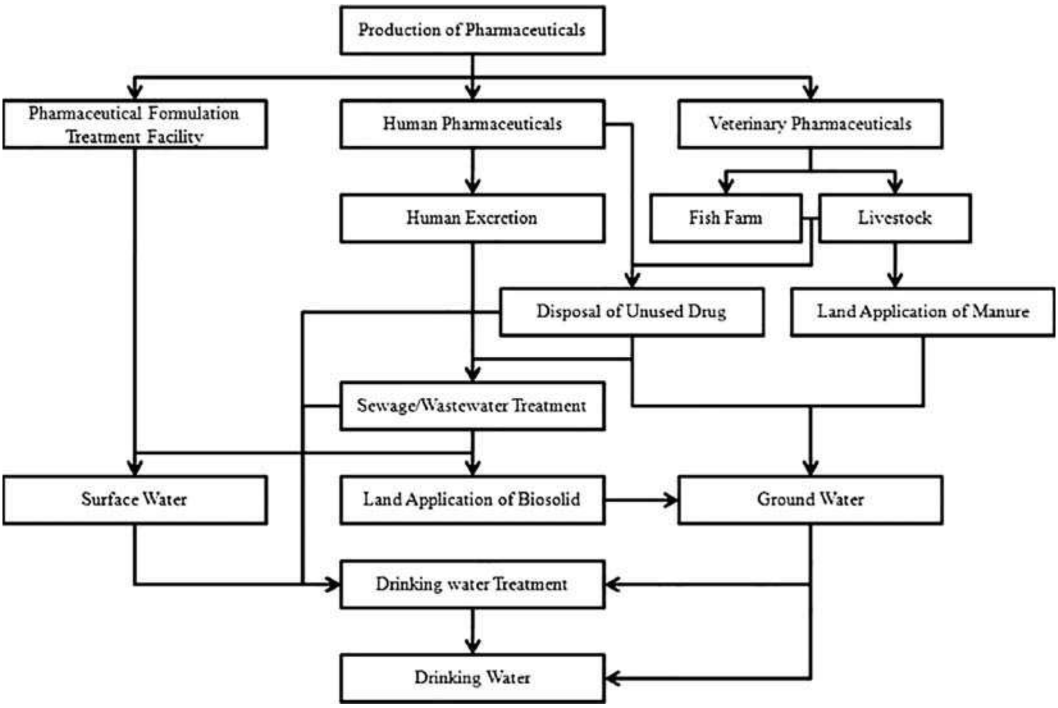

FIGURE 1 Exposure routes of pharmaceuticals in the environment.

fraction of the organic pollutants before entering groundwater systems.[10] Nevertheless, contamination of groundwater by pharmaceuticals is a significant issue because these compounds are not readily biodegradable under anoxic conditions.[9] The persistence of pharmaceuticals in the groundwater aquifer is a concern because groundwater is a major source of drinking water in many areas in the United States and around the world.[8] If the contaminated groundwater is used as drinking water source, pharmaceuticals may eventually reach finished drinking water systems[4] and may not be degraded during conventional drinking water treatment processes.

In the first comprehensive study on the occurrence of pharmaceuticals in the United States surface waters, Kol-pin et al.[1] reported detection of 95 organic contaminants, which included 30 antibiotics, 12 prescribed drugs, 4 nonprescribed drugs, and 6 drug metabolites. A later report summarized the occurrence of 80 pharmaceuticals and drug metabolites in the aquatic systems for eight different countries.[11] The concentrations of pharmaceuticals in surface water and groundwater depend on several factors, such as removal processes employed in the WWTPs, source variability, dilution, retardation, and weather events.[12]

Table 1 shows examples of the types of pharmaceuticals frequently detected in the environment and their typical removal rates (high, medium, low) in conventional activated sludge (CAS) systems during wastewater treatment.[13,14] Consequently, these pharmaceuticals are often detected in receiving surface waters at a wide range of concentrations as depicted in Figure 2. The variability in pharmaceutical concentrations in

TABLE 1 Classification of Pharmaceuticals Based on Their Typical Removal Rates in CAS Systems

Group	Pharmaceutical	Usage
High removal (>65%)	Acetaminophen (ACE)	Analgesic (non-NSAID)
	Ibuprofen (IBP)	Analgesic (NSAID)
	Naproxen (NAP)	Analgesic (NSAID)
	Paroxetine (PRX)	Antidepressant
	Iopamidol (IOM)	Iodinated contrast agent
	Caffeine (CAF)	Psychoactive stimulant
Medium removal (30%–65%)	Sulfamethoxazole (SMX)	Antibiotic
	Gemfibrozil (GFB)	Lipid regulator
	Atenolol (ATN)	β-Blocker
	Propranolol (PRN)	β-Blocker
	Ranitidine (RTD)	Antihistamine (Zantac)
	Fluoxetene (FXT)	Antidepressant
	Iopromide (IOP)	Iodinated contrast agent
Low removal (<30%)	Diclofenac (DCF)	Analgesic (NSAID)
	Mefenamic acid (MFN)	Analgesic (NSAID)
	Ciprofloxacin (CIP)	Antibiotic
	Erythromycin (ERY)	Antibiotic—macrolide
	Roxythromycin (ROX)	Antibiotic—macrolide
	Trimethoprim (TMP)	Antibiotic
	Clofibric acid (CLO)	Lipid regulator
	Carbamazepine (CBZ)	Anticonvulsant
	Dilantin (DLT)	Anticonvulsant
	Meprobamate (MPB)	Anti-anxiety drug

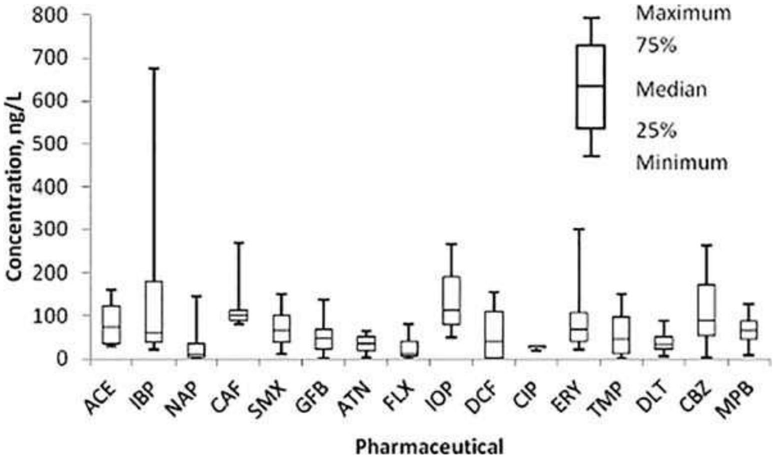

FIGURE 2 Typical concentrations of selected pharmaceuticals in surface waters in the U.S. The middle line in the box plot indicates median value of the data; The upper edge (hinge) of the box indicates 75th percentile of the data set; the lower hinge indicates 25th percentile. The whiskers indicate minimum and maximum data values.

the environment can be attributed to the types of WWTPs, the frequency and time of sampling, and the biodegradability of the pharmaceuticals in a given environmental conditions, among others.

Despite the relatively low concentrations of pharmaceuticals typically found in the environment, the ecological effects of pharmaceutical pollution cannot be ignored. Several standard toxicity tests reveal that while acute toxicity is not a concern because of the high effective concentrations needed to elicit observable acute effects, chronic toxicity may be important at environmentally relevant concentrations.

Acute and chronic toxicity of several pharmaceuticals, including non-steroidal anti-inflammatory drugs (NSAIDs) and β-blockers, against phytoplankton, zooplankton, and other aquatic organisms[21–23] have been reported. Similarly, chronic toxicity studies toward aquatic organisms of lipid-lowering agents,[24,25] neuroactive pharmaceuticals (antidepressants),[22,26] and anti-epileptic drugs[22] have been conducted at concentrations typically found in the environment. Some of the documented ecological effects of pharmaceuticalsin the environment are summarized in Table 2. Both the U.S. Environmental Protection Agency (USEPA) and European Union (EU) have recognized residues of pharmaceuticals and personal care products as emerging contaminants of concern that may require future environmental regulation if their persistence in the environment proves to be ecologically significant. In fact, diclofenac, ibuprofen, triclosan, and clofibric acid have been identified as future emerging priority candidates by the EU water framework directive, which is a priority substance list that is updated every 4 years.[27]

TABLE 2 Reported Ecotoxicity for Selected Pharmaceuticals Using Various Test Organisms

Pharmaceutical	Effect Observed	Effective Concentration	Environmentally Relevant[a]	References
Atenolol	Fathead minnow	1.0 mg/L (21 days)—NOEC	No	[28]
		3.2 mg/L (21 days)—LOEC	No	
Carbamazepine	*Daphnia magna*	0.492 μg/L—multigeneration (up to 6 generations) effect	Yes	[29]

(*Continued*)

TABLE 2 (*Continued*) Reported Ecotoxicity for Selected Pharmaceuticals Using Various Test Organisms

Pharmaceutical	Effect Observed	Effective Concentration	Environmentally Relevant[a]	References
	Japanese medaka	6.15 mg/L—swim speed effect (9 days)	No	[30]
	Oryzias latipes	45.87 mg/L—LC50 (96 hours)	No	[31]
	Thamnocephalus platyurus	>100 mg/L—LC50 (24 hours)	No	[31]
Clarithromycin	*Oryzias latipes*	>100 mg/L—LC50 (96 hours)	No	[31]
	Thamnocephalus platyurus	94.23 mg/L—LC50 (24 hours)	No	[31]
Diclofenac	*Daphnia magna*	0.355 µg/L—multigeneration (up to 6 generations) effect	Yes	[29]
	Hyalella azteca	0.467 mg/kg—LC50 (72 hours) with sediment	No	[32]
	Rainbow trout	25 µg/L—accumulation test on gall (21 days)	Yes	[33]
Fluoxetene	Sheepshead minnow	>2.0 mg/L—LC50 2.0 mg/L—LOEC 1.87 mg/L—NOEC (All for 96 hours)	No	[34]
	Western mosquitofish	0.546 mg/L—LC50 (7 days)	No	[35]
	Western mosquitofish	0.5 µg/L—increasing lethargy in 59–159 days	Yes	[35]
Ibuprofen	*Oryzias latipes*	>100 mg/L—LC50 (96 hours)	No	[31]
	Planorbis carinatus	17.1 mg/L—LC50 (48 and 72 hours)	No	[36]
	Planorbis carinatus	>5.36 mg/L—LOEC 5.36 mg/L—NOEC (All for 21 days)	No	[36]
	Thamnocephalus platyurus	19.59 mg/L—LC50 (24 hours)	No	[31]
Metoprolol	*Daphnia magna*	1.170 µg/L—multigeneration (up to 6 generations) effect	Yes	[29]
Paracetamol (Acetaminophen)	Wheat	22.4 mg/L—damage in 21 days exposure	No	[37]
Propranolol	Fathead minnow	1.0 mg/L—NOEC (female) 3.4 mg/L—LOEC (female) 0.1 mg/L—NOEC (male) 1.0 mg/L—LOEC (male) (All for 21 days)	No (Yes for NOEC male)	[38]
	Rainbow trout	1.0 mg/L—NOEC 10 mg/L—LOEC (All for 10 days)	No	[39]
	Oryzias latipes	11.40 mg/L—LC50 (96 hours)	No	[31]
	Thamnocephalus platyurus	10.31 mg/L—LC50 (24 hours)	No	[31]
Verapamil	Juvenile rainbow trout	2.72 mg/L—LC50 (96 hours)	No	[40]

Note: NOEC, no observed effect concentration; LOEC, lowest observed effect concentration; LC50, 50% lethal concentration.

[a] Environmentally relevant—"Yes" for concentrations of compounds are in the ranges in surface water and WWTP effluent reported through 2011.

Treatment of Pharmaceuticals in the Aquatic Systems

Alternative Systems for Water Treatment

Activated sludge treatment, which relies on microbes to biodegrade contaminants in wastewater, is the most widely used waste water treatment system in the United States and around the world. While many pharmaceuticals are removed partially or completely during CAS treatment, there are a significant number of pharmaceuticals that have very little to no removal. Therefore, alternative treatment systems are being explored to improve removal efficiencies for these trace organic contaminants. Examples of treatment systems that are suspected to be more efficient are membrane bioreactors (MBRs)[41–44]; membrane treatment with nano-, micro-, and ultrafiltration (NF/MF/UF); and reverse osmosis (RO).[45] Granular activated carbon (GAC) is also used as another alternative system in the Unites States and Canada for removal of trace organic matters through filtration and adsorption.[45] Recent studies have also shown that advanced oxidation processes, such as ozonation and UV–H_2O_2 disinfection, which are employed during tertiary treatment before discharging the treated wastewater, could have additional benefits in removing pharmaceuticals from water.[15,46,47]

For drinking water treatment systems, the removal of many pharmaceuticals during the first three steps (coagulation, flocculation, and sand filtration) before disinfection is typically incomplete.[16,48] On the other hand, similar to wastewater treatment, pharmaceuticals may be effectively removed by activated carbon adsorption, ozone oxidation, and membrane filtration.[49] Chlorination, the most common disinfection step, may also remove pharmaceuticals but produce unwanted by-products.[16]

Alternative water treatment systems are summarized and compared in Table 3.[50,51] These systems are advantageous because they offer increased removal of pharmaceuticals and other organic contaminants that cause undesirable odor and taste in water. To enhance the efficiency of treatment, combining systems such as MBRs followed by activated carbon adsorption system maybe applied.

TABLE 3 Summary and Comparison of Alternative Systems: Membrane Process, Activated Carbon Adsorption Process, and Advanced Oxidation Process for Contaminant Removal

Process		Operation and Application	Important Notes
Membrane process	Reverse osmosis (RO)	• Pressure driven (150–400 psi)	• Best removal performance • Possible for desalination
		• Removes organics with molecular weight >100	• Needs pretreatment such as UF or MF to prevent plugging and fouling; hence, high cost
		• Demineralization	• Low product recovery (30%–85%)
	Nanofiltration (NF)	• Pressure driven (80–200 psi)	• Good removal performance
		• Removes organics with molecular weight between 100 and 500	• Needs pretreatment such as UF or MF to prevent plugging and fouling; hence, high cost
		• Removes NOM	• Medium product recovery (70%–90%)
	Ultrafiltration (UF)	• Pressure driven (15–60 psi)	• Replacement for CT • High product recovery (80%–95%) • Higher cost than CT
		• Pretreatment for NF or RO	• Sensitive with water temperature and viscosity

(*Continued*)

TABLE 3 (*Continued*) Summary and Comparison of Alternative Systems: Membrane Process, Activated Carbon Adsorption Process, and Advanced Oxidation Process for Contaminant Removal

Process		Operation and Application	Important Notes
	Microfiltration (MF)	• Macromolecule removal includes viruses	• Needs other process to increase treatment performance
		• Pressure driven (5–40 psi)	• Replacement for CT
			• High product recovery (95%–98%)
			• Higher cost than CT
		• Pretreatment for NF or RO	• Sensitive with water temperature and viscosity
		• Bacteria removal	• Needs other process to increase treatment performance
Activated carbon adsorption	Powder activated carbon (PAC)	• Used in early steps of treatment process	• Good performance in combination with MF or UF membrane systems
			• Usually used for drinking water treatment
			• Good for emergency situations, with high organic pollutants
			• Handling problem—dry PAC causes dust problem
		• Controls taste or odor	• May pass through filters and enter the final treated water
		• Applied for small or mid-sized plants with moderate or severe taste, odor, or organic contaminants problem	• Cannot be mixed with chlorine
	Granular activated carbon (GAC)	• Used in adsorption beds or tanks	• Replacement of conventional gravity filter
			• Possible for WWTPs
			• Fouling by chemicals—need to consider breakthrough for design
			• Backwash requirement
		• Gravity or pressure driven	• Need to monitor carbon bed depth
		• Applied for plants with moderate or severe taste, odor, or organic contaminants problem	• Needs carbon regeneration
Advanced oxidation process	Ultraviolet (UV)	• Chemical treatment	• Disinfection benefit
		• Low pressure ($\lambda = 253.7$ nm) or medium pressure ($\lambda = 180–1370$ nm)	• Controls taste and odor
		• UV radiation with H_2O_2 addition (hydroxyl radical oxidation)	• Relatively high cost and complexity
		• Combined with ozonation	• Treatment effectiveness is weakened by turbidity or color in water
		• NOM in water may inhibit or promote oxidation	• Unwanted by-products

Note: NOM, natural organic matter; CT, conventional treatment.

Removal Efficiencies in Municipal WWTP Systems

Several reports have shown that MBRs generally have higher removal efficiencies for NSAIDs than CAS systems. For example, it was demonstrated that up to 98%–100% ketiprofen and 86%–89% naproxen were removed in MBRs.[41,44] In addition, MBRs also have better removal efficiencies for the antibiotics roxythromycin, sulfamethoxazole, trimethoprim, and diclofenac relative to the CAS systems.[43,44] However, certain compounds, such as carbamazepine, remain mostly undegraded in both conventional WWTP and MBRs.[43] A study compared different filter systems such as MBR, MF/UF, and RO in removing pharmaceuticals using WWTP primary effluent as the feed water.[45] In contrast to other studies, most pharmaceuticals were removed well (except for phenytoin and meprobamate) in the MBR, including a 90% removal of carbamazepine. These differences in results suggest that design and operation of MBRs can be optimized to increase removal efficiencies of pharmaceuticals in wastewater. Additionally, it was demonstrated that more than 90% of all pharmaceuticals tested were removed in the RO system alone; however, the use of combined systems such as UF/RO, MF/RO, and MBR/RO resulted in more than 99% removal for all pharmaceuticals. However, membrane systems are expensive and may not be affordable to many municipalities. In addition, membrane systems require that the brine, in which the rejected pharmaceuticals are concentrated after removing pharmaceuticals from mother water, must be appropriately treated.

Granular activated carbon (GAC) adsorption systems were also investigated in two facilities, one with regular regeneration of GAC and the other without regular replacement/regeneration of GAC.[45] As summarized in Table 4, the latter facility had poor removal efficiencies for most of the pharmaceuticals tested. Hence, it is important to determine the breakthrough for individual pharmaceuticals so that regeneration or replacement GAC can be scheduled on a timely fashion to be most effective in removing pharmaceutical residues in the water.

Ozone oxidation has been investigated for sulfonamides, macrolides, and iodinated contrast media, as well as other acidic pharmaceuticals spiked in MBR-treated wastewater effluent.[46] As may be expected, increased ozone concentrations resulted in increased degradation of pharmaceuticals. However, while the sulfonamides and macrolides were very sensitive toward ozone degradation and were completely removed with high ozone concentration, iodinated contrast media were only 40% degraded. Ozone oxidation experiments have been performed to investigate the removal of 17 pharmaceuticals, as well as other personal care products and endocrine-disrupting chemicals, in bench-top pilot plants and in one full-scale WWTP system. The removal efficiencies of pharmaceuticals by ozonation can be classified into four groups: >80% removal, 80%–50% removal, 50%–10% removal, and <20% removal.[15] Most of the pharmaceuticals exhibited >80% removal; diazepam, phenytoin, and ibuprofen had 80%–50% removal; and iopromide and meprobamate were in the group of 50%–10% removal. In a separate

TABLE 4 Comparing Removal Efficiencies of Pharmaceuticals for GAC Facilities with and without Regular Regeneration or Replacement of Activated Carbon

Pharmaceuticals	Removal (%) in Facility 1 (with Regular GAC Regeneration)	Removal (%) in Facility 2 (without Regular GAC Regeneration)
Caffeine	>41.2	16.3
Carbamazepine	>54.5	15.6
Phenytoin (Dilantin)	>44.4	22.7
Erythromycin–H_2O	>44.4	7.9
Gemfibrozil	>16.7	8.2
Ibuprofen	>9.1	16.4
Iopromide	>69.7	72.0
Meprobamate	>16.7	13.3
Sulfamethoxazole	>83.3	83.8

study using two different wastewater matrices, one with effluent water from a conventional WWTP and the other with effluent from an MBR system, it was shown that the removal efficiencies by ozonation, ozone–UV, and H_2O_2–UV may be slightly lower in the presence of higher dissolved organic carbon.[47]

The removal of 13 selected pharmaceuticals in full-scale WWTP with CAS system, followed by advanced treatment by ozonation, was evaluated.[52] Interestingly, most of the pharmaceuticals that are typically poorly removed (<20% removal) in the secondary clarifier, such as crotamiton, sulfapyridine, and roxithromycin, were almost completely-degraded upon ozonation. An exception to the pharmaceuticals effectively removed by ozonation was carbamazepine (which was only <5% degraded by ozonation).

In a separate study, the efficiency of UV oxidation was examined with and without H_2O_2 for atenolol, carbamazepine, phenytoin, meprobamate, primidone, and trimethoprim, using three different wastewater matrices.[53] Results of this study indicated that the nature of the aqueous matrix, most likely defined by the amount and composition of the natural organic matter, is an important factor in optimizing the removal efficiencies of pharmaceuticals by advanced oxidation. For example, removal efficiencies between 16% and 95% were observed for the pharmaceuticals tested in one WWTP using a high power of UV (fluence of 700 mJ/cm^2) with H_2O_2. However, removal efficiencies of the same pharmaceuticals in water from other sampling locations with high organic matter content were relatively lower (10%–85%), although the same UV treatment conditions were used.

Removal Efficiencies in Drinking Water Treatment Systems

Polar and persistent pharmaceuticals may eventually enter the drinking water systems.[49] Since conventional processes used in drinking water treatment may not completely remove pharmaceuticals, other advanced oxidation processes have been considered for treatment of pharmaceuticals in drinking water. Ozonation appears to be the most effective way to disinfect the water and at the same time oxidize organic chemicals via direct reaction with ozone, or through reactions with hydroxyl radicals (OH) formed during ozonation.[15] For disinfection purposes, monochromatic UV at 254 nm is used for drinking water treatment. In UV advanced oxidation process, the oxidation of pharmaceuticals is enhanced by addition of H_2O_2 to facilitate formation of hydroxyl radicals and promote indirect photolysis.[54] The oxidation of diclofenac, a frequently detected NSAID in the environment, was evaluated using ozone, UV, and UV–H_2O_2. Ozonation showed 100% removal, while UV–H_2O_2 oxidation showed only 52% removal of diclofenac at conditions that corresponded to a 35% decrease in total organic carbon, after 90 minutes of oxidation time.[55] The antidepressant pharmaceutical fluoxetene (trade name of Prozac), which is typically detected at parts per billion levels in U.S. streams,[1] was used as test compound to evaluate the efficiency of direct and indirect photolysis in removing pharmaceuticals in water. The degradation rate for fluoxetene reached up to 9.60×10^9/M.s for indirect photolysis.[561] It has been shown that the use of TiO2 catalyst can significantly increase the photolysis rate constants for NSAIDs, including diclofenac, naproxen, and ibuprofen in water.[57] Experimental oxidation rates of the hydroxyl radical for β-blockers, atenolol, metoprolol, and propranolol, were found to be 7.05×10^9, 8.39×10^9, and 1.07×10^9/M/s, respectively.[58] Ozonation of tetracycline showed the complete removal within 4–6 minutes of ozonation despite the maximum degradation of 40% total organic carbon after 2 hours of ozonation.[59] Finally, photo-Fenton (Fe(II)) reaction is another oxidation method that can be applicable to drinking water treatment systems owing to its cost effectiveness and ease of operation.[60] It was demonstrated that diclofenac can be 100% degraded within 60 minutes of photo-Fenton oxidation.[60]

Organic pollutants in drinking water sources, including pharmaceuticals, can be removed by activated carbon adsorption.[16] Laboratory-scale tests mimicking full-scale drinking water treatment system using activated carbon-showed good removal efficiencies of trace organic compounds, except for the more hydrophilic pharmaceuticals (e.g., clofibric acid and ibuprofen were only 40% removed) after 3 hours of contact time.[61]

Water filters can provide an additional step, at a point-of-use consumption treatment, to remove trace levels of pharmaceuticals and other drinking water contaminants from tap water. The removal efficiencies of chlorination by-products, including trihalomethanes, bromodichloromethane, dibromochloromethane, and bromoform, by "Envirofilter" (made of nutshell carbon and commercial water filters) have been reported.[62] Water filters are made with activated carbon to remove dissolved organic matter,[62,63] together with polar and ion-exchange resins to remove charged species such as metal ions.[64,65] Since activated carbon has been shown to have high removal efficiencies for many pharmaceuticals in wastewater,[16,66–71] it is reasonable to expect that water filters will be effective in removing trace levels of pharmaceuticals from drinking water.

Conclusion

The decreasing amount of clean water resources for drinking water and for food production has become one of the most challenging problems in the world.[72] To alleviate the shortage in water supply, reuse of treated wastewater for irrigation[72–74] and as drinking water source[75] is becoming more and more common. Therefore, pharmaceuticals can enter the groundwater and drinking water systems, as shown in Figure 1 depicting the routes of entry of pharmaceuticals into the environment. It is encouraging to see a recent survey reporting that only very few pharmaceuticals from biosolid application and wastewater irrigation can be transported to the groundwater aquifer.[72] Because only lipophilic pharmaceuticals tend to sorb onto the biosolids, and these pharmaceuticals in turn are not mobile in soil, contamination of groundwater aquifer from biosolids application may not pose a significant source of pharmaceutical pollution. With the exception of four pharmaceuticals (two iodinated contrast media of diatrizoate and iopamidol, carbamazepine and sulfamethoxazole) most of the 52 pharmaceuticals being targeted for analysis were not detected in the said study. Nevertheless, optimization of the design and operating conditions of wastewater treatment systems is key to eliminating pharmaceuticals and their deleterious ecological effects in the environment. Advanced oxidation processes are very promising treatment technologies that are waiting to be tested and implemented under full-scale treatment plants.

Buildings: Climate Change

Lisa Guan and
Guangnan Chen

Introduction

The greenhouse effect is a natural warming process of the earth. It is caused by the greenhouse gases, such as water vapor, carbon dioxide (CO_2), and methane (CH_4), which trap long-wave radiation and then radiate the energy in all directions, warming the earth's surface and atmosphere (Figure 1).[1] Without the heat-trapping greenhouse gases, scientists estimate that the average earth surface temperature would likely to be some 30°C colder than it is today, or –18°C instead of the present mild average 15°C.[1]

The enhanced greenhouse effect is additional to the natural process of greenhouse effect and is mainly due to human activities (human induced), including burning fossil fuels, land clearing, and agriculture, which change the makeup of the atmosphere and lead to an increased concentration of greenhouse gases.[1] This has the potential to cause significant changes in the global climate system (referred to as climate change), including increased temperature, changed patterns of rainfall, tropical cyclone activities, and other extreme climatic events.

Climate change has now become one of the most important global environmental issues facing the world today. It is now widely recognized as having significant potential to seriously affect the integrity of our ecosystems and human welfare.[2] The effects, or impacts, of climate change may be in physical, ecological, social, and/or economic areas.

In this entry, the likely future climate change is first presented. The cycling interaction between climate change and buildings is then discussed, which includes both aspects of the implication of climate change on building performance and the contribution of buildings to the process of human-induced climate change. The potential strategies for building design and operation are then highlighted, in order to reduce the greenhouse gas emissions from buildings and to prepare the buildings to withstand a range of possible climate change scenarios.

Likely Future Climate Change

Due to uncertainties in future emissions and concentrations of greenhouse gases, as well as the climate system's response to the changing conditions and the natural influences (e.g., changes in the sun and volcanic activity), it may be difficult to accurately predict the extent of climate changes.[2] However, the advancements in climate model simulations, combined with more and more observed data on climate changes, led the Intergovernmental Panel on Climate Change (IPCC) to predict the following likely scenarios of climate changes[2]:

- Average global surface temperature will likely rise a further 1.1–6.4°C (2.0–11.5°F) during the 21st century. It is expected that the average rate of warming is very likely to be at least twice as large as that experienced during the 20th century.
- Warming will not be evenly distributed around the globe and will vary with different seasons. For example, land areas will warm more than oceans, high latitudes will warm more than low latitudes, and winters will be warming more than summers in most areas.
- There will be significant changes to the amount and pattern of precipitation, including an increase in droughts, tropical cyclones, and extreme high tides. The changes in precipitation, either an increase or a decrease, will vary from region to region.
- The global average sea level is estimated to rise by 18–59 cm (7.2 to 23.6 in.) by 2100 relative to 1980–1999. Current model projections also indicate substantial variability in future sea level rise between different locations.
- Increases in the intensity of extreme weather events, such as storms, heat waves, and drought, are also predicted.
- In regard to the projection of future climate change, it is noted that there are different levels of confidence (e.g., in terms of accuracies and reliability) for different climate parameters. For

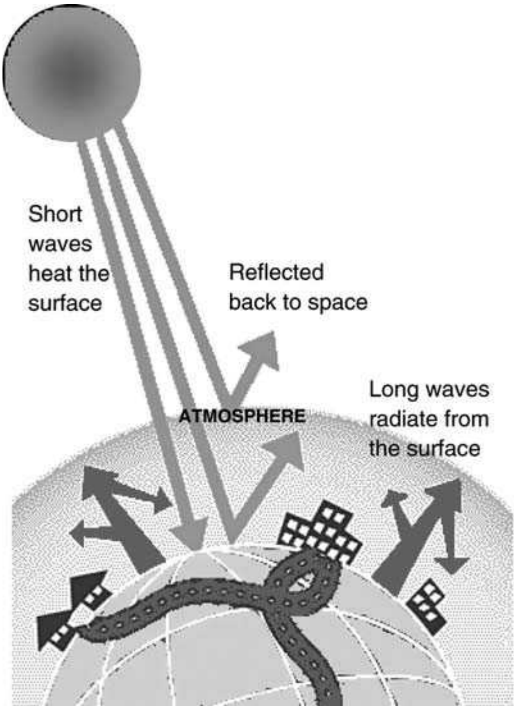

FIGURE 1 Natural/enhanced greenhouse effect.

TABLE 1 List of Climate and Associated Scenario Variables, Ranked Subjectively in Decreasing Order of Confidence

Climate Variable	Confidence
Atmospheric CO_2 concentration	Global—mean sea level	
Global—mean temperature	
Regional seasonal temperature	
Regional temperature extremes	
Regional seasonal precipitation and cloud cover	
Regional potential evapotranspiration	
Changes in climatic variability (e.g., El Niño, daily precipitation regimes)	
Climate surprises (e.g., disintegration of the West Antarctic Ice Sheet)	

Source: Hulmer and Sheard.[3]

example, it is believed that there is higher confidence in the projection of increases in carbon dioxide concentrations and rises in sea level than in storminess or intense precipitation events. A list of climate and associated scenario variables, ranked subjectively in decreasing order of confidence, had been recommended by Hulme and Sheard[3] and is shown in Table 1.

Implication of Climate Change on Buildings

Climate change is likely to affect both the performance of existing building stock and the design of new buildings. For example, under climate change, buildings will have more overheating hours in summer and less underheating hours in winter, thus use more cooling energy and less heating energy. Where heating and cooling are provided by different fuels, this could have a significant influence on the design and operations of energy delivery systems.

Because climate change entails new climatic conditions for the building industries, it is expected that climate change will have a significant impact on the design, construction, and performance of buildings, as well as the health and productivity of people living and working inside them.[4] These impacts may include the following:

- *Higher building energy consumption*: Climate change may require higher capacity and more uses of air-conditioning equipment to provide comfort indoor environment. For example, it has been predicted that for air-conditioned office buildings in Australia, the cooling load may increase by 2%–47%, depending on the assumed future climate scenarios, as well as different locations.[5] The increases of total building energy use would range from 0.4% to 15.1%. However, due to the potential decrease of heating energy in winter, skin-dominated buildings located in cold regions could receive some benefits from the climate change. Moreover, the expected increased stringencies in building energy codes around the world would also offset some increases of building energy use due to climate change.[6,7]
- *Deteriorating internal thermal environment*, such as more overheating in summer. It has been found that for air-conditioned office buildings in Australia, when the annual average temperature increase exceeds 2°C "threshold," the risk of current office buildings subjected to overheating will be significantly increased.[5] When the increase of external air temperature is more than 5°C, all the Australian office buildings would suffer from the overheating problem regardless where they are located. This could have significant implications on people's health and capacity to work and productivity. It has been estimated that global warming is currently contributing to the death of about 160,000 people every year.[8]

- *Structural integrity*, such as more severe wind and snow loading, and foundation movement. For example, shrinkage or expansion in clay soils can lead to foundation movement and cracking of walls, which may cause damage in building structure. In Northwest Norway, severe damage to buildings was caused by the hurricane on January 1, 1992, and several buildings collapsed due to heavy snow loads on roofs during the 1999/2000 winter.[9]
- *External fabric*: Durability of external fabric becomes shorter due to increased storm, rain, flood, and other weather conditions. For example, the strength and durability properties of concrete may be influenced by the changes in its environment (e.g., temperature, humidity).
- *Construction process* may be disrupted due to adverse weather condition. This may have implication in the project planning and the associated challenges to complete the project on time and within the budget.
- *Service infrastructure* may become inadequate. For example, changing weather patterns and more frequent and intense storm may lead to the drainage problem. The existing drainage system in many parts of the world may not be able to cope with increased storm loads.

Contribution of Buildings to Human-Induced Climate Change

The climate system is a dynamic system in transient balance.[10] A change of external and/or internal climate forcing imposed on the planetary energy balance would cause a corresponding change in global temperature.[10] Overall, scientists have now been able to reach a broad consensus and provide overwhelming evidence to suggest that human activities are having a discernible influence on the global climate.[2] In particular, it has been found that the recent rapid increase in global temperature is closely aligning with the strong growth in use of fossil fuel over the past 50 years.

The construction and operation of modern buildings consume a considerable amount of energy and materials and therefore contribute significantly to the process of human-induced climate change. Figure 2 shows the world greenhouse gas emissions by sector, end use, activity, and gas types.[11] It can be seen that buildings, including both commercial buildings and residential buildings, account for 15.3% of world greenhouse gas emission, which is greater than the sectors of transportation, agriculture, and waste. Indeed, buildings are one of the most significant infrastructures in modern societies.

Worldwide, the Worldwatch Institute estimates that the construction and operation of buildings is responsible for 40% of the world's total energy use, 30% of raw materials consumption, 55% of timber harvests, 16% of freshwater withdrawal, 35% of global carbon dioxide (CO_2) emissions, and 40% of municipal solid waste sent to landfill.[12] In 2004, it was estimated that worldwide, the total emissions from the building sector, including the electricity consumed, were 8.6 Gt CO_2, 0.1 Gt CO_2–eq N_2O, 0.4 Gt CO_2–eq CH_4, and 1.5 Gt CO_2–eq halocarbons (including CFCs and HCFCs).[13]

Basically, the impact of buildings on the human-induced climate change is through three routes, including building operational energy, building embodied energy, and building-related refrigerants. Operational energy includes all energy used for mechanical services [e.g., heating, ventilation, and air conditioning (HVAC) systems], electrical services (e.g., lighting and other office appliances), and hydraulic services (e.g., pumping system). Embodied energy includes all energy used for the production of building materials, their transportation and handling, and building construction processes. Building-related refrigerants include the refrigerants used in air-conditioning systems (e.g., Freon used in compressors and chillers) and other building appliances (e.g., refrigerators and freezers), which may have ozone depletion potential (e.g., depleting the ozone in the upper atmosphere) and/or global warming potential that persists in the upper atmosphere, trapping the radiation emitted by the earth.

Previous studies of Life Cycle Assessment (LCA) have shown that the CO_2 emission from the sources of building embodied energy and building-related refrigerants is often fairly small for commercial office buildings. For instance, based on the assumption of a building having a 40 years life span, it has been

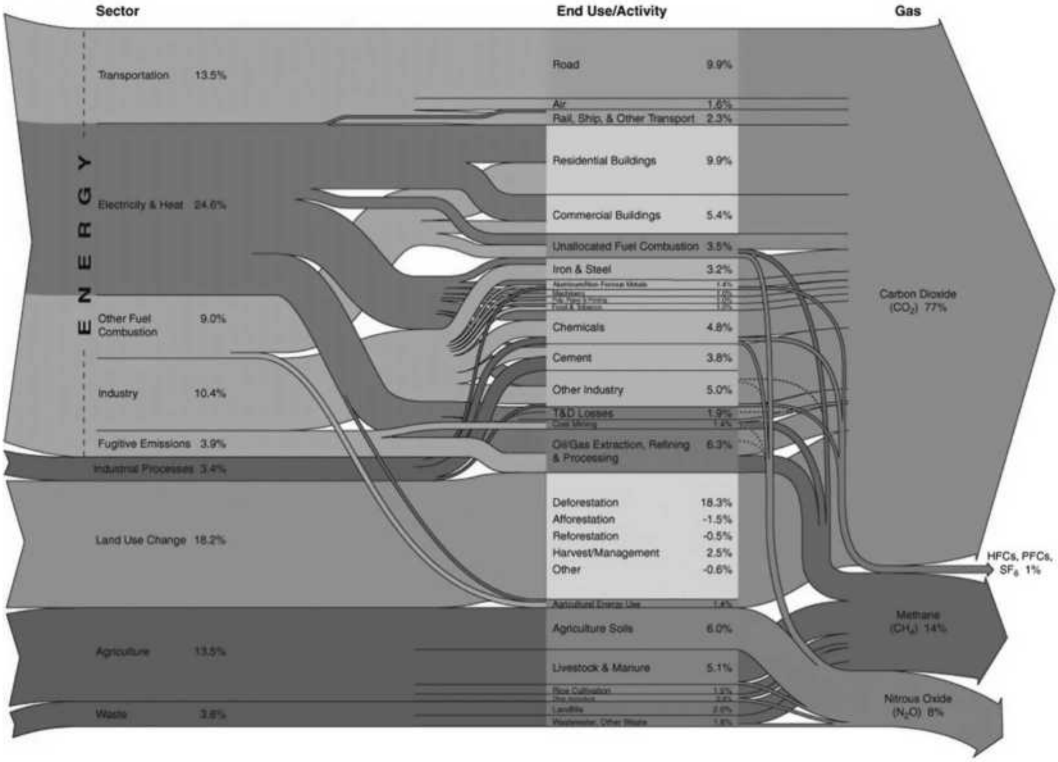

FIGURE 2 World greenhouse gas emissions by sector, end use, activity, and gas types.
Notes: All data are for 2000. All calculations are based on CO_2 equivalents, using 100 years global warming potentials from the IPCC (1996), based on a total global estimate of 41,755 $MtCO_2$ equivalent. Land use change includes both emissions and absorptions. Dotted lines represent flows of less than 0.1% of total greenhouse gas emissions.
Source: World Resources Institute.[11]

shown that the embodied energy emissions contributed only approximately 8%–10% of building total emission.[14] More than 90% of building energy consumption occurs during the use/operational phase, so the energy performance of the buildings is particularly important, especially for buildings with 24 hours occupancy.

Relationship between Climate Change and Buildings

As discussed above and also illustrated in Figure 3, the cycling interaction between climate change and buildings is of dynamic nature. Climate change, for instance, would generally lead to more use of air conditioning, which leads to more greenhouse gas emission and then climate change. Therefore, both climate change and buildings are essentially the cause and the effect of each other.[15] On one hand, climate change is expected to impact on many aspects of building design, construction, and operation. On the other hand, buildings have also contributed significantly to the human-induced climate change. They have produced more greenhouse gas emission than the sectors of transportation, agriculture, and waste.

Because greenhouse gas concentrations are still continuing to increase, the process of climate change will continue and may accelerate. This requires the building sector to develop suitable strategies, including the enhancement in building energy codes, to mitigate the greenhouse gas emissions, which should

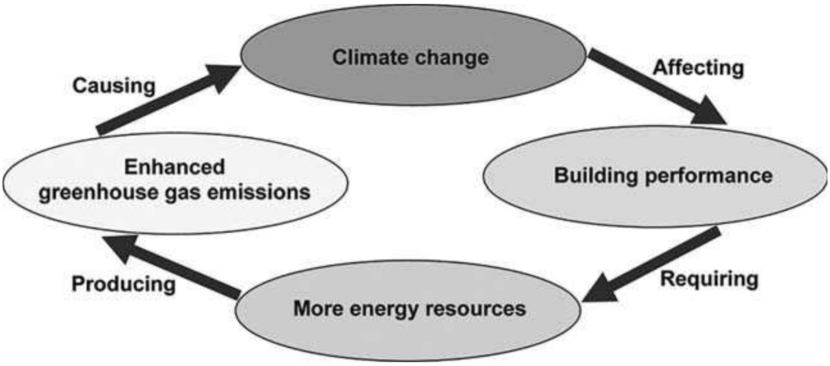

FIGURE 3 The cycling interaction between global warming and buildings.

be not only environmentally effective but also economically efficient. In parallel, appropriate adaptation strategies are also needed to prepare buildings to withstand the future inevitable climate change. Adaptation to climate change has now become one of the key requirements for buildings.

It is noted that there may be both potential synergy and conflict between adaptation and mitigation measures and strategies. This will require the development of integrated rather than separate responses.[16–18] Moreover, it seems that there is a tight intertwining between the issues of adaptation and mitigation.[19,20] The energy-efficient and renewable energy technologies, for instance, often can play dual roles in mitigating greenhouse gas emissions while increasing adaptive capacity by making buildings more disaster resilient. An effective response to climate change may not always be costly and could even be both profitable and socially beneficial.

Potential Strategies for Building Design and Operation

Buildings are one of the most significant infrastructures in modern societies, having significant impact on health and productivity of people living and working inside them. In particular, as buildings have a very long life span, typically 50–100 years, it is very important that all the current and future building stocks be designed and maintained to perform satisfactorily in future climates.

For both new and existing buildings, potential mitigation may include the utilization of renewable energy and low emission energy, energy efficiency, and energy conservation. Appropriate adaptation may also be achieved by focusing on major building design parameters for new buildings or retrofit of building envelope and/or internal heat sources such as lighting systems for existing buildings. In particular, those improved building energy codes currently adopted around the world, including the requirement of thermal conductance values for building envelope, lighting power densities for internal heat sources, and HVAC system efficiency for building mechanical services,[6,7] could play key roles in both the potential mitigation and adaptation of buildings. Overall, the aim is to ensure that all the existing and new buildings not only perform and operate satisfactorily in the new environment but also satisfy the environmental performance criteria of sustainability.

Building Envelope

The building envelope is a significant determinant of energy required to heat and cool a building. Building designers can use the building envelope as a “filter” to accept or reject solar radiation and outside air, depending on the need for heating, cooling, ventilation, and lighting.[13] The heat storage capacity of the building envelope can also be used to reduce peak thermal loads. As a result, a well-designed building shell can substantially reduce the building cooling and heating demands and lighting energy through the provision of daylighting, particularly at the perimeter zones. This can result in not only substantial capital cost savings by enabling smaller sizing of the air-conditioning plant to be used but also significant operating cost saving by reducing the quantity of air circulation and fan power, and partial load situation for the HVAC systems.

It is particularly important that building designers employ energy-efficient principles, as well as integrated building design approaches at design and construction of the building envelope. Overall, for the building envelope, the potential mitigation and adaptation strategies in the face of climate change may include the following:

- Installation of insulation in foundation, walls, and/or roofs to minimize conductive heat loss/gain.
- Optimum design of windows, including careful determination of window-to-wall ratio (WWR) and selection of types of glass and shading to optimize use of solar heat and light.
- Sealing gaps to prevent draughts and heat infiltration to minimize uncontrolled movement of air into the building.
- Utilizing thermal mass, reflective roofs, and trees for shade, etc., if it is appropriate.

Internal Heat Sources

The internal heat sources include the occupants, lights, electric appliances, and machines. Their influence may be not only directly on the total energy consumption of the building but also on the building thermal loads, which indirectly influence the energy consumption of HVAC systems. The selection of lights, for example, can have significant impact on the building energy and thermal performance. Advances in higher-efficiency light sources, lower-loss ballasts and control gear, and more efficient luminaries will therefore enable lighting energy usage to be significantly reduced. Developments in the technology of daylighting will further increase the potential lighting energy savings. The potential mitigation and adaptation strategies to manage internal heat sources may include the following:

- Optimum integration of lamp (lighting sources), ballasts (for electric-discharge lamps), and fixtures (e.g., reflectors, diffusers, and/or polarizing panels). It was found that to maintain the same lighting level of 320 lux, lighting power densities can vary from 2 to 5 W/m^2 (averaged over time) for having state-of-the-art lighting technology to 25–35 W/m^2 for having only mediocre level of efficiency.[21]
- Purchasing energy-efficient office equipment and running it wisely. Energy-efficient office equipment can use less than half the energy as the standard models—at no or little additional capital cost.[21] Recommendations may include the use of “energy star” office equipment and “energy labeling” appliance. It was found that every dollar invested in energy efficiency, at a 20%–30% saving rate, is equivalent to increasing net operating income by 3%–4% and net asset value by $2.50–$3.75.[22]

Using the building simulation technique, it has been shown that for Australian office buildings, if the building total internal load density, which includes all internal heat sources of lighting, plug load, and occupants, is reduced from 43 to 21.5 W/m^2, the building total energy use under the future 2070 high scenario (the worst case) can be reduced by up to 89–120 kWh/m^2 per annum and the overheating problem could be completely avoided and the office building will perform as good as at the current climate scenario.[23]

Building Mechanical Services

Building mechanical service or HVAC systems are used to control factors affecting thermal comfort, with the ultimate purpose being to provide a clean, noise-free, and efficient working environment.[24] Since air-conditioning systems account for around one-third of the total energy use in typical office buildings, the proper design and selection of HVAC systems are critical for the performance of these buildings.

Generally, according to the purpose of the building, as well as local site information and climate condition, a building may be designed as naturally ventilated, mechanically ventilated, air conditioned, or a combination of these three options (hybrid mixed-mode system). Potential mitigation and adaptation strategies for design and selection of building service systems include the following:

- Using passive design for heating, cooling, and ventilation. A building relying entirely on air conditioning should be avoided as much as possible.
- Utilization of renewable energy and/or low emission energy for the operation of the building. It was found that on clear days throughout the year, reductions of conventional power use of at least 60% can be achieved with optimum photovoltaic cladding densities targeted to lighting and small power load demands.[25]
- Selecting energy-efficient technologies. Such technologies may include evaporative cooling, desiccant cooling, chilled ceilings, displacement ventilation, cogeneration and district heating and cooling, active solar and heat pump systems, and underground earth pipes.[26]
- Good control of HVAC systems. It was found that the performance of the HVAC system is subject to the significant influence of its control strategy and maintenance. Building energy management systems (BEMSs) can also be a useful tool for energy saving in the range of 5%–40%.[26]
- Good commissioning, operation, and maintenance of HVAC systems. It was found that of the deficiencies found in the retro-commissioning of buildings, 85% were related to HVAC systems.[22] In the same study, it was also reported that energy savings between 7% and 29% may be achieved with paybacks ranging from 0.2 to 2.1 years.

Recommendations on Implementation of Strategies

Overall, it is recommended that the potential mitigation and adaptation strategies should be taken at the early planning and design stage. This is because the thermal loads gained/lost from the building envelope and internal heat sources are the “base load” for the selection of HVAC equipment. Appropriate selection and design of these systems are therefore vital for the energy efficiency of the building. Without a suitable choice, all later work will be built on an unsatisfactory foundation. It is also noted that the mitigation and adaptation strategies taken at the early design stage will future-proof the building and be more effective in the longer term. Although the initial capital cost of taking the measures may be higher, the overall cost in many cases would actually be much lower than having to do retrofit strengthening at a later stage.[16]

Building regulation and design codes can also play a crucial role in the anticipation and avoidance of risk.[27] Because climate change would have a major impact on the frequency of extreme weather events, building codes need to be reviewed regularly in order to maintain a proper level of reliability and be adhered to in practice.[9] For instance, changes in the frequency of storms will have building code implications.[28] However, it is argued that simply raising performance standards as a response to climate change, without dealing with the issue of noncompliance with existing standards, may not be desirable. It may run the risk of undermining the legitimacy of regulation generally.[27]

In the face of inevitable climate change, the shifting from a reliance on historical data to a reliance on predicted future data may be also necessary, as it is increasingly important to precisely predict the conditions under which buildings and other infrastructure will need to withstand in the future. It is understood that using different sets of design conditions will have significant implication on the cost and performance of buildings. For example, using the building simulation technique, it has been shown that for typical Australian office buildings, the required cooling capacity may increase from 28% to 59% if the new buildings were designed using the future project climate (e.g., 2070 high scenario) rather than the current climate condition.[5] In order to maintain comfort indoor condition, a further increase of 4%–10% may be required in addition to the possible increase of 27%–47% cooling load if the buildings were designed at current climate conditions.

Conclusion

The climate change induced by the emissions of greenhouse gases is one of the most important global environmental issues facing the world today. Buildings are one of the most significant infrastructures in modern societies, and they need to be prepared to withstand climate change. On one hand, climate change is going to impact on many aspects of buildings, including both building design and building operation. On the other hand, buildings have also contributed significantly to the process of human-induced climate change. In this entry, both aspects of knowledge have been discussed.

It has been suggested that the potential mitigation and adaptation strategies should focus on major energy-related factors, such as design and construction of building envelope, design and careful selection of the air-conditioning system, and selection of management of internal heat sources including both lighting systems and electrical equipment. In many cases, it has been demonstrated that the energy-efficient and renewable energy technologies can play dual roles in mitigating greenhouse gas emissions while increasing adaptive capacity by making buildings more disaster resilient.

It has also been recommended that energy efficiency principles, such as adopting passive design principles for heating, cooling, ventilation, and lighting, and integrated design approaches should be adopted at the early design stage and be maintained in the whole life of buildings. These strategies have the potential of not only being environmentally effective but also economically efficient and socially beneficial.

Economic Growth: Slower by Design, Not Disaster

Peter A. Victor
and Tim Jackson

Introduction

Economic growth is a very recent phenomenon, dating back two or three centuries and limited in its extent to only some parts of the world. While economic growth has dramatically improved the lives of billions of people, billions more remain in abject poverty. The mainstream view is that all countries should strive for economic growth, and through a process of convergence where poorer countries grow the fastest, all the people of the world will eventually enjoy a high and secure material standard of living.

There are many problems with this vision of growth for all. Foremost is the mounting evidence that the world's economy is already bumping up against and even surpassing the biophysical limits of the planet. This is showing up in terms of global and local environmental degradation and resource scarcity. Consequently, a different vision is emerging, one in which rich countries no longer pursue economic growth as a primary objective, leaving room for the economies of poorer countries and regions to expand, at least temporally. An additional motivation for low and no growth is to reduce competition with other species with which humans share the planet.

This chapter examines the possibility of rich countries managing without growth, by which is meant achieving improvements in well-being without economic growth. That such an outcome is possible is illustrated with the use of LowGrow SFC, an interactive macroeconomic model of the Canadian economy. The chapter concludes with a discussion of policy directions implied by such a scenario with special emphasis on employment policies and funding public services in a low-/no-growth economy.

A Brief History of Economic Growth

In terms of human history, economic growth is a very recent phenomenon. World gross domestic product (GDP) was only 14% higher at the end of the first millennium than when it began. GDP is the "total unduplicated value of the goods and services produced in the economic territory of a country or region during a given period" (Statistics Canada). GDP per capita was no higher at all, slightly less even, owing to population growth. From the year 1000 to 1400, world GDP increased by 140%, but GDP per capita grew only 60% and at a barely perceptible rate, as population expanded. Over the next 400 years, world GDP increased a further 140%, and although GDP per capita increased by 30% by 1700, it fell back again in 1800 to the same level as in 1400. Average world GDP per capita declined further in the early 1800s, after which economic growth accelerated. By 1900, world GDP was over five times greater than in the previous 100 years, growing at an average annual rate of 1.7%, and GDP per capita was more than three times greater. The rate of economic growth increased in the 20th century such that annual world GDP grew almost ninefold at an average annual rate of 2.2% and GDP per capita rose 2 1/2 times.

These figures,[1] approximate as they are especially early on, show that economic growth has been exceptional in human history. The vast majority of people have lived in circumstances where they had no reason to believe that their children's lives would be materially any different from their own. To think otherwise is a very modern idea dating back perhaps a dozen or so generations, and even then, only in some parts of the world.

Of course, global averages conceal much of the huge variation in experiences from country to country and region to region. In the 18th and 19th centuries, most of the world's economic growth was confined to Europe and ex-colonies of European powers. Some regions were impoverished in the process, 19th-century India being a prime example through the deliberate destruction of cotton manufacturing at the behest of British industrialists. The rest of the world continued to experience lives in which economic growth had little or no impact and was not part of the lived experience of most people. Even in places where growth rates were highest, there were substantial areas of poverty. In the 20th century and into the 21st century, economic growth spread to more parts of the globe but unevenly with 735 million people in 2015 still living in extreme poverty (less than US$1.90 per day) and 3.4 billion living below US$5.50 per day, about the price of a single cup of coffee in the United States. While the number living in extreme poverty declined by 40% since 1990, the number living below $5.50 only declined by 5%, and the rate of reduction in extreme poverty is slowing down.[2] Contrary to earlier expectations that global economic growth would close the gap between rich and poor, the spread has increased, just as it has done within even the richest countries.[3]

All this economic growth has required a massive increase in the use of natural resources. In the 20th century, the global use of construction materials, ores and industrial materials, fossil fuels, and biomass increased eightfold, almost as much as GDP.[4] Since 2000, the global use of these resources has risen even faster than GDP. The much-vaunted "green growth" which depends fundamentally on increasing GDP with declining use resources is nowhere to be seen.[5] The increasing extraction, use, and disposal of materials have resulted in large-scale, adverse environmental impacts. One prominent list includes the following: climate change, ocean acidification, stratospheric ozone depletion, overloading of the nitrogen and phosphorus cycles, global freshwater uses, land system change, biodiversity loss, atmospheric aerosol loading, and chemical pollution.[6] Then, there is the looming threat of peak oil from conventional sources[7] and the more general concern that the age of cheap energy is coming to an end,[8] as well as an emerging scarcity of "critical" minerals for new technologies.[9] All this plus serious doubts about future prospects for increases in productivity[10,11] and concerns over secular stagnation,[12] make for a bleak outlook for real, long-term, comprehensive, global economic growth. With the world human population approaching 8 billion, projected to rise to nearly 10 billion by mid-century, the question arises as to whether economic growth for all is a viable option in the 21st century and if not, what are the alternatives?

One alternative is to shift the over-riding economic priority of the richest economies away from the single-minded pursuit of growth and to reduce “growth dependency.” After all, economic growth has only held this position as the single most important economic policy objective since about 1960. “There is in fact hardly a trace of interest in economic growth as a policy objective in the official or professional literature of western countries before 1950.”[13] And even when it was introduced, it was as a means to fulfill other policy objectives such as full employment, rather than as an end in itself. Now the pursuit of economic growth is deemed so important that it is customary for policy proposals across many domains including environment, education, and the arts to be judged in terms of their implications for growth, or one of its surrogates such as competitiveness or productivity.

If the poor countries of the world are to benefit from economic growth, and the world economy is to function within the “safe operating space” of the planet,[6] then rich countries, those that have benefited the most from economic growth in the past, must be prepared to make room for them. Otherwise, disaster threatens, brought about by the excessive pressure on Earth systems.

One approach to this predicament based on principles of distributive justice would be to determine fair shares of access to global resources, accounting also for the interests of other species. This is the kind of dialogue that is underway in the slow progression of international climate negotiations, illustrating most profoundly the difficulties in reaching and then implementing agreement in a global world divided into national and regional power blocs. Nonetheless, a country or group of countries could adopt a view of its fair share independently of an international agreement and set these as boundaries within which their economy must function. Depending on the specification of the boundaries and the capability of economies to adjust, economic growth, measured in the conventional way as an increase in real (inflation) adjusted GDP, could conceivably continue for a time, but incidentally rather than as a primary objective.

What would such development entail? Total environmental (including resource) impact is the product of GDP and impact per unit of GDP (e.g., GDP × greenhouse gas (GHG) emissions per unit of GDP or GDP × energy used per unit of GDP). Therefore, if environmental impact is to decline as GDP grows, environmental impact per unit GDP must decline faster than the rate of economic growth. This is one meaning of “green” growth, and it underlies the downward-sloping portion of the Environmental Kuznets Curve.[14] (The Environmental Kuznets Curve is an inverted “U” with a measure of environmental impact plotted on the y-axis and GDP plotted on the x-axis. The hypothesis is that in the early stages of economic growth, environmental impact rises to a maximum after which it declines as growth continues.) There are examples of obvious, local problems such as urban air quality whose history can be described by an Environmental Kuznets Curve, but it is a poor description of global materials and energy use or global environmental impacts over the past century.

Whether green growth defined in this way (i.e., impact/GDP declining faster than GDP increases) is possible at the global level remains an open question. It is complicated by the fact that many environmental and resource depletion problems relate to stocks such as accumulating GHGs in the atmosphere, diminishing rain forests, and declining fish stocks. Reducing the flows that determine these stocks may be insufficient to bring the stocks to the required levels fast enough or at all. If it is not possible to sufficiently decouple economic growth from its environmental and resource impacts, growth will have to cease and even turn negative for a time as proponents of degrowth argue.[15] Otherwise, it will not be possible to bring the global economy back within the planetary boundaries that are already being exceeded and others which will be exceeded if present trends are not reversed. Given what we know about the state of the environment, and concern over supplies of low-cost energy and critical materials, there is a very strong case on ethical and practical grounds for rich countries to take the lead in managing without growth.

Economists Question Growth

At the same time as economic growth was reaching the pinnacle of policy objectives, dissenting voices were beginning to be heard. One of the most widely prominent was John Kenneth Galbraith. In *The Affluent Society*[16] published in 1958 and revised through multiple editions, Galbraith compared private affluence in the United States with public squalor. He also questioned the efficacy of dealing with poverty through a general rise in incomes. Many academic economists regarded Galbraith as more of a political commentator than a serious economist because of his disdain for theoretical economics, and on these tenuous grounds, they resisted his arguments. The same could not be said of British economist Ezra Mishan who published *The Costs of Economic Growth* in 1967.[17] Mishan was a highly regarded and well-published expert in "welfare economics," the field within mainstream economics that is concerned with the relationship between economic activity and well-being. Thus, although Mishan's analysis of the costs of economic growth was aimed at a broad audience, no one could dismiss the author as not really understanding modern economic theory.

Perhaps this is one reason why Mishan's critique of economic growth, unlike Galbraith's, ignited a heated debate that went on for several years between him and Wilfred Beckerman, another well-established British economist. Beckerman wrote "Why We Need Economic Growth"[18] and *In Defence of Economic Growth*.[19] Later, Beckerman wrote *Small Is Stupid*[20] in response to Schumacher's widely read *Small Is Beautiful*,[21] Schumacher's critique of modern industrialized economies. Many of Schumacher's arguments about the optimal scale of an economy were anticipated, echoed, and augmented by other economists such as Kenneth Boulding in his seminal essay "The Economics of the Coming Spaceship Earth,"[22] N. Georgescu-Roegen,[23] who explored the implications of the second law of thermodynamics for economics and economic growth, and Herman Daly who has promoted a steady-state economy for more than three decades.[24] The publication of *The Limits to Growth*[25] in 1972 addressed similar themes using systems dynamics but was roundly and largely unfairly criticized especially by economists (e.g. Maddison,[1] pp. 90–94). It remains influential to this day. A useful summary of the state of the growth and no-growth debate, largely where it was left in the 1970s, can be found in Olson and Landsberg's collection of essays.[26] (For a contemporary assessment of the Limits to Growth debate see the review by Jackson and Webster.[27])

After this flurry of publications in the 1960s and 1970s, the growth debate subsided. In the late 1990s, the criticisms of growth resurfaced stronger than ever with economists such as Douthwaite, *The Growth Illusion*,[28] Daly, *Beyond Growth: The Economics of Sustainable Development*,[29] and Booth, *The Environmental Consequences of Growth: Steady-State Economics*[30] leading the charge. By this time, the transdisciplinary, ecological economics was almost 20 years old, with a dedicated peer-reviewed journal, *Ecological Economics*, publishing 12 times a year including many papers dealing with problematic aspects of economic growth. In the first part of the 21st century, it is impossible to keep up with the many papers, reports, blogs, conferences, media entries, and YouTube videos questioning economic growth. And there are many books such as Hamilton, *Growth Fetish*,[31] Booth, *Hooked on Growth*,[32] Victor, *Managing without Growth*,[33] Speth, *The Bridge at the End of the World*,[34] Brown, *Right Relationship*,[35] Jackson, *Prosperity without Growth*,[36] Schor, *Plenitude*,[37] Dietz and O'Neill,[38] *Enough Is Enough*, Czech, *Supply Shock*,[39] and von Weizsäcker and Wijkman, *Come On!*[40] just to name a few in the English language alone.

The remainder of this chapter describes an investigation into what might be possible in an economy in which economic growth ceases. In particular, the following question is addressed: is it possible to have low unemployment, reduced GHG emissions and other environmental pressures, reduced income inequality, and reduced hours of paid work while maintaining reasonable debt levels in the public and household sectors, all in the absence of economic growth? And, if so, what policy frameworks or initiatives would be required? LowGrow SFC, an interactive macroeconomic systems dynamics model, was developed for the Canadian economy specifically to help answer these questions. In the next section, LowGrow SFC is described in fairly general terms and three very different scenarios for Canada to the year 2067 are presented. Brief comments on policy directions suggested by the simulation of low/no growth are followed by a more detailed consideration of employment in a no-/low-growth economy and the implications for government finance and the provision of public services.

Exploring Low and No Growth in Canada with LowGrow SFC

LowGrow SFC is a quantitative model of the Canadian economy designed to explore future scenarios. LowGrow SFC has been calibrated using Canadian data with simulation results reported from 2017 to 2067. The scenarios are not predictions. Rather, they are offered as consistent and plausible future possibilities intended to feed discussions about current choices and alternative futures. The model integrates three primary spheres of interest within a system dynamics framework: (1) the environmental and resource constraints on economic activity; (2) a full account of production, consumption, employment, and public finances in the "real economy" at the level of the nation state; and (3) a comprehensive account of the financial economy, including the main interactions between financial agents. LowGrow SFC conforms quite closely to standard economic frameworks. Data are drawn directly from the Canadian national accounts and some of the behavioral relationships in the model are estimated econometrically on the basis of time-series data from the Canadian economy. At the same time, LowGrow SFC departs from more conventional economic modeling approaches by incorporating time-lags, feedbacks and expectations in the model, and also by allowing for some potentially radical variations on "typical" macroeconomic policy.

The theoretical basis for LowGrow SFC draws heavily on the post-Keynesian macroeconomic approach of Godley and Lavoie (2012), which places a particular emphasis on a full and consistent account of the relationships between monetary stocks and flows within and between different financial sectors. In the aftermath of the 2008 financial crisis, so-called stock-flow consistent (SFC) modeling has gained a particular traction because of its ability to provide a comprehensive account of financial transactions in the economy and to map the impact of these on financial balance sheets—something that was conspicuously missing in the run-up to the crisis. LowGrow SFC is articulated in terms of six interrelated sectors: households, firms, banks, government, a central bank and the "rest of the world" (or "foreign" sector). It models a range of financial assets and liabilities including deposits, loans, mortgages, government bonds, and firms' equities.

In LowGrow SFC, as in the economy that it represents, economic growth is driven primarily by net investment which increases the capital stock and hence labor productivity, combined with growth in the labor force. The extent to which the full productive capacity of the economy is employed depends on aggregate demand comprising expenditures by the private and public sectors on consumption and investment, and international trade. LowGrow SFC incorporates numerous features related to the overall environmental performance of the economy. For instance, a key focus of the model is on climate change and GHG emissions. LowGrow SFC includes a sub-model of the electricity sector. This is useful for assessing the economic and environmental effects of a transition to renewable sources of electricity and the widespread electrification of the economy.

One of the most important elements in the model relates to investments undertaken to reduce environmental impact. Key to a future in which economies reduce the burden they place on the biosphere is a shift from "brown" investment in activities that increases environmental impacts to "green" investment in activities that reduces them. Some green investments such as cost-competitive, energy-efficient equipment can add to the productive capacity of the economy. Other green investments such as seawalls built to protect coastlines from rising sea levels, protect productive capital but do not add to it, reducing the rate of economic growth. A further consideration that is important for determining macroeconomic outcomes is whether green investment is "additional" or "non-additional." Additional green investment increases total investment expenditures whereas "non-additional" green investment simply displaces brown investment without adding to total investment. Only additional green investment increases GDP.

LowGrow SFC generates the values of many variables relevant to an assessment of the performance of the economy. Seven of these are incorporated in a Sustainable Prosperity Index (SPI) for evaluating the scenarios:

- GDP per capita (more relevant to well-being than GDP).
- The rate of unemployment.
- The ratio of government debt to GDP.
- The ratio of household debt to household net worth.
- The Gini coefficient on household incomes (a measure of inequality).

- The average hours of paid work.
- The Environmental Burden Index (EBI).

The EBI is designed to capture the environmental impacts of economic activity notably absent from GDP. While comprehensive in scope, the EBI lacks specificity other than with respect to GHG emissions. Both the SPI and EBI are preliminary and could be improved with better data. However, they share with GDP the redeeming feature that they emerge from a model of the system in whose performance we are interested and so can be used to measure the effect of measures designed to make the system work better.

Scenarios for the Canadian Economy

Former British Prime Minister, Margaret Thatcher, insisted that "there is no alternative" to the market economy and economic growth. She was mistaken. There are in fact many alternatives. We describe three scenarios for the Canadian economy. None of them is a prediction of the future. Rather they are intended to illustrate some of the possibilities facing Canada, to inform discussion and debate, and to suggest the kinds of choices available, not just in Canada but in other advanced economies. The three scenarios are summarized in Table 1.

The Base Case scenario is a benchmark against which other scenarios can be compared. It is a description of what would happen, broadly speaking, at the national level, if current trends continue through and beyond mid-century. The GHG Reduction scenario includes several measures specifically to reduce GHG emissions: a price on GHG emissions from the electric power sector rising from $0 in 2017 to $300 per ton over 15 years, gradual electrification of road and rail, and substantial expenditures to reduce GHG emissions from other sources. In addition to these GHG reducing measures, the Sustainable Prosperity scenario includes more green investment aimed at reducing a wider set of environmental impacts, transfer payments rising to $20 billion per year to reduce inequality and poverty, a shorter work year and a slower rate of population growth.

Figure 1 shows GDP per capita for the three scenarios. Under the Base Case, per capita GDP increases from $50,000 in 2017 to $97,000 in 2067, with an average growth rate of 1.3%. (Unless otherwise stated, values are in 2007$.) This is essentially a conventional, growth-based view of the future, in which the economy as a whole (taking into account population growth of around 44%) increases 2.8 times by the year 2067. The GHG Reduction scenario has a somewhat lower average growth rate in GDP per capita of 1.1%, with incomes in 2067 achieving a level of $87,000 per year. In this scenario, some of the green investment is "unproductive" in the sense that it does not add to the capital stock with which labor produces output. Hence, labor productivity is not as high as in the Base Case and so neither is GDP. The

TABLE 1 Three Scenarios for Canada 2017–2067

Scenario	Main Features
1. Base case	Scenario 1 • Continuation of current trends and relationships
2. GHG reduction	Scenario 1 plus: • Carbon price on GHG emissions from electricity generation • GHG abatement by non-electric industrial sources • Electrification of road and rail transport
3. Sustainable prosperity	Scenario 2 plus: • Switch from brown to green investment • Increased transfer payments to reduce income inequality and reduce poverty • Lower rate of population growth • Reduced average hours worked

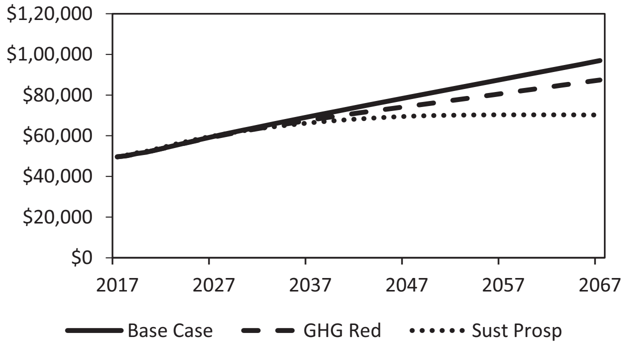

FIGURE 1 GDP per capita in the LowGrow SFC scenarios.

projected reduction in GDP growth is at the high end of the range of published estimates.[41] It also runs counter to the view that a green economy grows faster than a brown one.[42]

The most marked difference, however, is between the Base Case and the Sustainable Prosperity scenario. The latter illustrates a stabilization of per capita income at a level above current income levels. Specifically, the GDP per capita in 2067 is $70,000, an average annual increase of 0.7% over the period. More significantly, GDP and GDP per capita are essentially stable over the final 20 years of the scenario because of the stabilization of population. This scenario thus illustrates a transition from a growth-based economy to an economy managing without growth. The lower rate of economic growth and ultimately its cessation altogether result from the reduced investment in brown capital and the consequential lower increase in labor productivity combined with a reduction in average hours of paid work. Conventional wisdom suggests that such a transition toward what is effectively a steady-state economy is impossible without causing irreparable damage to prosperity and well-being in society. But Figure 2 suggests that this undesirable outcome can be avoided. In fact, the composite SPI described above rises significantly in the Sustainable Prosperity scenario despite falling in both the other two scenarios. Starting from a base of 100 in 2017, the SPI falls precipitously by more than 50% in the Base Case. Even in the GHG Reduction scenario, the SPI declines 10%. In the Sustainable Prosperity scenario, by contrast, the SPI increases 35% from 2017 to 2067.

To understand these differences, all of the components of the SPI must be considered. One of these is GDP per capita, which tends to push the SPI upwards, the higher the level of GDP. Principal among the factors that favor the Sustainable Prosperity scenario over the Base Case is the EBI, which includes the negative impact of GHG emissions and other environmental pressures which are significantly reduced in the Sustainable Prosperity scenario. The EBI for the Base Case more than triples over

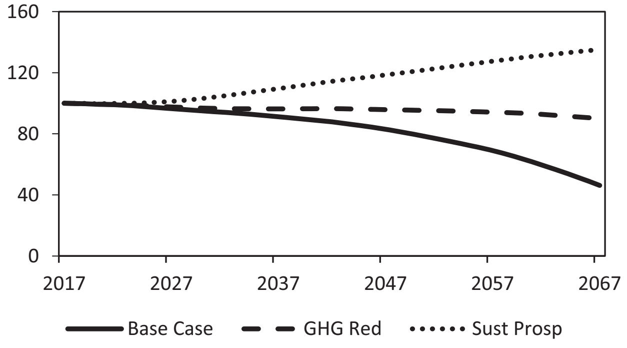

FIGURE 2 SPI in the LowGrow SFC scenarios.

the period of the scenario, as GHGs continue to rise and little is done to offset other environmental impacts from the economy. The EBI for the GHG Reduction scenario performs significantly better. The main reason for this is a significant decline in GHG emissions, which suppresses the rise in the EBI and in doing so has a notably positive effect on the SPI as compared with the Base Case. However, because of the continued expansion of economic output in the GHG Reduction scenario, the reduction in GHG emissions while substantial falls far short of the Canadian government's target of 80% reduction by 2050 from 2005 levels. By comparison, the Sustainable Prosperity scenario more than meets this target. Some of the decline in the EBI, in particular for the Sustainable Prosperity scenario, is also due to the deliberate policy of shifting the electricity sector toward renewable energy sources induced by the carbon price on GHG emissions. The rest of the decline comes from the lower level of economic activity in this scenario.

Two specific social measures adopted in the Sustainable Prosperity scenario also contribute to the improved performance of this latter case over the other two scenarios. The first of these is the redistributive fiscal policy in which transfer payments are progressively increased from 2020 and distributed preferentially to the lower-income categories. Also in the Sustainable Prosperity scenario, annual average hours of paid work decline from more than 1,700 h/yr in 2017 to less than 1,400 h/yr in 2067. Fewer hours working offers more opportunities for people to enjoy time with their families and friends, perhaps volunteering in the community or taking advantage of increased leisure, all of which contribute to people's well-being and quality of life and help increase the SPI.

LowGrow SFC keeps track of the financial flows among sectors as well as sector balance sheets. From this information, two measures of financial prudence included in the SPI are generated by the model: government debt and household loans to value (i.e., net worth). In the Base Case and GHG Reduction scenarios, government debt to GDP increases slightly but more so in the Sustainable Prosperity scenario where it rises from 55% to 70% by the end of the run. This has a negative impact on the SPI. Nonetheless, even at the end of the run, the debt-to-GDP ratio remains at a level that has been far surpassed by many countries without the collapse of their economies reaching 250% in Japan in 2016.

With government running a deficit, it follows from the SFC of the model and the financial behaviors of the other sectors that the overall net lending position of the household sector is positive in all three scenarios, leading to a healthy position in terms of household net worth. There are minor increases in the ratio of household loans to net worth in all three scenarios, with the smallest being in the SP scenario.

In summary, the results discussed in this section suggest that the Sustainable Prosperity scenario remains a realistic alternative to the conventional wisdom of continual exponential growth, outperforming the Base Case in several important ways over the next half a century. Even the financial indicators of a low-growth economy can, under the right conditions, remain relatively sustainable. Investment portfolios change, productivity growth declines, consumption expenditures stabilize, but the economy is nonetheless still financially resilient, its social outcomes improve, and its environmental burden on the planet is dramatically reduced.

Recognizing that the results described here are exploratory, it is fair to conclude that they support the following three conclusions:

1. The pursuit of economic growth at the expense of a deepening environmental crisis has a very high probability of catastrophe.
2. Substantial reductions in GHG emissions can clearly be achieved without massive changes to the structure of society. But the impact on the rate of growth, while modest, is larger than others have suggested and at odds with those who see a "green" economy as growing faster than a "brown" one. Furthermore, this "green growth" scenario falls well short of the Government of Canada's GHG target reduction of 80% by 2050.
3. Sustainable prosperity is attainable, but it will require a major reorientation of society's priorities toward improvements in social equity, economic security, and environmental quality. These changes may well lead to low- or no-growth economy, but they will also deliver a better quality

of life. The result may not be entirely incompatible with capitalism, but it will look very different from the over-financialized consumer capitalism of the early 21st century and may well be worthy of a different name altogether.

Policy Directions for a Low-/No-Growth Economy

The achievement of sustainable prosperity will require some very significant changes in the economy and in society at large. Policy and policy-related measures that drive the Sustainable Prosperity scenario include the following:

- *Investment*: a shift from brown to green investment and from private to public goods through changes in taxation and expenditures.
- *Labor force*: stabilization through changing age structure of the population and population stabilization.
- *Population*: stabilization through a declining fertility rate and changes to immigration policy.
- *Poverty and inequality*: trickle down replaced with focused antipoverty programs that address the social determinants of illness and provide more direct income support.
- *Technological change*: slower, more discriminating, preventative rather than end-of pipe, through technology assessment and changes in the education of scientists and engineers.
- *Government expenditures*: a declining rate of increase until stabilization is reached.
- *Trade*: a neutral net trade balance and diversification of markets.
- *Workweek*: shorter, more leisure through changes in compensation, work organization and standard working hours, and active market labor policies.
- *Environment and energy*: a comprehensive environmental program of pricing, regulation, green investment, land use planning, and education to achieve a rapid transition from fossil fuels to renewable sources of energy, significant reductions in material and energy throughput, and a reversal of habitat destruction conversion.
- *Consumption and lifestyles*: more public goods and fewer positional (status) goods through changes in taxation and marketing.
- *Localization*: fiscal and trade policies to strengthen local economies.

The next two sections look more closely at two specific policy areas in relation to the low/no-growth scenario: strategies for full employment and funding government programs.

Economic Growth and Employment

In 1960, the UN World Economic Survey stated that “the reinterpretation of the objective of full employment under the United Nations Charter to embrace the goal of economic growth marks a second fundamental change in public policy thinking.”[43] This statement from the UN is based on the insight derived from the early work on economic growth by Harrod, Domar, and others that if aggregate expenditure required for full employment in the short run expands the productive capacity of the economy, further increases in aggregate expenditure will be required in the future if full employment is to be maintained. This relationship between growth and employment is accentuated if the size of the labor force is increasing as well.

Equation 1 expresses the relationship between GDP, productivity, the labor force, and unemployment:

$$\text{GDP} = P(1-u)L \tag{1}$$

where GDP is the real gross domestic product, P is the productivity (real GDP per employed person), L is the labor force (employed plus unemployed persons), and u is the unemployment rate (unemployed/labor force).

Between 1971 and 2016, Canadian real GDP grew 234%, productivity increased by 50%, the labor force rose by 125%, and the unemployment rate increased from 6.2% to 7.1%. While the increase in GDP had a positive impact on employment (and vice versa), it was more than offset by the increase in productivity (P). The net effect was an increase in the rate of unemployment (u).

This is a classic dilemma. A growing economy stimulates employment, an increase in productivity reduces it. How can the advantages of increased productivity be realized in an economy that is not growing without causing high unemployment? One way is to reap the benefits of increased productivity as more leisure rather than more goods and services. This can be accomplished by reducing the average number of hours worked by an employed person so that unemployment for a few becomes more leisure for the many. If more people worked fewer hours, it should be possible to have high levels of employment without relying on economic growth.

Some counterfactuals from the past show how this could work. From 1971 to 2016, the average hours worked per year by a Canadian employee decreased by 10.9%. If the decrease in average hours worked had been 13.8%, the rate of unemployment would have been 4% not 7.1% in 2016 given the same increases in GDP and the labor force. At an average of 1647 hours of work per employed Canadian, employees in Canada would still have been working about the same number of hours per year as the average employee in Sweden and the United Kingdom and more than the average employee in seven other OECD countries, in some cases substantially more. Had there been no decrease in the average hours worked between 1971 and 2016, the rate of unemployment would have been 17.3% not 7.1% for the same increases in GDP, productivity, and the labor force.

These calculations show that the average length of the work year, which includes vacation days, can have a marked impact on the rate of unemployment. By spreading the same amount of work among a larger number of employees, the unemployment rate can be lowered and the relationship, as shown by the above examples, is strong. For this reason, researchers have examined the potential for reductions in the average number of hours worked per employee to contribute to full employment. From the standpoint of managing without growth, the benefits of increased productivity would be experienced as increases in leisure and reduced impacts on the environment rather than as increases in output, consumption, and environmental impacts.

A shorter average work year is one of the factors included in the Sustainable Prosperity scenario illustrated in Figures 1 and 2. Over the 50 years of the scenario, the work year declines by 28% to 1400 in 2067. This compares with levels already approached or surpassed in 2015 in Belgium (1427), the Netherlands (1420), Norway (1408), and Germany (1370). In general, European countries have been more proactive than Canada and the United States in reducing the working time as an instrument of employment policy. During the 2008/2009 recession, some countries, Germany for example, mitigated the impact on employment by relying more heavily on reductions in work time.

The arithmetic of reducing the rate of unemployment by reducing the average hours each employed person works is compelling. Achieving such gains in employment in the real world is another matter, but in a review of studies of the employment effects of working time reductions, Bosch finds that most show a gain of “25–70 percent of the arithmetically possible effect.”[44] Bosch has examined the European experience, and the six conditions he identified as particularly important for the success or failure of this policy are summarized in Table 1. He points out that the general political conditions must be suitable for a policy of reducing work time to reduce unemployment. There must be acceptance from employees, trade unions, and employers and support of the State.

Looking at working time policy in the future, Bosch concludes that “shorter working hours are an indicator of prosperity.”[44] They have been in the past, though more recently we have seen the emergence of a sector of the labor force that is “overemployed,” working long hours and “failing to achieve a desired balance in their lives between paid work, family life, personal, and civic time.”[45] These are usually men with higher levels of education in management positions. Simultaneously, there are people who are underemployed and poorly paid, more often than not women. These circumstances contribute to and accentuate rising income inequality.

TABLE 2 Policies for Reducing the Workweek

1. Wage compensation—"If working time reductions and pay increases are negotiated as a total package, then the compensatory increase for the working time reduction can be offset by lower pay rises." This could become more difficult with no or low growth.
2. Changes in work organization—"Larger reductions in working time generally have to be accompanied by changes in work organization"; otherwise, firms will rely on overtime and the employment effects will not materialize.
3. Shortages of skilled labor—"An active training policy is an indispensable supplement to working-time policy" to ensure that there are people with the necessary skills to pick up the slack when skilled workers reduce their hours.
4. Fixed cost per employee—Such as benefits paid on a per-employee basis rather than an hourly basis are an obstacle to reducing working hours because it is costly to employers. Canada shares with most Western European countries the practice of financing statutory social programs through contributions that are usually a proportion of earnings or through taxation, minimizing this fixed cost problem.
5. The evolution of earnings—"The decreasing rate of real wage rises in most industrialized countries has reduced the scope for implementing cuts in working time and wage increases simultaneously." This would be a serious obstacle unless there is widespread support for seeking prosperity without growth though it can be mitigated by a more equal distribution of income. "One fundamental precondition for the working time policy pursued in Germany and Denmark, for example, was a stable and relatively equal earning distribution".
6. The standardization of working hours—Any reduction in standard working hours must strongly influence actual hours worked. If it merely generates more overtime for those already with jobs, it will fail to increase employment. Work reorganization will be required to allow more flexibility in hours worked.

Source: Summarized from Bosch.[44]

Layard in his work on economics and happiness concludes "that people over-estimate the extra happiness they will get from extra possessions" because of habituation. "The required correction is towards lower work effort and thus lower consumption."[46] This means that a shorter work year would not only contribute to reducing unemployment but may also increase the general level of happiness for employees who find themselves better off working fewer hours, for less income and consuming at lower levels.

Funding Public Services in a Low-/No-Growth Economy

Economic growth provides government with increasing resources without increasing tax rates. In times of rapid growth, receipts from corporation profits taxes, personal income taxes, and value-added taxes tend to increase faster than the economy as a whole, allowing governments to provide more services, invest more in infrastructure, redeem outstanding debt, reduce tax rates, or some combination of all these. Governments welcome these circumstances. They have as much to gain from economic growth as anyone. How might this be different in an economy that eschewed economic growth as a policy objective?

Insight into this matter can be gained by considering in some detail the Sustainable Prosperity scenario in which economic growth slows and eventually ceases. In particular, we look at the projected ratio of government debt to GDP, the government's net lending position, and government expenditure in total and per capita. We have already seen that in this scenario, the ratio of government debt to GDP rises from 55% to 75% over the 50-year simulation, which though not necessarily desirable, is well within the bounds of viability based on the experience of other countries and in Canada as well. It is interesting to note here that modern money theorists advise against the use of the debt-to-GDP measure as an indicator of long-run resilience, on the grounds that in countries with sovereign monetary systems such as Canada, the United Kingdom, and the United States, the state does not have a budget constraint comparable to that of a household.[45] The argument is that government can always pay debts denominated in their own currency. In the Sustainable Prosperity scenario, government borrowing continues while GDP stabilizes leading to a rise in the debt-to-GDP ratio. Another reason for thinking that this is unlikely to be a significant problem is that government borrowing is projected to decline, approaching zero by the end of the simulation. This evolution of the government's net lending position coincides, as it must under SFC, with a decline in lending by the other sectors of the economy.

Government expenditures on consumption and investment are assumed in the model to be constant proportions of GDP, modified by countercyclical expenditures to moderate increases in unemployment above a target rate. These expenditures represent the utilization by government of the output of the economy. In the Sustainable Prosperity scenario, the sum of these government expenditures increases gradually from 25% in 2017 to 29% by 2040, remaining at that level as GDP stabilizes. As well as these expenditures, government supplements those with low incomes and supports selected business activities. These "transfer" payments affect the incomes of non-government sectors to pay for expenditures, which are included in GDP in household consumption and private sector investment. It would be double-counting to also include them in government expenditure in the calculation of GDP. However, they are included in the calculation of government net lending.

In the Sustainable Prosperity scenario, government expenditure per capita stabilizes about 70% higher than in 2017 in real, inflation-adjusted terms. This substantial increase should allay any concern of insufficient government funding for services in the absence of economic growth.

Conclusion

There are many reasons for considering how rich economies might manage without growth: growth rates are slowing down, biophysical constraints to continued growth are becoming more apparent, mounting evidence indicates that higher incomes do not make people happier beyond a level of per capita incomes far surpassed in rich countries, economic inequality continues to rise, and despite decades of substantial economic growth many social and environmental problems remain. It is past time to set aside contributions to economic growth as a criterion for assessing measures to improve well-being for humans and other species over the long term and to replace it with the pursuit of sustainable prosperity in all its various dimensions.

Food–Energy–Water Nexus

Nemi Vora

Introduction

The United Nations established 17 distinct goals (referred to as the sustainable development goals or SDGs) for the 2030 agenda for global sustainable development ranging from climate action to economic growth. It has been noted that the agenda can only be achieved successfully if their interconnections are recognized and incorporated into planning (Nilsson, Griggs, and Visbeck 2016). For instance, SDG 2 outlines ending hunger, providing nutrition, achieving food security, and promoting sustainable agriculture. It is closely related to SDG 14 of life below water and SDG 15 of life on land, which in turn requires planning for quality and quantity supply of water (SDG 6), renewable, affordable energy (SDG 7), and sustainable consumption and production (SDG 12). The concept of interconnections between Food–Energy–Water (referred to as the FEW nexus) is one such piece to a much larger puzzle of managing for the SDGs. Recently, international and national funding calls on the FEW nexus (National Science Foundation, National Science Foundation (U.S.–China), European Commission 2015) have mobilized research around the topic. These organizations recognize the challenges and benefits of managing the FEW nexus, as individual management has often resulted in unintended consequences.

The connections between food, energy, and water resources are apparent in daily lives, although numerous examples exist of policies focusing on managing one resource but resulting in straining the others deeply connected with them. One such an example is the well-intended, but damaging irrigation policies in Gujarat two decades ago. Gujarat, a relatively arid state in western India, saw a rise in agriculture productivity through investments in irrigation infrastructure, land reforms, and advances in seed technology since the 1980s (Mathur and Kashyap 2000). Due to erratic precipitation patterns, groundwater irrigation became central to the success of Gujarat's farmers. The government supported groundwater use through a series of initiatives including access to cheap electricity for pumping water out (Narula et al. 2011). However, decades of excessive pumping coupled with low recharge levels resulted in severe groundwater depletion, posing a threat for the future of agriculture in the region. As the water levels declined, farmers pumped deeper, putting undue pressure on the power grid and the government for continuing to subsidize expensive electricity (Narula et al. 2011). Thus, managing electricity for promotion of agriculture without considering impacts on water use resulted in severe and long-lasting consequences. In 2012, a drought in eastern India resulted in farmers turning to groundwater for irrigation. Sudden excessive pumping and lack of water for power plants caused a massive grid failure. Comparable situations were reported during California's recent 7-year drought (Webber 2015). From an energy policy perspective, the promotion of biofuels from food and oilseed crops, and their effects on water, land, and biodiversity have been a center of debate and contention for a while (Searchinger et al. 2008). The context of these issues may be different, but they demonstrate the potential tradeoffs that may occur if resources are managed without regarding their connections.

The concept of the FEW nexus is not new; similar calls for integrated water resource management (IWRM; an approach to promote simultaneous development of water and associated resources for social and economic benefits) date back to 1962 (Lloyd 1963). Similarly, the integrated natural resource management concept was put forward to couple agrarian objectives with ecosystem services (Twomlow, Love, and Walker 2008). In 2011, Hoff et al. highlighted the concept of "nexus approach" to simultaneously target food, energy, and water security for the background paper at the Bonn Conference (Hoff 2011). With the FEW nexus, a clearly defined scope of focusing on three essential resources was put forth. In the scientific literature, many variations of the term FEW nexus exist with studies coining the terms Energy–Water–Food (EWF) nexus, Water–Energy–Food (WEF) nexus, Climate–Land–Energy–Water (CLEW nexus), etc.; however, the underlying message of the interlinkages remains the same.

Defining the Food–Energy–Water Nexus

There is no single agreed-upon definition of FEW nexus in the literature, apart from recognizing the FEW nexus as linkages. It often makes the scope of the work more complex as numerous connections exist between these three resources. For example, growing food requires water for agriculture and energy to employ machinery on farm and transport food. Global agriculture is the largest consumer of water amounting to 69% of total withdrawals, while food supply chain accounts for 30% of global energy consumption (Dubois 2011). Water is integral in generating energy from renewable and fossil resources alike: water is required in thermoelectric power plants, and for hydraulic fracturing to obtain natural gas. Renewable resources, such as hydropower, and biofuels production also heavily depend on water availability. Energy is

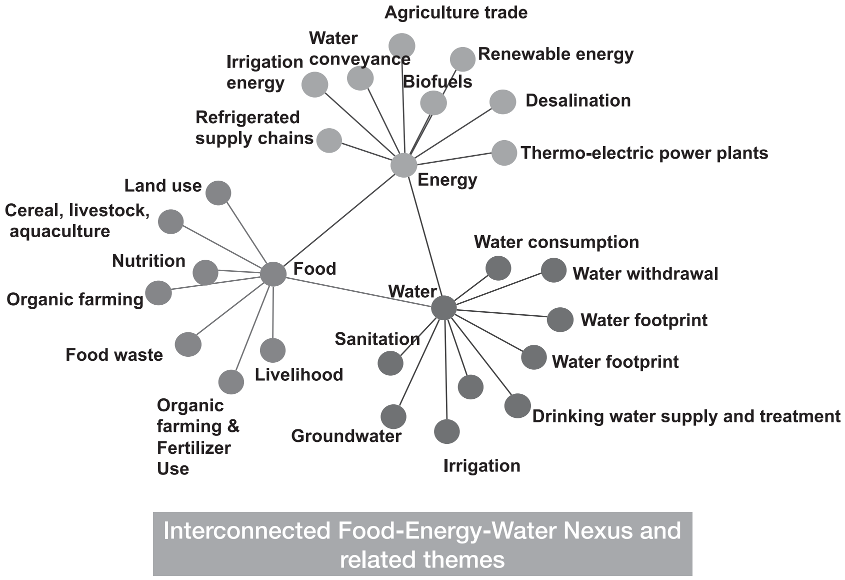

FIGURE 1 Common research and policy themes under the umbrella of Food–Energy–Water nexus.

required to withdraw, treat, and convey water for municipal, agriculture, and industrial use. Desalination, an important alternative for fresh water in water-stressed countries, is also highly energy intensive.

While still relevant to the nexus, some studies are often not included in the FEW nexus if they focus on less than three resources (i.e. food–water, energy–water), or if they go beyond the three to include climate, livelihoods, and biodiversity in their analysis. Additionally, the focus of FEW nexus studies is often on physical interactions and environmental concerns alone, while the crucial social component is overlooked. It has also been argued that calling a study "a nexus approach" does not increase its scientific merit, and therefore FEW nexus does not add anything new to the literature (Wichelns 2017). Here, I adopt the perspective that establishing universal criteria for inclusion in the FEW nexus is not as important as recognizing the existence of interconnections, both hidden and visible, between resources, and resources and the rest of the environment. Thus, managing one resource requires effort to identify and evaluate the influence on/of other resources.

Admittedly, merely recognizing the interconnections may not simplify their management, it does initiate a discourse. In the aforementioned case of Gujarat, the issue of expensive subsidies and groundwater depletion was tackled by separating and tightly rationing farm electricity supply from the rest of the rural areas, while providing superior quality supply on a pre-announced schedule. The "Jyotigram (electrified village)" scheme was instrumental in overhauling Gujarat's rural electrification while reducing groundwater overdraft and boosting non-farm rural economy (Shah et al. 2008). Using the irrigation–energy nexus to tackle not only energy-water tradeoffs but also to benefit rural economy has been touted a win–win scheme and is now being implemented across other Indian states.

The scientific community has largely agreed upon managing resources by recognizing their interconnections, and it has been widely acknowledged to adopt a systems perspective in tackling the complex issue (Bazilian et al. 2011, Liu et al. 2018). Systems analysis recognizes that real-world issues do not strictly arise from a linear chain of cause and effect but are rather a result of complex feedback loops between individual components. As such, it recognizes that a system is often greater than the sum of its parts. Thus, rather than focusing on individual components, systems analysis examines how each component interacts with other components and the external environment. The result of these multiple interactions, often unobservable by studying just one component, can be understood through a holistic perspective. In a more practical sense, this is done by employing a collection of models and assumptions from different disciplines to represent a simplified version of reality. This approach helps identify potential side effects and address the issue of considering biophysical and socio-economic interactions together. The following section briefly talks about already existing models and methods used in the FEW nexus context.

Quantitative Analysis of the FEW Nexus

Much has been written regarding the FEW nexus and models to quantify linkages (Bazilian et al. 2011, Newell, Goldstein, and Foster 2019). As the research under the wide umbrella of FEW nexus studies is highly interdisciplinary, a series of methods and their combinations have been used to model one or more FEW interactions. Studies have used methods such as life cycle assessment, network analysis, footprint approach, optimization, input–output analysis, computable general equilibrium models, and hydrological models to model FEW interactions. These methods are adopted from disparate disciplines including ecology, social science, probability and statistics, thermodynamics, and hydrology. In their review articles, Albrecht et al. and Newell et al. provide a detailed list enumerating the studies of various methods that have been used to tackle FEW challenges (Albrecht, Crootof, and Scott 2018, Newell, Goldstein, and Foster 2019). Therefore, instead of repeating such a list, a few examples are provided here that show the use of interdisciplinary methods to help answer specific FEW issues at different geographical scales.

Vora et al. used social network analysis combined with environmental life cycle assessment to assess energy and greenhouse gas emissions associated with irrigated food trade in the United States (Vora et al. 2017). Davis et al. developed an optimization framework using spatially explicit data and crop water use models to assess redistribution of crops at an international scale with the goal to reduce global water use, without compromising nutritional benefits or loss of crop diversity (Davis et al. 2017). Ramaswami et al. developed a framework around cities as emerging demand centers and quantified FEW nexus impacts associated with meeting current demand from cities (Ramaswami et al. 2017). Using regression models, Herrera-Estrada et al. assessed the effect of drought on air emissions from electricity sector with a focus on regions heavily relying on hydropower and thermoelectric power plants (Herrera-Estrada et al. 2018). Keskinen et al. utilized a combination of mathematical models pertaining to hydrology and climate to understand tradeoffs between new hydropower development and its effect on soil fertility and local agriculture in Mekong Basin (Keskinen et al. 2015). Not all of the studies cited here framed their work explicitly within the FEW nexus contexts, nevertheless their focus on inter-linkages makes them nexus studies. The key takeaway is that there is no singular method and discipline that can provide a comprehensive quantification of FEW linkages, but requires interdisciplinary approach spanning both natural and social systems.

While these studies piece together different methods to develop a FEW nexus frameworks, there are also already existing models that help quantify some of these linkages. Pollitt et al. provide a detailed assessment of large-scale models along with their drawbacks and advantages (Pollitt et al. 2010), and Bazilian et al. provide a brief list of sectoral and integrated models and methods specifically pertaining to the FEW nexus (Bazilian et al. 2011). Some of the notable and widely used models include Climate, Land-Use, Energy and Water Strategies (CLEW) by International Atomic Energy Agency (Howells et al. 2013), Global Agro Ecological Zones (GAEZ) by Food and Agriculture Organization (Fischer et al. 2012), and the Integrated Solutions for Water, Energy, and Land (ISWEL) project that links multiple open-source models such as MESSAGE for energy modeling and GLOBIOM for land-use modeling (Willaarts et al. 2018).

Method and Model Selection

As there is no dearth of different methods and models that can be used for FEW nexus modeling, selecting an appropriate one depends on several factors: (1) scope and objective of the work, (2) availability and quality of data, (3) appropriate spatial scale, and (4) usefulness of analyzing long-, medium- and short-term temporal trends. Table 1 lists each factor and relevant questions for choosing appropriate models and methods.

TABLE 1 Decision Factors Influencing Model and Method Selection for the FEW Nexus

Scope	• Goal of the study (e.g. new policy formulation, infrastructure decisions, disaster preparedness) • Already known information about resource linkages (e.g. groundwater levels affecting irrigation, fossil heavy grid) • Defining system boundary of the work (e.g. production-based impacts vs. consumption impacts, inclusion/exclusion of other resource connections)
Data	• Availability of open data and time/money budget if none available (i.e. budget for purchasing data or gathering yourself) • Sensitivity of the chosen method to the size of data (e.g. certain methods may only work for larger datasets) • Quality of the datasets and quantification of uncertainty (precision of data collection methods, survey methodologies used, representativeness of data) • Appropriate assumptions and relying on substitutable data to fill data gaps (e.g. using national averages when local not available) • Age of the data (are 10-year old datasets appropriate to represent the current situation)?
Spatial and temporal scales	• Spatial scale of the study (local, metropolitan, state/province, basin level) • Integrating multiple datasets and models available for different spatial scale (e.g. hydrology models developed at basin scale vs. energy models for specific electricity markets and grids) • Available data reconciliation methods and their complexity (e.g. downscaling aggregate global data to local through cross-entropy, spatial estimation) • Relevance of long-term impacts on study results (e.g. climate-induced change on water availability, increase in crop yields) • Usefulness of incorporating historical trends

Scope

Although FEW nexus is circular, there is generally a particular resource of interest that is established (e.g. reservoir water management for agriculture, municipal, and energy supply) and subsequent linkages are then assessed. If there are previous assessments and known information about historical connections between resources, it should be incorporated in the study. For example, decision on upgrading irrigation technologies should consider impact on groundwater levels. Additionally, depending on the work, it should be determined whether the study should be limited to FEW nexus linkages alone or FEW nexus-everything studies that consider economy-wide impacts as well (Lant et al. 2018). This relates to setting a system boundary to contain the complexity of the system. A system boundary delineates impacts and resources to be considered, and those that will be out of the scope for the work. However, system boundary should be selected carefully as to not leave out relevant and important impacts. This can be done based on expert judgment, literature review of similar case studies, and use of screening tools such as economic input–output life cycle assessment (Hendrickson et al. 1998).

In the FEW nexus discourses, choosing a systems boundary is particularly important due to the connectedness of the products and services through global supply chains. Global trade and goods exchange are driven by competitive advantage and endowment of resources between regions, domestic and international policies and agreement, and politics. Depending on the production practices and environmental regulations in the production region, trade can alleviate or increase environmental impacts associated with consumption (Dalin and Rodríguez-Iturbe 2016). Studies have shown that domestic policies promoting human and environmental health have driven production out of the country causing environmental damages elsewhere (Nesme et al. 2016, Plevin et al. 2010). Therefore, careful consideration needs to be made to assess whether distant impacts should be incorporated as to not under/overestimate the resource use and impacts. FEW nexus studies have used the concept of embodied (virtual) resource/impacts trade to incorporate the role of global supply chains and connect distant locations (Kastner, Erb, and Haberl 2014, Konar et al. 2016). Here, the embodied trade refers to not the physical trade but indirect use of resources and resulting impacts from the production of specific goods and services in distant locations. Finally, the scope of the analysis may need to be adjusted depending on whether there are existing models that can be used to establish and quantify linkages or new models need to be built from scratch and required investment of time, effort, and interdisciplinary expertise.

Data

Freely available quality data are a necessity for carrying out insightful quantitative analysis and modeling. Numerous international agencies (UN Statistics division, International Energy Agency, Food and Agriculture Organization, World Resource Institute, etc.) and country-specific agencies (US Department of Agriculture, US Geological Survey, Government of India Planning Commission, Statistics Canada, etc.) collect and host data (see Data.Gov, data.gov, data.europa.eu, data.un.org for a single point of access to disparate databases) pertaining to food supply, agriculture, energy use, trade, water withdrawal statistics. Data collection is a time-consuming and money-intensive process, and therefore necessary data may not be available for a specific year, a time period, or a specific location. To this end, appropriate assumptions and substitutions may need to be made to fill in data gaps. These assumptions can be made with the help of scientific principles such as mass–energy balance, engineering equations, or based on peer-reviewed literature. A common method for data substitutions is based on similarity, be it geographical or technological: for example, substituting lack of data for one developed country with another developed country with similar gross domestic product (GDP).

However, many of the datasets are usually limited at country level and/or by time scale. Therefore, success of any integrated management approach hinges on data being available at an appropriate spatial scale and for a longer time frame. Therefore, new data collection and compilation techniques are needed to analyze systems at specific scales with recent/current data and for impoverished countries that may not be able to spend money on census surveys. Currently, the research work is driven toward bypassing traditional government surveys and using novel techniques such as satellite imagery, remote sensing, and cellphone data to gain important insights on living conditions (Azzari, Jain, and Lobell 2017, Blumenstock, Cadamuro, and On 2015). Although, more work is needed before such methods can replace the need for traditional surveys. Finally, methods such as sensitivity analysis and uncertainty quantification should be used to help convey quality of the data. Sensitivity analysis is useful in understanding which parameters affect the results the most and indicates where data collection improvements can be made. Uncertainty quantification helps in conveying variability and reliability of the results. Due to limited scope, these concepts are mentioned here in brief. However, the open-source life cycle assessment textbook from Matthews et al. is a good source for introductory material on conducting both types of analysis (Matthews, Hendrickson, and Matthews 2015).

Spatial and Temporal Scales

As shown with aforementioned examples of quantitative studies, the spatial scale for FEW analyses has varied from local to international. However, the appropriate scale in which these systems should be analyzed for effective policymaking and decisions is still ambiguous. While local challenges of drought and crop failure remain, the global supply chains have extended the system boundary and made it more fragile as distant events can cause cascading failures. Marston et al. noted in their analysis that depletion of major ground water aquifers in the United States would not only impact domestic food consumption but also affect distant countries such as Japan relying on food exports from these regions (Marston et al. 2015). Boundaries for water management can also be unclear as interconnectivity between water basins can go beyond political boundaries. There are numerous examples of water conflicts within a country such as water wars in the Western United States between different states (Tory 2018) and international issues such as the Brahmaputra river basin spanning China, India, Bangladesh, and Bhutan (Yang et al. 2016). The interconnectedness of economic and political tensions and extreme weather events to energy supply has been evident in numerous examples of energy crisis across the world (Hamilton 2011). Thus, the connections between places are not only based on political or physical boundaries but also through common pool of resources, infrastructure, and social systems. To integrate this complexity in analysis will require redefining how distant FEW systems are connected as regulations may stop at political boundaries, but the actual environmental impact may be larger beyond the traditional perceived boundaries. Recently, Lant et al. (2019) discussed the need of "mesoscale" analysis to capture differences that cannot be captured by analysis at two extremes of local scale vs. international scale (Lant et al. 2019). Based on the chosen temporal aspect (long term vs. short term), climate narratives provided by the shared socio-economic pathway projections and national climate assessments can be incorporated.

There is also ambiguity regarding the best approach to analyze such complex interactions: specifically pertaining to a bottom-up approach that builds up from a smaller system or a top-down approach that looks at interactions between different sectors and economy. We need integration of both approaches (top-down, bottom-up) and multiple spatial and temporal scales as decisions are made at various levels from household and local community level actions to national and international policies and agreement. As one size does not fit all, analyzing such complex systems will require both multi-sector and multilevel actions.

The Criticism and Cautions for the Food–Energy–Water Nexus

A few have criticized the overuse of the word FEW nexus indicating that while it is undisputable that these resources are interconnected, the phrase is ambiguous in terms of prescribing a framework in tackling these issues (Cairns and Krzywoszynska 2016, Wichelns 2017). The critics point out that by setting such arbitrary bounds on only looking at three resources, the FEW nexus misses the opportunity to consider other factors such as human health, livelihood, and farm chemicals. However, as mentioned earlier, the study of FEW nexus should be looked at in the much larger context of assessing connections between SDGs. While FEW nexus has indeed become a buzzword (Cairns and Krzywoszynska 2016), the interest garnered can be successful in raising awareness at both policy and stakeholder levels. Additionally, having a general umbrella under which such case studies, policies, and research can be compiled provides a huge opportunity to mobilize large-scale funding, exchange knowledge, and support interdisciplinary and interagency collaboration.

An important consideration that nexus proponents should keep in mind is that when managing for tradeoffs, one interest lobby may be stronger than the others and argue for their interest over an optimal solution (Jensen 2013). Furthermore, the economic cost, time, and expertise required for an integrated approach will be much higher than traditional silos approach and would involve substantial work toward capacity building, making the decision process lengthy (Liu et al. 2018). Additionally, an integrated approach may not be the panacea as considering too many factors at once may make a system unsolvable or at best provide a solution that may not be agreeable to all.

Conclusion

It is important to note that beyond the three resources, the usefulness of the concept lies in the term "nexus thinking." A nexus approach involves addressing the interlinkages and feedback between different systems, so synergies are promoted and tradeoffs minimized. However, in some instances, even a FEW nexus approach may not provide optimal outcomes and overlook unintended consequences on interdependent systems such as human livelihood or biodiversity. Therefore, a context-specific analysis that prioritizes local stakeholders' benefits should be adopted in policymaking with an overarching goal of achieving the sustainable development agenda. Going forward, the FEW nexus literature should explicitly recognize that there is no one suitable method, model, or spatial/temporal scales to conduct such complex analysis. But interdisciplinary multi-scale effort is needed to understand the issues in entirety. Good quality open data is at heart of such analysis and future work and studies should focus on novel data collection and data treatment approaches that take care of bridging the spatial and temporal resolution gaps, conducting hybrid analysis that incorporate both top-down and bottom-up approaches, and adopt/develop methods that provide a robust statistical framework for empirical data analysis.

Despite its drawbacks, FEW nexus has been successful in mobilizing the scientific and policy community to go beyond the "silos thinking" approach and recognize the need for interdisciplinary work. By incorporating three large policy and scientific communities of agriculture, hydrology, and energy analysis, FEW nexus has also merged expertise within these communities, with studies formulating novel frameworks and techniques to overcome issues of data availability, spatial and temporal scope, and model integration. FEW nexus has also drawn the scientific communities' attention back to SDG interlinkages and driven the policy community to engage in quantitative prospective analysis before making large-scale decisions. The penetration of FEW nexus in humanities has also incorporated more dialogue through stakeholder engagement. Finally, the primary takeaway lesson from the FEW nexus for environmental management is to adopt holistic approach and recognize that there may be hidden or visible links connected to the system being managed, and therefore, these links need to be identified and incorporated in the management plan.

Geographic Information System (GIS): Land Use Planning

Egide Nizeyimana
and Jacob Opadeyi

Introduction

Agricultural scientists are required to provide information needed to address land degradation and land use conflicts confronting the world today. As the population increases and land becomes a commodity in many parts of the world, careful planning of the use of land must be undertaken to accommodate conflicting people's needs and preserve and/or protect the environment. The decision about the use of land must be made based on analyses of each potential use in terms of its economic and biophysical suitability to the specific tract of land and possible impact to environmental degradation.

Geographic information system (GIS) and related technologies (e.g., remote sensing, global position system) have proven to be a valuable tool in land use planning activities. The GIS approach is important in this area because it provides functions to capture, store, organize, and analyze spatially referenced data. Moreover, GIS has been coupled to a variety of models (e.g., crop productivity, hydrology, and water quality simulations) and may be an important component of spatial decision support systems (SDSS) and land resource information systems (LRIS). GIS enhances model flexibility and efficiency in these systems where it is often regarded as a centralized data analysis, management, and planning system. As a result, decision makers and land use planners in private companies, universities, and at various levels of the government are using GIS to develop spatial environmental databases, perform land evaluations, and analyze and manage resources. There is no doubt that the use of GIS and GIS-based systems in land use planning activities will continue to increase in the future, as more detailed digital environmental datasets become available and the capability of computers to handle large volumes of data increases.

GIS Use in Land Use Planning Activities

The goal of land use planning is to make decisions about the use of land and resources.[1] Its implementation is often driven by future people's needs in terms of productivity and environmental sustainability. Land use planning is important in highly populated communities primarily due to conflicts between competing uses and interests of users.[2] In this case, planning activities are tailored to make the optimal use of the limited land resources. In general, the land use planning involves sequentially an organization of thoughts and establishment of long-term goals, a land evaluation that includes appraising alternatives, and finally designing and implementing the plan. Land evaluation is the most important aspect of this process.

The information within a GIS consists of a spatial component represented by points (e.g., well locations), lines (e.g., streams, road networks), or polygons (e.g., soil delineations) and attribute data or information that describes characteristics of the spatial features. The spatial entity is referenced to a geographic coordinate system and is stored either in a vector or raster format.[3] GIS is primarily used in the development of spatial databases and land evaluation, a procedure in the land use planning process that is aimed at determining the suitability of land units to current and alternative uses and the potential impact of each on the environment.

Development of Spatial Databases

GIS stores, retrieves, and allows efficient manipulation of database information. It provides powerful analysis and relational database facilities to modify and/or integrate spatial data from different sources and resolutions as well as advanced visualization functions to display output data in the form of interpretative maps. In this case, land attributes and qualities are derived from geographic databases and used to determine land suitability, limitations, or ratings for various land use types. The analysis results may be presented in tabular or graphical form and are intended to provide key information necessary for land users or planners to make meaningful decisions about land management and conservation and/or land use planning.

Site Suitability Analyses

A site suitability analysis typically involves the assessment of the level of affinity a specific land has for a particular use. Soil information available in soil databases is rarely enough for site evaluations. In addition to soils, the analysis often integrates local information on landforms, current land uses, the relative location of the land, and associated social and political restrictions. The proposed use may have additional limitations that should be taken into account. For example, an analysis for suitable sites for land application of sewage sludge should consider the physical, chemical, and biological properties of the waste in soil and water.[4,5]

GIS is efficient in identifying and ranking sites for various land use planning activities. First, site-specific analyses often require many and detailed data sources. Second, GIS overlay features, logical operations, and display functions are tailored to speed up data processing and therefore allow efficiently suitability class assignment and graphical display of results. A good example is the use of GIS for locating appropriate sites for forestland application of sewage waste.[6] The authors derived physical site suitability ratings for an area in Vermont based on EPA guidelines[7] and merged them with social and political restrictions of the state and counties to derive a land applicability classification. Similar GIS-based approaches have been used to locate sites for solid waste disposals.[8]

Linking GIS and Models

The spatial databases and associated attribute data described above may be part of a GIS/model graphical user interface (GUI). These models may be those that determine land suitabilities or those that simulate water quality for environmental impact assessments. As an entity of GIS/model interface, GIS allows easy access to database attributes by various algorithms, statistical software, and environmental models for a variety of land use analyses. In addition to model parameterization, a full integration of GIS and models also allows the user to interact with various modules, select data input and module utilities, and display graphical and/or tabular representations of modeling results.[9] The use of this type of interface reduces significantly the processing time and resources required to develop input data and run the model. GIS/model linkage has been accomplished for field- and watershed-scale hydrology/water quality models such as the leaching and chemistry estimation (LEACHM)[10] and agricultural non-point source pollution (AGNPS)[11] models. Results of these analyses are used to support management and land use planning activities in the farm or watershed.

The GIS/model interface may also be part of an SDSS. In addition to modeling parameterization, SDSS offer the users with functions to evaluate different land use scenarios necessary for making management recommendations and/or land use planning decisions. Results may be used by farmers to adjust management practices of distinct fields in a given farm or may be used by field officers to help farmers set priorities while providing technical assistance for nutrient management planning. Figure 1 shows a flow diagram indicating data integration in a GIS with models for water quality assessment in watersheds.

GIS has been incorporated in many land evaluation systems so that planners and public officials can take advantage of its spatial modeling and visualization capabilities. An example of such a system is the USDA–NRCS land evaluation and site assessment (LESA).[12] The land evaluation portion of LESA determines soil productivity levels, farm size and agricultural sales volume; the site assessment portion deals with factors such as location, amount of nonagricultural land, zoning restrictions, etc.[13] GIS, in GIS-based LESA systems, is used in both modules and at all levels of the analysis.

Development of Land Resource Information Systems

A number of land information delivery systems have been developed in recent years to make spatial data available to users for application in various aspects of land use planning. These systems, also called LRIS, are multipurpose systems that integrate geographic databases and GIS tools to analyze, record, report, and display spatial data relationships. Some of these systems have been embedded into the World Wide Web (WWW) for quick and easy access and analysis via Internet browsers.

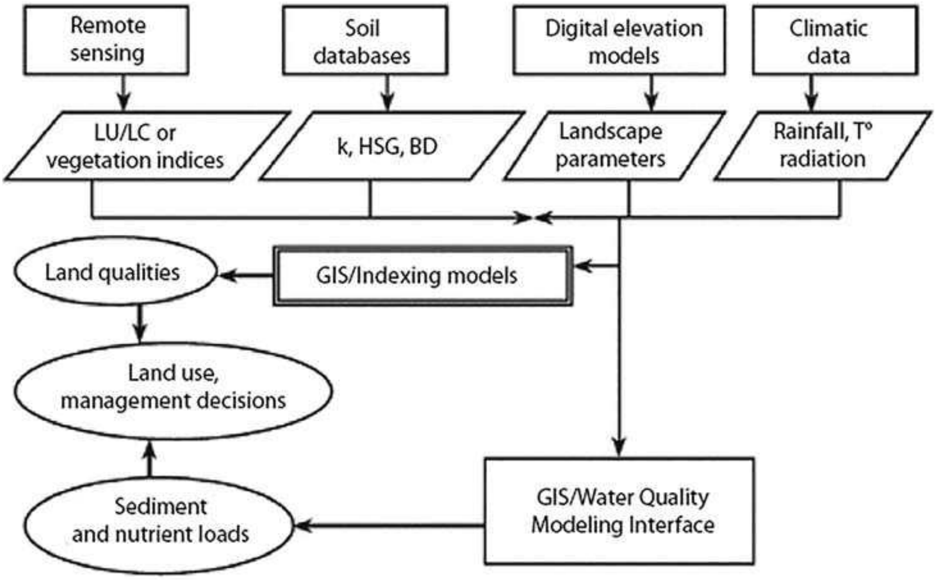

FIGURE 1 Integration of GIS, spatial database, and models.

Reliability of GIS-Based Analysis Results

GIS and GIS-based systems used in spatial data analyses for land use planning have grown in recent years. GIS is particularly attractive in these areas because it allows overlay of spatial data sets and the merging and analysis of attribute data from different sources. The resulting data are obtained using data from digital and paper maps of different scales or acquired at different resolutions such as in the case of digital elevation models (DEM) and remote sensing imagery. The combination of such data layers may produce unrealistic data and consequently lead to erroneous predictions. The question is how reliable are these results when used for developing land use and management plans. A discussion on the propagation of error and uncertainty in GIS-based systems is provided elsewhere.[14]

The accuracy of GIS-based land evaluations is a function of the quality of attribute data and mapping delineations of databases, and the type of model or assessment scheme used in the analyses. Various algorithms for assessing the quality of GIS analysis results as affected by error and uncertainty in GIS layers, and their propagation are part of popular GIS and image analysis software (e.g., Arc/Info, ERDAS Imagine). The results, which are often in the form of reliability diagrams are not used by average GIS practitioners. This is probably due to the fact that they are not easy to understand or interpret. Similarly, models vary depending on how each represents various processes of the system. Lumped-parameter models and indexing/ ranking schemes are mostly used in land evaluations because they are easy to parameterize. However, these models ignore spatial variations of parameters throughout the field, watershed, or region of study. Furthermore, models originally designed for fields and watersheds are often applied to regional analyses, thus adding some level of uncertainty in modeling predictions. For example, most land use planning programs use conventional methods of land evaluation. Each land parameter is given a range of values with corresponding ratings showing its suitability to crop production. These indexes are added or multiplied to create a single index that is to rank land units. The method is simple, but carries a high uncertainty because breaks between two ranges or ranks are subjective.

The effect of map scale and resolution on environmental assessment and modeling output data has been subject to many studies. Raster-based GIS systems require that a grid cell size be defined prior to the analysis. However, as pixel size increases above the resolution of the original data, the spatial variability decreases. This causes a decrease of the predictive power of generated input parameters particularly for small land areas.

Conclusions

GIS has been used primarily in land evaluation, a procedure in the land use planning process that deals with determining land suitability to current and alternative uses and the potential impact of each use on the environment. GIS and GIS-based systems are often considered as integrated spatial information systems (ISIS) for data analysis needed in land use management and planning activities. Despite the advantages of GIS outlined above, the land use planner should be aware of the error and uncertainty in GIS and GIS-based analyses resulting from digitizing and scaling inaccuracies, data conversion between vector and raster formats, and others. Finally, GIS implementation in land use planning activities can be expensive. In addition to costs associated with hardware and software purchase and maintenance, a high level of technical expertise is required to perform complex modeling tasks in land evaluations for alternative uses and to sustain databases. Nonetheless, the demand for GIS and GIS-based analysis systems in land use planning is to increase in the future as more detailed spatial datasets become available.

Industrial Networks

Sven E. Jørgensen

The Importance of System Networks

An important property known from ecosystems, operation in networks, can be implemented in industries by building a network of several industries. This would facilitate the possibilities to find a better matter and energy (or rather, work energy or exergy) efficiency, understood as the entire efficiency, equal to the sum of all outputs (products) divided by the sum of all inputs. Inputs and outputs may be either matter or work energy (exergy; see the entries about exergy and eco-exergy). The matter can eventually be multiplied by the price or costs of products and of inputs to express matter efficiency in economic terms.

Industrial symbiosis in the form of a network is similar to the ecological network of an ecosystem, i.e., the network consists of flows of energy, matter, and information.

An Example of an Industrial Network

The use of industrial networks has been tested in the Danish town Kalundborg. The network (for further details, see Jørgensen[1]) is shown in Figure 1.

The heart of the system is the Asnæs Power Station (APS), the largest power plant in Denmark. Half of the plant is fueled by coal and half by a new fuel called orimulsion, a bituminous product made from Venezuelan tar sand. The use of orimulsion was introduced in 1998 and gave an 18% reduction in carbon dioxide emission compared with the use of 100% coal but, due to the sulfur content of Venezuelan tar, gave a higher production of gypsum by the sulfur dioxide scrubber. By exporting half of the former waste energy, APS has reduced the fraction of available energy directly discharged by about 80%. Since 1981, the municipality of Kalundborg has eliminated the use of 3,500 oil-fired residential furnaces by distributing heat from the power plant through a network of well-insulated underground pipes. The homeowners have paid for the pipeline but receive cheap reliable heat in return.

The power plant also supplies cooling water that is warmed 7–8°C to an on-site fish farm producing about 200 tons of trout per year. The APS also delivers process steam to its neighbors, Novo Nordisk (a pharmaceutical and biotechnological industry) and Statoil (an oil refinery). The APS produces 70,000 tons of ash that is sold for road building and cement production.

In 1993, APS installed a sulfur dioxide scrubber that produces calcium sulfate or industrial gypsum. Gypsum is the primary ingredient of wallboard, and ASP is the primary supplier of gypsum to the

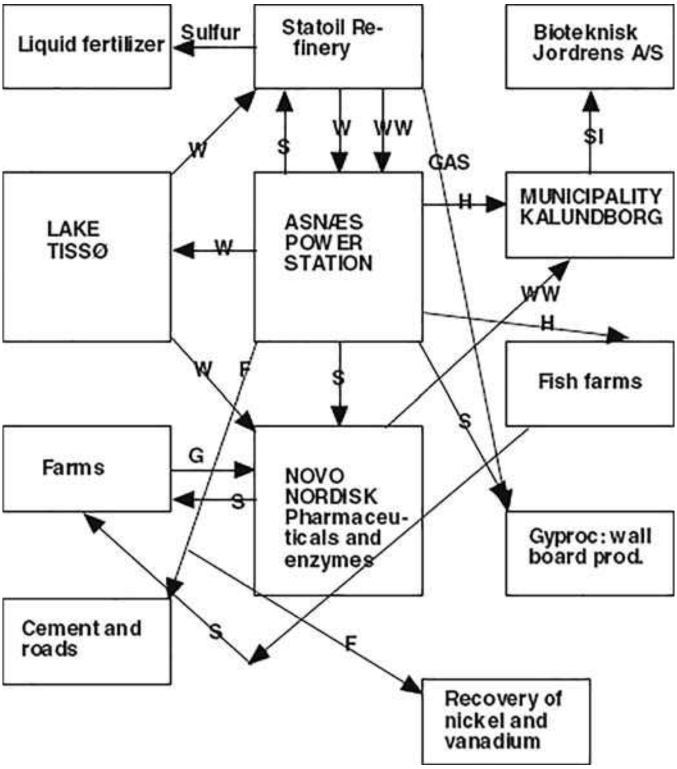

FIGURE 1 The industrial symbiosis at Kalundborg, Denmark. The flows of energy and matter make up an "ecological" network that implies that the overall efficiency of the utilization of the exergy input to the network is high. W, water; F, fly ash; WW, wastewater; S, steam; Sl, sludge; H, heat; G, grains.

wallboard factory Gyproc. The refinery has refinery gas as a waste product that is sold after desulfurization as natural gas to be used in the town or elsewhere. The desulfurization process produces liquid sulfur that is used to produce a liquid fertilizer, ammonium thiosulfate.

Novo Nordisk and its sister firm Novozymes are world leaders in the production of insulin and enzymes. The plant employs 1,000 people, and the products are produced by fermentation processes. Based on agricultural crops, valuable products are produced by microorganisms. The waste is a nutrient-rich sludge that can be used by the nearby farmers as animal feed (the yeast sludge) or fertilizers (the microorganisms sludge). More than 3,000 tons of the two types of sludge are produced daily. The yeast sludge is sold, and the microorganism sludge is given away, due to the firm's concern for disposal security. Distribution of the sludge was the least cost-effective way to comply with environmental regulations.

A new partner, A/S Bioteknisk Jordrens (meaning Biotechnical Soil Purification), joined the industrial symbiosis in 1999. The company uses municipal sludge as a nutrient in a bioremediation process to decompose pollution by toxic substances in contaminated soil.

The Benefits of Industrial Networks

It is clear from a review of the industrial ecological network in Kalundborg that there is an enormous potential to save energy or, rather, work energy or exergy in the use of industrial symbiosis. In this context, the Nordiske Affaldsbørs (Nordic Waste Exchange) could also be mentioned, an Internet page that gives information about wastes produced in the Nordic countries of Finland, Iceland, Norway, Sweden, and Denmark. The idea is that what may be waste for one industry could maybe be used as a raw material for another. For instance, used solvent from the pharmaceutical industry may be applicable for the production of paint or dyestuff. It is very important to see such opportunities if we want to reduce the loss of exergy in the form of fuel or raw-material waste to the environment. The idea behind industrial symbiosis—an ecological-industrial network—has been used in agriculture, but it could be applied much more widely, which would make agriculture much more sustainable.[1]

The industries have already adopted several of the characteristic properties of ecosystems, because it has been profitable for the companies. The discipline behind this application of ecological principles in industries is called industrial ecology.[2] The most significant losses of work energy in the industries are waste and the ineffective use of energy. These losses can be reduced by recycling and reuse, which the industries are using increasingly, but only to the extent that it is profitable. If several companies, industries, and the local municipalities are forming an ecological symbiotic network, it is, however, possible to reduce the overall losses of work energy or exergy and at the same time increase the profit. The possibilities of finding an optimum solution are generally bigger for a large system than for a small system. The experience gained so far from an industrial symbiotic network is so positive that it is surprising that it has not found a wider application.

Changes to the rules, taxes, and legislation for discharge of wastes may also increase the motivation for companies to recycle and reuse.[1] If the industries have to pay for the discharge of wastes or pay more for raw materials, it is a question of economic optimization how much the company should recycle and reuse the waste. The conclusion is clear: A higher direct utilization efficiency of work energy or exergy coupled with increased use of recycling and reuse are the key methods to decrease the eco-exergy losses by industries. Moreover, the use of ecological symbiotic networks increases the possibilities for recycling and reuse.

Land Restoration

Richard W. Bell

Introduction

Land degradation is widespread globally[1–3] and is devaluing the natural capital of land as well as compromising the provision of soil ecosystem services. Arresting the degradation of land should be a high-priority goal. However, restoration of land that has previously been degraded represents an untapped opportunity to increase the natural capital of land and the provision of key soil and plant ecosystem services, particularly those related to plant productivity and water supply. Many forms of disturbance such as overgrazing, excessive tillage, overirrigation lead to land degradation including water erosion, wind erosion, decline of soil structure, acidification, salinization, waterlogging, and decline in soil fertility. Land disturbance after mining is comparatively extreme, but research and adaptive management on these sites have fostered the development of sound principles and practices of land restoration. In the present entry, most examples of land restoration are drawn from mine land restoration to illustrate the principles of the emerging discipline of land restoration. While land restoration can be quite site specific in its practice, there are general principles that can be applied and these have a degree of relevance to most forms of land degradation.

Land as a Finite Resource

For sustainable environmental management, land should be regarded as a finite global resource. The critical surface layer of the finite land resource is the soil profile that varies from a few millimeters' thickness to several meters. While soils are continually forming, the rate is slow, equivalent to 1 mm every 100 years[4] or even less.[5] Land may be created by reclamation of submerged areas along shorelines or in wetlands, and river deltas create new land surfaces as they deposit sediments when they reach the sea or lakes. Locally, these processes that create new land surfaces may contribute significantly to available land resources, but at a global scale, the amounts created are small relative to the total area and to the areas being degraded. Moreover, there is already evidence that in low-lying coastal zones, land is being inundated by rising sea levels or eroded by storm surges associated with rising sea levels. These processes are offsetting gains from natural or anthropogenic land creation. There seems little alternative but to regard land as a finite resource, to slow and prevent degrading processes, and to implement restoration programs on land that has suffered degradation.

Natural Capital and Soil Services

While most emphasis in the past was on food and fiber production from land, the concept of its value is broadening. Land is a form of natural capital that underpins several critical ecosystem services.[6] The soil ecosystem services outlined in Table 1 comprise supporting, regulating, provisioning, and cultural services.[6] The emergence of the concept of natural capital is beginning to redefine the notion of land and its value. Production of food is still a critical function of land, indeed one whose importance is predicted to rise over the next several decades as the challenge of providing sufficient quantity and nutritional quality of food for a rising population becomes more evident.[7,8] In addition, the role of land and soil in regulating major elemental cycles, the hydrological cycle, and the disposal of wastes and dead organic matter is gaining increasing importance.

Land Degradation

Land as a finite resource is susceptible to a range of degrading processes that limit its productivity, its land use potential, and its value in providing ecosystem services. Conacher and Conacher[9] define land degradation broadly as "alteration of all aspects of the natural (biophysical) environment by human actions, to the detriment of vegetation, soils, landforms and water (surface and subsurface, terrestrial and marine) and ecosystems." More broadly, land degradation can be defined as those processes that lower the natural capital of land and compromise the provision of soil ecosystem services.

The processes of land degradation, their measurement, impact, and management have been dealt with else- where.[10–12] Most commonly, the impact of land degradation is described in terms of areas of land degraded.[13] However, this approach has several limitations. Apart from the difficulty of acquiring good quality data that are consistent across large areas to make such estimates, the different impacts of degrading processes makes it impossible to compare processes based only on area affected. For example, the degradation of soil structure by tillage may have an incremental effect on crop yields but cause a quantum increase in water runoff. The degradation of land by salinity, which raises soil salinity levels above a critical threshold for growth of most plants, prevents continuation of current land use options, while opening up others (such as salt-tolerant vegetation). By contrast, soil acidification may have no effect on plants until a critical threshold is crossed, leading to the release of toxic Al^{3+} concentrations that impair plant growth. Hence, the key to predicting the effects of land disturbance is to understand the threshold values of soil properties for plant growth and for

Source: Adapted from Robinson et al.[6]

ecosystem services. The differences among degrading processes are also critically important in planning the restoration of degraded land.

Alternatives to assessing and comparing only the land areas suffering degradation are to estimate the value of lost production from the degradation or to estimate the cost of restoration. The latter is generally considered to be critical since restoration costs will be a major impediment to reversing the effects of degradation. The cost per hectare for land restoration on mine sites is much larger than that on production lands not only because of the more extreme degradation but also because of the greater capacity to pay for restoration. Costing the restoration works for different forms of degradation and different areas of degraded land provides a basis for prioritization of restoration works. However, costs of restoration commonly only consider land productivity, rather than biodiversity and the full range of ecosystem services. If the natural capital of land in total was considered, there may be less variation in costs of land restoration among different forms of disturbance.

Land Restoration Definition

The term *land restoration* has a generic meaning, first proposed by Hobbs and Norton,[14] to indicate "that restoration occurs along a continuum and that different activities are simply different forms of restoration." The term *land rehabilitation,* as defined by Aronson et al.,[15] is also appropriate when applied to land degraded by mining. In the United States, the term *reclamation* is commonly used to describe activities that replace ecological functions by planting different vegetation to what previously grew.

Land restoration will usually focus on re-establishing ecological functions such as nutrient cycling, hydrological balance, and ecosystem resilience.[16] In some situations, restoring the original flora is in addition a realistic and appropriate goal. A case study based on the application of this goal is outlined below for restoration of eucalyptus forest after bauxite mining. Further expansion of the concept of land restoration should consider its role in the recovery of natural capital and soil ecosystem services.

Land Restoration Principles

The process of land restoration comprises the following: determination of the end land use, definition of the main limiting factors for restoration and means of alleviating them, and, finally, planning and implementation of a restoration program including monitoring and evaluation against success or completion criteria. This entry focuses on the first two components, while the latter component is described in more detail by Hobbs.[16]

End Land Use

Development of a land restoration strategy is generally considered to need a well-defined end land use. The key constraints that need to be alleviated depend on the land use envisaged. Hence, definition of the end land use is often considered to be a prerequisite to the restoration of degraded land. From the defined end land use, it is possible to identify the stakeholders whose interests need to be considered, the scope of the restoration challenge, and the prime constraints that will have to be alleviated.[16,17] It is also a prerequisite for the establishment of the measurable goals and targets for restoration that are used in setting success or completion criteria. End land use will largely define the complexity and difficulty of the restoration task and the costs associated with achieving a successful outcome. At one end of the spectrum, the complete restoration of the pre-existing ecosystem is a challenging goal. It may require decades of systematic research and continuous improvement of the restoration procedures before that goal is achieved and before the success criteria can be defined and validated. On the other hand, simply achieving a stable land surface or creating a pasture suited to low-intensity grazing would be more easily achieved.

Existing land use on surrounding areas, or prior land use at the site, often determine the end land use. However, degradation such as salinization may alter the substrate for plant growth so radically as to make the pre-existing land use impossible or undesirable. Furthermore, on mine sites, the alteration in landforms may require a change in land use in order to achieve land stability. In the case where land use change is necessary, stakeholders will need to be engaged to arrive at an acceptable alternative end land use.

A great diversity of end land uses has been applied during land restoration. Apart from natural ecosystems, agriculture, forestry, nature conservation, grazing, housing, wetlands, amenity and recreational facilities, and waste disposal are all possible options. Sociopolitical and economic factors will generally determine the selection of end land use particularly if the land is in a protected area, on production land, or in a densely settled zone.

While a well-defined end land use is necessary to set realistic goals and targets for restoration, there are risks associated with setting a highly prescriptive end land use if the restoration technology has not been well developed and based on solid research. The development of best practice for restoration of a particular type of degraded land may require decades of research and adaptive management. Hence, the premature setting of the end land use and targets for achievement may lock in an inferior set of outcomes. Using an adaptive management approach will allow continuous improvements in restoration practice to be made and tested. As improved practices and outcomes become possible, new benchmarks for completion can be set and new possibilities for end land use emerge. The bauxite-mining case study below illustrates this process.

Diagnosis of Limiting Factors

Degradation of land takes many forms and is triggered by many agents.[10] The types of constraints and their severity and the consequences for the restoration plan will clearly vary from site to site. Correct diagnosis of the key constraints and identification of likely feasible solutions are a prerequisite for successful restoration of degraded land. Identification of the key agents causing degradation is also essential. At a mine site, the active cause of degradation is mining and its associated disturbance. In other cases, the degrading agent may be tillage, overgrazing, wind erosion, saline groundwater discharge, etc. Apart from the biophysical constraints related to substrate properties, landform, climate, and hydrology, limiting factors may be associated with socioeconomic factors that prevent the degrading processes from being arrested. In the present entry, the focus is on the biophysical constraints to restoration (Table 2).

Biophysical Factors Limiting Land Restoration

Climate

The growing conditions for plants when restoring degraded land are determined primarily by climate. Climate is the main limitation on potential land uses for each site. Species that are indigenous to the site will usually be well adapted to the rainfall, temperature, and extreme conditions that occasionally occur in a given climatic regime such as drought, heat stress, and frost. However, if the substrate is unsuitable for the indigenous species, or the end land use requires a different selection of species such as agricultural species, then the chosen species need to be well adapted to the site climate.

When considering climate-related constraints, it is not just the average conditions that should be examined, but also the frequency and severity of extreme events, such as drought, heavy rain storms (e.g., cyclones), frost, snow, hail, etc. The coincidence of extreme events with commencement of a land restoration project may prevent seed germination or cause the loss of seed and topsoil due to erosion.

TABLE 2 Biophysical Factors Limiting Land Restoration, Their Consequences for Site Stability and Plant Growth, and Common Treatment Methods

Factor	Constraint	Consequence	Treatment
Climate	Drought	Failure of germination, poor emergence or establishment, plant death	Irrigation, drought-tolerant or drought-avoiding species, adjust time of sowing
	High temperature	Poor germination and emergence, plant death	Mulching, retention of crop/plant residue
	Low temperature/ frost	Delayed emergence, plant death, poor seed set	Frost- or cold-tolerant species, adjust time of sowing
	Extreme rainfall/ wind events	Water or wind erosion episodes, loss of seeds	Contour banks, soil cover by foliage, mulch or stubble, windbreaks
Landform	Slope	Land slippage, soil creep, unsafe conditions for machinery operation	Deep-rooted plants, reshape to lower slope angle, contour banks, engineering design, prevent water run-on from upslope
	Runoff	Water loss, sediment loss, downslope deposition	Contour banks, reshape to lower slope angle, improve infiltration and soil water storage
	Exposure	Drought, high winds, extreme temperatures	Tolerant plant species especially as windbreaks
	Aspect	High winds, extreme temperatures	Tolerant plant species especially as shade plants
Hydrology	Runoff	Reduced soil water storage, waterlogging, flooding downslope	Contour banks, increased drainage intensity
	Limited profile water storage	Drought, runoff, increased groundwater recharge	Tolerant plant species, deep ripping, treatment of subsoil chemical constraints
	Groundwater discharge	Water-filled voids, acid mine drainage, waterlogging, salinity	Containment of water, wetland treatment ponds, drainage
Substrate properties	Acidity	Poor plant growth especially roots, nutrient deficiencies, plant death	Lime, acid-tolerant species, P fertilizer
	Alkalinity	Poor plant growth, nutrient deficiencies, plant death	Gypsum, leaching, alkaline tolerant species, acidifying materials
	Salinity	Poor plant growth, plant death	Leaching, salt-tolerant species, drainage
	Sodicity	Soil dispersion, crusting, poor seedling emergence, runoff, water erosion	Gypsum, leaching, organic matter addition
	Nutrient deficiency	Poor plant growth	Fertilizer (mineral and organic)
	Metal toxicity	Poor plant growth, plant death	Lime, tolerant species, burial or capping of substrate, removal of substrate, phytoremediation
	Low water availability	Poor plant growth, plant death	Irrigation, mulching, organic matter, deep ripping, adjust time of sowing, drought tolerant species
	Waterlogging	Poor plant growth, plant death	Drainage, tolerant plant species
	Poorly structured soils	Crusting, poor water holding capacity, poor root growth	Mulching, organic matter, gypsum
	Mycorrhiza	Poor plant growth, nutrient deficiency	Topsoil management, inoculation of nursery plants
	Rhizobium	Nitrogen deficiency	Topsoil management, inoculation, liming acid soils
	Soil microbes	Slow mineralization of soil organic matter	Topsoil management

Source: Modified from Bell.[18]

Landform

Mining creates voids below ground level and waste material that is stacked above ground level. Hence, the overall slope angle of land on a degraded mine site will be increased relative to the pre-existing landform. Hence, the creation of stable, non-eroding surfaces is generally the first major goal of restoration after mining. The key landform factors that limit the achievement of stable surfaces are slope angle, elevation, aspect, and surface drainage. Maximum slope angles are generally set by regulation and vary among jurisdictions. In West Australia, a maximum of 20° is the guideline for restored mine slopes such as the outer surface of waste rock dumps.[19] The change in landform is less of a consideration with other forms of disturbance apart from mining.

Hydrology

Any significant removal or disturbance of vegetation, change in surface soil properties, increase in average slope angle, or change in drainage density on a degraded site will alter the water balance. Reduced vegetation cover will increase runoff and there may also be increased deep drainage. The increase in slope angle on disturbed sites will generally increase the proportion of rainfall that becomes runoff. Erosion and downstream flooding and/or sedimentation are the likely consequences of altered hydrology unless precautions are taken to avoid these effects. Where sulfidic substrates are excavated by mining and stored in contact with moisture and oxygen, acid mine drainage may be discharged into groundwater or surface water. The discharge of acidic water alters downstream ecology and may damage the infrastructure it contacts, such as concrete structures in bridges.

Substrate Properties

Physical *properties:* Degrading processes such as erosion, overgrazing, or excessive tillage may alter the physical properties of the surface substrate in ways that decrease its suitability for plant establishment and growth, particularly by changing water storage and availability. Mining substrates and mineral processing residues are commonly poorly sorted, which alters physical properties such as available water capacity, porosity, soil strength, crusting, and susceptibility to wind or water erosion.

Water erosion strips away topsoil, decreases soil depth, and exposes subsoil material with different texture, lower organic matter levels, and degraded soil structure. The eroded soil has less favorable physical properties for water infiltration, water holding capacity, seed germination, and root growth. Wind erosion selectively removes clay and humus from the soil surface, increasing the prevalence of coarse materials. Fine sand deposits from wind erosion may bury topsoil and vegetation. Dust from bare surfaces can be a health hazard especially if it contains alkali salts or other toxic elements.

The passage of heavy machines on agricultural, forest, and mine sites causes compaction of the substrate, and this may be a major constraint to plant growth by restricting root depth. In drought-prone environments, the failure of roots to penetrate to depth may cause stunting or death of plants. Deep ripping to break the compacted layer is generally necessary in order to achieve deep root growth in mine pits.

Chemical *properties:* Plant growth may be hampered by low nutrient levels, acidity, alkalinity, salinity, sodicity, low organic matter levels, and excessive levels of toxic elements or compounds in the substrate. Therefore, effective land restoration depends on thorough chemical characterization of the substrate for these likely chemical constraints. Where feasible, any substrate that is likely to hinder plant growth should be isolated or buried under more benign materials so that root contact with it is avoided or minimized. This approach, which is practiced on mine sites, is clearly not possible on agricultural land. Soil and plant analysis are the most common methods for predicting likely nutrient deficiency or toxicity in the substrate.[20] Fertilizer applications can usually be effective in correcting nutrient deficiencies although determination of appropriate rates of application requires expert judgement or decision support systems and depends on the end land use. For acidity, alkalinity, salinity, or ion toxicities in the substrate, plant tolerance is the most cost-effective strategy for achieving successful plant growth. This may mean selecting a different suite of species or ecotypes to those that existed before mining unless the local species are already adapted to those constraints.

Biological *properties:* The disturbance of topsoil during mining, through stripping, transport, replacement, and/or storage, all have negative effects on soil biological activity.[21] Maximum soil microbial activity is retained when topsoil is used immediately after stripping without a period of storage. Storage for extended periods should be avoided, but in those mining operations where long-term storage is unavoidable, the stockpile should be uncompacted, should be <2 m deep, and should support a vegetative cover that maintains soil biological activity. Restoration of microbial biomass in replaced topsoil on revegetated mine sites may take 7–10 years.[21,22] In southwest Australia, the presence or absence of the pathogen *Phytophthora cinnamomi* in topsoil determines how it should be stored and reused.

Plant Establishment

Except in rare circumstances, vegetation cover is a requirement for land restoration. The alleviation of substrate constraints that limit plant establishment or growth is a prerequisite for successful vegetation establishment. Where a choice of substrate materials is available, the most benign of these should be placed at the surface to create a favorable root zone. This will minimize the need for expensive amelioration procedures for any adverse soil conditions. Topsoil, if available, is generally the most favorable substrate.

In land restoration, plant establishment is pursued through direct application of seed, the application of topsoil containing viable seed banks, transplanting of seedlings, or combinations of two or more approaches. Topsoil typically contains a substantial seed bank. Use of topsoil for revegetation can achieve large cost savings by avoiding seed collection and spreading. Topsoil is most commonly used for revegetation when the indigenous species of the area are to be replaced. However, where the topsoil contains seed of exotic species or has a large proportion of weeds in the seed bank, it may be preferable to avoid its use as the seedbed. In addition to the seed bank, topsoil contains soil microorganisms that are required for the restoration of soil functions such as organic matter decomposition and nutrient cycling. The nutrient stores in topsoil may be critically important for the production of adequate biomass in the restored ecosystem. The physical conditions in the topsoil are generally more favorable for seed germination and emergence than from other substrates. However, well-characterized subsoils or regolith materials may be suitable for revegetation when topsoil is absent or where topsoil is unsuitable due to chemical constraints or heavy weed infestation.

In some plant communities, seed is stored in the canopy of key species rather than in the topsoil. Placement of cut branches on the soil surface may be used in these cases to maximize recruitment of indigenous species.

Transplanting nursery-raised seedlings is a reliable approach for ensuring rapid plant establishment and canopy cover on a degraded site. Transplanted seedlings compete effectively against weeds and have greater survival under grazing by herbivores than plants recruited from direct seeding. For species that are difficult to propagate from seed, nursery-raised seedlings using tissue culture or other vegetative means of propagation may be the only reliable method for introducing those species during land restoration. However, raising nursery seedlings is relatively expensive, especially if only few plants of a large number of species need to be treated in this way.

Ecosystem Restoration

According to Hobbs and Norton,[14] the following are the ecosystem characteristics that should be considered when setting goals for land restoration: vegetation composition, structure, pattern, and heterogeneity; species interactions; and ecosystem function, dynamics, and resilience. A set of measures is needed to determine the success of restoration. They need to be not only low-cost and reliable indicators of present condition and function but also predictors of future trajectories for the restored ecosystem. Composition and structure of vegetation are the most commonly used indicators.[23] For pattern, heterogeneity, dynamics, and resilience, the indicators are less advanced in their development, in part because these indicators can only be identified and validated from long-term data. As a nutrient cycling indicator, microbial biomass has been proposed,[22] while Koch and Hobbs[23] concluded that soil organic matter was the best indicator of the restoration of nutrient cycling processes for bauxite mine restoration.

Increasingly, the land restoration activities in the mining industry are being assessed against completion criteria or success criteria.[17] These are legal instruments established following negotiation between regulators, mining companies, government advisers, and the community. Their aim is to provide certainty for all stakeholders about the restoration process to be followed and the expected outcome. They are designed to avoid future liability to government agencies or private landowners once mining has ceased and mine ownership has passed to new owners.

Case Study: Bauxite Mine Restoration

The restoration of land after bauxite mining in southwest Australia is recognized globally for its excellent practice.[24] Current practice is based on more than 40 years of research and development and adaptive management. There are important lessons to be learned about land restoration from this case study. Bauxite mining in the dry sclerophyll eucalyptus forest of southwest Australia is a shallow surface mining operation. The current restoration goal is to restore the forest values.[24] One hundred percent of the species are now routinely returned. Nutrient cycling appears to be on a trajectory towards restoring the nutrient stores and the fluxes of nutrients present in the premining forest.[22,25] Hydrological balance is disturbed for up to 12 years after land clearing for bauxite mining and subsequent revegetation.[26] Thereafter, water levels return to premining levels, but may drop below premining levels due to the increase in leaf area index relative to premining levels.[27] The restored forest is resilient to fire.[25] Completion criteria have been developed for bauxite mine restoration and several areas have been determined to meet the designated targets.[24]

The present restoration practice as described by Koch[28] is the result of four major revisions in the goals over 40 years and several other significant improvements in practice. The first rehabilitation simply planted *Pinus radiata* as a single species plantation. This was followed by a *Eucalyptus saligna* plantation and then by a goal to restore a diverse forest rather than a plantation. At this stage, it was thought that planting of local eucalyptus would not succeed because of the existence of *P. cinnamomi* in the soils and its threat to the survival of a wide range of native species. Further research demonstrated that the reconstructed profile would produce low risk of *P. cinnamomi* infection in susceptible species, and hence, it was decided to change the end land use goal to that of a forest compatible with the jarrah forest, using jarrah and marri as the overstory species.[24] Finally, it was decided to revise the end land use goal to achieve the restoration of the jarrah forest.[17,25] The selection of this goal was based on research breakthroughs that demonstrated that it was possible to stimulate the germination and emergence of recalcitrant species and hence reach close to 100% species return.

The main learning from this case study is that reaching the point when practices enable full ecosystem restoration takes several cycles of research and adaptive management. It will be based on a systematic program of research into biotic and abiotic constraints. A flexible approach from regulators enabled end land use goals to be revised over time as new research demonstrated the potential to achieve more challenging goals and targets. The end land use goals set in 1963 would have only resulted in exotic pine plantation on the mined bauxite pits. The present end land use goal is a fully functioning jarrah forest that can be integrated into existing forest management programs and achieve the multiple land use goals for the forest estate.[24]

A comprehensive report of the background research on bauxite mine restoration is found in *Restoration Ecology Special Issue* of 2007. It is a worthy model for study and emulation in land restoration on mine sites.

Case Study: Restoration of Land Affected By Dryland Salinity

Unlike the first case study of restoration on mined land, where disturbance is localized, dryland salinity has a more widespread impact and requires a landscape-scale response for land restoration. This case study is illustrated using examples of dryland salinity in southwest Australia and Northeast Thailand. By 2003, about 1 million ha in the wheatbelt of southwest Australia was affected by dryland salinity.[29] In Northeast Thailand, up to 30% of land could potentially become salt affected.[30]

Dryland salinity demonstrates how perturbation in water balance can have devastating consequences for the natural capital of landscapes. Whereas the native plants were predominantly deep-rooted perennial species, those agricultural species that replaced them were predominantly shallow rooted and annual. Annual plants use water only during their growing season, and their usage is limited by the fact that roots are generally confined to the surface 50–100 cm. Thus, the additional water under agricultural species is distributed to increased runoff, causing erosion and waterlogging, and to increased recharge to groundwater (Table 3). Williamson et al.[31] similarly concluded that dryland salinity in Northeast Thailand was triggered by deforestation of the uplands to produce crops like kenaf and cassava.

Two attributes of the landscape that gave rise to dryland salinity in southwest Australia were the deeply weathered regolith and the accumulation of salts from rainfall accretion.[33] Salt contents in extreme cases of up to 20,000 tons/ha have been reported,[34] most of it stored below 5 m depth.[32] Prior to clearing the native vegetation, plant roots in the upper 5 m of the regolith were largely separated from the salt bulge below, and the semipermeable aquifer at the base of the regolith was often dry.[32] However, with increased recharge, the aquifers have filled, causing water levels to rise at the rate of 0.2–1 m/yr. After a 20–30 years period of groundwater rise, saline groundwater discharge is observed commencing generally in valley floor land- forms. In Northeast Thailand, the origin of salt discharge is not rainfall accretion but salt mobilized from halite sequences in the Mesozoic sediments that underlie the Korat Plateau.[31]

Reversing Dryland Salinity

Ultimately, restoring the preclearing water balance is the only complete solution to the dryland salinity problem. This requires treatments in recharge zones of landscapes to decrease recharge rates. The species that can mimic recharge rates that existed before clearing will therefore probably need to be deep rooted and perennial. They will also have to be adapted to a variety of soil conditions and climatic regimes across the affected environment. Finally, it is imperative that the species chosen to fulfill the above functions are economically viable within the farm enterprise to accelerate their adoption by land managers.

In order to manage dryland salinity, it is necessary to understand the groundwater systems as well as water balance components. With intense winter rainfall, in landscapes extensively covered by shallow-rooted annual species, recharge can occur virtually anywhere in the landscape that is not

TABLE 3 Changes in Water Balances for Cleared Catchments before and after Clearing

Catchment	Year	Rainfall (mm)	Interception (mm)	Evapotranspiration (mm)	Change in Water Storage (mm)	Change in Groundwater Storage (mm)	Stream Flow (mm)
Wights forested	1975	1027	130	855	−28	−11	81
Wights cleared	1985	1147	0	565	–	−21	115
Lemon forested	1975	739	74	656	4	−1	5
Lemon cleared	1983	821	38	708	–	−19	56

Source: Williamson.[32]

actively discharging.[33] Computer modeling adds weight to the conclusion that the only fully effective revegetation solutions for salinity control in southwest Australia are with deep-rooted perennial vegetation over most of the whole catchment.[33] Even systems like agro-forestry that place a high density of woody shrubs and small trees in rows 30 m apart were insufficient in the modeling scenarios to restore water balance and achieve complete control of salinity. Continued reliance in the farming system on annual shallow-rooted crops such as cereals is problematic because these crops will allow continued recharge. Loss of these species is also problematic because they are the main source of income for farmers.

Until recharge control treatments start to decrease saline groundwater discharge, treatments are also needed in the discharge areas. These may include both engineering treatments to alleviate waterlogging[35] as well as vegetation options that cope with saline waterlogged conditions.[36] In Northeast Thailand, there has been considerable investigation of salt-tolerant species that can be grown on various classes of salt-affected soil.[30]

The case study on dryland salinity may therefore serve as a useful model for landscape-scale restoration. As with the case of land restoration after bauxite mining, the present approach has involved background research to understand the underlying physical processes (landscape water balance, water fluxes, hydrogeology) and to develop effective solutions (the effect of land use and vegetation type on water balance). The present set of strategies to control dryland salinity has evolved out of several phases of research and adaptive management leading to current understanding and solutions.

Conclusions

Land is a form of natural capital that is essentially finite and non-renewable. Every effort must be exerted to avoid degradation of land because degradation diminishes its natural capital value and compromises the ecosystem services provided by soil. The restoration of degraded land has the potential to increase its natural capital value and enhance ecosystem services. Since large areas of land globally are degraded, there is substantial scope for increasing ecosystem services by restoring degraded land. Land restoration is a relatively new discipline, which, along with restoration ecology, consists of successful practices for land restoration at a site-specific scale. Examples of best practice can be found in restored mine sites. The challenge remaining is to scale up land restoration from site-specific cases on mine sites to regional or landscape scales for a variety of degrading land disturbances. Most success at both scales has, to date, been concerned with restoring key ecosystems functions such as organic matter accumulation, nutrient cycling, and water balance.

Limits to Growth

Brian D. Fath

Introduction

In thermodynamic-based systems science terminology, the Earth is considered a closed system. This means that it is open to energy exchanges, but not matter exchanges. Regarding energy, the Earth receives on average 1,300 W/m^2 of solar radiation at the top of the atmosphere and radiates or reflects a near equal amount back to space (the current increase in greenhouse gases causes a small difference in the radiation balance enough to be responsible for the current observed warming). The amount of matter on the Earth is more or less fixed, with only negligible exchanges from receiving meteorite impacts or outgassing. The Earth's matter is distributed in the following way: The Earth has a polar radius of 6.37×10^3 km, giving it 501.1 million km^2 of surface area, of which 70.8% is covered with water. The overall volume of the Earth is 1.08×10^{12} km^3, with a mass of 5.98×10^{24} kg. Those physical dimensions are hard evidence of the limits of the available space and material resources. The *Blue Marble* (Figure 1) shows this celestial body in all its complexities, opportunities, and beauty; and it also shows starkly the scale and boundaries of the one world that humans and all known species have. This photo, taken during the Apollo 17 Lunar Mission in 1972, coincided with the emergence of the modern environmental movement (more on that below). It was not the first environmental movement, but those ideas from the 1970s still cast a strong shadow on the discussions today that deal closely and explicitly about living in balance on the Earth as represented in among other things, the United Nations Sustainable Development Goals.

The ideas of bio-physical limits impacting human growth and resource consumption are not new. At the turn of the 19th century, Thomas Malthus was already writing about the convergence of population growth and food supply. He foresaw an inevitable turning point in which the finite resources of the planet could not support an exponentially growing population. His dour predictions later became the face of resource-limited, doom-and-gloom environmentalism, referred to as Malthusian. This discouraging perspective is a label that most modern environmentalists try to avoid, while still holding the reality of his concerns. At the time Malthus was writing, the global human population was around 1 billion, and today is approaching 8 billion, moving from abundant nature and scarce humanity to abundant humanity and scarce nature. Yet, there is not an absolute food shortage in terms of total calories produced, only hunger due to regional and distributional dilemmas. In fact, obesity is a more serious and growing problem in many countries than food deficiencies. Nonetheless, the effort that humans have taken to supply this food has meant the conversion of most arable land to agriculture leading to extensive direct impacts

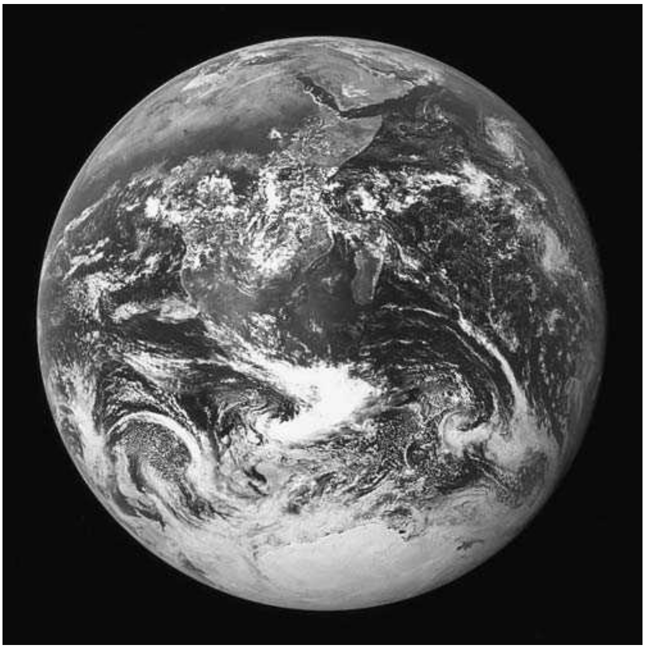

FIGURE 1 The *Blue Marble*, view of the Earth from Apollo 17 (1972).

such as habitat loss, soil degradation, and biodiversity loss. It has also led to the doubling of nitrogen flows through industrial fixation (as a result of the Haber–Bosch process) and the tripling of phosphorus flows (benefitting from massive industrial, fossil fuel-based mining efforts). The proximate result of increasing the amount of these typically limiting nutrients expands food supply, but the production of both nitrogen and phosphorus is highly fossil fuel-intensive creating energy supply dependencies. Furthermore, excess nitrogen and phosphorus that runs off agricultural fields creates massive eutrophication problems that are evident in almost every heavily populated estuary and water body in the world. Agricultural production to meet the world's needs is also responsible for rapid groundwater withdrawals, pesticide applications, and abundant greenhouse gas emissions at numerous stages from the fossil fuel use, to soil alterations, to methane from rice and livestock production. So, while the verdict is not in regarding absolute constraint of food production on human population growth, it does appear clear that we are in fact not feeding the people of the planet in a sustainable manner, nor whether it is even possible to do so at this scale. Malthus' concerns should not be dismissed lightly.

Environmental Limits

Recognition of limits can also be found in the seminal writing of George Perkins Marsh. Marsh wrote *Man and Nature* in 1864, which was one of the first scientific treatises on the impacts humans have on nature and the consequential conditions that coincide. Marsh warned that we should take notice of the scale and extent to which humans can continue to modify nature for our own benefit. Presciently, he wrote:

> A certain measure of transformation of terrestrial surface, of suppression of natural, and stimulation of artificially modified productivity becomes necessary. This measure man has unfortunately exceeded.
>
> **Marsh (1964)**

It is interesting that he recognized that humans will and must modify their environments similar to any species. There is a feedback in which the modifications, the other ecological interactions, and the environmental conditions reach a dynamic balance if the system is to sustain over time. Of course, this does not mean that the systems become rigid without change or variation because innovation, adaptation, evolution, information gain, and learning all allow for continual resilience and flexibility to meet the self-enhanced, recursive dynamic conditions. The path dependency between the interaction of the ecosystem constituents is one of the key features of living systems. Nonetheless, when humans erode too much land, deforest too many hectares, divert too much water, degrade too much habitat, etc., there are limits to which the ecosystem can recover and continue to provide the services we have come to expect. The diminishment first comes in the form of provisioning services when farms and fisheries fail, but then impacts cascade to supporting and regulating services, undermining the capacity of the land to regenerate and function sustainably. Continuation of an approach that overuses and abuses the natural resources will lead to eventual ruin, as Marsh noted in many earlier civilizations, which has been the topic of a recent plethora of research and books describing the collapse of complex societies (e.g., Tainter 1988, Diamond 2005, Kriwaczek 2010, Cline 2014).

The United States of America was settled on the notion of boundless space and opportunity, a land of cornucopia, which influenced not only the profligate physical resource use but also the psychological engagement that one had with resources. However, around the time that Marsh was writing, the transcontinental railroad was being completed. In 1869, the Union Pacific and Central Pacific railroads were joined in Promontory Point, Utah Territory, enabling rapid transportation access across the United States. Travel that previously took 4–6 months could be completed in 6 days. A few decades following both Marsh and transcontinental rail, another measure of limits was recognized in the closing of the Western frontier. The 1890 census showed the first time the disappearance of a contiguous frontier line of a migrating population. The westward wave of expansion was not endless as it had been (naively and myopically) perceived. Historian Frederick Jackson Turner used this moment to refer to the "closing of the American Frontier" (1893). At this bifurcation point, it should have been obvious that the solution to resource shortages, for example, in the form of eroded agricultural land, could not be found by simply relocating to the next plentiful area. While there was still plenty of "under-utilized land" (from a human economic perspective), the new reality meant filling in the middle states rather than experiencing an expansionary boundary. It should have been a time to rethink and reformulate our relationship with land and nature, thus confronting limits and working within constraints. However, the notion of boundless resources remains deeply held by many and institutionalized in many core economic practices (e.g., debt-based money supply, Ponzi-style retirement benefits, high future discount factors). Therefore, recognizing and accepting bio-physical limits was not the first impulse when faced with this new reality.

Ethical Limits

In the 1940s, limits were given another dimension by Aldo Leopold and his *Land Ethic* referring now not only to physical limits but also moral ones. He questioned, why would we pursue certain things (namely economic growth through resource consumption and technologies with unintended consequences) if the result is to destroy and degrade the life and ecosystems around us, loss of species and wild places. He eloquently wrote:

> Our grandfathers were less well-housed, well-fed, well-clothed than we are. The strivings by which they bettered their lot are also those which deprived us of [passenger] pigeons. Perhaps we now grieve because we are not sure, in our hearts, that we have gained by the exchange. The gadgets of industry bring us more comforts than the pigeons did, but do they add as much to the glory of the spring?
>
> **Leopold (1949)**

He elaborated this new perspective in what he called a Land Ethic:

> A thing is right when it tends to preserve the integrity, stability, and beauty of the biotic community. It is wrong when it tends otherwise.
>
> **Leopold (1949)**

His Land Ethic puts an environmental ethic clearly on the table as to what is right and wrong, expanding the boundaries of moral concern to the living environment and to the land itself, thus providing new limits of our actions. This ethic is informed by an ecological as well as a systems perspective. Leopold called on humans to constrain certain activities if those actions were detrimental to natural systems. He recognized, for example, the intricate balance cascading between the predator wolves and soils passing through the grass and deer. Too few wolves meant consequences for the soils. There are limits to the control which humans can exert over the ecosystem with a desire for favored species in certain times and places (e.g., the domestic chicken is the most abundant bird in the world, and *Zea mays* (corn) the most abundant plant). In the ensuing decades, we have better knowledge of complex systems, and with this we can have better management, but that does not obliviate the presence of limits imposed from outside and fostered from within. The Land Ethic allows one to see that beyond our own immediate sphere we interact with other bounded spheres, thus implying that the limit we sense is in fact an indication of another system beyond that we are pushing up against. In a zero-sum interaction, expanding our boundary, for example, into nature, diminishes nature. However, there are many non-zero-sum interactions and relations prevalent in ecosystems and complex adaptive systems. The challenge is not to completely disengage when we encounter another system, but to acknowledge it, respect it, work to understand it, and then try to find a way to engage it for the benefit of both parties (see, e.g., Fiscus and Fath 2019).

Socio-Economic Limits

These ideas of limits coalesced in a seminal work by Meadows et al. sponsored by the Club of Rome in the *Limits to Growth* report released in 1972. Their conclusion was based on the results of one of the first global systems dynamics models developed that included state variables representing human population, agricultural productivity, industrial production, resources, and pollution. The dire results were that under no scenario would unlimited growth be able to continue, and the only steady state was found by strict conditions of stable population, 100% use of renewable resources, and investment in business that equaled depreciation. The report was an important contribution to the debate about limits from a bio-physical perspective but was largely ignored by economists and politicians since the approach did not fit their existing growth-oriented mental model. The study was dismissed out-of-hand as having no relevance since their models—absent of any environmental resources or feedbacks—could grow forever. The Meadows et al. model was viewed as Malthusian and overly doom-and-gloom, a stigma that dogged the environmental community for decades. Nonetheless, the Club of Rome work continued as decadal update reports were published showing the projections were in line with reality.

Coincident with the release of the original *Limits to Growth*, the modern environmental movement was gaining traction (as stated above, spurred on by images such as the *Blue Marble* and the Spaceship Earth concept). In the United States, it was a period of aggressive federal policy protections for the environment (Table 1), most passing with very wide margins in both the House and Senate and signed by both Republican (Nixon and Ford) and Democratic (Carter) Presidents. Shy of 50 years later, the pendulum has swung far the other way. Concerted efforts within the United States Congress to dismantle or weaken these Acts, in particular the Endangered Species Act (ESA), is rampant; including news just today (August 13, 2019) of efforts to sign a Presidential Executive order to weaken ESA protections. It would be humorous if it were not sad that one prime argument against the ESA is the stated negative impact that it may have on the economy. However, measuring the success of this

TABLE 1 Major United States Legislation Passed in the 1970s during the Resurgent Environmental Movement

Coastal Management Zone (1972)
Clean Air Act (1972)
Clean Air Act Amendments (1977)
Comprehensive Environmental Response, Compensation and Liability Act (1980)
Endangered Species Act (1973)
Federal Land Policy and Management Act of 1976
Fishery Conservation and Management Act of 1976
Marine Mammal Protection Act (1972)
National Environmental Policy Act (1970)
National Forest Management Act (NFMA) of 1976
Forest and Rangeland Renewable Resources Planning Act of 1974
Noise Pollution and Abatement Act of 1972
Marine Protection, Research and Sanctuaries Act of 1972
Resource Conservation and Recovery Act (RCRA), enacted in 1976
Safe Drinking Water Act (SDWA) (1974)
Surface Mining Control and Reclamation Act of 1977 (SMCRA)
Toxic Substances Control Act of 1976

legislation by its economic contribution is fundamentally misunderstanding its purpose. Framing the ESA as a failure due to its hindrance of capital gain is historical revisionism. The language of the ESA was clear that protections were being put in place precisely because of a lack of concern for the environment and an alarming over-prioritization of economic growth at the expense of ecological limits. The first sentence of the ESA reads:

> (a) Findings—The Congress finds and declares that—(1) various species of fish, wildlife, and plants in the United States **have been rendered extinct as a consequence of economic growth and development untempered by adequate concern and conservation** (emphasis added).
>
> **Endangered Species Act (1973)**

The whole point of the legislation was to put a brake on growth and remember the limits of nature. It was also encouraging that the drafters of the legislation appreciated and recognized the interconnectedness of nature and that species are part of larger ecosystems.

> (b) Purposes—The purposes of this Act are to provide a means whereby **the ecosystems upon which endangered species and threatened species depend may be conserved** … (emphasis added).
>
> **Endangered Species Act (1973)**

The tension between pressures for economic growth and environmental constraints continued and elevated in the ensuing decades.

Flourishing within Limits

The idea of limits has been renewed but with a more positive outlook. In particular is the perspective that the presence of a limit does not need to invoke immediately negative connotations. For example, Jane Jacobs (2000) has focused on the opportunities that constraints and limits bring about. She insightfully remarked that

> Natural principles of chemistry, mechanics and biology are not merely limits. They're invitations to work along with them.

In other words, our understanding of thermodynamics, the periodic table, and biological principles should help to design smarter and better performing systems than without this knowledge. Ecosystems and socio-economic systems are self-organizing and thrive even in the presence of constraints. Think back to the energy flows mentioned in the opening, around 1,300 W/m^2, yet that is enough energy to drive atmospheric circulation, global ocean currents, and complex ecosystems in almost every niche on the planet. Nature has evolved to utilize this energy in a very efficient and also robust manner, resulting in highly complex, diverse, well-functioning systems that arose and are maintained all within the real-time bio-physical constraints.

The message to learn from ecosystems is elaborated in Jørgensen et al. (2015), *Flourishing within Limits: Following Nature's Way*. The authors, all systems ecologists, have drawn upon ecological theory of growth and development to identify a number of attributes that are evident in ecosystems. Using these properties and approaches—within the known bio-physical constraints—ecosystems are able to thrive and flourish, as the most diverse, complex, integrated, and sustainable systems on the Earth.

In a nutshell, the idea is that ecosystems are constrained by both the available resources as inputs and outputs as they reside as gradient-enhancing conduits between these two flows (see Figure 2, Fath 2017). In addition to solar energy, the rate of material availability is controlled by the bio-geochemical cycles at local and global scales. The rates of water, carbon, nitrogen, phosphorus, etc. all have local and global

TABLE 2 Fourteen Properties Observed in Ecosystems

1. Ecosystems conserve matter and energy
2. There are no trashcans in nature
3. All processes (in nature and society) are irreversible
4. All life uses largely the same biochemical processes
5. Ecosystems are open systems and require an input of work energy to maintain their function
6. An ecosystem uses surplus energy to move further away from thermodynamic equilibrium
7. Ecosystems use three growth and development forms: (1) biomass, (2) network, (3) information
8. Ecosystems select the pathways that move it most away from thermodynamic equilibrium
9. Ecosystems are organized hierarchically
10. Ecosystems have a high diversity in all levels of the hierarchy
11. Ecosystems resist (destructive) changes
12. Ecosystems work together in networks that improve the resource use efficiency
13. Ecosystems contain an enormous amount of information
14. Ecosystems have emergent system properties

Ecosystem Input Constraints
- Solar radiation
- Global carbon cycle
- Rate of nutrient cycling
- Rate of hydrological cycle

Ecosystem Output Constraints
- Rate of decomposition
- Rate of accumulation of unwanted byproducts
- Finding others to take your waste

FIGURE 2 Some basic constraints that ecosystems have evolved to thrive within.

constituents that influence what is available and these constraints then lead to the type of ecosystem observed whether it is a tropical rain forest, deciduous forest, steppe grassland, or Arctic tundra, for example. On the output side, the main constraint is that the products and flows out cannot exceed the capacity of the environment to assimilate them. Often this occurs by linking processes such that the output of one process is the input to another in an integrated, coupled fashion. The most obvious example is photosynthesis and respiration in that the former takes in CO_2 and gives off O_2, while the latter does the opposite. Other wastes, such as organic ones, need to be decomposed and returned back to elemental constituents. Therefore, the rate of decomposition is a main factor for the uptake of outflows, which are biologically mediated and influenced by temperature and water (warm, wet environments have faster rates of decomposition). The biomass foundation for fossil fuels occurred during a time period when for various reasons, the material was unable to be decomposed and therefore was buried under conditions that promoted the conversion to fossil fuels. Today's society is generating plastic pollution faster than it can be decomposed, and will likely also leave a recognizable and discernable (and perhaps useful) layer for future generations, and also likely that some organisms will eventually evolve better processes to decompose plastics thus reaching a new balance between production and consumption.

There are of course key differences between nature and society, namely a temporal aspect that ecosystems happen in the present, in real time—although the consequences, building biomass, building soils, establishing drainage patterns, and biogeochemical cycles, etc. have lasting effects. Socio-economic systems operate with a more future-oriented perspective, in that while the actions are short term, there is thought for a future pay-off. For example, a lion takes only what is needed to satisfy the immediate hunger. There is no utility in killing more prey at that moment as they would be absconded by competitors or would spoil; there is no profit motive or line of credit. A hunter today has in mind to take as many prey (or fish or trees or minerals, etc.) as possible since the surplus can be exchanged for other goods or services or turned into a storable currency commodity. It is not clear how to reconcile this basic difference. Humans cannot and should not give up the intellectual foresight that has evolved, but rather it could be used to see the systemic consequences of actions that exceed the limits, that exceed the regenerative rates provided by nature's processes. The remaining question is both philosophical and one of management, which is: How to align our activities within these available flows and constraints?

Conclusion

If humanity desires to stay within limits, then a first consideration is to know where those limits are. How much resources can humans use from the environment and still be within the limits? A standard ecological concept is one of carry capacity, the maximum number of individuals that can be maintained in an area without degrading that area. Carry capacity is a dynamic concept—it can move higher as we innovate new efficient methods and technologies as observed in agriculture since the time of Malthus; yet, it can also move lower as we despoil forests and fields with logging, erosion, and desertification as observed by Marsh and other witnesses to the collapse of civilizations. Metrics such as Ecological Footprint and Ecological Biocapacity that try to make estimates of both the consumption (footprint) and the resource (Biocapacity) have shown that we have outstripped our resource base. Ecological Footprint exceeds Biocapacity, and at a global level, attention is drawn to a notion called overshoot day, which for 2019 occurred on July 29. Meaning on that date, humanity had already used all the resources "sustainably available" to it for that year. After this date, the remainder of the year represents overshoot or dipping into future reserves and leaving future generations with reduced resources. Given this temporal aspect, we see that limits are not simply bio-physical but also ethical as Leopold instructed. Yet, a rigorous debate continues to this day as to whether there are limits of any kind or not. This creates tension between perspectives on policies and approaches, as some see limits as absent or challenges to overcome, while others want to recast the human scale to accommodate them. The planetary boundaries highlighted through the text give a clear indication of one scale of limits. If perhaps we break beyond the Blue Marble and our progeny lives elsewhere than within the Earth's gravitational pull, then this will shift and delay the ultimate confrontation with those concrete limits. Can this line always be receding into the future? I prefer to take care of the home that we do have on which we have co-evolved rather than rely on one that is only in our imagination.

Nuclear Energy: Economics

James G. Hewlett

Introduction

In an entry published in the *Encyclopedia of Energy Engineering and Technology,* I attempted to answer the following question: Is nuclear power economic? Unfortunately, I was unable to give a definitive answer to this question. Most of the work on that entry was done in the 2004–2005 time frame, and at that time, there was very little information on the realized costs of building nuclear power plants in the United States. There was some information on the realized cost of building nuclear power plants abroad (mainly in the Far East). However, that information was at best "sketchy" and difficult to use to estimate costs in the United States. Additionally, in the United States, a number of cost estimates of building hypothetical ("paper") plants at hypothetical ("Middletown USA") sites were published. History has shown that such estimates are always too low.[1] In short, at that time, there was a large amount of uncertainty about nuclear power plant construction costs. Thus, the best that could be done was to conclude that nuclear capital costs would have to be less than $1500 per kW before nuclear power would be economic. (This was substantially less than the cost of building nuclear power plants in the Far East.)

Over the last few years, the economic and political environment has changed, and thus, the question of whether nuclear power is economic needs to be reevaluated. First, a number of estimates of building actual nuclear power plants at actual sites have recently become available. This, by itself, would reduce some of the uncertainty about nuclear power plant construction costs. However, these estimates are two to three times higher than the ones made in the mid-2000s. Additionally, power plant construction costs in general have increased substantially. For example, the realized costs of building coal-fired power plants and wind farms have increased by about 80%–100%.[2] Such increases in construction costs would have major effects on the economics of nuclear power.

Second, unlike when the original entry was written, for a variety of reasons, utilities are now far more interested in nuclear power. In 2006, licensing activity at the U.S. Nuclear Regulatory Commission (NRC) was limited to four early site permit approvals. By issuing an early site permit (ESP), the U.S. NRC approves one or more sites for a nuclear power plant, independent of an application for a combined license to build and operate a power plant. This ESP can be valid for up to 40 years. Since then, 16 utilities have filed applications with the NRC to build and operate a total of 28 nuclear units. Given this increased licensing activity, a reexamination of the underlying economics of nuclear power is certainly in order.

Third, in the 2004–2005 time frame, most forecasts of coal and natural gas prices in 2015–2020 time frame were about $1.45 and $6 ($2009) per mmBtu, respectively.[3] Since then, fossil fuel prices increased substantially and then fell. As of 2010, most forecasts of fossil fuel prices are now greater than the ones made 5–6 years ago. Increased fossil fuel prices will clearly affect the economics of nuclear power.

The purpose of this entry is to reexamine the economies of nuclear power in light of the changed economic environment. Before proceeding with the analysis, two comments about the scope of the analysis will be made. First, in this entry, it is assumed that the investment decision—e.g., the decision to build a nuclear unit or coal-fired power plant—will be made by the owner of a traditional utility. This utility owns and operates other power plants, and the operation of all of them is interrelated. That is, if the utility chooses to operate power plant X less, it would have to operate power plant Y more to meet demand. Otherwise, "the lights would go out." In such cases, the decision maker's objective is to build the unit that minimizes the total cost of building the plant in question and operating all power plants. Suppose, for example, that the decision maker has the choice of building a nuclear or coal-fired power plant. The decision maker will calculate the total system costs if the nuclear plant is built and compare that estimate with the total system costs if the coal plant is built. The decision maker would choose to build the plant that yields the lower total system costs.

The available software to estimate total system costs is complex and expensive and requires many assumptions, and thus, using this approach is beyond the scope of this entry. However, if the alternative to the nuclear power plant is another baseload plant type operating in the same portion of the merit order (baseload demand), total system costs would be minimized by choosing the plant type that has the lower "stand-alone" or levelized cost. (Levelized costs will be defined below. Additionally, because electricity is costly to store, demand will vary over the day, month, and/or year. The portion of total demand that does not vary is called baseload, and the units that are used to meet this demand will run at close to full capacity over the entire year.) This is because the operation of both units under consideration will have the same effect on the operation of the other units. For example, suppose that the levelized cost of building and operating a nuclear power plant for 40 years is 6 cents per kWh, and the levelized cost of building and operating a combined-cycle natural gas–fired power plant is 8 cents per kWh. If both units are assumed to operate in the baseload mode, then the operation of both units will have the same effect on the operation of the other units. In such a case, total system costs would be minimized by building the nuclear plant.

Thus, in this entry, the alternatives to the nuclear power plant are two other baseload plant types—namely, coalfired and combined-cycle natural gas–fired units. By limiting the comparisons to other baseload plant types, the analysis becomes much more tractable and transparent. Unfortunately, by just computing levelized stand-alone costs, many of the renewable technologies must be excluded from the analysis. The stand-alone cost of building and operating a wind farm, for example, can be computed. However, total system costs may not be minimized by building the wind farm even though that plant type has lower stand-alone costs. This is because the effects of the operation of the wind farm and the nuclear unit on the operation of the other units will not be the same.

Second, since fossil fuel prices will probably increase over time, there is a time dimension to the question of whether nuclear power is economic. Because of the recession and utility conservation programs, additional baseload capacity will probably not be needed until around 2020. Thus, in this analysis, the first year of a unit's operation is assumed to be 2020. By focusing on the mid-term, the carbon capture and storage (CCS) technologies will not be considered. Recently, a CCS task force was formed with a goal of bringing 5 to 10 commercial-size CCS units online by 2016.[4] Even if this goal, which is very ambitious, is met, to demonstrate that the technology works, the units would have to operate for probably 5–10 years. In all probably, it would take 15–20 years before the CCS technologies would be commercially available on a widespread basis.

Capital Costs for Nuclear and Coal-Fired Powerplants

One of the major uncertainties in any analysis of the economics of nuclear power deals with the construction cost estimates. This section begins with a discussion about nuclear and coal-fired powerplants' overnight capital cost estimates. Overnight cost is defined as the cost of building a power plant instantaneously at some point in time. It is also a direct measure of the value of the land, labor, and materials needed to build a nuclear power plant. Thus, differences in overnight costs reflect differences in the values of the land, labor, and material needed to build the same unit.

It is obviously impossible to build a plant overnight, so the second part of this section describes how the total project costs are derived from the overnight costs. To do this, a number of important assumptions are needed, and in many studies, they are not articulated. This section will also show why comparisons of total project costs must be made with great care. The fuel costs for coal and natural gas–fired power plants are discussed in Section 4. The other assumptions will be briefly discussed in Section 6. These include nonfuel operating costs and nuclear fuel costs.

Nuclear and Coal-Fired Power Plant Overnight Costs

Prior to about 2007, most analyses/discussions about nuclear power plant overnight capital costs tended to focus on either realized costs of units built in the Far East (mainly Japan) or on the estimated costs of building generic units at generic sites in the United States.[5] Each of these sources had their own set of problems. There are always problems with transferring the experience of reactors built in foreign countries to the United States. Also, publicly available foreign overnight capital cost data are not well documented, so all the costs may not be included in the reported figures. Additionally, research has indicated that cost estimates of generic units built on generic sites were always too low, so there were problems with using the resulting estimates. Nonetheless, the analyses/discussions that based their cost estimates on foreign reactors tended to use overnight nuclear capital costs of about \$2700 per kW (2009 dollars).[6] The ones that used the cost estimates of generic units tended to use overnight nuclear construction costs of about \$1500–\$2000 per kW (2009 dollars).

Over the last few years, as part of the process of getting approval from the state public utility commissions (PUCs) to proceed with their NRC licensing activities, utilities filed cost estimates of building actual powerplants at actual sites. In some cases, it was possible to determine what cost items were and were not included in the estimates. More important, if the overnight construction costs were not directly reported on the filings, they could be directly estimated. On average, these overnight nuclear construction cost estimates, shown in Table 1, were about \$4000 per kW.

These estimates are clearly much better than the ones based on generic units built at generic sites. Because problems with the transfer of foreign cost information to the United States are avoided, they are much better than the estimates based on realized overnight costs of reactors built in Japan. However, they are also much higher than the ones based on generic designs at generic sites and were also much greater than the realized overnight costs of units built in Japan.

There are probably at least four reasons why the recent U.S. overnight cost estimates are greater than the realized costs of reactors built the Far East (mainly Japan). First, there are clearly cultural factors at play. Second, over the last 15 years, there has been a slow but relatively constant expansion of nuclear power in Japan, so Japanese builders are further down their learning curves than their counterparts in the United States. (The South Texas project is being built by Toshiba, a large Japanese firm that has built

TABLE 1 Estimated Overnight Costs and Lead Times of Selected Proposed Nuclear Plants

Owner	Plant Type	Plant	Capacity (mWe)	Costs (2009 Dollars per kW of Capacity)	Lead Times (Years)
Tennessee Valley Authority	ABWR	Bellefonte	1371	$3164	NA
Florida Power and Light	ESBWR	Turkey Point	3040	$3811	5–6
Progress Energy (Florida)	AP1000	Levy County	2212	$4541	5
South Carolina Electric and Gas	AP1000	Summer	2234	$4089	5 (unit 2) and 8 (unit 3)
Southern	AP1000	Vogtle	2200	$4535	6
NRG	ABWR	South Texas	2700	$3758	NA
Average				$3983

Note: A correction was made to the Vogtle Estimate reported in Du and Parsons.[7]

ABWR, advanced boiling water reactor; ESBWR, economically simplified boiling water reactor; AP1000, advanced pressurized water reactor.

some nuclear power plants in Japan to another. The cost estimates for that project are not that much different from the others. Thus, the learning may not be transferred from one country to another). Third, it is not clear whether all the costs are being reported in the Japanese figures. This is especially true for the so-called owners' costs. Costs which are the ones incurred by the utility over and above the ones paid to the firms building the unit. In fact, it was never clear if the reported Japanese costs even included any owners' costs. Lastly, many of the major components for the proposed U.S. reactors, such as the reactor vessel, are being manufactured in Asia, so some exchange rate issues could exist.

There are also a number of reasons why the overnight nuclear construction cost estimates obtained from the PUC filings are higher than the ones for generic units. As was just noted, research has shown that generic cost estimates at generic sites are always too low. Additionally, a number of analysts have argued that the growth in overnight costs was due to increases in commodity prices—the prices of iron, steel, cement, and so on—that occurred from around 2005 to 2008.[8] However, about 40%–50% of the overnight cost of building a nuclear power plant is labor related, and therefore, the effects of increases in commodity prices on total construction costs are probably modest. Moreover, the cost estimates based on generic units might have assumed that all of the components were manufactured in the United States. Over the last 10 years, the value of the dollar relative to the yen has fallen. Since many of the major nuclear components for proposed U.S. plants will be imported from Japan, some of the increases in overnight costs could be due to the fall of the dollar. This, however, would depend upon how the contracts with the Japanese firms are structured, and there is very little public information about this. Lastly, with the rapid expansion of nuclear power in China, some bottlenecks in the production of the major components that would increase costs appeared.

The increases in nuclear power plant overnight construction cost estimates raise the question of whether the current cost levels will be permanent. The effects of commodity price increases and/or decreases in the value of the dollar on the cost estimates are very unclear. Thus, the effects of decreases in commodity prices (or increases in the value of the dollar relative to the yen) on costs would also be unclear. Additionally, even with the rapid expansion of nuclear power in the Far East, in the long run, markets would adjust, and the bottlenecks would no longer exist. Because of the complexity of the technology, it would take a number of years for existing firms to build new production facilities and for new firms to enter the market. Thus, the bottlenecks may not be removed for a number of years.

Lastly, currently, only a few firms produce the large nuclear components and build the power plants. In such cases, the behavior of one firm (e.g., Westinghouse) could possibly affect the behavior of its competitor (e.g., General Electric). In economist's jargon, such a market structure is called an oligopoly.

TABLE 2 Estimated Overnight Construction Costs of Selected Proposed Coal-Fired Power Plants

Owner	Plant	Capacity (mWe)	Costs (2009 Dollars per kW of Capacity)
Florida Power and Light	Glades	1960	$2130
Duke Power	Cliffside	800	$2124
AMP Ohio	Megis Co.	960	$3277
AEP Swepco	John W Turk Jr	600	$2508
Average			$2510

Source: Adapted from Du ans Parsons.[7]

One major characteristic of an oligopolistic market is price "stickiness"—i.e., when the firm's costs fall, prices will fall, but with a lag. Thus, even if the costs of the firms that produce the components and build the plants fall, it would take some time before reductions in costs would be reflected in reductions in the prices charged to the utilities.[9,10]

The availability of some actual overnight cost estimates from the PUC filing reduces some of the uncertainty in nuclear power plant construction costs. Unfortunately, the large increases in the estimates introduce another source of uncertainty—namely, whether the current cost levels will be permanent. Given current publicly available information, one can only speculate why overnight capital costs increased and whether they will fall in the future. Moreover, no nuclear power plants in the United States have been built on time and on budget, and cost overruns in the two units under construction in Europe have occurred. Thus, even with a number of detailed cost estimates of building actual units at actual sites, there is still a considerable amount of uncertainty about nuclear overnight construction costs. Indeed, until a few units are actually built, nuclear construction costs are essentially unknown.

Table 1 also shows estimated date of commercial operation leadtimes for a number of proposed nuclear units. As can be seen from Table 1, with the exception of one unit, the estimated leadtimes ranged from 6 to 7 years. It should be noted that these lead time estimates were made just before or at the beginning of the recession. Recently, the date of commercial operation for a number of these units was moved back simply because the capacity was not needed. In all probability, the utilities will also move back the construction start date and keep leadtimes the same. If, however, they begin construction and then revise their estimated date of commercial operation, lead times could actually increase. In the 1970s and 1980s, many utilities building nuclear power plants also increased leadtimes because of the lack of need for capacity. I have shown elsewhere that these actions also affected overnight costs.[11] Thus, this issue is important.

Lastly, Table 2 shows that the average estimated overnight cost of building a number of recent coal-fired power plants was about $2500 per kW. A 2007 Massachusetts Institute of Technology (MIT) study estimated that the costs of building a wide range of coal-fired powerplants were about $1280 to $1360 per kW (2005 dollars).[12] Thus, the cost of building coal-fired power plants also increased substantially, and therefore, the cost growth was not limited to nuclear power.

Derivation of Total Project Costs

The focus of the preceding section was on overnight costs, because they are a direct measure of the values of the land, labor, and materials needed to build a power plant. However, the analysis will use total project (capital) costs. The best way to explain how total capital costs are computed is to outline the steps taken to derive an estimate of the total cost of building any power plant. The first step is to prepare a detailed "bottom-up" estimate using current commodity prices, labor wage rates, and so on. This bottom-up estimate is the product of the estimated quantities of the land, labor, and materials needed to build the unit times the prices of these inputs. Suppose, for example, that the firm is making an estimate in 2010 of the cost of building a nuclear unit that will become operational in 2020. Given a 6-yr lead time, construction must begin in 2015. Thus, the firm would first make a bottom-up estimate using 2010 prices and wage rates. This is the estimate of the overnight costs using 2010 prices. In the example shown in Table 3, the 2010 estimated overnight cost is $4000 per kW of capacity.

Next, the cost of building the unit overnight in 2015—the year that construction of the unit begins—must be estimated. To do this, the firm would make assumptions about how commodity prices, labor wage rates, and so on would change from 2010 to 2015. In the example shown in Table 3, commodity prices, labor wage rates, etc., are assumed to increase at a rate equal to the general inflation rate of 3% per year. Given this assumption, the 2015 overnight cost would be about $4600 per kW ($\$4000 \times 1.03^5$). Then, assumptions about how the funds are expended over each year of the construction period and how prices change over the construction period would be used to compute total costs in the dollars of the year the funds are expended. In the example shown in column 3 in Table 3, total construction costs excluding financing charges would be about $5000 per kW of capacity. Note that simply because of increases in prices and wages over the 2010–2020 period, costs increased by more than $1000 per kW.

Lastly, there is the issue of how to include the financing costs in total capital costs and analyses of the economics of nuclear power. Because of the complexity of this issue, there are wide variations in both the financing rates and the costs that are included in the total capital cost estimates. In some analyses, including the present one, for a variety of reasons, the total capital cost estimates that are computed do not include any financing costs. In such cases, financing issues are accounted for elsewhere.[7] In other analyses, the total capital cost estimates do include financing costs. Sometimes, the total capital cost estimates include just interest charges on the monies that are actually borrowed.[6] If the analysis is used by a utility that is subject to state-level rate-of-return regulation, the financing charges included in the total capital cost estimate often consist of interest on the funds that are borrowed (debt financing) and an implied charge for the funds that are internally generated (equity financing).

It is always tempting to compare total capital cost estimates that are reported in the media. Columns 4–7 in Table 3 illustrate that this must be done with great care. In particular, these columns show total capital cost estimates using four different assumptions about the financing costs that are included

TABLE 3 Derivation of Total Capital Costs

	Total Capital Costs						
	(1)	(2)	(3)	(4)	(5)	(6)	(7)
Year	Percent of Total Overnight Costs Spent in Each Year of Construction Period	Expenditures in 2015 Dollars (per kW)[a]	Expenditures in Dollars of Year Funds Expended (per kW)[a]	Financial Costs Not Included (per kW)	Column 4 Plus Financing Charges—Lower Financing Rate (per kW)[b]	Column 4 Plus Financing Charges—Higher Financing Rate (per kW)[c]	Column 4 Plus Just Debt Component (per kW)[d]
2015	10.00%	463.7	$463.7	$463.7	$695.9	$925.1	$560.2
2016	15.00%	$695.6	$716.4	$716.4	$1004.8	$1273.9	$838.6
2017	20.00%	$927.4	$983.9	$983.9	$1289.7	$1559.3	$1116.0
2018	30.00%	$1391.1	$1520.1	$1520.1	$1862.2	$2147.1	$1670.8
2019	15.00%	$695.6	$782.9	$782.9	$896.3	$985.5	$833.8
2020	10.00%	$463.7	$537.6	$537.6	$575.2	$603.1	$554.8
Total Capital Costs per kW		$4637.1	$5004.6	$5004.6	$6324.1	$7494.1	$5574.1
Total Capital Costs Billions of Dollars		$ 10.2	$ 11.0	$ 11.0	$ 13.9	$ 16.5	$ 12.3

[a] Overnight capital costs in $2010 of $4000 per kW of capacity and a 3% annual escalation rate in costs were used to derive the data in columns 2 and 3

[b] A 7% financing rate was used.

[c] A 12 % financing rate was used.

[d] An 8 % debt rate was used.

in them. As can be seen from this table, the total capital costs range from $5000 to $7500 per kW, depending upon how the financing costs are reported. Again, comparisons of cost estimates without detailed knowledge about what is included in them should not be done.

Environmental Costs and Regulations

In the long run, another important factor is the environmental costs of generating electricity from fossil fuel–fired and nuclear power plants. The fossil fuel–fired power plant's capital cost estimates shown in Table 2 include the expenses needed to meet sulfur dioxide and nitrogen oxide limits imposed by the Environmental Protection Agency. The estimates also include the costs of meeting current federal and state water discharge regulations. Additionally, in the analysis reported in Section 6, an explicit fee on carbon dioxide emissions will be included. The costs of all existing laws and regulations affecting fossil fuel–fired power plants, and an important proposed one are, therefore, included in the analysis.

Nuclear power has its own set of environmental costs—namely, the possibility of exposing the public to radiation, decommissioning, and radioactive waste disposal. The cost estimates of the units shown in Table 1 reflect designs that met NRC requirements as of about 2007 and 2008. These designs may, however, have to be changed because of additional NRC requirements, which could have cost implications. The design of the AP1000, a 1100-MW pressurized water reactor, was approved by the NRC in 2006. However, a number of changes to that design have been approved, and one additional change is currently under review by the NRC. Similarly, the design of the ABWR, a 1600-MW boiling water reactor developed by GE, was approved by the NRC in 1997. Currently, GE is in the process of renewing the NRC approval of that design. Additionally, in 2009, a number of design changes were submitted by GE to the NRC. The NRC is currently reviewing these changes.

Nuclear power decommissioning deals with the dismantlement of the plant and the decontamination of the site so it can be used for other purposes. The NRC must approve the utilities' plans, set residual radiation standards, and oversee the actual dismantlement of the plant. To insure that funds will be available when units are decommissioned, the state PUCs require that monies be placed in trusts. In the analysis presented in Section 6, it was assumed that decommissioning would cost $600 million and would occur 40 years after the plant's date of commercial operation.

The spent fuel from a light water reactor will be radioactive for millions of years, and the disposal of that waste is a major economic and political issue. There are two basic methods of disposing of the spent fuel from nuclear reactors: geological disposal and reprocessing/recycling. Reprocessing/recycling consists of extracting usable fuel from the waste and using it in other reactors. Currently, this is done in a few countries, most notably France and Japan. Needless to say, reprocessing/recycling is very controversial. It is very expensive and, at least in its current form, the reprocessed spent fuel could be used for military purposes. Thus, there are major proliferation concerns with reprocessing. Lastly, reprocessing has its own set of waste disposal problems.

With the passage of the Nuclear Waste Policy Act (NWPA) of 1982, the United States formally chose direct geological disposal of the waste. The initial act directed that the Department of Energy (DOE) study the feasibility of burying the waste at a number of sites. In 1988, however, Congress directed DOE to focus on just one site—Yucca Mountain, Nevada—and in 2003, the President formally chose Yucca Mountain as the country's high-level waste repository site. Under the NWPA, the state of Nevada could veto the President's decision, which they did. This veto was then overturned by Congress, and in 2008, the DOE submitted an application to the NRC for their approval to build the repository.

In 2010, the Obama Administration decided to stop work on Yucca Mountain, and DOE formally requested the NRC to permit them to withdraw the application. As of early 2011, the NRC has yet to publicly announce their decision. Additionally, the Administration abolished the Office of Civilian Radioactive Waste Management—the office within DOE that was managing the Yucca Mountain project. In response to the Obama Administration's actions, a number of lawsuits were filed by various states and localities in Federal Court. These lawsuits claim that DOE does not have the authority to unilaterally stop work on Yucca Mountain. As of early 2011, the ultimate outcomes of these lawsuits are unknown, and it is unclear what would happen if the courts ruled against DOE.

The NWPA requires that the government collect a fee of one mill (one-tenth of a cent) per kilowatt hour of electricity generated from nuclear power, and this charge is included in the analysis. Given the state of the U.S. spent fuel disposal policy, it is impossible to say anything about ultimate waste disposal costs. Regardless of what the ultimate cost is, at least for geological disposal, many of the costs will be incurred by future generations, and because of the "magic of compound interest," the total costs "today" will be small. To illustrate the effects of discounting, the yearly estimated costs of building and operating Yucca Mountain will be used. These costs were derived from a 2008 estimate prepared by DOE and the total undiscounted costs were about $100 billion. (Since Yucca Mountain has been abandoned, these estimates should be viewed as the cost of some hypothetical repository.) The cumulative costs are shown in Figure 1. As can be seen from this figure, roughly 50% of the expenditures will be made from year 50 to year 150, and the bulk of the expenditures will be made from year 30 to year 80. The point here is that the bulk of the costs of a geological repository will probably be incurred many years in the future.

Because of the complexities involved in geological disposal of the waste, it is quite possible that the ultimate cost of such a repository will be much greater than $100 billion. For argument's sake, suppose that the yearly expenditures are five times those shown in Figure 1. Figure 2 shows the present value "today" of the yearly expenditures using various discount rates. Using a 2% discount rate, which is very low, the present value "today" of the yearly expenditures is about $200 billion. Many private sector discount rates range from 7.5% to 10%, and if these rates were used, the present value "today" of $500 billion s incurred over a 150 years period would be less than $50 billion—roughly one tenth of the undiscounted costs.

Because of the discounting process, very large costs imposed on future generations will appear to be very small "today." Consequently, some intergenerational equity issues dealing with evaluating the back-end costs exist. Some economists have attempted to include intergenerational fairness considerations in discounting, but unfortunately, there is no consensus about how to incorporate equity issues in discounting.[14,15] Thus, there are some equity issues dealing with nuclear power that cannot be resolved with economic analysis.

Discount Rates

The choice of the appropriate discount rate is another very important assumption in any analysis of the economics of nuclear power. To compare the economics of different plant types, costs that are incurred in the future must be discounted back of the present (“today"). This discounting process will account for the fact that “a dollar today is worth more than a dollar tomorrow.” Nuclear capital costs are much greater and the operating costs are much less when compared with fossil fuel–fired power plants, especially natural gas–fired units. Thus, a larger percentage of the total cost of building and operating a nuclear plant is incurred “upfront” when compared with a fossil–fired power plant. The higher the discount rate, the greater would be the weight placed on the “up-front” costs, and thus, higher discount rates would tend to favor natural gas and, to a lesser extent, coal-fired power plants relative to a nuclear unit.

Since most spreadsheets have routines that calculate present values, the mechanics of discounting are trivial. However, the same cannot be said for the choice of the discount rate. The discount rate should reflect the risk of the project—i.e., building and operating a power plant. There is a long literature on estimating discount rates, but unfortunately, in most cases, the necessary financial data (stock prices and bond yields) are at the utility and not at the project level.[16] This presents some problems when utilities own assets that have different risks. In particular, most but not all utilities own transmission and distribution facilities in addition to generating plants. The risks associated with building and operating the transmission/distribution (TD) system are very different from the risks of building and operating powerplants. Thus, the risks reflected in observed utility level data are some type of weighed average of the risks of the TD and generating plant assets. Additionally, the risks reflected in recent utility level data largely deal with operating factors because very few baseload power plants are currently under construction. Thus, project specific risks (i.e., discount rates) for large-baseload power plants cannot be estimated with actual data. Indeed, this is one of the classic problems in finance—the choice of a discount rate when a low-risk firm undertakes a high-risk investment.

Since the choice of a discount rate is largely judgmental, the analysis described in Section 6 will use two of them. (See Table 4.) Financial theory states that investors will require higher returns for bearing risks that are nonrandom.[16] (Financial economists often refer to nonrandom risk as nondiversifiable or systematic risk. Even when observable data can be used, the estimation of such risks is very difficult).

TABLE 4 Assumption Used in the Analysis

	Plant Type		
Assumption	Nuclear	Coal	Combined-Cycle Natural Gas
Unit size (mWe)	1,000	1,000	1,000
Capacity factor	85.00%	85.00%	85.00%
Heat rate	10,400	8,870	6,800
Overnight costs (dollars per kW of capacity)	NA	2300	850
Lead times (years)	6	4	3
Fixed O&M costs (dollars per kW of capacity)	96	51	23
Variable O&M (dollars per kwh)	0.0004	0.00357	
Fuel costs (mills per kwh)	7	NA	NA
Waste fee (mills per kwh)	1	NA	NA
Decommissioning (million $s)	600	NA	NA
CO2 fee for each dollar per metric ton CO2 (2009 $/mmBtu)[a]	0	0.095	0.053
Escalation/Inflation Rates:			
Inflation rate	2.00%	2.00%	2.00%
Annual O&M real escalation rates	1.00%	1.00%	1.00%
Annual fuel cost real escalation rate	0.50%	0.20%	1.70%
Annual real capital cost escalation rate	0.00%	0.00%	0.00%
Financial:			
Tax rate	37.00%	37.00%	37.00%
Debt fraction—higher rate	40.00%	40.00%	40.00%
Debt fraction—lower rate	60.00%	60.00%	60.00%
Cost of debt capital—higher rate	8.00%	8.00%	8.00%
Cost of debt capital—lower rate	6.50%	6.50%	6.50%
Cost of equity capital—higher rate	15.00%	15.00%	15.00%
Cost of equity capital—lower rate	11.00%	11.00%	11.00%
Weighted after-tax cost of capital—higherrate[b]	11.02%	11.02%	11.02%
Weighted after-tax cost of capital—lower rate[b]	6.04%	6.04%	6.04%

Source: Adapted from Du and Parsons.[7]

Note: All costs are in 2009 dollars. Except for the financial assumptions, the others were generally obtained from Du and Parsons.[7]

[a] These values were used to compute the increase in fuel costs per kilowatt hour because of a carbon fee. For example, the increase in fuel costs for a coal plant caused by a fee of \$20 per metric ton carbon was computed as follows: $20^{*}.095^{*}(8870/1000)=16.86$ mills per kwh.

[b] These values were used as the discount rates. These rates cannot be compared with the ones used in any study that excluded corporate income taxes.

This is because random risks can be eliminated by constructing portfolios of diversified assets. Thus, the discount rate will be a direct function of the level of nonrandom risk. The higher discount rate assumes that the nonrandom risks of building and operating any power plant are 50% greater than the risk for the average investment. The lower discount rate assumes that the nonrandom risks are about 20% less than the risk for the average investment. The higher and lower discount rates are consistent with the nonrandom risks observed in the airlines/telecommunications and manufacturing industries, respectively. The higher discount rate is also slightly greater than the one used for nuclear power in the MIT study, and the lower rate is slightly less than the one used for fossil fuel–fired power plants in the MIT study.[6]

To properly interpret the differences in the two rates, the distinction between risk reduction and risk shifting becomes important. One example of risk shifting, as opposed to risk reduction, is the cost-based rate-of-return regulation of utilities. Under this form of regulation, utilities can recover all the costs for projects that are ex ante prudently expended but ex post uneconomic. In such cases, some of the risks are being shifted from utility shareholders to electricity consumers. State-level rate-of-return regulation, therefore, does not reduce risks but rather shifts some of the risks to consumers. Another example is long-term fixed-price purchase power contracts between deregulated generating companies and the regulated transmission and distribution firms. Again, such contracts do not reduce risks but instead shift the risks associated with volatile wholesale electricity prices from utility shareholders to consumers. In short, the difference in the two discount rates shown in Table 4 reflects differences in the underlying risks of building and operating power plants and not who bears that risk.

As Table 3 shows, the total cost of building a 2200-MW-nuclear power plant could be in the range of $10 to $15 billion. Given the size of many U.S. utilities, the failure of a $10-billion project may result in the firm's bankruptcy or insolvency. Thus, many utilities who are planning to build nuclear power plants are attempting to dilute bankruptcy possibilities by forming joint ventures or, in one case, a merger. The discussion above abstracts from bankruptcy risk per se because it a function of the size of the project relative to the size of the firm along with the underlying risk of the project. In other words, the risk of a project is not a function of the firm's size but instead is determined by the variability in the underlying costs and revenues.

Cost of the Alternative

A fourth factor affecting the decision to build a nuclear power plant is the cost of the alternative. As was noted in Section 2, coal-fired power plant construction costs have escalated over the last few years. This cost growth has introduced some uncertainties related to the permanency of the increases. However, environmental considerations aside, most of the uncertainty related to the cost of generating electricity from fossil fuel–fired power plants deals with fuel prices. Historical and projected coal prices are shown in Figure 3. As this figure shows, after adjusting for inflation, coal prices fell until about the year 2000 and then increased by about 30% from 2005 to 2010. Two projections suggest that coal prices will remain relatively constant at about $2.00 per mmBtu over the 2010–2020 period, and the other one shows coal prices increasing to their 2009 levels. (In this section, all the prices are in 2009 dollar. Additionally, the first year of the unit's commercial operation is assumed to be 2020.)

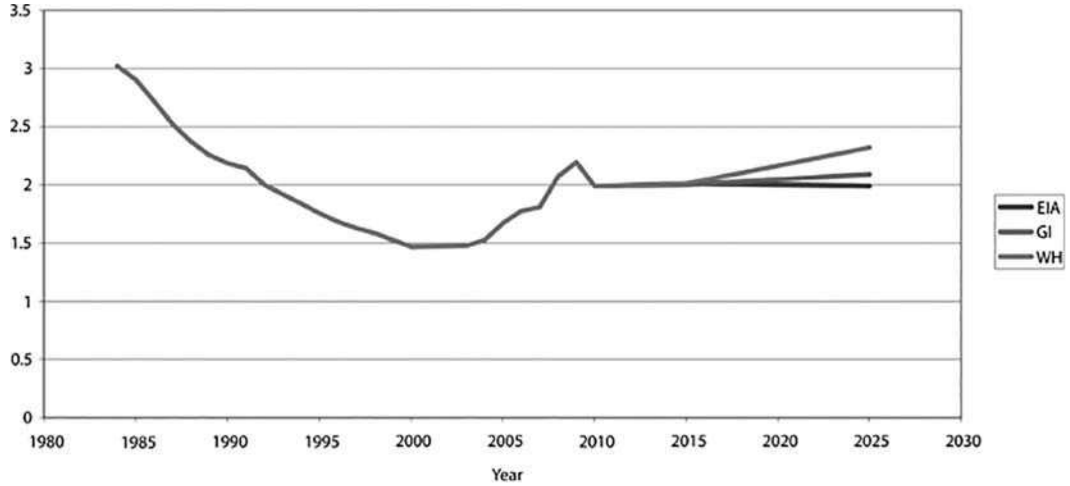

FIGURE 3 Delivered price of coal to electric utilities, 1984–2025 (2009 dollars per mmBtu).

Source: Annual Energy Outlook, 2010.[17]

Historically, natural gas prices have been much more volatile than coal prices (see Figure 4). After natural gas prices were deregulated in the early 1980s, they fell from more than $6 to about $3–4 mmBtu. In about 1998, natural gas prices began to increase, and by 2008, they increased to more than $9.00 mmBtu. Then, partly because of the recession, they fell by more than 100% to about $5 mmBtu. All three projections shown in Figure 4 have natural gas prices increasing to more than $6 mmBtu by about 2014. Over the 2015–2020 period, two of the three projections have natural gas prices increasing by relatively small amounts, whereas the third one has prices continuing to increase to more than $8.00 mmBtu by 2020.

As Table 5 shows, there are also wide regional variations in prices of coal and, to a lesser extent, natural gas. These variations are largely due to the cost of getting the fuel from the source of supply to the end users. Regions of the country that are far away from the source of supply tend to have higher costs, and the ones located close to the coal mines or gas fields have lower costs. Thus, the economics of nuclear power have a regional dimension.

TABLE 5 2010 Delivered Price of Coal and Natural Gas to Electricutilities (2009 Dollars per mmBtu)

Census Region	Coal	Natural Gas
New England	3.14	5.70
Mid Atlantic	2.23	5.03
South Atlantic	2.86	5.87
East North Central	1.88	4.30
East South Central	2.24	4.66
West North Central	1.25	4.62
West South Central	1.55	4.40
Mountain	1.55	5.00
Pacific	2.24	4.89
US average	1.99	4.85

Results

As was noted in Section 2, the cost of building nuclear power plants is highly uncertain. There are issues dealing with the permanency of current construction cost levels and also their accuracy. Wide regional variations in coal prices and uncertainty about future natural gas prices also exist. Because of these factors, point estimates of the levelized cost of generating electricity from coal, natural gas, and/or nuclear power plants have little value. The general approach used here is, therefore, to derive various combinations of nuclear overnight capital costs and "current" coal (natural gas) prices that would result in nuclear power and coal (natural gas) being equally economic—i.e., the levelized costs of coal (natural gas) and nuclear power are the same. The levelized cost is defined as the constant real price of electricity that would result in the net present value of the project (discounted revenues less discounted costs) equal to zero. The method used to compute the levelized costs can be found in the work of Du and Parsons.[7] Then, the combinations of fossil fuel prices and overnight nuclear capital costs that would result in nuclear power being economic (or uneconomic) could be determined. While this is not ideal, it is the best that can be done, given all the uncertainty.

To implement this approach, it was necessary to "fix" all the other variables affecting the economics of nuclear power, and unfortunately, there is some uncertainty in all of them. Some unreported sensitivity analyses suggested that variations in leadtimes, heatrates, and nonfuel Operations and Maintenance (O&M) costs had relatively minor effects on the basic conclusions of this analysis. Additionally, as was discussed in Section 2, there is uncertainty about the permanency of the increases in the coalfired power plant overnight construction costs. As will be seen shortly, fixing the coal capital costs will not have any major impact on the basic conclusions of this analysis.

The results of a comparison of the economics of nuclear power relative to coal-fired powerplants using the higher discount rate are shown in Figure 5a. (In this section, except where noted, all costs and prices are in 2009 dollars.) The solid line shows the combinations of overnight nuclear capital expenses and current coal prices that would result in both plant types having the same levelized cost. Thus, any combination of overnight nuclear capital costs and coal prices that fall in the region denoted as E would result in nuclear power being economic. Similarly, any combination of these two factors that fall in the region U would result in nuclear power being uneconomic relative to coalfired power plants.

As was noted above, overnight nuclear capital costs derived from a small number of PUC filings averaged about $4000 per kW. Given overnight capital costs of $4000 per kW, projected coal prices would have to be about $6 per mmBtu in 2020 before nuclear power would be competitive with coal-fired power plants (point A in Figure 5a). These coal prices are about two and a half to three times their 2010 levels and are also much greater than the projected values. Coal prices of $6 per mmBtu are also much greater than their 2010 levels in regions of the United States that are not close to the coal reserves.

Similarly, given projected coal prices in the midterm of about $2 mmBtu, nuclear overnight capital costs would have to fall to levels roughly comparable with the ones for the coal-fired power plants, before nuclear power would be economic. Given $2 per mmBtu coal prices and the nuclear operating cost assumptions shown in Table 4, the operating costs of both plant types are about the same. Thus, for nuclear power to be competitive with coal-fired powerplants, the overnight capital costs of the two technologies would have to be similar (point B in Figure 5a).

The results of the comparison of nuclear power to coalfired power plants using the lower discount rate are shown in Figure 5b. These results are qualitatively similar to the ones using the higher discount rate. That is, if the overnight nuclear capital costs would be about $4000 per kW, coal prices in 2020 would have to be much greater than the ones reported in a number of recent studies. Additionally, using projected coal prices in 2020 of about $2 per mmBtu, overnight nuclear capital costs would have to fall to about $2500 per kW before nuclear power would be competitive with coal-fired power plants.

To summarize, if nuclear overnight capital cost estimates found in a number of recent PUC filing are at all indicative of what it would actually cost to build a nuclear power plant, and if the external costs of carbon dioxide (CO_2) emissions are ignored, nuclear power is not competitive with efficient coal-fired

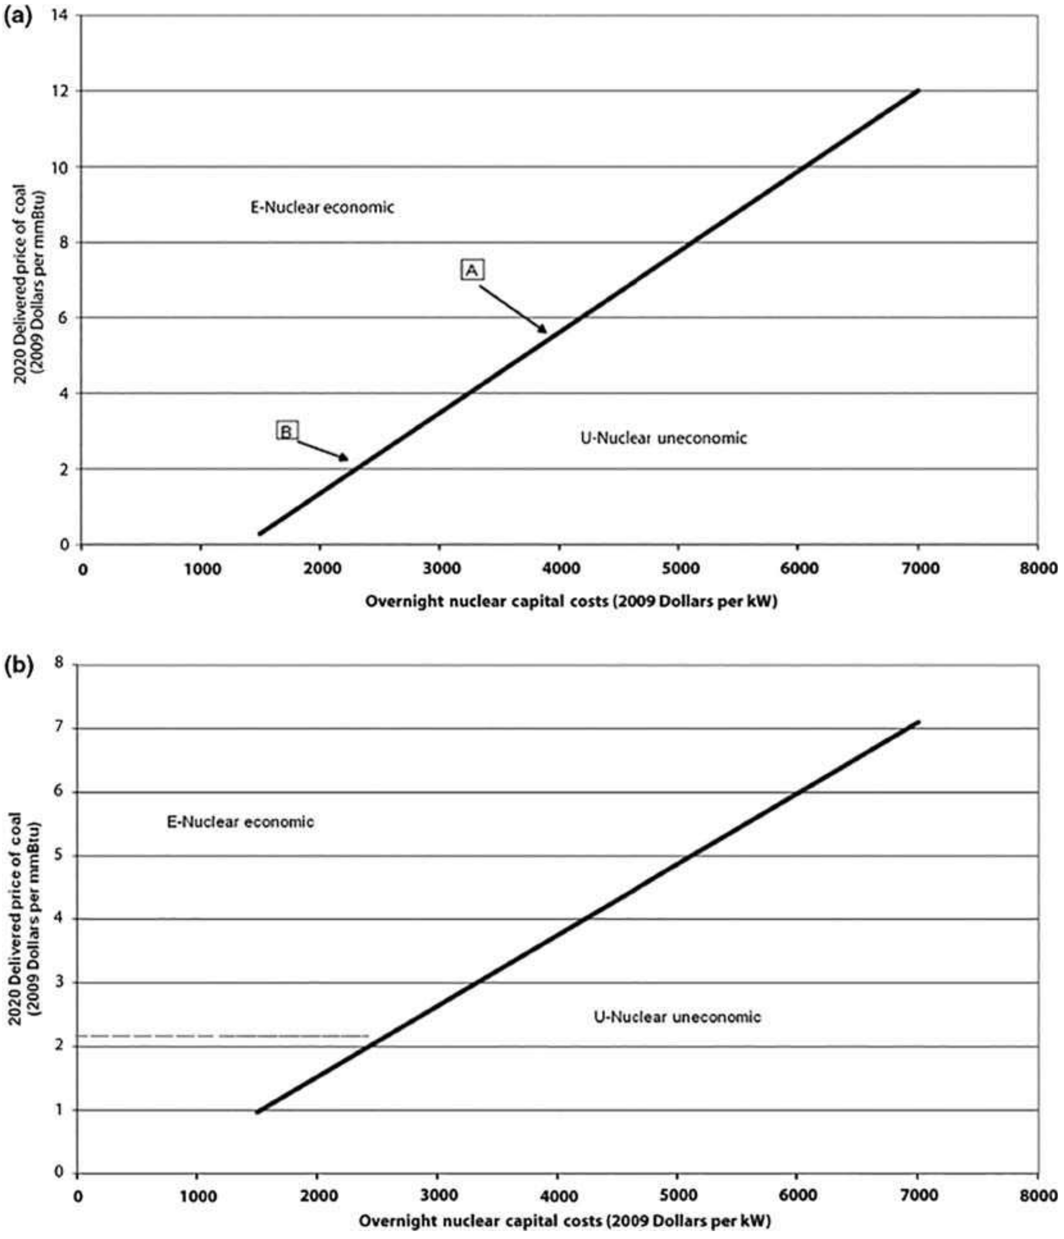

FIGURE 5 The economics of a nuclear power plant relative to a coal-fired power plant: (a) higher discount rate (b) lower discount rate.

Note: The solid line shows the combinations of 2020 coal prices and nuclear capital costs that would produce the same levelized cost for both plants. The combinations of coal prices and nuclear capital costs that would fall in the region E (U) would produce levelized costs that are lower (higher) for the nuclear plant than for the coal plant.

power plants. Given nuclear capital costs of about $4000 per kW, coal prices would have to increase substantially before nuclear power would be competitive with coal-fired power plants. Also, given the assumptions shown in Table 4, these conclusions do not depend upon the assumed discount rate. As will be seen shortly, the same is not true for comparisons of nuclear power with natural gas–fired power plants.

The economics of nuclear power relative to an efficient combined-cycle natural gas–fired power plant using the higher discount rate is shown in Figure 6a. Given overnight nuclear capital costs of $4000 per kW, natural gas prices would have to increase to about $9.50 per mmBtu before nuclear power would be economic relative to gas–fired power plants (point A in Figure 6a). Natural gas prices of over $9 per mmBtu in 2020 are much higher than their 2010 levels and are also higher than their projected levels shown in Figure 4. Similarly, using the higher discount rate and 2020 natural gas prices

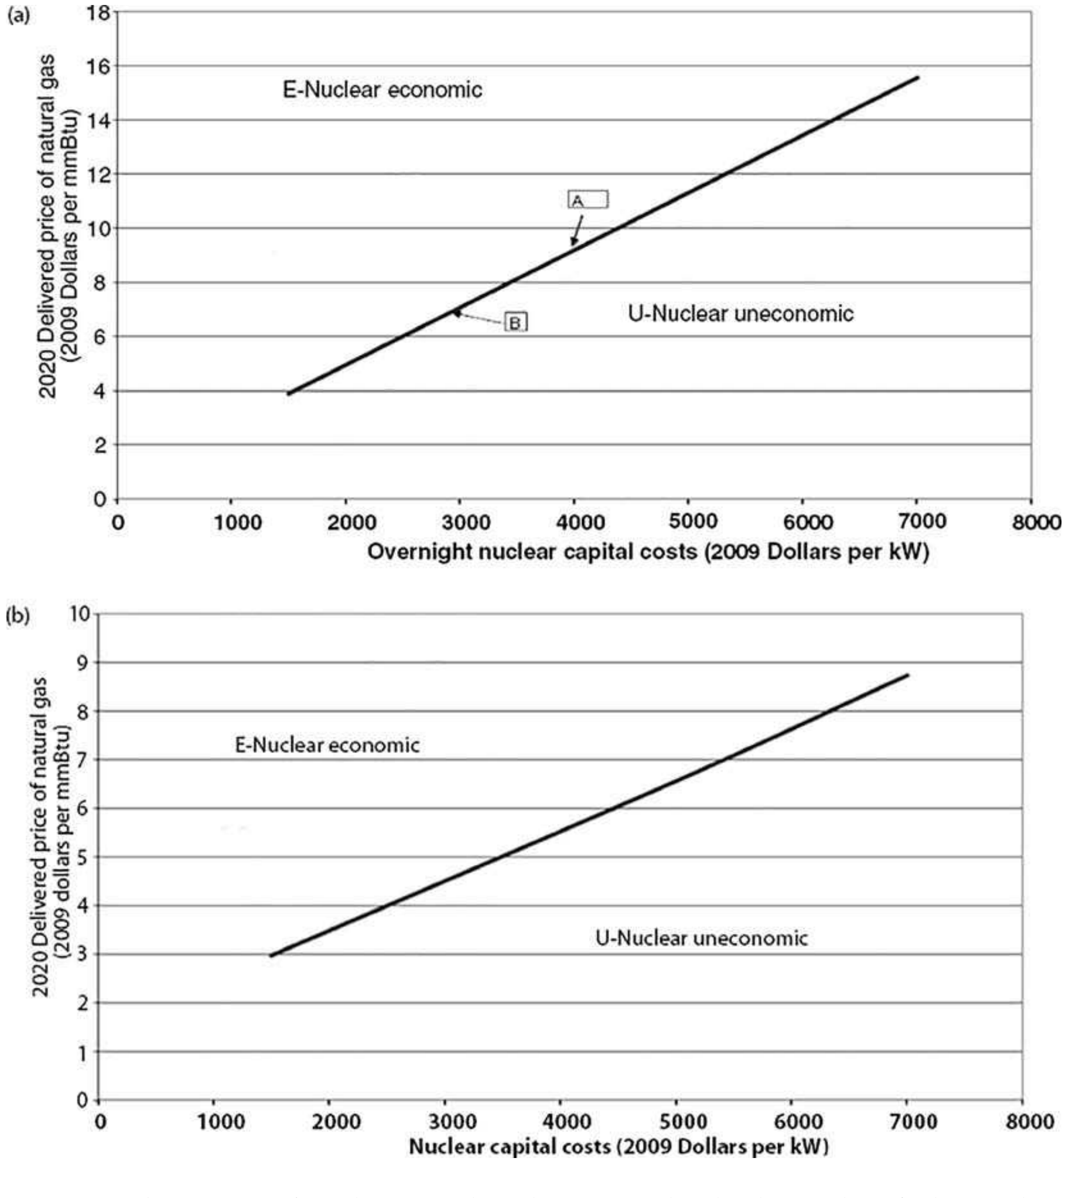

FIGURE 6 The economics of a nuclear power plant relative to a combined cycle natural gas–fired power plant: (a) higher discount rate (b) lower discount rate.

Note: The solid line shows the combinations of 2020 natural–gas prices and nuclear capital costs that would produce the same levelized cost for both plants. The combinations of gas prices and nuclear capital costs that would fall in the region E (U) would produce levelized costs that are lower (higher) for the nuclear plant than for the gas–fired plant.

of about \$7 per mmBtu, overnight nuclear capital costs would have to be about \$3000 per kW before nuclear power would be competitive with natural gas-fired power plants.

Given overnight nuclear capital costs of \$4000 per kW, roughly 75% of the total cost of generating electricity from the nuclear unit is incurred upfront in terms of construction costs. However, about 75% of the total cost of generating electricity from a combined-cycle natural gas–fired plant is incurred in future years. Again, the lower the discount rate, the lesser will be the weight placed on the up-front costs, and thus, lower discount rates would favor nuclear power. The comparison of the economics of nuclear power plants relative to gas–fired power plants using the lower discount rate, shown in Figure 6b, suggests that this is the case. Using the lower discount rate and nuclear capital costs of about \$4000 per kW, natural gas prices would have to increase from their 2010 levels of about \$5.00 to about \$6.00 per mmBtu by 2020 before the nuclear power plant would be economic. Natural gas prices of about \$6 per mmBtu in 2020 are slightly lower than two of the three projections shown in Figure 4. Thus, if building and operating any power plant is perceived to be a relatively low-risk endeavor, even if the external costs related to CO_2 emissions are ignored, nuclear power is marginally economic relative to combined-cycle natural gas–fired power plants.

This result was based on the assumption that real natural gas prices would increase at an annual rate of .75% from 2021 to 2061. At least through 2035, this escalation rate is relatively high. If a lower escalation rate in annual real natural gas prices of 0.3% were assumed, and given nuclear overnight capital costs of \$4000 per kW, 2020 real natural gas prices would have to be about \$7 per mmBtu before a nuclear power plant would be competitive with a combined-cycle natural gas–fired power plant. Natural gas prices of \$7 per mmBtu in 2020 are greater than two of the three projection shown in Figure 4. Thus, using lower discount rate, nuclear power would be extremely marginally competitive with combined-cycle natural gas–fired power plants.

As was noted above, the fossil fuel capital costs include the expenses needed to meet current sulfur dioxide and nitrogen oxide emission levels. However, the external costs related to CO_2 emissions have not been included. The size of these costs is, however, highly uncertain. Indeed, the extent to which CO_2 emissions have resulted in global warming and the associated costs of the warming of the atmosphere are still being debated. However, one recent study recommended using external costs in 2020 of about \$7 to \$42 or perhaps about \$80 per metric ton of CO_2 emissions if the Earth warms faster than expected.[18] Additionally, some recent analyses of the effects of recently proposed U.S. "cap-and-trade" programs estimated that in 2020, the "price" of CO_2 emissions would range from about \$20 to \$100 per metric ton in 2020.[19] Lastly, in Europe's CO_2 cap-and-trade program, over the last few years, CO_2 emission permits have been trading in the range of 15€–20€ per metric ton.

Because of these uncertainties, the best that could be done is to compute the combinations of nuclear capital costs and CO_2 prices that would result in nuclear power being economic relative to coal and combined-cycle natural gas–fired power plants. This, of course, requires that coal and natural gas prices in 2020 be fixed at \$2.00 and \$7.00 per mmBtu, respectively. The results of this exercise for coal and natural gas–fired power plants are shown in Figures 7 and 8, respectively. As before, both the higher and lower discount rates were used.

These results suggest that if nuclear power construction costs were about \$4000 per kW, CO_2 prices in 2020 would have to exceed \$20–\$40 per metric ton before nuclear power would be economic relative to coal-fired power plants (see Figure 7). These CO_2 prices are in the same range as ones used in a number of discussions. Thus, once the external costs related to CO_2 emissions from very efficient coal-fired power plants are considered, nuclear power could very well be economic relative to coal-fired power plants. However, using the higher discount rate, the price of CO_2 emissions would have to be somewhat higher (about \$50–\$60 per ton) before nuclear power would be competitive with combined-cycle natural gas–fired power plants. As was just noted, using the lower discount rate, nuclear power would be very marginally economic relative to gas–fired power plants even if the price of carbon were zero.

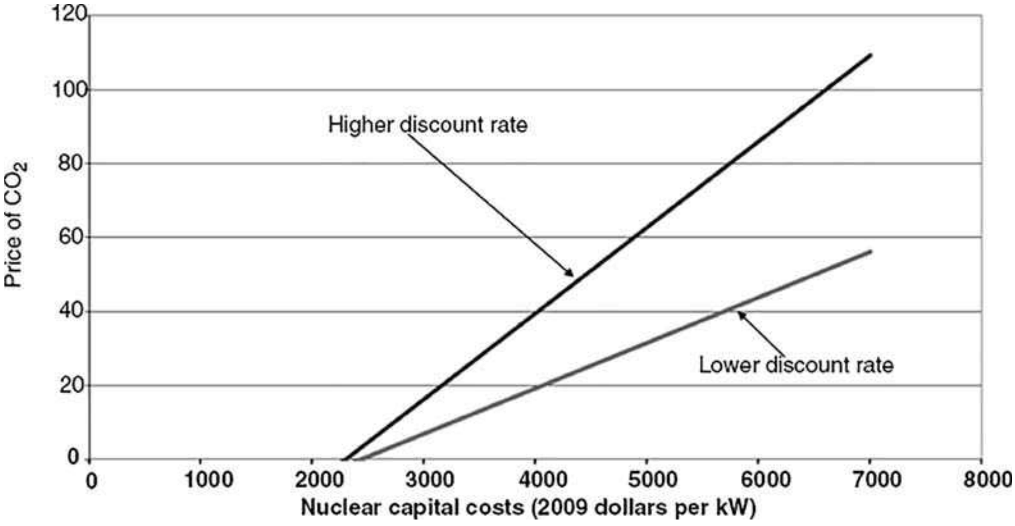

FIGURE 7 The economics of a nuclear power plant relative to a coal-fired power plant: costs of CO_2 emissions included.

Note: The solid line shows the combinations of CO_2 prices and nuclear capital costs that would produce the same levelized cost for both plants. The combinations of coal prices and nuclear capital costs that would fall in the region above (below) or to the left (right) would produce levelized costs that are lower (higher) for the nuclear plant than for the coal plant. Real coal prices in 2020 were assumed to be about $2.10 per mmBtu. The carbon prices are in 2009 dollars per metric ton.

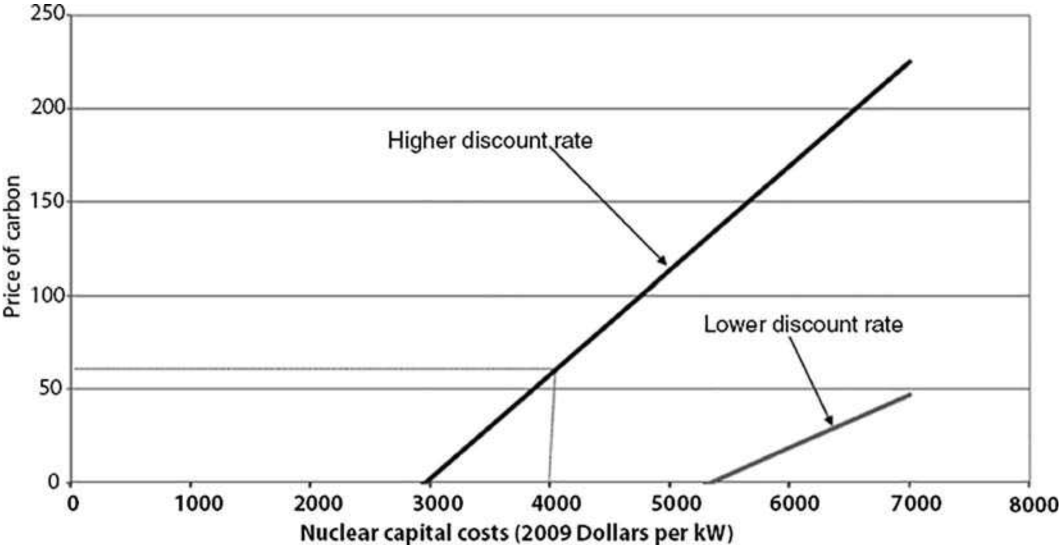

FIGURE 8 The economics of a nuclear power plant relative to a combined-cycle gas–fired power plant: cost of CO_2 emissions included.

Note: The solid line shows the combinations of CO_2 prices and nuclear capital costs that would produce the same levelized cost for both plants. The combinations of natural gas prices and nuclear capital costs that would fall in the region above (below) or to the left (right) would produce levelized costs that are lower (higher) for the nuclear plant than for the gas plant. Real natural prices in 2020 were assumed to be about $7.00 per mmBtu. The carbon price is in 2009 dollars per metric ton.

Conclusions

This entry attempted to answer the following question: Is nuclear power economic? Two major factors will influence the economics of nuclear power, and since there are major uncertainties with both of them, it is impossible to give an unqualified answer. The most obvious one is the cost of building a nuclear power plant. In a number of recent PUC rate cases, overnight nuclear power plant capital costs of around $4000 per kW were used. If these estimates are indicative of realized overnight costs, environmental considerations aside, then nuclear power would generally not be economic. The analysis in this entry suggests that overnight nuclear power plant capital costs would have to fall to between $2500 and $3000 per kW before nuclear power would be economic. The one exception to this conclusion is if a very low discount rate is used.

The second factor is the cost of the alternative, which would be either coal-fired power plants or combined-cycle natural gas–fired units. The major uncertainty here is the enactment of policies limiting CO_2 emissions. The economics of nuclear power would be greatly improved if all of the external costs related to global warming were included in the cost of generating electricity from fossil fuel–fired power plants. It must be noted that nuclear power has its own set of environmental costs in the form of nuclear waste disposal and decommissioning. Since these costs will be incurred over hundreds of years, because of discounting, the back-end costs are very small "today." Some have objected to discounting expenses incurred over very long time periods because this procedure represents a strong incentive to impose large costs on future generations. However, such equity considerations are outside the realm of economic analysis.

Lastly, there are probably at least two reasons why some utilities are interested in nuclear power even though the economics appears to be unfavorable. First, recent research using data from the United Kingdom found that nuclear power can be used as a hedge against volatile natural gas prices if the utility was subject to price regulation.[20] It is possible that utilities are using nuclear power as a hedge. This might partially explain why most of the utilities interested in nuclear power are located in states that have not been deregulated. Second, a number of utilities that are interested in nuclear power and their state-level regulators are assuming that eventually some type of explicit carbon price will be enacted. The analysis in the present entry does show that the economics of nuclear power is improved considerably when the cost of CO_2 emissions from fossil fuel–fired power plants is included.

Addendum—The Impact of the Fukushima Nuclear Disaster on the Cost of Nuclear Power

On March 11, 2011, as a result of a major earthquake and tsunami in Japan, the Fukushima nuclear power plant lost all of its on-site and off-site power, which is needed to operate the plant's safety systems. At least as of May 2011, it appears that the earthquake damaged the transmission facilities needed to supply off-site power, and the tsunami damaged all of the on-site power sources, including the emergency on-site backup diesel generators. As a result, without any source of power, the safety systems could not cool the reactor, and the fuel literally melted. The spent fuel is submerged in water in large storage pools, which cool the high-level waste. When the plant lost all power, and water could not cool the spent fuel, this resulted in a number of explosions. Because of these explosions and attempts to cool the reactor and spent fuel from off-site water sources, significant amounts of radiation were discharged into the air and water surrounding the plant.

As of May 2011, the owner of Fukushima and the Japanese government estimates that the plant will not be stabilized (cooled) until January 2012. Thus, it could take months or even years before authorities can determine what exactly happened to the plant. Indeed, it took 5 years before workers could enter the Three Mile Island plant to determine the exact nature of that accident. Consequently, at this point, it is impossible to determine with any degree of confidence what the impact of the Fukushima disaster will be on the cost of nuclear power. Nevertheless, it is possible that the disaster could affect the economics of nuclear power in a number of ways. First, there could be design changes to existing and new power plants that will increase capital costs, especially in the areas of backup power and spent fuel storage. Second, the disaster will clearly affect public acceptance of nuclear power, and the licensing hearings at the NRC could become more controversial, which would increase leadtimes. Third, in other research, I found evidence of a very small (1 to 2 percentage points) risk premium on the common stock of nuclear U.S. utilities resulting from the accident at Three Mile Island.[21] Over time, capital markets could have similar reactions to the Fukushima disaster. This would increase the cost of financing the construction and operation of a nuclear plant.

Acknowledgments

I would like to thank my past and present colleagues at the Energy Information Administration for their many useful discussions with me about the economics of nuclear power and their assistance in my research in studying this subject. However, the views and opinions stated in this entry are the author's alone and do not represent the official position of the Energy Information Administration or the United States DOE. Remote Sensing and GIS Integration

Egide Nizeyimana

Compatibility Issues between Remote Sensing and GIS

A GIS can be defined as a set of computer tools for capturing, storing, analyzing, and displaying spatially referenced data. The data within a GIS consists of two elements: spatial entities represented by points (e.g., well locations), lines (e.g., streams, road networks), and polygons (e.g., soil delineations) and attribute data or information that describes characteristics of the spatial features. The spatial entity is referenced to a geographic coordinate system and is stored in either a vector or raster model. GIS is primarily a platform that integrates spatial information from variable data sources and provides tools to overlay and analyze it.

RS is compatible with GIS because the information acquired by imaging sensors carried aboard satellites and airplanes is geographic in nature, referenced to a known coordinate system, and in a grid layout, a raster data model commonly found in most popular GIS software packages. In a raster model environment, the analysis is performed pixel by pixel. Current commercial GIS-based software packages have vector and raster capability analyses and allow data conversion from one data model to the other. Nonimaging systems are also important to RS/GIS integration because they provide point data, which at georeferenced locations, are often combined with other environmental data for site-specific assessments.

Linking Remote Sensing and GIS

Remote Sensing as a Source of Spatial Data

RS is one of the most important sources of land use/cover information used in GIS analyses. It provides information on the location and spatial and temporal distribution of land cover on the Earth's surface. Land use/cover distributions may be derived from aerial photographs after they are corrected for relief displacement and distortions caused by camera angle, and registered to a coordinate system. Delineations of different land use/cover types on photographs are made from visual interpretations of characteristics (e.g., tone, texture and color) aided by optical devices. Digital maps of these classes are created by digitizing and processing boundaries between land uses or by scanning photographs covering the area of interest and screen-digitizing their boundaries.

Land use distributions on the Earth's surface may also be obtained using RS imaging systems. In this case, RS provides opportunities in the area of land use planning which would not be otherwise available. While aerial photographs are effective and appropriate for analyses of small areas, RS offers tremendous advantages when planning for large areas such as river basins and regions. The fact that the land surface is observed from reflected/emitted energy for large areas and over a wide range of wavelengths allows for easy differentiation of existing land uses (e.g., wetlands, degraded landscapes).[1] Earth observation satellites also offer a repetitive coverage of the land, thus providing the possibility of monitoring land use pattern changes over time. Gathering information on land uses at several time intervals is particularly important in the monitoring and land evaluation stages of the land use planning process. Factors such as plant stress, crop growth and yields that serve as measures of agricultural productivity can be rapidly estimated following digital processing and analysis of RS imagery. RS has been used in many instances to monitor land surface conditions such as soil degradation and soil salinity.[2] It is true that RS cannot replace field mapping of land use/cover. However, RS supplements provide information that would not otherwise be available to land use planners and managers. There is no doubt that the development of sensors of high spatial resolution (1 m and higher) presently in orbits would increase the use of RS in land use planning and management.

As indicated before, RS and GIS technologies are highly compatible primarily because of the nature of RS as a source of spatial land use/land cover used in various environmental applications. Remote sensed imagery is a grid cell layer, a data format easily handled by GISs. In the RS/GIS integration, GIS appears as a platform that stores and integrates spatial data from different sources including remote sensing and output information needed for environmental analyses depending on the type of analysis sought. Land use/cover distributions derived from RS are input to GIS, GIS-based systems (SDSS), and models (e.g., hydrologic/water quality, crop yields, primary productivity) commonly used in land evaluation for land use planning and management. GIS has been proven to be a valuable tool in integrating RS-derived data with climate and land surface parameters (soils, terrain, etc.) to generate digital maps of ecosystem productivity or vulnerability to environmental factors.[3] The parameterization of the Terrestrial Ecology Model (TEM) and a forest ecosystem model using GIS- and RS-derived data at regional scales has also been accomplished.[4,5] The RS/GIS approach has been adopted by many state and federal agencies involved in environmental assessments. For example, in the GAP Analysis Program, the U.S. Geological Survey (USGS) and collaborative institutions map and/or model potential natural habitats of native vertebrate species from remotely sensed data across the country, and use GIS map overlay tools to determine the degree of richness of habitats in these species.[6]

Finally, GIS and RS applications have promoted the development of other high-resolution spatial technologies that enhance the land use assessment and planning. Some of these are the global positioning system (GPS) and digital orthophoto quadrangles (DOQ). GPS allows the user to record accurately and rapidly geographic coordinates of any location in the field with precisions ranging from several meters to a centimeter. Soil, terrain and land use attributes observed or measured can then be input to a GIS along with their precise locations and extent. GPS coupled with a GIS can improve the accuracy of land quality mapping by increasing the spatial variability of soil and landscape attributes. DOQs, on the other hand, are digital images of aerial photographs that were corrected to remove relief displacement and distortion caused by the camera angle. The USGS distributes single-band, 256-scale, gray-scaled DOQs at 1 m grid resolution. Although DOQs have not been used extensively in land use planning in the past, their high resolution and photograph-like characteristics make them a potential source of data in this area. Furthermore, repetitive DOQs acquired at different times can be used to monitor the magnitude of changes in land use over time. The relationship between GIS, RS, and other data sources is shown in Figure 1.

Applications of Remote Sensing/GIS in Soil Science

The need for geospatial data for use in various spatial database development and analyses in industry, government, and universities have increased the demand for remotely sensed data. In the area of soil science, the remote sensing technology is used to acquire data, and digitally process and analyze it. Subsequent analyses may involve error assessment, and data conversion from raster to vector format and vice versa before the data is merged with other datasets in GIS for specific analyses. Table 1 summarizes remote sensing techniques used in various aspects of soil science and potential limitations for use in GIS and advantages of each. These are laboratory approaches, field methods, and aircraft-/satellite-based methods. The latter involves interpretation and analyses of digital images, color composites, or radiances.

Remote Sensing/GIS integration for Site-Specific Farming

The goal of site-specific farming (SSF) or precision farming is to optimize the profitability of a farm practicing variable management according to soil conditions found at each site. The concept is based primarily on the fact that soil chemical and physical properties that affect crop production (e.g., pH, nutrients, available water, impeding layers) vary spatially across agricultural landscapes Management practices such as fertilizer and pesticide applications, irrigation water, and crop varieties should, therefore, be prescribed according to this soil variability. The profitability associated with variable rate applications of SSTs should avoid or reduce waste and the risk for environmental pollution because these agrochemicals are applied to the field only in amounts needed for optimal crop growth.

In an SST, the real-time detection of continuous soil variable is made possible by mobile devices including sensors and differential GPS units while agrochemicals are applied using variable rate field applicators mounted on farm equipments. These sensors are based on the same principles as RS and have been developed to detect, directly or indirectly, soil properties such as soil moisture, soil texture, nitrates, etc. The data acquired, along with their respective locations, are often integrated with spatial information from other sources such as soil databases, climate, landscape, and satellite/airborne remote sensing to delineate meaningful management zones within the farm.

TABLE 1 Documented Uses of Remote Sensing in Various Areas of Soil Science

Application	Advantages	Potential Limitations	References
Laboratory methods	Provides accurate measurements of reflectance values	Provide point data rather than areal extent of soil properties	[8]
Field methods	Easily related to on-site conditions	Provide limited data coverage; measurements are affected by soil conditions (soil roughness, moisture), sun angle, etc.	[9]
Airborne -/ satellite-based methods	Provides areal extent and temporal coverage of soil properties	Radiance measurements affected by atmospheric and soil-surface conditions	(–)
a) Interpretation of digital images	Good results when data are well analyzed and interpreted	Image analysis can be costly; requires experienced technician for good results; field verification or prior knowledge of area required for best results	[10]
b) Interpretation of color composites	Easy to use and rapid interpretations	Intensive field verification is needed for good results due to the fact that interpretation is based on differences in tone and physical characteristics of objects; requires experienced interpreter for good results	[11]
c) Interpretation of radiances	Relatively easy, cheap, quantitative; data can be normalized to remove environmental effects	Results often unreliable	[12]

Solid Waste: Municipal

Angelique
Chettiparamb

Introduction

Waste is normally understood as something that has no value. The *Oxford Dictionary* defines waste as "unwanted or unusable material, substance, or by-product" (http://oxforddictionaries.com/definition/waste). The United Nations Statistical Division defines it as

> Wastes are materials that are not primary products (produced for the market) and for which the generator has no further use in terms of production, transformation or consumption and therefore wants to dispose of [cited in Basel Convention, 2006][1] (p. 140).

The centrality of "value" and "use" in defining waste draws attention to ways and means by which these come to be attributed to waste. Since this attribution can vary greatly with users, with time, and across societies, it becomes difficult to objectively define waste. As Davoudi[2] (p. 131) says

> … it is difficult to determine the boundaries between what *is* and what is *not* waste. In other words it is difficult to determine exactly when a material ceases to be a resource (with social, economic and environmental values) and *becomes* a waste [original italics].

Understanding waste and its value or lack of it as an attribute bestowed upon it by society allows for an examination of societal values and practices that lead to the formation of waste. Waste can thus be understood in two distinct but complementary ways: first, in terms of its intrinsic qualities, which then suggest particular use and nuisance values, and second, its socially constructed qualities that draw attention to the political economy and the socio-cultural practices that reproduce the worth or worthlessness of waste.

This entry is concerned with "municipal solid waste" (MSW). It includes waste produced by households, small businesses, and industry, which are of a similar nature and therefore collected by the municipal authorities. Wastes such as construction and demolition wastes, heavy industrial wastes, etc., are excluded from this definition.[3] However, it is not uncommon to find contamination of municipal waste by small quantities of other types of waste, and often these can be made up of harmful substances such as pathological hospital waste, abattoir waste, harmful industrial waste, or even feces.[4]

The aim of this entry is to provide a broad-ranging overview of the nature of MSW and managerial practices associated with it. Particularly stressed are the historical growth of MSW as an environmental problem and the geographical variations—the global commonalities and differences—in the nature of MSW. The historical trajectories and geographical constancies in the nature of solid waste in turn have given rise to particular normative principles for the management of MSW. These are reviewed. These principles emanate from an understanding of the intrinsic nature of solid waste, but are, however, mediated by place- and time-specific ways of organizing governance. The patterning of these ways of organizing governance is finally reviewed.

Waste: A Historical Overview

Waste has always been an issue since human beings started living in societies. The severity of waste management has, however, varied, culminating in it becoming a serious environmental issue today. Compared with present times, in pre-industrial times, material possessions and artifacts were limited and consequently valued more highly. Everything that could be repaired and reused would be repaired and reused. Also, with limited population numbers and densities, more space for disposal and limited waste generation, waste was, relatively speaking, manageable and less polluting. In terms of waste composition, in most societies during these times, domestic waste was made up of ash from fires (for cooking and heating), wood, bones, and vegetable waste.[5] These were allowed to either compost or decay aerobically (i.e., decomposition that takes place in the presence of abundant oxygen, which then do not result in foul odors). This is a viable form of managing organic waste if the quantity of waste produced is less and if the waste is spread out to decay.

The above situation changed with industrialization and consequent urbanization, first, in the Western, now developed world. Rising population numbers in cities led to high densities and less space for aerobic waste disposal. Besides, waste generation itself increased with the availability of cheaper goods through mass production and the rise of a consumer culture. The nature of waste generated also saw a diversification with new waste materials such as plastics entering into the waste stream in significant quantities and materials such as ash declining due to the emergence of water-, gas-, oil-, and electricity-based central heating systems and cooking appliances. Roberts[6] reports that during this period, waste was being dumped in streets, alleys, open land, or common water sources, where pigs and other animals could devour them. Thus, waste management during the early periods of industrialization was almost non-existent and very similar in both England and the United States.

The history of institutionalization of waste management practices in the United Kingdom begins with the Public Health Act of 1848. This is when management of waste was directly linked to public health outcomes. The subsequent Public Health Act of 1875 required all local authorities to arrange for the removal and disposal of domestic solid waste.[5] In the United States, the first public health code was enacted in 1866 in New York City. With the establishment of a correlation between sanitation and public health and the occurrences of a series of epidemics in different states, the federal government of the United States came to establish the National Board of Health in 1879. Waste handling and disposal systems then came to be gradually set up in the United States. However, dumping in landfill sites (mostly near water sources) was the most common disposal method adopted.[6] In Britain, additionally, incineration plants (destructors) were constructed in around 250 locations in an attempt to recover energy.[5]

The environmental impacts of unsanitary disposal methods were soon felt. Thus, in 1929, the federal government in the United States first issued restrictions on the location of waste dumps by requiring these to be away from river banks. Waste disposal at sea was prohibited in 1934 and restrictions on disposing waste 20 miles within the shoreline came into existence in the 1930s.[6] During this time, the concept of a sanitary landfill (waste alternated with layers of sand or other inert material) was developed in Britain. The sanitary landfills were thought to be less polluting and less dangerous than the previous waste dumps. Further, explicit planning powers over waste management sites were granted to local authorities by the Town and Country Planning Act of 1947. The concept of sanitary landfills subsequently spread to the United States, and the 1930s and 1940s saw the establishment of a number of sanitary landfills in the country. However, in overall terms, these sanitary landfills were still just around 37% of the total landfills.[5,6]

The post-war years saw a rise in consumer culture. Easy access to mass-produced material goods soon saw an increase in the quantity of waste generation. Also, new nonbiodegradable products started entering the waste stream. Although the practice of sanitary landfills grew both in the United States and the United Kingdom, the unseen environmental effects of landfill sites started to surface. This, together with increasing environmental awareness, led to more proactive intervention in waste management. For instance, the Resource Conservation and Recovery Act, which aimed at conserving resources and reducing waste, thereby protecting the environment, was enacted in the United States in 1976. Similarly, in the United Kingdom, the Control of Pollutions Act was enacted in 1974, which then later evolved into the Environmental Protection Act 1990 wherein waste minimization and recycling are priorities in waste management.[5,6]

The above broad overview of the history of waste management in the West, particularly the United States and United Kingdom, show that differing socio-economic conditions through time have led to differences in waste characteristics and notions of how it should be handled and treated. Overall economic growth and development have, in the past, resulted in a growth in the quantity of solid domestic waste generated, and the very composition of waste. Historic differences in solid waste management (SWM) practices can today be seen in geographical differences in SWM practices. Thus, in developing countries, the quantity of waste generated tends to be less and the composition of waste tends to be distinctly different from the composition of waste in developed countries. However, waste characteristics can also differ with climate, seasons, the location, and the developmental status of specific locations. The next section further explores the nature and quantity of domestic solid waste and geographical differences in the same.

Waste Characteristics and Waste Quantities

There are many ways of classifying MSW and different degrees to which component streams can be differentiated. The forms of classification used in a particular instance will normally depend on the purpose of classification. In this entry, to understand the environmental pollution associated with domestic solid waste in broad terms, and the geographical variations in the type and severity of environmental pollution, a broad classification adopted by the United Nations Environmental Programme (UNEP)[4] is used. This classification is useful to understand some of the major differences in the nature of waste produced in developed and developing regions.

The UNEP[4] classifies MSW into two: organic wastes and inorganic wastes. Organic wastes can be further classified into putrescible, fermentable, and non-fermentable organic wastes. The putrescible components within domestic waste can decompose very rapidly with the production of unpleasant odors (e.g., food). The fermentable components also decompose rapidly, but do not give rise to the unpleasant odors associated with putrescible waste (e.g., crop). Non-fermentable wastes decompose very slowly (e.g., wood).

One of the major differences in waste characteristics between the developed and the developing world is in the higher proportionate amount of organic material present in the municipal waste generated in developing countries. This can be seen in Table 1 below.

The proportionate weight of putrescibles in waste in India is around 4.5 times more than that of Paris (75.2% vs. 16.3%). Significant difference can also be seen in the quantity of paper present in waste. Generally, the quantity of paper in the waste varies with the level of economic development of an area. Therefore, from Table 1, it can be seen that the quantity of waste in Paris and California is 40.9% and 40.8%, respectively, while the quantity of waste present in India is just 1.5%. This difference is mainly due to low levels of packaging combined with high levels of formal and informal reuse, recycling, and recovery practices widely prevalent in developing countries. Further, waste from warm and humid tropical

TABLE 1 Comparison of Solid Waste Characteristics Worldwide (% wet wt)

Location	Putrescibles	Paper	Metals	Glass	Plastics, Rubber, Leather	Textiles	Ceramics, Dust, Stones	Wt (g)/ cap/ day
Bangalore, India[1]	75.2	1.5	0.1	0.2	0.9	3.1	19.0	400

[b] Includes “all others.”
[c] Includes small amounts of wood, hay, and straw.
[d] Includes garden waste.
Source: Data from UNEP (2005, p. 2).

and subtropical countries (where most of the developing world in located) also tend to be high in plant content, while waste from colder climates may have higher levels of ash (if coal or wood is used).

Besides differences in waste characteristics, a significant observation from Table 1 is the differences in overall quantities of waste production. Lower levels of consumption, lower levels of packaging in consumption practices, as well as higher levels of formal and informal reuse and recycling mentioned earlier, result in significantly low levels of waste production and accumulation. Thus, Table 1 shows that California produces 5 times more waste per capita per day than does Bangalore in India. However, it must be remembered that the management of solid waste, especially collection and disposal, continues to remain a significant municipal challenge in most developing countries and can thus result in less overall quantities of waste collected and disposed.[7]

The above account draws a sharp distinction between waste characteristics found in the developed world and the developing worlds. It is, however, useful to remember that the boundaries of this distinction may be blurred in practice as particular locations in developed countries may reveal characteristic very similar to those found in developing countries and vice versa. Therefore in many ways, the above distinction provides a caricature. It nevertheless performs a pragmatic function in that it alerts an observer to potential differences based on level of development that may be found in municipal waste characteristics and quantities. The actual use of this distinction as applied to particular locations must, in the end, be necessarily informed by concrete realities.

While the quantity and composition of waste may vary with time and location, two significant attributes remain intrinsic to municipal waste regardless of the context: first, the site of production of waste is diffused and variable, and, second, municipal waste has potential environmental nuisance values. Solid waste management practices instituted by municipalities worldwide reflect the challenges posed by these intrinsic characteristics and therefore certain managerial practices have come to be identified as constitutive of municipal waste management worldwide. The next section provides an overview of such managerial practices.

Municipal Solid Waste Management Practices

Municipal solid waste management practices can be generally said to comprise of storage and collection practices (including practices of collection for reuse, recycle, and recovery), transportation practices (sometimes including practices of transferring waste from one form of transport to the other), and disposal practices. All, or some of the above, may occur through formal practices designed and implemented by the municipal authority or through informal voluntary initiatives organized individually or in community groups.

Storage and collection practices include various types of storage receptacles designed for waste production units such as households/commercial establishments and community storage receptacles for storage of collected waste. Organization of proper storage of waste is essential as in its absence waste can be dumped in public spaces/drains. Storage units may also be custom made to suit particular waste management technologies such as the use of receptacles of particular design to suit waste transportation vehicles. Further, storage systems may include practices to encourage reuse/recycle/recovery by using specific color-coded waste receptacles that enable the streamlining of various streams.

Transportation practices consist of the movement of collected waste to disposal sites or transfer sites (where waste is collected and then transferred to vehicles suitable for transporting to more distant final disposal sites). Collection and transportation practices may also include managerial contracts forged with the private sector or voluntary sector for the collection and transportation of waste produced in dispersed locations.

Disposal practices include the many options through which waste is disposed, such as incineration plants, compost plants, landfills sites, and anaerobic biogasification plants, for the end disposal of wastes that are not reused and recycled. Disposal options can include material recovery options (such as composting) or energy recovery options (such as anaerobic biogasification plants or energy recovery from landfill sites). Disposal options may also aim to just get the waste out of sight by either dumping it in waterways, quarries, and other similar areas, or by transporting it afar (often to less developed areas). Further, disposal practices need not always be organized by municipal authorities, but can also be found at individual, household/establishment, or community level.

The above SWM practices are typically organized in accordance with generally acknowledged principles. Some of the principles that are widely adopted in SWM practices today are reviewed below.

Normative Principles in SWM

The "waste hierarchy" is a normative principle that has had a significant impact on practices of SWM in recent times (for instance, the principle has been very influential in the formulation of European waste management practices).[8] A diagrammatic representation of this is given in Figure 1.

The waste hierarchy advocates a waste management system oriented toward a hierarchy of managerial options that target waste reduction, reuse, recycling, and recovery, in that order of preference, thus reducing the amount of waste that needs to be finally disposed in a landfill. Strategic aims such as "zero waste" initiatives' aimed at minimizing waste toward zero by reducing consumption, arranging for reuse by repair or modification, and maximizing recycling, thereby bringing materials back into nature or the marketplace, are based on the normative principle promoted by the "waste hierarchy".

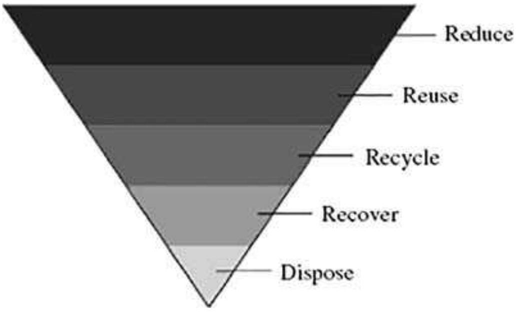

FIGURE 1 Waste hierarchy.
Source: Chettiparamb et al. (p. 327).[7]

Such initiatives are typically aimed toward instilling a re-valuation of waste as a resource rather than as something to be disposed off.[9]

Life cycle assessment (LCA) in waste has influenced waste reduction practices since around the 1990s.[10] It focuses on the environmental burdens associated with a product, a process, or an activity. LCA encompasses the entire life cycle of the system studied, including material and energy flows in raw materials, their acquisition, manufacturing processes, usage, and waste disposal/treatment, leading to what is known as a "cradle to grave approach." Thus, LCA helps expand the framework of analysis to beyond the relatively limited confines of the actual SWM system, thereby bringing in wider environmental impacts, some of which may have a greater impact on the environment than just the analysis of the SWM system itself. The LCA can thus lead to an improvement analysis that suggests ways in which the impacts on the environment can be reduced.[9] In practice, however, the LCA, although normatively influential, has been difficult to implement mainly because of the enormity of data demanded, problems in the reliability of the data, and other pragmatic difficulties in employing the technique.[11]

Integrated solid waste management (ISWM) is yet another principle that has been influential in organizing whole SWM systems. ISWM is based on the idea that any one method of SWM may not be adequate in addressing the challenges that the various streams of waste present. Instead of viewing the many streams of solid waste as distinct and separate, ISWM proposes that the most appropriate method must be adopted for each stream in a way that the sum total of the environmental impact is kept to a minimum. Thus, paper and other recyclable material must be recycled, while compostable material must be composted or digested anaerobically, and so on. The overall key aim is to minimize landfill while maximizing recycling and recovery.

The above account suggests that there is relative stability surrounding understandings of ideal ways of managing MSW. Studies of the governance of MSW, however, show wide variations, including shifting relative emphasis on these normative principles occurring both historically and within and across particular contexts. These variations are reviewed in the next section.

Policy Drivers, Policy Regimes, and Modes of Governance in SWM

The nature of the "political economy" of a region has been identified as a key determinant of MSW. The term "political economy" is defined by O'Brien[12] (p. 270) as "a regulated social framework for transacting values, comprising an arrangement of practices, relationships and institutions." He argues that industrialized societies are primarily "rubbish societies" in that these societies are infused with a relationship to waste and wasting that allows their social, political, and cultural systems and their own self-understanding to develop and change. If the centrality of wasting processes in industrialized societies is acknowledged, a political economy around wasting needs to develop, what O'Brien terms as "rubbish relationships'[12] (p. 287). Further, it then becomes necessary to valorize and promote particular institutional relations that organize and stabilize rubbish flows in ways that allow the reproduction and survival of society. This valorization and promotion reconfigures SWM practices, thus lending more credibility to particular normative principles resulting in patterns in what has been termed as "drivers,"[13] "policy regimes,"[14] or "modes of governance"[15] in SWM. These then give rise to new terminologies such as "waste citizenship" (how waste is accessed),[16] waste networks and waste flows (how waste is distributed),[17] and "waste commons" (hard rubbish meant for scavenging),[18] to name a few.

The study by Wilson[13] sought to identify key drivers that have led to the adoption of particular mechanisms or strategies in SWM both historically and around the world. A survey conducted by Wilson[13] among "colleagues" identified six key drivers for the organization of SWM practices: 1) public health; 2) environmental protection; 3) resource value of waste; 4) closing the loop; 5) institutional and responsibility issues; and 6) public awareness. The relative emphasis among these varies over time and differs with local circumstances. Wilson[13] argues that public health emerged as a key driver in the 19th century and has been more or less taken for granted in developed countries. It, however, still persists as a key driver in emerging and developing countries with hot climates. The environmental protection driver came to the fore in the 1970s and still remains a key driver in the developed world. Energy/climate change has now become central to this agenda. In developing countries, on the other hand, the focus remains on initial steps such as the phasing out of uncontrolled disposal and the promotion of clean development mechanisms. The resource value of waste was a driver until the early 20th century underpinning major industrial economies in 19th century London, and 20th century China, Soviet Union, and Eastern Europe. In developed countries, however, this driver was soon replaced by a more holistic approach to waste management. The resource value of waste remains a key driver in developing countries as large numbers of the poor survive on reuse, recycling, and recovery practices. Further, the import of waste as an industrial raw material continues in some developing countries, thus making waste integral to those economies. The waste hierarchy came to be advocated in the late 1970s and triggered a more holistic approach to resource management. Wilson[13] argues that this now means that waste prevention and recycling are key priorities in the developed world with sustainable production and consumption, integrated production policies, and zero waste policies emerging as key drivers. Notions of institutional responsibility emerged as a key driver when municipalities were charged with waste collection responsibilities in the late 19th century. While in the developed world, this responsibility is more or less taken for granted, with even an extended notion involving the private sector emerging, in developing countries, the ability to discharge this function is still limited with notions of capacity building and good governance emerging as key drivers. Finally, Wilson[13] argues that public awareness has become a key driver with waste management moving up in people's priorities as living standards increase. The environment, climate change, and resource management is informing this increase in public awareness in the developed world. In the developing world, however, public awareness remains focused on food, shelter, security, and livelihoods, with waste drawing attention only when these are threatened. The study concludes that

> "There is no one, single driver that can be seen as 'dominant'; rather, all of the six groups of drivers are important, and the balance between them will vary between countries depending on local circumstances, and indeed between stakeholder groups depending on their particular perspective"—Wilson (pp. 205–206).[13]

The "development drivers" described above therefore have a key role in organizing practices and selecting particular normative orientations and stabilizing these within institutional relations and a variety of governing instruments.

Gille[14] extends Young's[19] concept of "resource regimes" to waste. He defines it as follows:

> At their [resource regime's] core is a structure of rights and rules, which implies a certain distribution of advantages and disadvantages. Social institutions determine what wastes, and not just what resources are considered valuable by society, and these institutions regulate the production and distribution of waste in empirically tangible ways (p. 1056).

Gille explores the history of waste management in Hungary and identifies three distinct regimes in the history. He calls these "the metallic regime (1948–1974), the efficiency regime (1975–1984), and the chemical regime (1985–present)" (p. 1056). In the metallic regime, Gille argues that waste was seen as a particular kind of material—something that was like metal scrap and thus discrete, non-toxic, and infinitely recyclable and reusable. Under this benevolent perception of waste, the key actors were class-conscious workers and citizens who would collect and find new uses for all sorts of wastes. The efficiency regime was marked by a "monetized concept of waste: [where] waste was seen as a cost of production, and waste reduction and reuse were seen as steps to increase efficiency" (p. 1057). Policy tools thus included financial incentives and professionals with economic and technical expertise came to be valued. In the chemical regime, waste came to be seen as useless and even harmful. Waste liquidation came to be very important, and scientists, engineers, and the chemical industry became key players. The waste regime concept thus traces the broad patterns that structure certain normative values in particular periods and locations. **Table 2** Modes of governing MSW.

TABLE 2 Modes of Governing MSW

Mode	Components				
Disposal	Governmental rationality (policies and programmes)	Governing agencies	Institutional relations	Governmental technologies (examples)	Governed entities
	Economic efficiency	Local authorities	Devolved hierarchy	Dustbins	Municipal waste
	Public health Environmental efficiency	Regulator		Weekly collections Landfill sites Contracts Best Practicable Environmental Option assessment	Ratepayers
Diversion	Reducing the (global) environmental impact of landfill (EU Landfill Directive 1999 *Waste Strategy WOO*)	European Union	Multilevel	Performance targets and auditing	Successively lower government tiers
		DEFRA	Strongly hierarchical	New policy instruments	Individuals as passive citizens
		Local authorities		Funding mechanisms and criteria Education campaigns	Differentiated waste streams
Eco-efficiency	Reducing the environmental impacts of waste; recovering value (waste hierarchy; meeting targets)	Local authorities, waste contractors, community-waste-sector organizations	Heterarchy	Kerbside collections	Individuals as active citizens
			Networks	New technologies	Differentiated waste streams
				Reuse and reduction practices (e.g., nappies, compost)	
Waste as resource	Reducing the environmental impacts of waste; social and economic benefits	Nongovernmental organizations and networks	Solidarity	Provision of alternative infrastructures and collections	Individuals as community members
			Community		Waste as a resource

Source: Data from Bulkeley and Watson (p. 2740).

Bulkeley and Watson[15] develop the notion of "modes of governance" in waste in order to capture both structures and processes of governing while also recognizing the plurality of modes through which governance is established. They define a mode of governing as

> A set of governmental technologies deployed through particular institutional relations through which agents seek to act on the world/other people in order to attain distinctive objectives in line with particular kinds of governmental rationality (p. 2739).

The authors analyze SWM in the United Kingdom and identify four distinctive, but coexisting, modes of governance. These are the disposal mode, the diversion mode, the ecoefficiency mode, and the waste as resource mode. The various components of waste management associated with these different modes are reproduced in Table 2 above.

The three examples of development drivers, regimes, and modes of governance reviewed above illustrate how the management of solid waste can be very different across geographical regions even if the fundamental building blocks of managing waste—those that emanate from its intrinsic qualities—remain the same.

Conclusions

This entry has provided a broad overview of the nature of MSW and the management of it. It has highlighted that the definition of what waste is, will depend on particular contexts as the attribution of value and non-value takes place subjectively and contingently. Further, the history of waste management practices shows that the nature of municipal waste has varied with the level of industrialization and climatic conditions of a location. This variation can also be seen today in the difference in waste characteristics of developed and developing countries.

The dispersed nature of production sites of MSW and the potential environmental nuisance value of MSW can, however, be said to be intrinsic to waste. Fairly consistent management practices have arisen from these intrinsic attributes. Further, certain normative principles have also arisen to guide the organization of these managerial practices. The selection and mobilization of the normative principles, however, take place within broader governance frameworks that have been variously termed as development drivers, waste regimes, or modes of governance in waste. These have also been reviewed. In conclusion, this entry has shown that while the intrinsic nature of SWM has led to selective widely stabilized managerial practices, the organization of these practices and the governance of the same may be embedded in very different governance frameworks, thereby giving rise to a myriad of permutations in the actual practices of SWM.

Sustainability and Planning

Richard Cowell

Introduction

This chapter offers a critical assessment of the role of planning in promoting sustainability. "Planning" can be defined broadly as an activity by which humans seek consciously to shape their collective future,[1] but it embraces activities with enormous variation in scope and scale. Planning can be undertaken from the local through to the national scale, and it entails the detailed regulation of land use and management as well as the setting of strategic direction for an array of public and private sector actions.

The first half of this entry charts the emergence of a worldwide interest in "planning for sustainability" and outlines key features of the dominant, conventional approach. This typically involves the following components: identifying sustainability goals, allocating actions, seeking integration between governmental sectors, engagement of different stakeholder groups, and appraisal and monitoring.

The second half of the entry assesses the extent to which planning for sustainability has achieved results and offers explanations for these outcomes. It notes that there have been significant shortfalls in implementation, partly attributable to the deficiencies of planning as a force for change but also because of the fundamentally contested nature of sustainable development as an objective. In response, two alternative perspectives to the conventional approach to planning for sustainability are discussed: (1) adaptive planning and transition management, which emphasizes the complexity of the task and the need to respond to uncertainty, and (2) a more critical perspective, which highlights how planning systems have actually exerted leverage over business as usual.

Some preliminary points of definition are required. A distinction is often made between "sustainability," a concept with an environmental focus that describes the long-term continuation of a system, and "sustainable development," a concept that is more overtly concerned with social progress and distributive equity as well as environmental quality. However, there is much debate about the meaning of either term and little consistency in the way that they are used.[2] This handbook entry adopts the term

TABLE 1 The Two Main Categories of Planning for Sustainability

Type of Approach	Scale	Focus	Power
National sustainability planning	National, with focused attention on individual sectors	Achieving environmental targets consistent with sustainability	Overarching coordination, target-setting, backed by monitoring, oversight arrangements and sector-specific measures
Land use or spatial planning	Mainly local, but subject to national policy guidance	Land use implications arising from array of environmental, social, and economic demands	Regulation of land use change through zoning procedures and spatial steering; wider coordinating role

"sustainability" and argues that rather than focusing on *ex ante* definition, practitioners must be alert to the particular interpretations of the concept that get used in any given planning process, and to what is actually being sustained.

"Planning," too, requires some further explanation. Although planning can be undertaken by any kind of organization—public, private, or voluntary sector—here, we are primarily concerned with planning as a collective, public activity, undertaken by governments at all levels (local, regional, national). Planning can thus be seen as one of a number of tools available to government to promote sustainability, working alongside, or sometimes in conjunction with, regulations, market-based instruments, voluntary measures, and so on.

There are a number of categories of approach to "planning for sustainability" that are covered within this entry. The first category is the creation of "national sustainable development plans" designed specifically to promote the achievement of sustainable development (as encouraged by Agenda 21), which tends to provide high-level strategic direction across an array of activities.[3] An exemplar is the National Environmental Policy Plans (NEPPs) that were drawn up for the Netherlands from the 1980s to the early years of the 21st century. The second category of approaches is the incorporation of sustainability objectives into existing planning processes for coordinating the use of land ("land use planning" or "spatial planning"). Many countries have planning systems that seek to steer the use and development of land, and provide a framework for making decisions about development projects. Key features of the two categories are set out in Table 1 (above).

History and Context

Ever since "sustainable development" first arrived on global policy agendas, planning has been identified as a means of achieving it. A commitment to producing national sustainability plans was a key outcome of the United Nations Conference on Environment and Development, held in Rio in 1992, with its main statement of principles—Agenda 21—regarding "environmentally sound physical planning" as essential to sustainable development.[4] The European Union, too, has given planning a significant role in shifting from reactive responses to environmental problems toward anticipatory and strategic solutions.[5]

Over the same period, sustainable development took hold as a powerful ethical and intellectual framework for existing planning activities, notably land use planning or spatial planning, but also planning across a range of sectors—transport, economic development, tourism, and so on. By way of definition, land use planning usually concerns the management of competing uses of land, typically through regulatory means. This differs somewhat from "spatial planning," which—in the form adopted in the Netherlands or France, for example—has a wider role in coordinating the actions of all sectors that have spatial consequences (transport, economic development, etc.). For convenience, "land use planning" is the term used here, but the analysis also applies to forms of spatial planning. Many countries around the world have instituted requirements that their land use or spatial planning procedures promote sustainability.[6–11]

For many commentators, the connections between sustainability and planning are self-evident. The planning profession has long identified itself with shaping the future[12] and sustainability is a long-term goal, bound up with moral responsibilities to future generations. Thus, if sustainability can be regarded as a preferred future state of affairs—whether that is applied to an ecosystem, a nation, or a city—planning provides a vehicle for steering society toward it. Planning offers the prospect that the transition to sustainability can be orderly, rather than precipitated by ecological, social, or economic crises.

Planning also provides important coordinating and integrating functions. Planning offers mechanisms for identifying and fostering "win-win-win" solutions between economic development, environmental protection, and social equity, the prospect of which has always been central to the political appeal of sustainable development. Planning has also been identified as having procedural virtues for promoting sustainability, in that the processes of formulating plans can allow for the engagement of civil society, diverse stakeholders, and foster wider learning.[13]

However, if it is widely asserted that we should "plan for sustainability," the reality is more complex. At a fundamental level, some would contest the possibility of steering complex societies and unpredictable ecosystems toward pre-given goals; for Lindblom, the best societies can hope for is "muddling through."[14] Governments and societies vary in the faith that they place in (state) planning compared with markets as means of coordination. States also vary in the wider effectiveness of their governance institutions, with developing countries especially often lacking capacity. Consequently (as discussed further below), many efforts to plan for sustainability fail to fully achieve their goals, for all sorts of reasons—some economic, some political, and some practical.

Thus, to understand the prospects of planning for sustainability, one needs to consider both ideals and what happens in practice, as this entry seeks to do.

Planning for Sustainability—A Conventional Perspective

This account of planning for sustainability is organized around what can be regarded as the conventional perspective, as depicted in Figure 1 below. It echoes core features of long-standing rational planning models: exhibiting the procedural stages of "survey-analyze-plan-monitor," and with a clear relationship between means and ends. Although this traditional, instrumental view of planning has come under criticism from various directions,[15] it still provides a useful structuring device for this review. Moreover, this perspective remains deeply entrenched in planning practice in many arenas, and concern for sustainability has arguably reinforced its position.[16] Problems with this perspective are discussed later in this entry.

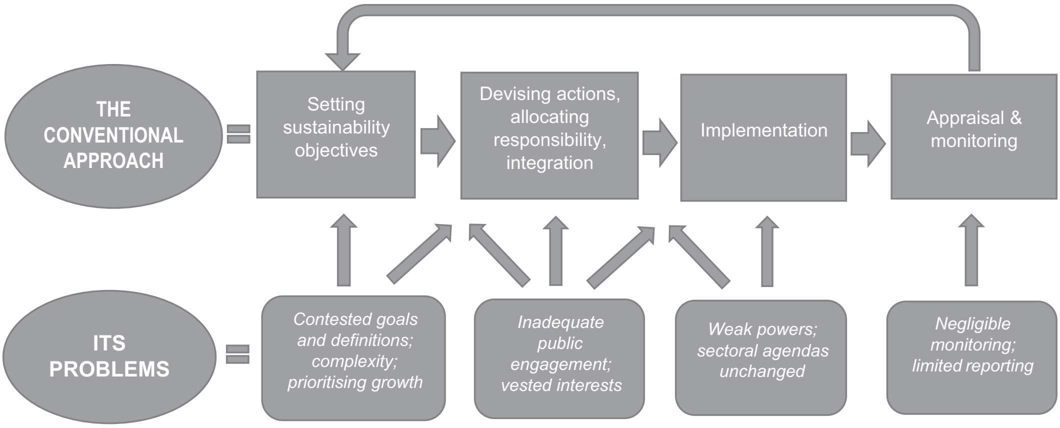

FIGURE 1 The conventional approach to planning for sustainability and its problems.

Setting Objectives and Interpreting Sustainability

At the core of the conventional view of planning for sustainability is the assumption that one can specify what makes a society more sustainable and express this in objectives toward which development can be steered. These objectives might be environmental constraints, trends or targets, or some vision of a more sustainable urban form. Objectives might be designed to avoid losses of biodiversity; to reduce the depletion of primary resources and/or replace them with renewable or less polluting substitutes; to limit the release of certain wastes or pollutants; or to express social goals for literacy, health, poverty, access to services, and so on.

In effect, this part of the process is an exercise in defining outcomes, which seek to capture "the overall quality or sustainability of human well-being and the eco-systems on which it ultimately depends."[17] Sometimes the process of determining objectives takes place within the planning process, but very often objectives are "imported" from other policy arenas. A pre-eminent example is climate change, where targets for greenhouse gas emission reductions cascade down from international agreements into national action plans and then into planning. Other examples include air quality standards, which may emanate from debates in public health. Where the objectives relate closely to land use, then they may be expressed in vision statements, diagrams, or maps.

Of course, there is no singular, neutral definition of sustainability, but a range of interpretations with quite different developmental consequences. Planning for sustainability is often therefore more than an exercise in applying pre-given goals; it forms part of the process of working out how sustainability should be interpreted. Planning processes may exhibit "weak" forms of sustainability,[18] so-called either because they explicitly prioritize economic growth or because they give no clear priority between economic, social, and environmental goals. The goal of planning for sustainability may thus be expressed as finding a "balance" between these goals, allowing for environmental quality to be traded off for economic development.

Alternatively, planning approaches may pursue "stronger" conceptions of sustainability.[18] Here, the guiding assumption is that society should be precautionary in the face of significant, irreversible losses of valued environmental assets—be they planetary life support systems or treasured landscapes—and give priority to maintaining their value over time. The implications for planning are that environmental constraints are pre-eminent, goals should be set to reflect this, and that development trajectories must be adjusted to observe these constraints and avoid degrading the ability of the environment to support human welfare. Stronger conceptions of sustainability draw support from justice to future generations, and the idea that they should inherit an equivalent stock of "environmental capital"[19]; or from biological notions of observing the "carrying capacity" of an environment to sustain a particular activity without deterioration.[20]

One example of a stronger approach to planning for sustainability is the NEPPs of the Netherlands. From the 1980s, the Dutch Environment Ministry began developing plans that sought to respond to the worsening and interconnected nature of environmental problems through what was regarded as a "holistic" planning process. A key starting point was analysis of the level of pollution reduction and resource efficiency that was required "to achieve sustainable development in one generation."[21] From this, the NEPPs identified targets and brought together steps for reducing pressures on the environment and "closing substance cycles" (e.g., reducing and recycling wastes).

Land use planning offers examples of weaker and stronger interpretations of sustainability. For example, since the early 1990s, U.K. governments have required all land use plans to promote sustainable development; however, national guidance has often interpreted this in weak terms—as achieving simultaneously economic growth, inclusive social progress, protecting the environment, and making prudent use of natural resources.[22] Nevertheless, one can point to land use plans at local and regional levels that have sought to determine the environmental capacity of their area to accommodate development, and introduce policies to ensure that development does not exceed it.[23,24] Observing environmental limits remains an important idea in planning for sustainability.[25]

Devising Actions and Allocating Responsibility

The creation of a plan can itself exercise persuasive effects. There is a long history of planning processes pursuing some form of "visionary idealism" to stimulate public, stakeholder and political support and promote change, many of them connected to aspects of sustainability.[26] However, the second stage of the conventional approach to planning for sustainability usually entails specifying the particular actions required to achieve the objectives of the plan.

Various approaches can be used to identify those activities most responsible for placing unsustainable pressures on the environment—be they industry, government or the public, or particular sectors of activity (transport, housing, agriculture, etc.)—and thus requiring action. One such approach is "backcasting," a form of futures study. The backcasting process begins by envisioning a desirable end state—in this context, one deemed to be sustainable—then works backward from that to identify actions that will move society toward it.[27]

Depending on the political culture of the country concerned, the process of preparing a sustainability plan may involve efforts to secure the participation of different sectors of society. This participation can take place at the objectives-forming stage as well as in the selection of actions. The rationale for participation is at least fourfold:

- To try to achieve some "buy-in" from those stakeholders with the capacity to affect outcomes, and reduce the chance of conflict at the implementation stage
- To draw in knowledge and ideas beyond that possessed by government alone
- To create potentially more just outcomes by conferring recognition and opportunities for participation on a range of social groups[28]
- To create greater democratic legitimacy and societal support for the transitions that sustainability requires.[13]

Some theories of planning see the participatory processes of planning as key to its role in achieving change, notably collaborative planning theory.[15] The interactions and dialogue that takes place in planning processes—where they require parties to make and defend arguments in relatively open arenas—can help shift the attitudes and beliefs of those involved. Planning exercises thus help foster wider learning, develop new knowledge and relations between groups of people, and assist in finding common ground between contending parties. This, in turn, builds up the capacity of society for resolving future problems.

Collaboration between stakeholders was a key element of producing the NEPPs in the Netherlands. Government and business constructed sectoral plans for reducing environmental impacts and technological change bound together by voluntary agreements called "covenants" (albeit often with the threat of tighter regulation should voluntary compliance fail). The Dutch NEPPs also incorporated environmental non-governmental organizations (NGOs) into the planning process. In many countries, the existing land use or spatial planning system has long-provided opportunities for the public and environmental groups to contribute to the decision-making process,[29] and planning for sustainability builds on these traditions.

If planning is to have some strategic role in promoting sustainability across society, then the process of allocating responsibility and devising actions may entail "environmental policy integration."[30] This is a process by which key policy sectors coordinate their actions toward shared sustainability objectives, cooperate on implementation, and reduce conflicting objectives. Examples would be agricultural policy and transport policy being attuned to the delivery of biodiversity or air quality objectives, rather than just their own developmental goals. In procedural terms, integration may be achieved by various innovative governance arrangements, including altering the objectives of sectors, or through various forms of deliberation (i.e., getting key departments round the table) and policy appraisal, as discussed below.

Closely connected with the assignment of responsibility is the identification of actions and policy instruments—the means by which the plan will actually be implemented. Where sustainability goals are being integrated into existing land use planning processes, then the powers of those processes will dictate how the goals can be achieved. In many countries, this entails the incorporation of policies into a plan, with some spatial expression of future goals, which then informs zoning controls or some other regulatory process to achieve compliance. Where sustainability is concerned, these regulations can embrace[31]:

- Promoting sustainable urban form (by controlling building density, or directing development to locations accessible by walking, cycling or public transport)
- Protecting sensitive, valued spaces from damaging development (e.g. for biodiversity)
- Requiring that new developments are designed and built in ways that reduce their adverse impacts.

With national sustainability plans, the plan may provide a long-term framework for shorter- and medium-term actions to be undertaken by a range of actors—government departments, industrial sectors, and the community and voluntary sector. Goals may therefore ultimately be implemented by an array of measures: standards and regulations, market-based instruments like green taxes, channeling investment or research funding, and various forms of voluntary mechanisms (like information campaigns, promoting best practice, etc.).

Appraisal and Monitoring

Forms of appraisal and monitoring are integral to conventional approaches to planning for sustainability and may be used either ex post or ex ante to guide the planning process. Ex post entails monitoring the effects of the plan after implementation (either progress toward goals or of wider unintended effects), and using the information to make adjustments or revisions in cyclical, learning processes. Ex ante appraisal entails assessing the likely effects of the plan while it is being formulated, perhaps to ensure that it is contributing sufficiently to sustainability.

The use of appraisal techniques has become a significant part of planning for sustainability and links to wider suites of tools used in environmental management, many drawing on international principles and methodologies.[10] Strategic Environmental Assessment (SEA) is required in many countries for plans, programs, and policies likely to affect the environment (e.g., under European Union Directive 2001/42/EC). Through SEA, the draft policies of plans are assessed for their environmental impacts and, in many formulations, this entails assessment against sustainability criteria and objectives.[32] SEA can also enable the comparison of different options and, potentially, facilitate debate over alternatives, as well as fostering environmental policy integration by identifying where sectoral policies are poorly aligned with sustainability goals.

Environmental indicators may be used to assess changes in the economy, society, and environment, and signal whether those changes lead us toward or away from sustainability. Some indicators reflect a particular environmental parameter. For example, in the United Kingdom, the percentage of new development located on brownfield land (i.e., land that has been built on before) is an important sustainability indicator for the land use planning system, with the goal being that increasing development on brownfield sites will reduce sprawl, slow down the consumption of "greenfield" land, and support compact, less car-dependent urban forms.

The search for better appraisal and measurement systems has been a constant feature of planning for sustainability debates: where "better" can be taken as more comprehensive, more integrated and quantifiable (i.e., combining different effects into single units), more comprehensible to diverse audiences or decision-makers, or better linked to core principles of sustainability like environmental limits. One example is the "ecological footprint," which seeks to provide a proxy measure of human demands on the environment by assessing how much biologically productive land and sea is appropriated to maintain a given consumption pattern and assimilate the waste produced.[33] There are other approaches also seeking to capture the totality of material and ecological flows associated with "urban metabolisms,"[34] including "exergy," a concept that derives from thermodynamics and ecosystem health analysis.[35]

Rising in profile from 2010 onwards has been interest in assessing the effects on ecosystem services; an approach that reflects a long-standing belief in environmental appraisal circles that for decision-makers to take environmental effects seriously they need to be expressed in economic terms.[36]

Has Planning for Sustainability Had Any Effect?

Across the world, numerous plans have been produced that would claim to be promoting sustainability. In many countries, sustainable development has become “mainstreamed” as a core goal of land use or spatial planning—with almost all such plans, and much national planning policy too, now making reference to the importance of sustainability.[7,8,10,11] What is less clear is how far these planning *outputs* have promoted more sustainable *outcomes*. This section reviews the effects of planning for sustainability and then explains why outcomes rarely match aspirations.

One can point to beneficial outcomes in a number of spheres. Sustainability-oriented land use plans have contributed to an incremental greening of urban development. By providing locational guidance, plans have helped steer development to sites where its impacts have been lower than they might otherwise have been, reducing inappropriate development in areas of high existing environmental value, and focused development on advantageous locations—such as sites that encourage access by public transport or foot, or face reduced risks from flooding. The planning system also confers greater protection to environmental assets, such as valued wildlife sites, and requires more exacting mitigation and compensation measures when development has damaging effects. Over the same period, plans have mobilized policies to enhance the environmental performance of built development, for example, by promoting better design, or as one of a suite of tools for ensuring development is adapted to the risks of climate change. Plans have developed innovative regulations,[31,37] such as the “One Planet Development” policy in Wales, allowing development in the countryside where it demonstrably attains a low Ecological Footprint.[38]

Nevertheless, the overall effects of planning on the sustainability of development have been modest, and uneven between issues and places. Unsurprisingly perhaps, land use planning has made the greatest progress where sustainability agendas link to traditional planning concerns, such as land allocation and siting policies, or issues like transportation where technical fixes are available. Where particular environmental issues are of recognized importance, then planning has addressed them, such as water scarcity in parts of the United States and Australia.[10,39] The contribution of planning is often less clear in relation to global, systemic issues, like reducing greenhouse gas emissions, poverty or resource depletion, where wider societal transformation is required.

With national sustainability planning, too, most strategies have gravitated “toward the cosmetic rather than the ideal.”[40] The NEPPs from the Netherlands were most successful in reducing wastes, pollution, and the use of toxic materials; however, progress has been greatest in areas where industry saw the potential for economic gains from improving environmental performance, and where technological solutions were readily available.[41] Moreover, the NEPP strategies have struggled to address issues caused by mass consumption and growing personal mobility, such as carbon emissions from transport. If there has been any decoupling of economic growth from environmental degradation, it is mostly relative decoupling (falling environmental impact per unit of growth) rather than absolute decoupling (environmental impacts falling in absolute terms). Many countries have still not produced national sustainability plans, and those that have done so too rarely institute cycles of reporting and updating.[3]

Thus, despite 30 years of “planning for sustainability” around the globe, progress in fostering more sustainable patterns of development has been patchy at best, and often disappointing. As noted above, nations differ greatly in their capacity for organized and effective planning.[42] That said, success is partial in many developed countries, including those with strong traditions of strategic plan-making and reputations for environmental concern, for example, the Netherlands[43] and Sweden.[44] Despite some modest gains, the overwhelming perception is one of a significant “implementation deficit,” in which the outcomes achieved through planning fail to match the rhetoric of sustainability or meet the more challenging targets. How might this “deficit” be explained?

Some see it as a simple time lag between aspiration and realization. Plans take time to prepare and implement; consequently, they can omit newer, emerging issues, like sustainable urban food.[45]

Ambitious planning for sustainability also confronts the limited power of planning mechanisms to effect change. The regulatory powers of land use planning do not apply to every sphere of social or technical change. It can be used to regulate new built development—indeed, new "eco-cities" or "sustainable communities" with higher sustainability credentials than the norm are frequently held up as exemplars of what can be achieved.[46] However, planning has limited scope to reshape existing buildings or economic systems, especially those that unfold at wider spatial scales. Thus, land use planning might be successful in steering the location of supermarkets, even influence the environmental performance of their built form (perhaps by requiring certain energy efficiency standards), but exercises little control over the systems of food production and consumption channeled through them. Research suggests that planning professionals have sometimes molded planning for sustainability toward orthodox planning tools and approaches rather than looking at problems afresh.[11,45]

However, there are fundamental problems in conceiving of this underachievement as an "implementation gap," with the expectation that this will be closed over time with "more knowledge," "better practices," or "improved participation."

One problem with the conventional, linear view of planning for sustainability is the assumption that sustainability has an agreed meaning that can be translated into clear consensual goals, which can inform singular blueprints for progress. In reality, although there may be broad agreement on the principles of sustainability, translating this into more specific interpretations in the planning process can cause dispute, as fundamental questions are raised about human wants and needs, the relationship between state and market, and environmental values. Planning for sustainable development cannot therefore be a value-free, technical exercise.[2] Even within the environmental sphere, there is often significant scientific uncertainty about the causes of change, and the position (or existence) of ecological thresholds or "capacities," which affects the definition of targets or indicators.

Planning for sustainable development has also exposed the difficulties of achieving outcomes that are win-win for social, economic, and environmental goals. Synergies between goals can be found: for example, planning for more walking-friendly cities has benefits for human health, environmental protection, and local economies where congestion is reduced. In many other circumstances, goals cannot readily be reconciled without winners and losers. Protecting valued landscapes or habitats can displace local livelihoods, including those which are highly sustainable.[9,45] Displacement can also be caused by the expansion of renewable energy like solar power.[47] Newly enhanced or created sustainable communities can make property too expensive for poorer existing residents.[39] Environmental constraints may challenge particular directions of economic growth. Planning for sustainability may thus struggle to align competing conceptions of what it means for development to be sustainable.[7]

One also needs to understand the political and economic context in which planning for sustainability takes place, particularly macro-economic shifts that have made communities and nations dependent on the private sector to deliver development, and public sector austerity programs that reduce the resources for long-term environmental activity.[48] The vulnerabilities this creates are illustrated by particular projects, for example, Masdar Eco-City in Abu Dhabi. This new settlement was planned with very high sustainability ambitions, but the 2008 financial crash undermined the economics of the project, leading to the most innovative environmental dimensions being abandoned.[49] More widely, economic concerns may explain why planning authorities may be reluctant to exercise stringently the regulatory powers they do possess, where that could threaten jobs and growth. Plans that have sought to promote "strong" interpretations of sustainability, by seeking to keep development within environmental limits, have faced resistance when confronting what "seem to be inexorable upward trends in production, consumption, and mobility."[7]

This also explains why many exercises in planning for sustainability have adopted "weaker" interpretations of the concept, seeking only to achieve some "balance" between economic, environmental, and social goals. Sometimes the interpretation of sustainability has been weaker still, with planning goals framed in ways that accommodate rather than question unsustainable patterns of production and demand, such as for road space, mineral resources, or speculative property assets, causing contradictions. For example, although Dutch spatial plans sought to encourage greener forms of travel, they still promoted the Netherlands' international role as a transport hub, incorporating goals for expanding seaports and airports, with deleterious environmental consequences.[50] Here, one can see that the problem is not a straightforward "implementation deficit," but that sustainable development has been defined in ways that accommodate the status quo.

These difficulties have raised further questions about the procedural dimensions of planning for sustainability.

- *Participation and expertise*: There is evidence to support the argument that wider societal participation helps support plans that emphasize sustainability.[8] However, securing "adequate" public engagement in planning processes encounters a number of problems. The range of complex ecological issues that sustainability has brought into planning processes raises questions about how different forms of knowledge are handled and tested. A common risk is that technical elites and industry representatives dominate the process, to the exclusion of other groups. These dilemmas, in turn, highlight the risks of collaborative planning processes that give privileged access to key economic players, which act to protect their immediate interests; Van der Straaten[51] suggests that the NEPPs underperformed because powerful actors were able to weaken targets.
- *Futurity and uncertainty*: For all that planning and sustainability both seek to respond to long time horizons, the realities on which present actions will be based are constantly shifting in the light of new knowledge and social changes. This creates tensions between instituting long-term plans and remaining responsive to change[52] without caving in to expedient short-termism.[53]
- *Environmental policy integration*: The idea that planning for sustainability requires "integration" has also been easier to say than to achieve in practice.[30] The kind of voluntarist, collaborative approaches to integration that planning processes tend to foster has proved insufficient in shifting dominant sectoral objectives toward sustainability goals.[54] National sustainability strategies are still often led by environment ministries, which then struggle to exercise much influence over other sections of government. Ironically, land use planning is often left managing the side effects of sectoral policies that national sustainability strategies have failed to integrate with sustainability goals.

The overall evidence of the years since Agenda 21 is that planning is a desirable but insufficient ingredient in progressing sustainable development. For some, the problem is the concept of sustainability itself, which has been accused of being vacuous, vague, too contradictory and too readily captured by powerful interests. Some have shifted their attention to goals that seem to offer firmer anchors for progress, like resilience or decarbonization,[26] but such concepts may be no less prone to interpretive and political challenges when used in actual planning.

Perhaps the problems lie partly in the planning approach? The implementation problems discussed above expose how conventional approaches to planning for sustainability, depicted in Figure 1, tend to adopt an "ineffective engineering ideal,"[21] seeing society as a technical system that can be steered from the center to deliver targets. This strategy can work for narrow issues like pollution control but performs less well for complex social problems. However, if the above analysis shows planning for sustainability to be a more complex and challenging task than it might at first appear, it also points the way to two alternative perspectives.

Rethinking Planning for Sustainability

Adaptive Planning and Transition Management

If initial interest in using planning to promote sustainability was often guilty of naive optimism in what could be achieved, one by-product of these implementation difficulties has been a better understanding of the problem.

> Sustainable development is pursued in a world of multidimensional, intersecting and dynamic complex systems. We cannot expect to describe them fully, much less predict future effects. We may lack even suggestive evidence about many emerging problems, whose influences will ripple unpredictably through complex socio-ecological systems.[55]

One response has been to advocate approaches to promoting sustainability that are better suited to this reality, by showing "explicit appreciation of complexity and uncertainty, likelihood of surprise, and need for flexibility and adaptive capacity."[55] Some would describe these approaches as "adaptive planning"[56]; others have developed concepts of "transition management."

In practice, adaptive planning and transition management embrace elements of the conventional approach to planning for sustainability, but with different emphases. They incorporate an interest in developing shared long-term objectives, sustainability visions, and being anticipatory, as well as the use of indicators and monitoring to assess progress. However, there is less emphasis on "the old plan-and-implement model aimed at achieving particular outcomes"[55] in favor of "a more open-ended, process oriented philosophy." Rather than pursuing a single vision of sustainability, there is a concern to explore a diversity of different routes in a more iterative way, using a portfolio of ideas including "transition experiments," to develop circles of learning and adaptation. Adaptive planning takes an iterative approach with a greater emphasis on "monitoring, researching, and adjusting," allowing the redirection of previous management goals and activities "in light of new information and surprise,"[57] which could be an environmental or social change. There is less accent on achieving specific goals and more on institutional designs that prove resilient in the event of failure.

Some transition management approaches also take a much wider view of what needs to be changed if sustainability is to become a reality; from more targeted, incremental improvements in existing development forms to "promoting the sustainable reconfiguration of entire socio-technical systems."[58] This reflects the fact that "the power to shape structural change in society and technology is distributed across a multitude of actors and societal subsystems."[59] Transition management also emphasizes fostering innovation.

There is limited evidence for the actual effects of transition management approaches,[60] but the ideas have been applied in the Netherlands. Dissatisfied by the poor performance of the NEPPs, and keen to "revitalize" the process,[58] policy makers incorporated transition management in the fourth NEPP, released in 2001, and committed the government to sustainability transitions in energy, transport, water management, natural resource use, and agriculture.[55] The process involved creating a series of "platforms" in which stakeholders came together, to develop "transition themes" and pathways to those goals, including "transition experiments" to explore in practical terms how to progress along those pathways.[58]

Whatever its theoretical merits, the Netherlands' initial experiences raise questions about how far, in practice, elements of transition management have actually exerted pressure on business-as-usual. Smith and Kern[58] show how, when applied to the energy sector, the desire to incorporate relevant, powerful actors from industry and government departments into the process left it open to being captured by them; a wider risk of stakeholder engagement, as noted above. The result was that the transitions management approach failed to displace a narrow focus on technological costs and benefits or to exert much influence on wider energy policy. Absent also was any wider public debate about the transition goals or pathways. Other commentators have expressed a concern that transition management does not avoid the problems of conventional, linear approaches to planning for sustainability in assuming that there could be a consensus among diverse stakeholders about what constitutes a sustainable development path.[61]

Arguably, transitions management approaches also display another problem of much planning for sustainability: a tendency to focus excessively on new, more innovative forms of development, and give insufficient attention to how societies challenge and displace existing, unsustainable development forms.[62] However, planning can have a role in this, as explained below.

Planning and the Politics of Sustainability Transitions

The second alternative perspective considered here requires us to look beyond the intended goals of planning, to understand how planning processes have actually served to promote more sustainable forms of development. This requires us to view planning less as an activity on its own and more in relation to wider systems of public policy, and the politics of decision making. Viewed in this way, the impact of planning on sustainability may be messier, and less obvious in the short term, but more profound over the long term.[7,63]

One important feature of planning processes is that they provide "opportunity structures"[64]—including consultation procedures over plans and projects, legal review mechanisms, and various forms of environmental assessment—that allow the involvement of the public and interest groups, and through which argument about social purpose can take place. A distinctive feature of the opportunity structures provided by planning is the scope they offer for cross-scalar discussions, that is, through engagement about future development projects or land uses participants may also come to question the wider policies and values that lie behind them. Participants may raise fundamental concerns about the environmental sustainability of certain forms of development, and press for lower-impact alternatives.[45,65] The arguments generated can also exert pressure on environmentally damaging forms of development through extra costs, delays, and the ever-present threat of veto. Over time, the cumulative effect of these discursive and material impacts has sometimes undermined previously dominant policy approaches, loosening the grip of powerful interests, fostering acceptance of tightening environmental conditions, and opening up long-held policy norms.[63]

One can see these dynamics in a number of contexts. Challenges made through (and beyond) planning processes to new road schemes and their environmental impacts have helped reinforce arguments for a change in transport policy, away from predicting travel demand and building road space to accommodate it, toward greater emphasis on public transport and managing travel demand. Airport expansion planning has also become an important venue for debates about the environmental risks and societal worth of unfettered aviation growth.[7,66] Hudalah et al.[67] chart the way in which environmental NGOs in Indonesia exploited moments of opportunity in project and plan decision making to form new coalitions, and increase the weight given to wider development agendas based on conserving ecological functions. Planning is important because it is where broad policies and otherwise abstract sustainability concepts meet real, concrete environmental changes, stimulating public engagement and demanding solutions.

For all that it might be messy, conflictual, and unintended, one can see how existing planning systems have generated the kind of debate and policy learning that transitions to sustainability are often deemed to demand.[55] It is often conflict as much as cooperation that forces new perspectives onto the agenda. Moreover, this function of planning has reinforced sustainability transitions by subjecting unsustainable development to intensive questioning and, in some cases, presaging its demise—a dimension of change that the technology/innovation-centered approaches of transitions management tend to neglect.[62]

The challenge is to maintain openness of planning processes to wide-ranging debate, often in face of efforts by governments to keep fundamental questions of need and risk off the agenda.[7]

Conclusion

A central problem with the proposition that one can "plan for sustainability" is that sustainability is not a concept that can be defined precisely and then implemented.[68] Rather, planning is one of a number of arenas in which the meaning of sustainability is debated and constructed, often in the face of significant challenges. Indeed, the experiences of planning have been important for showing that formulating policies for sustainability can open up quite fundamental questions about needs, demands, and environmental value. Such questions are implicit in asking—"what is it that we should sustain?" Because of the disagreements surrounding such fundamental questions, progressing toward sustainable development is inevitably a process of "muddling through,"[14] even when plans look clear on paper, and likely to be contested—especially perhaps if plans are seeking to make a real difference to unsustainable trends.

However, although the conventional, linear view of planning for sustainability displays a number of weaknesses, planning is a vital component of social progress toward sustainable development. Through the intended goals and actions of plans, more sustainable forms of development can be delivered; at the same time, the spaces for deliberation and challenge that planning creates form a key part of the "ongoing territorial struggle"[69] to understand and institutionalize more sustainable forms of growth.

This experience suggests that when examining processes of planning for sustainability, one needs to do more than look at whether the core features of the conventional approach are in place: clear goals and targets, well-chosen actions, mechanisms for public and interest group engagement, and systems for monitoring and review. One should also ask the following questions: what are the opportunity structures for influencing the plan and who is able to access and exploit them? What scope is there for raising alternative development strategies and challenging dominant but unsustainable development priorities?[70]

Sustainable Development

Mark A. Peterson

Introduction

This entry defines sustainable development and its three basic aspects. Because sustainable development is a relatively new concept, a short history and description of the drivers that lead to sustainable development are described. Then, a sustainable energy future is presented. To be sustainable as a society requires cooperation and collaboration rather than command and control management. A very key aspect of sustainable development, social synergy, is covered. Also, because sustainable development is relatively new but essential to build a better and viable future, children from the earliest age through college need to learn to understand and apply the concepts of sustainable development. A paragraph is included that describes current efforts in the United States to incorporate education in sustainable development (ESD) in K–12 and college curricula.

Sustainable development encompasses stewardship of many areas of human and planetary life. In business, one of the key motivators is to implement sustainable development measures to be profitably successful indefinitely. To do this requires that businesses show their due diligence to both society and the environment while maximizing profits. Sustainability reporting assists businesses in assessing their efforts. Sustainability reports are both management and public relations tools. An innovative, very effective, time-tested form of sustainable development, “renting a service” rather than “selling a product,” is covered. Then, sustainable development for community vitality is described. As the sizes, types, and socioeconomics of communities vary considerably, so do all of the related aspects of evolving them to be sustainable. Reference is made to a web site that thoroughly describes all aspects. Some of the subjects covered on the web site are briefly summarized in this entry. The final section covers the vast, opening market of sustainable development in developing countries.

What Is Sustainable Development?

Sustainable development is development that meets the needs of the present without compromising the ability of future generations to meet their needs. Sustainable development has three aspects:

1. Social (people)
2. Environmental (planet)
3. Economic (profits)/prosperity

All development affects all three aspects. All three aspects are interdependent. Thus, being mindful of these interdependencies in management and leadership decisions will result in the best overall solution—a win-win-win solution that maximizes success and minimizes any negative social, environmental, and economic costs. This is called managing the triple bottom line of people, planet, and profits. This is also called whole systems thinking[1,2] because all relevant factors are considered as a whole. The role of engineers is to help their clients be successful. This requires integrated whole systems thinking that covers all related liabilities that a company or community (their client) may have and provides the most efficient and profitable solution to the challenge. Often, the best whole system solution is also the most efficient and most sustainably profitable.

The environmental (planet) aspect is significantly affected by energy consumption and management, including: the entire national power infrastructure and distribution, transportation, plus the construction and renovation of all residential, commercial, and industrial facilities.

History, Environmental Degradation, and National Security

During the last century, while fossil fuels were abundant and cheap, those fuels fulfilled a majority of our energy conversion needs. The mounting problem is that combustion emissions have fouled the environment in a number of ways, resulting in increases in respiratory illnesses, mercury pollution, and a rise in global temperatures. The quantity of easily retrieved fossil fuels is significantly depleted. Coal is still relatively abundant, but it does not burn cleanly. Technologies need to be developed to both mine the coal safely and to burn it cleanly. Regarding petroleum, many countries that are not friendly to the United States control most of the remaining easily extractable sources. Many national security advisors have indicated the urgency of severing our dependence on foreign oil as a part of an overall strategy for the security of the United States and as a means to prevent oil-related conflicts.[3,4] It is also apparent that there is a need to protect and allow the environment to regenerate. The effect of using fossil fuels extensively and inefficiently is that we are simultaneously poisoning the environment and ourselves. Nuclear power emissions are clean, but the nuclear power industry has significant obstacles such as storage of radioactive wastes for many thousands of years. In addition, there are security concerns to safeguard radioactive material from being stolen for production of atomic weapons.

Governors and mayors are taking action to implement clean energy technologies. In response to clear signs of increased cost from continuing to use fossil fuels and scientific evidence showing that by burning fossil fuels we are initiating a possibly devastating global warming trend[5] that could flood coastal cities, disrupt the food chain, and change climate patterns significantly, many states have taken the initiative and enacted renewable energy portfolios to fund the transition to renewable energy resources. Many remaining states are in the process of developing their own renewable energy portfolios. These renewable energy portfolios provide significant state- and utility-sponsored financial incentives for the commercial, industrial, and residential use of renewable energy systems and fuels. On the city level, many mayors from major cities around the world have made commitments to cut greenhouse gas emissions to slow the rate of global warming.[6] Many of these cities are coastal and could be severely impaired or destroyed from rising sea levels from global warming. So, civic action to switch to cleaner energy options is beginning in earnest.

Energy Future

What this means to energy engineers is that petroleum-derived fuels are on their way out over the next half century. Hydrogen (where the hydrogen is derived from renewable energy sources), ethanol, biodiesel, and other forms of renewable fuels are on their way in. Direct and indirect conversion of solar energy, including wind, biomass, wave/tidal power, and small-scale hydroelectric power will increasingly be part of the energy infrastructure that energy engineers will design and build. The bottom line with energy is that it needs to be relatively nonpolluting and indefinitely available. It is a very dynamic time for energy engineers as the entire, worldwide energy picture transitions to clean renewable technologies. This will eventually add a lot of stability to the world economy, the world political environment and to everyone's lives. The stability will come from the fact that renewable energy technologies can be used to tap the natural energy resources that are available everywhere. Stability will also come, as the environment regenerates, the climate stabilizes and resources remain available for our sustenance.

How We Socially and Professionally Interact with Each Other Determines Our Degree of Success

Another aspect of sustainability has to do with how well we interact and collaborate. In the past, management of most activities was by a top-down hierarchy. Now humanity is evolving and it is driven by high levels of sophistication in technology and communications, which has resulted in individual knowledge and skill level increases. Plus, many families are now structured such that individual adults and children are taking more independent responsibilities for the many aspects of their lives. This has all created a desire by many people to be more intimately involved in solutions rather than just letting someone else do the thinking. In this new economy, teamwork and open communication are important to bring all stakeholders together, whether in a business or community, to manage by consensus and cooperation. Everyone affected should have the opportunity to be involved in the solution, even if just by being informed as the planning and decision-making are in process. The outcome then is one that promotes efficiency, for the simple reason that all persons affected are involved, which promotes enthusiasm and "buy-in." Typically with this process, more work and time are invested up-front such that all aspects are considered and thus everything proceeds more efficiently down-stream.[7]

Creative, Cooperative, Design and Planning Teamwork[2]

The ASHRAE GreenGuide recommends "integrated design teams" that have all of the design, economic, planning, and other related disciplines involved up-front to create better designs. If this process is not used, design typically proceeds in a series of "handoffs" that tend to compound problems, as each succeeding team designs "around" any incompatibilities that the previous designers have already finished. This adds unnecessary complexities and inefficiencies, which increase construction and life-cycle costs. Through coordination and the collaboration of designers, architects, engineers, and key players, an integral design can be created that functions as an efficient system and not as a collection of parts that are force-fit together. This approach has enabled design teams to design very energy efficient, comfortable, aesthetically and environmentally friendly buildings at or less than the conventional price per square foot of traditionally designed buildings. So, working as a team from the beginning is the most efficient way of designing because potential conflicts are resolved up-front rather than later at a higher cost. Effectually, when people are creating and they know that their contributions are respected, superior planning and designs are achieved. The upfront work of coordinating planning and brainstorming sessions with many people of diverse backgrounds can be a challenge. However, the results and life-cycle costs are almost assuredly optimal.

Education

The United Nations has declared the decade from 2005 to 2014 as The Decade of Education for Sustainable Development.[8]

There are many national teams around the world that have taken the lead to work across the educational spectrum—including public and private education, primary and higher education, independent, charter, and home-schooling—to incorporate ESD in their curricula. The U.S. Partnership for The Decade of Education for Sustainable Development[9] was formed to facilitate implementation of ESD in the United States.

Effective education can demonstrate the inter-relationship and interdependence of people, planet, and profits in all life activities. We have the technology to transition to a clean energy future and to manage materials in a cyclic manner. We know that pollution is causing global environmental change. We also know that teamwork and cooperation get better results than working in a hierarchical or isolated manner. Education in sustainable development will show that the current "consume and throw away" economy no longer works for the benefit of humanity and life. Rather, there is a need for cyclic, whole-systems thinking that integrates all relevant factors into the best, longest lasting results.

Sustainability Reporting

Realizing the importance of being "sustainable" and understanding that they are good long-term investments, many companies are developing sustainability reports. These reports are strong management tools that show how well a company is progressing with their sustainability, their corporate social responsibility (CSR), and their goals to continually improve. They provide an openness that stakeholders (employees, stockholders, regulatory agencies, customers, and community leaders) expect so they know if a company is a good place to work, a good investment, or a good neighbor. These reports are available to the public (free download).[10] For engineers, preparation of sustainability reports involves the collection and analysis of energy and environmental data. Demonstration of energy savings plans and associated pollutant emission reductions can have significant public relations and market share value. This can promote higher sales and flow of investor capital as companies prove their social responsibility and long-term viability.

"High 5!—Communicating your Business Success through Sustainability Reporting—A Guide for Small and Not-So-Small Businesses," from the Global Reporting Initiative, describes the benefits of sustainability reporting:

Sustainability reporting has many advantages that benefit different areas of your business. Some benefits are purely financial while others deal with customer or employee satisfaction. Sustainability reporting helps organizations identify and address their current and potential risks, saving time and money in the short and long term. As the public becomes more aware of your efforts, customer loyalty and credibility of your business will greatly increase. When you take a deeper look into your daily business operations through sustainability reporting you will be able to discover new opportunities.

Businesses continuously seek to generate income and acquire a competitive edge by identifying new market opportunities and determining current and potential risks. When your organization embraces a sustainability perspective, i.e., simultaneously addressing social, environmental and economic issues, you can benefit from cost-savings and improvements in product quality and employee performance.

When considering how to improve financial performance, many organizations only look at financial aspects, such as the cost of purchasing goods, personnel costs, or tax payments. However, working on environmental and social issues can also positively affect your financial bottom line.

Sustainability reporting is the way to identify these potential benefits and realize the economic gains. It helps you achieve your business goals by setting up a continuous improvement process based on target setting and progress measurement. All in all, sustainability reporting helps you to acquire that competitive advantage.

Renting vs. Buying (A Sustainability Innovation)[11,12]

Here is an example of systems thinking to ensure that a product has minimal environmental impact plus high social and economic value:

In today's consumer/throw-away economy, typically a product is manufactured and sold. There is producer incentive to minimize the use of labor and material resources put into a product, thus saving on cost. The product is sold as cheaply as possible to maximize sales. The product eventually wears out and is disposed of. A product that breaks and is disposed of soon after its warranty period is best for sales, so that a consumer will go out and buy a replacement. This is obviously a wasteful scenario, which is prevalent in commerce today. However, that is changing.

A more efficient scenario that many companies have successfully deployed for years is to manufacture and rent a product. Then, there is an incentive to maximize the utility and life of the product, thus ensuring an income to the owner/renter for as long as possible into the future. (This is what sustainable development is all about—maintaining economic flow for as long as possible into the future.) When this product is manufactured, due care in manufacturing processes and sufficient material are used to maximize durability, reliability, and longevity. Customer satisfaction is high from having a reliable product, which also builds name recognition and increases desirability. The product is designed to be easily maintainable, again, to maximize longevity, and also to facilitate dismantlement of the product when it has come to the end of its useful life. Thus, the parts can be easily remanufactured and reused or segregated for efficient recycling of the raw materials. So, maximum utility and income is achieved from the product, and most of the resources that went into manufacturing and maintaining the product throughout its life are recycled with minimal impact to the environment.

So, engineers with sustainable development in mind might be thinking of the "rented" product scenario, which is inherently efficient, rather than the "sold" product scenario, which is inherently wasteful. For example, Interface, Inc., the largest carpet manufacturer in the world and a company that has committed itself to be as sustainable as possible, is using this renting concept in its products. They rent carpet tiles. As the carpet eventually wears, tiles are replaced and recycled to make new tiles.

Community Development to Decrease Energy Costs[13]

Over the last three-quarters of a century, there was an assumption that gasoline and diesel fuel would be cheap and plentiful, indefinitely. Thus, urban sprawl developed because of the low cost of owning and operating one or more cars. This is not the case anymore! Now, with the realization that cars are expensive to both purchase and operate, there are efforts by many cities to re-establish neighborhoods that have all of the amenities needed for occupants all within a short distance that can be covered on foot, with a bicycle, or with convenient public transportation. These cities are excluding automobiles from certain areas and some are charging admission fees for cars to enter semirestricted areas. This has helped to revitalize many city commercial districts because of the park-like feeling of being in these areas without the noise and exhaust from cars. With the economic benefits that have been realized by these arrangements, more and more urban and suburban cities are pursuing these types of commercial district renovations in their cities.

Obviously, society has made a major investment that established urban/suburban sprawl. That investment now needs to be made sustainable. Consequently, there will be major investments in clean fuels such as biodiesel, ethanol, and renewably derived hydrogen to power the huge fleet of vehicles in the United States. A remaining economic burden to maintain suburban living is the maintenance of roads. However, that may be relieved as convenient, modern, and cleaner public transit busses, trains, and other guided vehicles are developed into transportation networks, thus decreasing the number of cars on the road. Energy engineers will be integral to this transition in transportation.

So, the paradigm for energy engineers will evolve as community structures around urban and suburban cities change and improve for energy efficiency. There will probably be a tendency to create nodes, where residents have a majority of the amenities nearby. Then, clean, comfortable, energy-efficient public transportation and express lanes for cars will connect each node.

Overview of the Many Aspects of Sustainable Communities Infrastructure and Nature

The web site http://www.conservationeconomy.net/IN-DEX.CFM (courtesy of the Ecotrust) summarizes the many and various aspects of sustainable communities and preserving our natural assets. Many social factors that play a role in the culture and systems changes associated with sustainable development are thoroughly explained on the web site. Engineers should know these social interactions, which are cohesive and essential to sustainable communities. Readers are encouraged to visit the web site to get a flavor of all of the aspects of sustainability or to narrow in on aspects that are of particular interest to them. The following is a narrative summary of some of the entries on the web site:

A conservation economy describes how social capital, natural capital, and economic capital can be synergetic and sustainable.

Social capital covers fundamental needs, which include: the strong need for local sources of food; accessible, healthy shelter; healthy environment and access to healthcare; plus access to knowledge about the interconnectedness of us to our environment and to each other. The section on community discusses collaborative processes that honor: social equity, which promotes prosperity for all; security from fear and violence; recognition of the wealth and strength in our cultural diversity and establishment of a will to preserve it; plus, local celebrations to honor a sense of place with the community and environment. It proceeds to describe the importance of enjoying beauty and play, to relieve stress from our busyness; learning to welcome transitions that improve communities as a whole; and establishment of civic society where all residents can manage their communities collaboratively.

Natural capital includes the atmosphere, biosphere, and earth. To sustain it requires ecological land use, which includes connected wild lands, in which indigenous animals, plant and people can coexist together. Protected core reserves can be set aside for native plants and animals to thrive, without interference. Wildlife corridors can connect reserves such that animals may migrate freely and parks can be established to act as buffer zones between developed and undeveloped areas. Productive rural areas can be re-established through: sustainable agriculture, which does not cause runoff of pollutants into streams and is more in harmony with natural processes; sustainable forestry, which thins rather than clear-cuts stands of trees; sustainable fisheries, which establish quotas, such that species are not depleted; and eco-tourism, to provide natural getaways and education for people that want to learn more about sustainability and to be close to nature. Compact towns and cities, with human scale neighborhoods, green buildings, convenient transit access, ecological infrastructure, and urban growth boundaries will create healthy, vibrant communities.

Economic capital in healthier communities and commerce will tend to expand through synergies with social and environmental capital, thus building prosperity.

Energy Engineering for Developing Countries[13]

Approximately four billion of the six and one half billion people on the planet live in extreme poverty, where a poor sanitation infrastructure results in disease, there is minimal economic productivity, and there is significant economic burden on governments and aid agencies. However, recently, it has been found that given some of the modern necessities such as water wells, electronic communication, and dependable energy, people that are impoverished can quickly and enthusiastically become productive to their communities and not be an economic burden.

The use of small photovoltaic power systems in villages has literally energized villages into minieconomic zones of relative wealth and flow of capital, thus creating self-sufficiency rather than dependence.

Just providing electricity for lighting, water pumps, and small power tools can tremendously boost the productive capabilities of a village.

The establishment of cell phone repeaters and wireless infrastructure is much less expensive than running miles of telephone cable. A limited number of cell phones in villages have also promoted prosperity because farmers and merchants can effectively communicate and market their products.

As developing countries continue to develop, water, energy, and communication will be vital to their success. So, energy engineers will be a key part of this process. Many multinational and small companies and financial institutions are tapping into bringing these four billion people into the world of commercial success and out of the world of poverty. So, engineers will play an important part in this next major step toward a sustainable world.

Conclusion

Though we are just now seeing the start of a transition to sustainable development, it is clearly economically, ecologically, and socially advantageous to choose this means to success, prosperity, well-being, stability, and peace. We have an abundance of all of the material and energy resources we need. We have the ability, knowledge, and conscience to do the best for humanity, all of life, and the planet. We have the inspiration and insight to transition to a sustainable world. Now all it takes is the willingness to accept change and make the transition to sustainability. The outcome will be a world that is more prosperous and stable than it is now. Sustainable development is a goal to embrace and make part of our daily decisions.

Urban Agriculture

Natalia Fath

> How we eat determines, to a considerable extent, how the world is used.
>
> **Wendell Berry (2010)**

Introduction

The practice of growing food in cities, or urban environments, is known as urban agriculture. Integration of food production into the urban ecosystem is not a new phenomenon; however, the reasons behind this growing practice have changed over the past few centuries. Urban agriculture arose during difficult times, such as during war or depression, when the growth of vegetables on any available plots was encouraged as a response to dwindling food supply and food shortages. In addition, this was considered as an activity that provided jobs and income and boosted spirits and community cohesion during harsh times. The concept of “allotment gardens” was developed in Germany as a response to rapid industrialization in Europe throughout the 19th century (Holmer and Drescher 2005). Growth of cities during that time was accompanied by growing food insecurity and by allowing citizens to use open spaces to grow food, originally called “the gardens of the poor”, the administrations of the cities, thus, contributed to the idea of urban farming. The late 19th century witnessed the initiative by Detroit’s Mayor, Hazen S. Pingree, when the citizens were asked to utilize any available land to grow vegetables as a response to economic slowdown (Austin 2019) – coincidentally, now that Detroit is again a leader in urban farming due to recent economic collapse with the loss of the automobile industry. These original initiatives were further developed during World War I and World War II (WWII) and received a new meaning – they were called “victory gardens”. Misallocation and devastation of agricultural land in Europe and loss of farmers to military recruitment led to the growth in popularity of these fruit and vegetable gardens, specifically in the United States, Canada, the United Kingdom, Germany, and Australia (Drescher 2001). In the United States alone, these gardens produced about 1.45 million quarts of canned fruits and vegetables in 1918 (Schumm 2018). The United States Department of Agriculture (USDA) further continued to encourage expansion of the victory gardens during the hardships of WWII. Thus, the existence of agricultural production in urban environments has evolved to be more systematic and expected.

The purpose of establishing those gardens in the cities has shifted since the end of WWII. During times of relative food abundance, these practices may be seen from a different perspective. While still providing food, which is especially crucial for food-insecure districts, and part-time or full-time jobs, urban farms also now looked at as a place for social gathering or as a green area that helps fighting air pollution in cities. Advantages of urban farming include but are not limited to social, economic, and health benefits. However, there are some risks involved as well, which include but are not limited to required high inputs of energy and time, and high probability of polluted urban soil and air. It has been attempted to estimate the proportion of food that is provided by urban agriculture globally. According to van Veenhuizen and Danso (2007), 15%–20% of the world's food supply comes from urban agriculture. A recent publication by Clinton et al. (2018) suggests that the above numbers are highly overestimated, perhaps because of inclusion of peri-urban areas and livestock production. The authors claim that if the space is utilized at its maximum, and the practices in place are intense, then urban agriculture could produce ~5% of the global crop production.

Types of Urban Farming

Food production in cities can take various forms. There are different projects and activities that have been developing and have now firmly established themselves in urban environments. Several major categories should be mentioned in respect to urban farming: (1) community-based, (2) institutional, (3) public, and (4) commercial (Steele 2017). The borderlines between them are not rigid and, in particular cases, may carry the features of two or three categories. Urban agriculture is a flexible concept and adjusts to the local conditions, thus acquiring various forms. There is not a widespread agreement on the classification of types of urban farming, however, there are types that are commonly recognized. Specifically, community and backyard gardens; rooftop and balcony gardening; growing in vacant lots, right-of-ways, and parks; aquaponics; hydroponics; fruit trees and orchards; market farms; raising livestock and beekeeping (Steele 2017). In addition, it can be stated that post-harvest activities, for example, "creating value-added products in community kitchens, farmers' markets and road-side farm stands, marketing crops and products, and addressing food waste" (Steele 2017), should also be considered as overall urban agricultural activities.

Community and backyard gardens involve growing food for the family or the neighborhood; rooftop gardening utilizes available space on roofs while growing in vacant lots puts a productive use on otherwise abandoned land; hydroponics practices soilless food growth; and aquaponics combines the latter with raising fish. Some cities allow raising chickens or keeping beehives in urban environments.

Additionally, the classification system of urban farming types can explore the following categories: location, people involved, products grown, economic activities, product destination, scale, and technology used (RUAF Foundation 2019). However, currently, urban agriculture researchers have been using their own approach to typify this activity, which has led to a significant variety of divisions and subdivisions of local urban farming systems. Thus, it appears to be beneficial to continue developing a consistent viewpoint of types of urban farms (van Veenhuizen and Danso 2007).

Regardless of the classification system used, it is imperative to realize that food production in cities is fully integrated into the urban economic and ecological systems, and thus should be an important part of urban planning policies (RUAF Foundation 2019).

Benefits of Urban Farming

Social and Cultural Benefits

The practice of growing food in cities can be viewed as an excellent opportunity for social integration, cultural exchanges, and education for both adults and youth. Through collective action and advocacy, city dwellers build and strengthen their communities, as urban farms in their various forms mostly appear to be based on a sense of community (Holland 2004). Working as a team on underutilized land plots and transforming them into productive environments that can feed them or can be sold, residents improve the quality of their immediate surroundings and develop bonding (see Figure 1). Of particular importance, relevant to urban food production is the opportunity for people of different ages to interact which promotes intergenerational bond, and the chance for disadvantaged or segregated groups such as people from different socioeconomic classes or different backgrounds, orphans, women, recent immigrants without jobs, elderly and disabled people, to get involved in community building, to become engaged citizens, and to maintain decent livelihoods (Santo et al. 2016).

Urban farming, thus, can be an "agent of change" as it encourages social bonding and activities that have the potential to promote social, economic, and environmental changes at the local level (Holland 2004).

Urban farms can also play an important role in educational functions – participants, and especially youth, learning about ecology and the process of food growth, which in turn, can encourage growth in agricultural literacy and reconnection to nature (Santo et al. 2016). Advancing urban dwellers' knowledge on how their food is grown and distributed, may lead to the appreciation of the urgent need for cities to adopt "circular" food production system rather than current "linear" to ensure their own sustainability. Specifically, urban "outputs", like organic waste production, can and should become an "input" into urban food production system (Deelstra and Girardet 2000). Recycling and composting of organic matter and nutrient recycling on local urban farms reduce dependence on delivered "inputs" and keeps this waste from landfills. By participating in the food-producing process, citizens foster an understanding and appreciation of systems thinking and the cycles of life; and therefore, the importance of urban sustainability as the world is predominantly urban and the pattern is predicted to continue into the future.

Economic Benefits

As some types of urban agriculture utilize vacant lots, it leads to increased property values, which in turn generates increased tax revenues (Steele 2017). This is particularly true in economically disadvantaged neighborhoods (see figure 1). Among other economic benefits, it can be mentioned that this activity

FIGURE 1 Baltimore, MD, USA – low-income neighborhood, underutilized land. Real Food Farm, Perlman Place. Planted fruit trees (fig). (*Photo credit: N. Fath.*)

adds jobs to the local economy and stimulates capital investment and redevelopment (Santo et al. 2016). Guitart et al. (2012) analyzed published research on community gardens. Their review found that all 13 of the studies which examined property values reported increased property values associated with the existence of the community garden. Similar research findings can be found in Voicu and Been (2008).

It can be argued that urban agriculture makes fresh produce more affordable. This is particularly important for low-income neighborhoods and for poorer countries where between 50% and 70% of income on being spent on food. However, based on the currently available studies, it can be concluded that the criteria and methods used to assess specific profits and other economic impacts differ markedly and/or are lacking (van Veenhuizen and Danso 2007). In addition to the direct economic benefits to the participants, urban agriculture also encourages the growth of small enterprises; farming activities require necessary agricultural inputs that can vary from compost and organic pesticides production to tool production and managing of the outputs that can include packaging, marketing, and transportation of products (Homem de Carvalho 2001).

Besides the above discussed economic advantages, urban farms surplus can be donated to food banks which, in turn, can help reduce money spent on food for low-income neighborhoods. In addition, when vacant land is utilized by urban agriculture activities, it can save maintenance costs for the city as illegal waste dumping and/or vandalism will decrease (Steele 2017).

It is important to note that there is a need for more research on economic outputs of urban farming, profitability of commercial food production in cities, long-term studies on employment opportunities and on neighborhoods' indicators, discussed above. Economic outcomes are the "least documented aspect of urban agriculture" (Hodgson et al. 2011).

Health Benefits

There are several aspects relevant to this topic that should be discussed, specifically, improved food security and physical and emotional well-being. Poorer neighborhoods often find themselves living in so-called "food deserts". USDA defines food deserts as "parts of the country vapid of fresh fruit, vegetables, and other healthful whole foods, usually found in impoverished areas" (*Nutrition Digest* 2019). To qualify as a food desert, "at least 500 people and/or at least 33 percent of the census tract's population must reside more than one mile from a supermarket or large grocery store (for rural census tracts, the distance is more than 10 miles)" (*Nutrition Digest* 2019). When analyzing the ability of urban agriculture to improve food security, one should look at the individual/household and municipal levels. Neither, though, should be understood as a substitute to traditional food retail (Santo et al. 2016). While not the whole answer to urban food deserts, farming in these locations provides participants with access to some fresh produce that otherwise is unavailable; thus, improving their food security and providing a better diet that includes more fresh fruits and vegetables (Zezza and Tasciotti 2008, Smith and Harrington 2014). Numerous studies report participants, their households, as well as their neighbors and friends, gaining access to a variety of seasonally appropriate foods while saving money for other needs (Corlett et al. 2003, Wakefield et al. 2007, Kortright and Wakefield 2011). However, more empirical evidence and longitudinal studies are necessary to support the claim that urban farming can significantly amend food security over time in poorer urban neighborhoods (Siegner et al. 2018). While there is accumulated evidence that supports increased produce consumption among the gardeners (Alaimo et al. 2008, Litt et al. 2011), experts suggest it is not an overall significant indicator of improved food security and/or quality of the diets in low-income households (Hallsworth and Wong 2013). Based on physical land availability in cities, along with other barriers, urban agriculture's capacity to ameliorate food security is not strongly supported; however, it can be a supplemental solution for the urban poor (Badami and Ramankutty 2015).

Improved access to fresh produce, fruits and vegetables, may lead to better nutrition, and thus can be considered a viable strategy to mitigate certain diet-related diseases, such as obesity and diabetes (Steele 2017). However, through many studies and research done, it appears that via urban farming activities most notable and well-documented gains are in improved mental health and physical health in participants. This is accomplished through acquiring a purpose, seeing the results of one's effort, and being physically active (Santo et al. 2016). In addition, simply being close to nature has been observed to be a stress-relieving activity (Armstrong 2000, Brown and Jameton 2000, Wolf and Robbins 2015). Increased green cover in cities associated with urban agriculture activities contributes to such ecosystem services as air filtration and temperature moderation, thus also benefiting the overall well-being of urban residents (Wolf and Robbins 2015).

Environmental Benefits

Besides social and human health benefits of urban agriculture, arguably, environmental advantages associated with this activity are the dominant ones. Among particular benefits to the environment are improved air quality and mitigation of the urban heat island effect. Extensive research studies support that replacing impervious surfaces with vegetation and trees, in particular, leads to cleaner air, as vegetation filters particulate matter, and to cooler temperatures during summer. For example, in the Phoenix metropolitan area, increased tree canopy cover by 25% leads to a total cooling of 7.9°F as compared to a bare neighborhood, and addition of greenery to residential backyards reduces average neighborhood temperatures by 0.4°F–0.5°F (Middel and Chhetri 2014). This phenomenon appears to be of particular importance for low-income neighborhoods as they tend to have fewer trees and grass cover and, thus, higher summertime temperatures (Jenerette et al. 2011).

Among other environmental advantages of urban agriculture are its ability to maintain and support biodiversity via creation of habitats; its contribution to recycling of nutrients when organic waste is turned into a resource – soil (see Figures 2 and 3); its ability to increase water infiltration, thus reducing stormwater runoff and decreasing the flooding potential (van Veenhuizen 2006, Santo et al. 2016).

FIGURE 3 Composting bins at urban farm, Towson University, MD, USA. (*Photo credit: N. Fath.*)

Urban farming should also be looked at from the perspective of one of the most pressing challenges present day – scarcity of freshwater and agriculture being the largest user of freshwater. Some types of urban farming contribute to lessening this issue by collecting rainwater on site and using it for irrigation (see Figure 4). Others are capable of re-using wastewater, thus lessening the demand for freshwater supply (Haysom 2009). A particular type of urban agriculture, aquaponics, attempts to recycle water used for fish and produce production. While initially the system requires a significant input of water, the continued operation is based on this water being re-used and accompanied only by some expected losses due to evaporation, spillage, etc., which could be replenished by rainwater collection (Love et al. 2015). United Nations' Food and Agriculture Organization, FAO, is particularly invested in exploring the possibilities of integrating aquaponics in drier climate cities, such as in the Near East and North Africa (FAO 2019).

The overall reduced ecological footprint of the cities practicing urban agriculture leads to the discussion of its positive influence on one of the dominant topics discussed today, climate change. There are many challenges faced by growing cities and continued urbanization throughout the world; however, climate change is recognized as one of the most pressing challenges (IPCC 2018). The most obvious way how urban farming can lessen the contribution of food production to climate change is by reducing carbon footprint. Increase in urban green spaces, including fruit trees and crops grown, will lead to increased carbon sequestration (Thornbush 2015).

By practicing food production close to the consumers, the greenhouse gas emissions associated with the food transportation, storage, and cooling will be reduced (Kulak et al. 2013). Numerous case studies exist that support the above, and while this has not been quantified on a global scale, urban agriculture can and should be promoted as both climate change mitigation and adaptation measures.

As a concluding remark on the benefits of urban agriculture, it is important to note that the extent of these benefits directly depends on the policies in practice, the type of urban farming, and the local environment. Summary of the benefits is presented in Table 1.

FIGURE 4 Rain barrels at urban farm, Towson University, MD, USA. (*Photo credit: N. Fath.*)

TABLE 1 Benefits of Urban Agriculture

Categories	Benefits
Social	• Builds and strengthens communities • Reconnection with food production • Renders an educational venue • Promotes social, economic, and environmental activism • Promotes social inclusion
Environmental	• Increases urban green spaces • Improves air quality • Reduces Urban Heat Island effect • Promotes biodiversity • Recycles organic waste • Increases stormwater infiltration • Reduces runoff • Reduces water usage and reuses wastewater • Reduces carbon footprint
Health	• Improves food security in urban food deserts • Improves access to fresh food and, thus, overall nutrition • Encourages physical activity • Cleaner air → improves overall health • Increases urban green spaces → improves psychological well-being and mental health

Challenges of Urban Farming

Securing Land for Food Production in Cities

One of the major obvious challenges and constraints is the lack of space in world cities to be used for growing food. On the other hand, there are many cities where plenty of underutilized or abandoned land is available. Particularly, in the cities that have experienced post-industrial decline and out-migration, such as in the city of Detroit, USA. While thousands of acres of land have been given over to unemployed workers for food growing in American cities of Detroit and New York (van Veenhuizen 2006), it is imperative to enhance access to this available vacant land by creating appropriate policies. These policies will need to enable sustainable urban agriculture and remove unnecessary obstacles that exist currently in securing land for food production in cities as agriculture traditionally refers to the rural areas; thus, urban agriculture currently has no institutional home (RUAF Foundation 2019).

Additional problem is that worldwide urban land value typically rises, and therefore urban farmers have to look for free land to use. Municipal land-use regulations do not guarantee long-term use of these plots, and frequently only temporary farms or gardens can be established (Steele 2017). Given the notable time and initial money and resources necessary to be invested in developing a productive urban farm, the temporary status may not appear to be an attractive venue to pursue as they are vulnerable to redevelopment.

A relatively new phenomenon called "guerrilla gardening" has been growing around the world over the last two or three decades, and it arose in part as a response to the difficulty of securing land for food production in the cities. The name suggests that the gardening is done without the securing legal rights to the land that is being used, thus making them vulnerable.

Health Risks

While food production in urban areas promotes some substantial benefits to human health (they were discussed above), it also may present some health risks to the participants and the nearby community. Specifically, if the gardens are not organic, farmers and consumers may be exposed to doses of fertilizers and pesticides that are used. This risk, however, is not pertinent only to urban agriculture, but to rural agriculture as well.

One of the most common concerns associated with urban farming is the high probability that urban air and soil may be contaminated with particulate matter, heavy metals, and others. These may result from heavy traffic congestion that is typical for cities, from industrial activities that tend to be concentrated in urban areas, and possibly, from waste dumping areas in or around the cities. Accumulation of these pollutants in air or soil may negatively impact health of the farmers and consumers; however, those can be reduced if adequate measures and regulations are put in place (van Veenhuizen and Danso 2007).

Remediation Costs

As mentioned in the section above, it is plausible that some land plots in urban areas have higher levels of contamination, and thus it is imperative that soil samples are analyzed prior to farming activities. If soil contamination is confirmed, then land requires remediation. Current remediation methods include soil removal, washing, or capping. They are costly and therefore are limiting factors in growth of outdoor urban agricultural systems (Wortman and Lovell 2013).

Eliminating contact between food grown and the ground via construction of raised beds is a cost-effective way to establish food production on sites where soil has been contaminated (see Figure 5).

Energy Usage

Certain types of urban agriculture, particularly, indoor activities such as vertical farming, greenhouses, hydroponics, and aquaponics, do require substantial energy input for their proper operation, especially

FIGURE 5 Raised beds at urban farm, Towson University, MD, USA. (*Photo credit: N. Fath.*)

if these facilities are located in cold or water-scarce regions. In the world where 64.5% of electricity production still falls on fossil fuels, coal being the largest source, this is a concern (IEA 2019).

An aquaponics farm, which integrates hydroponics (soilless plant cultivation) with aquaculture (fish farming), where both components complement each other to generate two products at once, crops and fish, is a good practice to reduce agricultural water footprint as it recirculates water initially added to the system, but it has been proved that it requires a significant energy usage. While the food produced at the aquaponics farm in Baltimore, Maryland, USA did not contain antibiotics, synthetic pesticides, or chemical fertilizers, the energy use was remarkably high, particularly during the winter months. When input costs were compared to market prices on tilapia, it demonstrated a net economic loss (Love et al. 2015). High energy costs forced the shutdown of a hydroponics farm in Buffalo, New York and its relocation to southwest Texas (Santo et al. 2016).

Alternative types of energy should be considered where applicable, in particular, in respect to the construction of new greenhouse systems or retrofitting conventional greenhouses. Solar-powered greenhouse systems are more popular in Europe and can achieve up to 70% of energy saving (Taki et al. 2018).

Summary of the challenges and risks are presented in Table 2.

TABLE 2 Challenges of Urban Agriculture

Categories	Problems/Limitations
Social	• If air and soil contamination → high remediation costs • Unavailable land due to other uses or unsuitable • Expensive or inaccessible land • Lack of zoning regulations and policies, which include urban farming as part of future urban development • Increased fresh produce consumption does not notably lessen food insecurity • Increased fresh produce consumption does not notably improve diets overall
Environmental	• Some instances require high energy input • Likelihood of air and soil being contaminated • If in drier climates, then increased water demand (drinking water used for irrigation)
Health	• Potential health risks to farmers and consumers from soil contaminants and air pollutants if adequate preventative remediation measures not taken

Future Projections

Urban agriculture appears to be growing in popularity around the world, although the goals behind their establishment range from aesthetics to communal activity, to actual crop production in low-income "food deserts". Assessment of feasibility and sustainability or these food-producing practices should be further continued. It is implied that the land available for urban agriculture is limited given all the traditional land-uses in cities. Nevertheless, the productivity of that land can be high and it can achieve high yields, but currently material and labor resources are used inefficiently (McDougall et al. 2019).

It seems unlikely that urban agriculture can or will replace rural agriculture, as the majority of food calories in the form of cereal grains will continue to be produced outside the cities. However, urban agriculture offers an important supplement, particularly to food impoverished areas, it promotes a strong sense of community in terms of caring and investing in local place and educates people on the cycles of nature and where food comes from. With the growth of the industrial food production system in the mid-20th century in the United States, a huge disconnect arose between farming and most people. This gap can be breached by promoting farming practices in cities.

The scale of food production in cities can vary from small community gardens to large urban farms, such as the one that is currently under construction in Paris and is scheduled to open in 2020. It is projected to be the world's largest urban rooftop farm, which will also incorporate closed-water hydroponic vertical system spanning overall ~14,000 m^2 (150,695 ft^2). They are expecting to cultivate more than 30 different plant species using entirely organic methods, with fruit and vegetable daily production amounting to ~1,000 kg in the high season (*The Guardian* 2019). This could become a globally acknowledged model for sustainable urban food production.

Cell Tower Procurement: Public School Placement

Joshua Steinfeld

Introduction

Personal wireless service providers, independently and through use of brokers, have installed cell towers at or close to public schools in the United States. The open space surrounding schools, typically baseball and football fields, allows for optimal transmission of radio frequency (RF) waves between towers. Furthermore, public school districts, in comparison with private enterprises, have been more easily won over in the cell tower proposal process. Surges in experimental research regarding health hazards to RF emission, especially the apparent increased susceptibility of children to RF radiation, have sparked controversy over the exact locations of cell towers.

The purpose of this manuscript is to present an argument opposing the placement of cell towers at public schools. First, scientific studies related to animals and humans are provided to show that RF waves may be harmful to humans, and there is concern over electromagnetism. Second, voluntary initiatives and cell tower proposal processes are discussed, highlighting the Rockville, Maryland, community's precedential victory in opposition to the placement of a cell tower at Wootton High School. Third, ethics and public policy considerations address the need for streamlining nationwide community efforts by amending the Telecommunications Act of 1996 to disallow the placement of cell towers near public schools. Fourth, areas for further research are presented, which include the compilation of data sets, tracking of exposed students at school, and new theory to address causality issues related to competing risks. Finally, the chapter concludes by providing commentary regarding invisible risks.

Impact and Study of RF Hazards

Recent Trends

Concerns regarding the safety of cell towers at school have risen across the country. In 2010, Vista del Monte Elementary School in Palm Springs, CA, was pegged as having a reputation for being a cancer school. In 2005, a cell tower was erected on campus. Since then, 12 people have been diagnosed with cancer, affecting those who worked closest to where the cell tower was installed, where the field-strength readings were highest.[1]

From 1975 to 2000, childhood cancer rates had increased dramatically by a rate of 32%. Some of the most severe and deadly cancers such as acute lymphocytic leukemia, brain, kidney, and bone cancer also increased considerably.[2] In 2004, there were 36 million prescriptions of sleeping medications. As of 2009, 56 million prescriptions were outstanding, a whopping 56% increase. In 2004, the number of residents using cell phones was 109 million. By 2009, the number was up to 271 million.[3] Public health officials and environmental experts alike have been searching for environmental stimuli that may be contributing to the increased childhood cancer rates and sleep deprivation. The placement of cell towers at schools has been an area of focus (Figures 1 and 2). This Florida community elementary school also has a narrow-band transmission device installed on the tower (Figure 3). Installation of narrow-band cell towers is generally more restrictive than wide-band cell towers because of the narrow band's compact, piercing wavelength. Electromagnetic stimuli emitted from cell devices have become an area of intense research interest.

Background Research

Just to get an idea of the strength of an electromagnetic force emitted from a cell tower in comparison with a more well-known object, cell phone technology operates on frequencies up to 3 gigahertz (GHz), and a microwave oven cooks food at 2,450 megahertz (MHz).[4] Three GHz is equal to 300,000 MHz! Coulomb's law states that the force of an electromagnetic field is proportional to the magnitude of the charge and inversely proportional to the square of the separation. From Coulomb's law, we can derive the Inverse law, which suggests that holding the magnitude of the charge constant, the electromagnetic force emitted on a subject increases exponentially as the subject moves closer to the source.[5] Using

FIGURE 1 Public elementary school.

FIGURE 2 Wide-band cell tower at elementary school.

FIGURE 3 Narrow-band cell tower at elementary school.

Ampere's law, which combines the magnetostatic equation for determining the magnitude of a magnetic field with Stokes' theorem dealing with surface area, it is possible to determine the strength of an electromagnetic force through a closed path that may be tangent or indirectly exposed to the source.[5,6] Coulomb's law and the resulting derivation of the Inverse law demonstrate key findings in the discussion of cell towers. The farther away the cell tower site is from the subject, the lower the field strength absorbed. Furthermore, due to the exponential nature of the Inverse law, being close means being really close. Ampere's law is especially helpful in determining indirect exposure to force strength in cities where waves regularly bounce off other buildings.

A given material is composed of atoms. Each atom consists of electrons orbiting a central positive nucleus. Electrons also spin around their own axis. The orbital array of activity occurring between magnetic forces of protons and electrons in atoms results in an organized disarray of unpredictability. This unpredictable orbital disarray is the normal, unaltered state of the atom. When an external RF field is applied, the bombardment of electrons (from the source) stimulates host atom movement changes (in the subject), and the atom has a magnetic moment.[7] The orbital path of the electrons is brought into a slight sense of organization, throwing normal behavior out of whack. It is the electron stimulus emitted from cell towers that has been of much focus in experimental studies.

Radio Frequency Research on Animals and Humans

Scientists and researchers have proceeded cautiously regarding the use of human subjects in testing the effects of RF exposure. As a result, numerous testing on animals has been done to learn about the effects of electromagnetic radiation on living organisms. A 1997 study on mice demonstrated the effects of radiation on prenatal development and resulted in a progressive decrease in the number of newborns per dam, ending in irreversible infertility. In a subsequent 1999 study, mice exposed for just 24–72 hours to weak electromagnetic waves increased the activity of natural killer cells by 130%. Meanwhile, exposure to microwave irradiation had no effect on the activity of natural killer cells.[8] Nonetheless, microwave stimulus interfered with cell immunity of mice, increasing T-cell proliferation in response to stimulus.[9]

Studies on other living organisms have also been conducted. In Germany, behavioral abnormalities were observed in a herd of dairy cows that grazed near a cell tower for over 2 years, leading to reduction in milk yield and increased health problems.[10] In Russia, the effects of electromagnetic radiation on sea urchin embryos were tested. Only sea urchins with preexisting weakened viability were impacted by the electromagnetic radiation, in which case the electromagnetic radiation stimulated the onset of early development of embryos.[11]

While much more rare than electromagnetic testing on animals, some testing on humans has taken place. It was discovered that electromagnetic fields affect the central nervous system in humans because visual reaction time was prolonged and scores on short-term memory tests were lower in high-intensity exposure test groups.[12] Also, in a controlled study aimed to investigate the impact of low-force electromagnetic fields on healthy humans, human subjects were exposed to a 900-MHz electromagnetic field and intermittently pulsed with 217 MHz. It was determined that low-force fields have no effect on nocturnal hormone secretion under polysomnographic controls. However, cortisol production increased, which is transient by classification, indicating the organism (human subject in this case) adapted to the stimulus.[13] It was unclear if any mental impediments or genetic responses may have taken place in addition to the increase in cortisol production, but it was certain that the human subjects endured a cellular response. Nonetheless, current research indicates that genes are at risk, even at low-force electromagnetic fields.

Genes that ward off cancer and other illness may be inhibited when a cell receives stimuli from the environment. The National Institute of Environmental Health Sciences has been using genomic techniques to determine the behavior of promoter-proximal paused polymerase (Pol II) with and without environmental stimuli.[14] Pol II is known to have a role in fighting disease. Transcriptional responses to environmental stimuli can cause alterations in Pol II distribution, gene expression, and epigenetic chromatin signatures, leading to transcription dysregulation that can cause etiology of cancers.[15] Additionally, recent work has revealed that signal-response pathways are loaded with Pol II prior to final gene activation, further enhancing the opportunity for cellular changes to take place as a result of harmful environmental stimuli.[16,17] Molecules transported from environmental stimuli can inhibit the signal-response pathways' ability to pause release of Pol II.[18] Pol II pausing is necessary in providing an accessible chromatin architecture for gene promoters that inevitably fight disease.[19,20] It has been determined that Pol II pausing facilities' precise control and coordination of genes is a crucial regulatory step in rate-limiting the expression of DNA damage responsive genes.[21]

The extent to which scientists and doctors alike understand the impact of RF waves on humans is unquestionable in its fineness. For example, RF waves are routinely manipulated in clinical medicine to achieve exact thermal dosimetry and thermal pattern poisoning of tumors. The important nuance to remember is that the beneficial uses of RF waves in medicine are based on the destructive qualities of the high-energy RF waves.[22]

Voluntary Initiative

Students Against Cell Towers

In 1963, a group of citizens became activists in opposition to the proposal of a Con Edison power plant on Storm King Mountain in New York.[23] If the Storm King success story gave life to an entire environmental movement, then the success of Students Against Cell Towers (SACT) in opposing a cell tower at Wootton High School in Rockville, Maryland, solidified the environmental movement's existence by the hundreds of cell tower opposition advocacy groups that spawned across the nation since the SACT community voluntary initiative spanned from 2003 to 2005. Although SACT is no longer an active organization, its over 100 former members carry with them knowledge of the vital considerations regarding placement of cell towers at schools.

In 2000, Cingular Wireless began an aggressive campaign to install cell towers at public schools in Montgomery County, Maryland. The high schools were targeted first, perhaps because younger children are known to be especially susceptible to the radiation emitted from cell towers, although we do not know for sure what Cingular's strategy was. Additionally, Cingular Wireless first targeted public high schools located in communities with relative economic disadvantages and therefore less likelihood of organizing against a cell tower proposal. Cingular installed cell towers at Wheaton High School, Sherwood High School, and Kennedy High School. The students in these school districts come from families with median household incomes of $55,562, $57,260, and $60,296, respectively. It was not until 2003 that Cingular approached the wealthier Wootton and Walter Johnson High Schools, with median household incomes of $74,655 and $77,568, respectively.[24] Cingular never approached Whitman High School and Churchill High School with cell tower proposals; families of students in these schools have median household incomes of $113,788 and $140,222, respectively. Cingular Wireless' schematic timeline for public school cell tower proposals aimed to first test the will of communities who were economically and educationally disadvantaged before targeting wealthier, resourceful communities. Eventually, the residents of the Wootton and Walter Johnson school districts successfully rejected the cell towers due to the organization of a community voluntary initiative.

Cingular Wireless hired an experienced attorney to implement objectives related to the Wootton cell tower proposal, the same attorney who had previously handled the installment of cell towers at ten other public schools in Montgomery County. With little to no resistance coming from the Montgomery County public schools where cell tower installation was already in place, there was no need for Cingular to hire more than one person, an attorney rightfully so, to execute public school cell tower proposals in Montgomery County. An emphasis is placed on Cingular's need for just a one-man proposal team to demonstrate two things. First, it may be surprising how little publicity and resistance cell tower proposals typically receive, considering how big and visible they are. Second, Cingular's one-man show enabled Cingular to circumvent the proposal process. According to the Telecommunications Act of 1996, personal wireless service providers are required to notify in writing students, employees, and local residents of any proposal to erect a cell tower on public school property. Cingular's attorney had the ability to make sole judgment in his decision to refuse to notify the community regarding the plan to install a cell tower at Wootton High School.

In attempting to reject Cingular's proposal to erect a cell tower at Wootton High School, local residents formed a coalition called SACT. Despite any protections that may be offered by the Telecommunications Act of 1996, it clearly states that cell towers may not be rejected because of health concerns of nearby subjects. However, since Wootton High School is situated in a valley with Frost

Middle School perched up on the adjacent valley ridge, the RF waves emitted from the cell tower at Wootton would be passing through Frost Middle School, creating the allowance for a new interpretation of the act and a platform to remain steadfast. Next, it was discovered by SACT that the principal of Wootton High School had the exclusive authority to decide on whether to allow a 150-ft cell tower to be erected next to the football field at Wootton. SACT contacted local neighborhood associations, cluster school principals and administrators of Frost Middle School and Fallsmead Elementary School, Rockville City management, Montgomery County executive offices, parent–teacher association groups, and other perceived interest groups to spread word of the issue and provide scientific research related to health risks of RF exposure. Through discussion with local government and administration, SACT realized that the community had the right to a town hall meeting prior to the consideration of a cell tower proposal. Over 100 advocates holding greater than 1,400 petitions standing against the placement of a cell tower at Wootton High School arrived at the town hall meeting held in the Wootton library to greet Cingular's attorney and his science expert, with state representatives and media in attendance anxiously awaiting the confrontation. When Cingular's scientific expert utilized research no more recent than the 1960s, it became clear even to Cingular's attorney that SACT's research was plausible and that cell tower radiation may indeed be harmful to humans. For the benefit of Cingular's attorney, it was likely that he did not believe in his own company's stance; instead, his involvement was probably based on solidaristic group loyalties.[25]

An insight deserving mention was a key leadership tactic used by SACT to retrieve petition signatures. One of the exemplary practices of leadership is to inspire a shared vision.[26] Considering the perceived lack of concrete scientific data regarding human exposure to cell towers, one of the most effective ways to gain support for the petitions was to focus on the negative aesthetics of a 150-ft tower that would be visible from a Rockville resident's nearby home. Realizing the eyesore created by cell towers and the fact that opposition due to aesthetic concerns frequently arise, personal wireless service providers have begun camouflaging the cell towers (Figure 4). Figure 4 shows a cell tower with elaborate camouflage meant to make the cell tower look like a tree. After further survey of the surrounding area, it was discovered the camouflage was an attempt to help the cell tower blend in with a tree line overlooked by a nearby middle school (Figure 5). The canvas makes the cell tower more difficult to notice and provides personal wireless service providers with a prompted solution to aesthetic concerns.

A key ingredient behind this chapter's explicit focus on the placement of cell towers at public schools as opposed to all schools, in general, was illustrated by the Wootton principal's authority to decide for or against installation of the cell tower. If Wootton were a private school, the principal may not have been dictated the authority of decision maker or, in the event that authority was dictated, may not have had the wherewithal to acknowledge responsibility to local residents not affiliated with the school. SACT was a community effort predominately fueled by advocates not directly associated with Wootton High School. The idea that public school principals and all public school administrators, in general, are public servants lends additional support for the case against cell towers at public schools in particular. However, the stance against cell towers at public schools applies to all schools because of the RF-related health hazards.

Discussion of Cell Tower Placement Process

The Telecommunications Act of 1934 established the Federal Communications Commission (FCC) as the regulatory authority over communications activities in the United States. Because digital cell phones were not available to the public until 1988, controversy over the placement of cell towers is a new phenomenon. It was not until the Energy Policy Act of 1992 and the Telecommunications Act of 1996 when the federal government realized the issues of RF signal strength and tower placement, respectively. In 2003, SACT became one of the first nongovernmental organizations to address hazards related to cell

FIGURE 4 RF tower with elaborate camouflage.

FIGURE 5 The tallest tree in this image is the cell tower.

tower placement near public institutions. However, a number of transformations in the telecommunications industry have taken place since the Telecommunications Act of 1934, which have shaped the current regulatory environment. The years 1945 and 1952 marked the first major oversight by the FCC on over-the-air television, regulating the spectrum allocations and color standards. In 1968, telecommunications service providers were authorized by the FCC to attach equipment to preexisting above-the-ground electrical lines. And, in 1992, the FCC ruled to let the market decide the appropriate standards for digital cell phones and related equipment.[27]

The political actors typically involved in the process of determining the placement of cell towers complicate the ability of community voluntary initiatives to succeed in opposing the placement of cell towers. Achieved by a 1999 amendment to the Telecommunications Act of 1934, the local government has authority over state and federal governments on the issue of tower placement.[28] However, the amendment to the Telecommunications Act of 1934 is pursuant to the Telecommunications Act of 1996 specified requirement of the federal government to assist licensees' pursuit of preferred sites.[29] Federal involvement in the tower placement process results in streamlining of policy action. Streamlining results in the shrinking of the policy window for community advocates, which reduces community advocates' opportunity to introduce their own policies.[30] Additionally, personal wireless service providers sometimes hire independent facilities siting companies who offer comprehensive tower placement services, from lobbying of local government and communities to addressing zoning regulatory concerns. Leasing of sites and fulfillment of regulatory and registration requirements may also be taken care of by facilities siting companies (Figures 6–8). "The local zoning authorities should therefore be aware that a facilities siting company may not be seeking the sites that are of most interest to particular Commission licensees [personal wireless service providers], but rather seek general sites on highly elevated locations in the hopes of leasing the sites, in turn, to Commission licensees."[31] It would be intuitive to reason that the existence of broker special interests in the placement of cell towers would be an additional obstacle to voluntary initiatives striving to oppose cell towers. However, the contrary is sometimes true. Policy brokers, such as independent facilities siting companies, are interested in maintaining a sustainable level of conflict in order for services being offered to remain in high demand.[32] Lingering, yet not overpowering, community opposition is welcomed by facilities siting companies. To combat the influence of the federal government and policy brokers in the tower placement process, community organizations need to adopt a policy of political efficacy, arising from political participation as a means to exert influence.[33] Political efficacy is especially important when it comes to the upholding of FCC guidelines on tower height and field strength. According to the Energy Policy Act of 1992, electric and magnetic field strength must be made public.[34] Yet, according to the Code of Federal Regulations pertaining to personal communications services, height-above average-terrain (HAAT) and field-strength guidelines may be waived if all parties involved agree.[35] If the community does not involve local government, the community will have no voice on the issue, and the already-flaccid federal guidelines will leave school children and staff insurmountably exposed.

Procurement and Contracting

The cell tower placement process as it involves local, state, and federal governance can be a separate, yet parallel set of activities to procurement and contracting processes. While law and statutes specific to cell tower placement may be directed at issues of allowability, the procurement and contracting functions deal specifically with the actual purchase in terms of cell tower specifications, features, pricing, contract terms and conditions between the public and private entity, solicitation for prospective vendors, competition for contract award, and contract administration, so that the private entities fulfill its obligations for the duration of the contract, among other procurement activities. In order to execute these functions, local government procurement units, which are typically housed in a department of procurement, finance, or budgeting, engage a contracting process involving pre-solicitation, solicitation, proposal evaluation, contract award, contract administration, and contract close-out.[36]

The pre-solicitation process involves procurement planning and communication with potential vendors who aim to install cell towers and provide cellular service to the area. Here, the government engages a process of discovery in which it learns about products and services and may hold formal or informal discussions with vendors. These discussions may involve policy matters, issues of feasibility for placement or service provision, the technology, and initial concerns regarding contract terms and conditions that may eventually follow. Generalities regarding the process for government's selection of the vendor for actual cell tower placement may also be discussed. These discussions may take place between a procurement agent and company representative over the phone, an in-person meeting, in writing, or at a trade show or conference. The pre-solicitation phase also enables government to prepare its formal solicitation document according to vendor concerns and considerations in conjunction with its own needs and priorities.

Oftentimes, wireless service providers may initially contact government to place cell towers on public properties. However, once government decides that it will entertain the possibility of placing a cell tower on public property, then it typically must engage a competitive process that allows the various companies an opportunity to compete for the contract. At the next phase, solicitation, the government may issue a request for proposals (RFP) or an invitation to bid (ITB). The RFP seeks proposals from vendors and provides them an opportunity to win the contract by setting forth a product and service to government, including various factors such as price, specifications, and commitments. Meanwhile, an ITB is a more rigid form of solicitation, in which the government sets forth its required criteria and the vendors simply respond regarding how they would perform to contract.

The justification behind having vendors compete for the contract award is so that government can be in a position to choose from the best product and service, i.e. the vendor who will commit the greatest amount of revenues at the most favorable contract terms and conditions for government and its community stakeholders. When vendors are required to compete for the contract award, then they will aim to increase the rent that they will commit to pay to government, or the public entity, for use of the property, as well as bolster their services or offerings in order to be the more attractive vendor. Furthermore, the vendors may make special accommodations in attempts to ameliorate public concerns that may have been vocalized during the pre-solicitation process such as issues of tower unsightliness, proximity, equipment dimensions, transmission power, servicing, and maintenance.

Once the RFPs or responses to the ITB have been submitted by the vendors to the procuring entity, then the procuring entity must evaluate these proposals to decide which vendor will be awarded with the contract. In this proposal evaluation phase, a team is formed to evaluate the documents submitted by the vendors. It is important to note that the proposal evaluation team members, per public procurement mandate, are usually required to consist of public personnel that were not involved in the pre-solicitation or solicitation phases in order to avoid conflict of interest. It may be the case that various personalized relationships were formed between the procurement agent and company representative during these early discussions, and it is important that the proposals are evaluated objectively according to the actual product and service to be delivered without consideration of prior personal relationships. Once the proposal evaluation team is in place, the evaluations are made based on factors of responsibility and responsiveness.

Responsibility refers to matters of vendor track record including their past performance on contracts with other public entities and the vendor's financial capitalization. The notions are that a vendor should be well capitalized in order to ensure that it has the resources to fulfill contractual obligations for the duration of the contract term and that past performance on contracts is an indicator of a company's ability to deliver its products and services as promised. Responsiveness deals with the extent to which a vendor's proposal reflects the needs as set forth by the public entity in the language of the RFP or ITB. A scoring methodology is then typically developed by the proposal evaluation team such as a weighted or other numerical scoring schemata, which assigns scores to various facets of the vendor proposals. The proposal that receives the highest score by the proposal evaluation team will be awarded with the contract.

Next, the contract award phase involves a debriefing process so that the winning and losing bidders are notified of the proposal evaluation team's selection. In this phase, any deviations between the vendor's proposal submitted and the RFP or ITB are addressed and a negotiation process may ensue between the selected vendor and procuring entity regarding actual contract terms and conditions. For example, some of the requirements set forth by the public entity in the RFP or ITB for the cell tower may be questioned by the vendor. Since the vendor has expertise regarding its own products and services, including the technology and equipment, it may be that the public entity is requiring features or specifications of the cell tower that may not be reasonable or feasible according to the vendor. Oppositely, the vendor's proposal as evaluated may lack some aspects of responsibility or responsiveness that need to be addressed, which may include community concerns or interests regarding cell towers, and it may be that the public entity has the greater knowledge and awareness in this particular political area. Of course, any deviations between the vendor's proposal and the RFP or ITB may reflect modifications in price, i.e., the rent that the public entity will be charging. If there are aspects of the RFP or ITB that the vendor cannot guarantee or conform to, then the public entity may offset those deficiencies by charging higher rent or setting forth other collateral commitments.

The first three phases of contracting involve pre-award processes, while contract administration and close-out are two phases that deal with post-award processes. Contract administration involves the actual delivery of products and services according to the contractual agreement known as performance to contract. This involves planning, preparation, and installation of the cell tower, and the administrative functions and procedures that will be involved such as oversight of construction, facilities monitoring, inspection, payment of rent, and other facets of interaction, communication, and coordination between the vendor and procuring entity. If the products and services delivered by the vendor are not consistent with the contract terms and conditions, which may include the manner that tower construction is taking place, the actual tower, or its servicing, then various modifications to the contract may be stipulated by the procuring entity. Meanwhile, if the procuring entity does not deliver its property site in the condition as promised, then the procuring entity may need to institute various change orders that could force it to reduce or avoid its rent payment obligations from the vendor for a specified time period or allow the vendor to make changes to its products or services. Thus, various change clauses will be written into the contract during negotiations in the event that unintended scenarios or problems arise during contract administration. Of course, it is difficult if not impossible to imagine and surmise all the potential scenarios and obstacles that may surface for a given procurement. If the vendor fails to adhere to the contract terms and conditions or does not adequately respond to the procuring entity's inquiry into contract violations, then the contract may be terminated by the procuring entity.

The final procurement phase is contract close-out. This phase involves quality assurance that the vendor has delivered as promised by installing a cell tower according to the requirements set forth by the procuring entity in the contract, and that servicing and maintenance are being executed accordingly. Any accounts receivable or rent payments owed to the public entity are accounted for and contract evaluation takes place to ensure that all contractual obligations are satisfied. Contract close-out is also important because of the lessons learned. The procuring entity, as the procurement unit within the government's department of procurement, finance, or budgeting, likely has other potential property sites in the municipality that could be attractive to wireless service providers. Hence, the lessons learned from the procurement and contracting process on the current contract may be applied and incorporated by the procuring entity into future cell tower procurements.

Meanwhile, the contract close-out phase also entails evaluation of the vendor on their performance to the contract, which could subsequently serve as performance evaluation data for the same or other procuring entities as they evaluate any future proposals by the vendor for aspects of responsibility. Whereas the early years of cell tower placement on public school and other public properties involved much more devolved processes that were more inconsistently applied on a case by case basis, even within the same municipality, the prevalence and debate surrounding cell tower placement has partially shifted the public authority on cell tower placement from public schools and school boards, and those public units or divisions having operations on the actual property, to procurement departments acting as agents on behalf of public schools or other public units. As a result, lessons learned from cell tower procurements can be more aptly applied to future contracts in order to address previous contract failures that may involve public concern and outcry. Essentially, the cell tower procurement is managed by the same procuring entity within a given municipality. Therefore, it has the opportunity to develop policy, politics, and process expertise from experience similar to the private entities who repeatedly write cell tower proposals to government.

The procuring entity does face a myriad of challenges though. The procuring entity must comply with local, state, and federal procurement law and policy, in addition to any local, state, and federal law and policy governing cell tower placement specifically. Additionally, there must be due consideration given to voluntary initiatives and advocacy groups. At times, these laws and policies may be conflicting or difficult to streamline into procurement and contracting methods.

Ethics and Public Administration

The three elements of corporate social responsibility are market actions, externally mandated actions, and voluntary actions.[36] Personal wireless service providers fail to address all three elements of social responsibility when dealing with the placement of cell towers. First, personal wireless service providers have poorly responded to market actions in their use of policy brokers to ensnare the tower placement process. Second, the mandated actions of the FCC related to HAAT and field-strength guidelines allow regulatory thresholds to be exceeded if no opposing voluntary organization is present at scheduled hearings. Third, voluntary actions that aim to avoid students' exposure to cell towers are not taken. In fact, the current trend is just the opposite, in which schools are targeted because of the surrounding open space that allows for enhanced RF wave transmission (Figures 9 and 10).

The ability of voluntary initiatives to oppose the placement of cell towers at public schools relies upon the formation of a nucleus of zealous participants; charismatic leadership alone does not result in the

FIGURE 9 RF tower overlooking playing fields.

FIGURE 10 RF tower installed adjacent to football field.

type of rapid expansion of the coalition that is necessary to fight seasoned corporate interests such as personal wireless service providers.[37] In addition, the media may be needed to intervene in facilitating changes in public perceptions. The media can help provide a transition and a way for the public to digest new policy initiatives.[38] In some cases, even with high visibility, the strongest coalitions are unable to defeat polyarchal interest groups on a particular issue, be it the placement of a cell tower at yet another school. Success depends on forging relationships with government officials as much as administrative competence.[39] Because of the variations in local government across the nation, including inconsistencies in the law and process governing zoning and other enforcement departments, there is a need to adopt a customizable approach when attempting to oppose a cell tower.

The SACT's ability to reject a cell tower proposal at Wootton High School but failure to impact policy change nationally brings into question the federalist debate. Hamilton, Madison, and Jay desired a strong central authority in their staunch support of federal government and ratification of the U.S. Constitution.[40] Opposing the federalists, Patrick Henry led the antifederalist approach arguing for decentralization and states' rights.[41] The federal government's determination to simultaneously support personal wireless service providers' cell tower installation campaign at public schools while allowing local communities to decide for themselves is rooted in both federalist and antifederalist modes. Nonetheless, the federal government's dual role is authoritarian.[42]

The cry for federal regulation disallowing placement of cell towers at or near public schools involves regulatory policy making, which inevitably will indulge or deprive one specific interest or another.[43] The regulatory approach offered does not necessarily favor some sort of Weberian chain-of-command hierarchy originating from the top down[44] but rather prefers reactionary cultural movement that reflects Thelen and Mahoney's,[45] Hacker's,[46] and Sheingate's[47] ideas on institutional change according to evolving assumptions of administrative and technological environments. If the dominant approach were favored, the solution would be to charge personal wireless service providers higher rental fees to compensate for any associated health care costs that may result.[48,49] Other rational socioeconomic approaches would seek to place value on the cost of the loss of human life and monetary damages due to the terminal pain and suffering induced by cell towers. Unfortunately, the most commonly observed failure in public management and the one associated with the egalitarian approach is a lack of ability to exert authority.[50]

Areas for Further Research

A logical area for further research is to track and survey humans. Tracking students who attend schools with cell towers on premises is the best way to determine the danger of cell towers to students. Tracking students while in school and in years beyond may help determine whether cell towers are indeed harmful to children or humans in general. An effective data set for a future study would need to take into account differentiation between student exposure at elementary, middle, and high schools, considering that young children are known to be more susceptible to RF exposure. Additionally, the data would need to differentiate between students who had many instances of intense exposure, such as student-athletes on a sports field containing a cell tower, and students who had fewer instances of intense exposure. Previously, this type of study was not possible. It was only since 2002 that the personal wireless service providers started targeting schools. Today, cell towers are erected on school properties across the country. However, obtaining access to student records for data collection of this type of study invokes the support of government. The resources and sheer number of people who would need to be mobilized by such a study requires congressional backing. Furthermore, the scientific community has questioned the methods that would underwrite such a study. Areas of inquiry that have been considered to be obstacles to a human study of this type are the competing risks when experimenting for causality. Oftentimes, it is difficult to determine which risk is the source of the illness. For example, did cancer clusters in the area form as a result of contaminated drinking water or exposure to a cell tower? New research indicates that margins of error in causality can be reduced. Building on time-dependent predictive accuracy measures,[51,52] the coefficient of the distribution of false positives among event-free subjects can be adjusted to reflect nearest neighbor (in our case, the highly exposed student-athletes on the sports fields containing cell towers) estimation of the distribution of input variables representing true positive incidents and length of exposure of competing risks in order to help determine causality.[53] The false-positive value is manipulated by a coefficient that is calculated from the estimate of true positive incidents in order to offset causality miscalculations stemming from overlapping incident rates of competing risks. Unconcerned citizens and proponents of cell tower placement on school property argue that cancer clusters related to cell towers have not emerged. However, it is impossible to predict what the health impacts may be over time. An evaluation technique is needed for cumulating, comparing, and contrasting varied results in order to establish an applied theory and framework.[54]

Conclusion

Just 2 years after the victory at Storm King Mountain paved the way for environmentalism, Olson's *The Logic of Collective Action* (1965) opened our eyes to the intuitiveness of equality and why the events of the 1960s were unlikely to ever recur.[55] Much different from the equal rights movement, the successful voluntary initiative at Wootton High School has not led to nationwide legislation and is embedded in an issue that is invisible. The inability to see the RF waves somehow precludes from our psyche the notion of harm. Invisible risks skew the indifference curve that guides our behavior in responding to risk. An indifference map is our collection of indifference curves and helps to shape our order of preferences.[56] The typical reaction to an invisible risk is a delay in response. After a 5-year pause, personal wireless service providers are once again proposing cell towers at public schools in Montgomery County, Maryland, this time at Whitman High School in Bethesda, Maryland.[57] Bethesda community advocates are citing Wootton's 2005 rejection of a cell tower as precedent in Montgomery County.[58] Currently, only the ten cell towers that were installed prior to the Wootton campaign exist in Montgomery County. Also, in the sense of a health-wise decision at Wootton, why have the ten previously erected towers not been taken down?

Cell towers should not be placed at schools. Scientific experimental research on animals and humans is conclusive that RF waves increase animal and human risk to cancer and other illnesses. Also, in the case of public schools, students have little to no choice in deciding whether or not to attend a particular school. To address personal wireless service providers' desire to bolster cell phone connectivity in communities, state and local governmental zoning boards should work together to designate specific areas where the placement of cell towers will be permitted. Assuming no cell tower is placed at or near a public school, the designated zones will enable the public to make their own decision regarding living or spending time near cell tower sites.

Community voluntary initiatives are the answer if the goal is to reject a cell tower proposal. Federal governments' involvement, not from the standpoint of assisting personal wireless service providers meet their objective of cell tower placement in a given community but from the standpoint of bringing together the nationwide advocacy groups and coalitions that have both successfully and unsuccessfully defended their schools from RF wave penetration, is the long-term solution to keeping schools safe from cell towers. Also, although the prospect of fair gamesmanship in the process of appeal against cell tower placement at public schools was not presented to be optimistic, consideration of bureaucratic red tape, or in this case, purposeful lack thereof, is essential to successfully implementing a strategy that leads to the rejection of a personal wireless service provider's cell tower proposal. In any case, policies that engage citizens in their own communities and ask them to do their own policy analysis are generally more preferable to those policies that do not.[59]

Community-Based Monitoring: Ngarenanyuki, Tanzania

Aiwerasia V.F. Ngowi, Larama M.B. Rongo, and Thomas J. Mbise

Introduction

Community-based monitoring was initiated in Ngarenanyuki, Tanzania, to study the impacts of pesticides on health and the environment. This entry is organized and divided into the following main sections: "Introduction," "Methodology," "Results and Discussion," and "Conclusion." Illustrations are included in the "Introduction," "Methodology," and "Results and Discussion" sections. The main goal of the study was to reduce exposure to pesticides among the farmers in Ngarenanyuki by training the farmers on health impacts related to exposure to pesticides, how to monitor such impacts, and how to reduce the risks.

Incidences of poisoning from pesticides are estimated to be highest in developing countries, despite the higher use of pesticides in developed countries.[1,2] The monitoring of pesticides and their health impacts on farmers and the public in general, which is normally performed by qualified researchers, is not sufficiently practiced in many developing countries, owing to financial constraints and to competing research interests. It therefore makes more sense to empower communities themselves to monitor the impact of pesticides and to take decisions that might reduce the risks to themselves and to their environment. Community-based monitoring of the impacts from pesticides enable those communities to determine whether or not the chemicals they are already exposed to, or might be exposed to, present any sort of hazard to their health and a potential threat to their environment.

Community pesticide-surveillance methods have been successfully used in the Asia Pacific[3] and could therefore be considered appropriate in Tanzania and other Southern African countries, both for establishing better data on the extent of pesticide poisoning and to raise awareness among farmers themselves. Using their own system of observation and evaluation of risks, for example, Malaysian plantation workers have developed the Community Pesticides Action Monitoring (CPAM) approach, in which they succeeded in documenting the health effects of airborne pesticides, identifying paraquat in particular as a major problem.[4]

They then proceeded to take action to prevent further exposure of plantation workers to paraquat. Communities in Kasargod District, Kerala (India), after investigation, monitoring, and documentation, using a CPAM approach, identified endosulfan as the major pesticide causing health and environmental problems and subsequently called for the ban on endosulfan to prevent further exposure and damage to the communities.[5]

Incorrect pesticide handling and management is thus known to be unsafe to both human and environmental health and jeopardizes biodiversity.[6] It is also further evident that most rural communities in Tanzania depend on farming and agribusinesses to earn their living. However, traditional agricultural production in the country has come under continuous pressure from globalization and other market forces, with the result that high-input agriculture has come to play an increasingly major role in the economies of rural communities. Although the use of pesticides in combating pests and diseases is widely encouraged among the farmers in these communities to promote production, less emphasis has been placed on safety practices and the proper handling and management of materials.

Ngarenanyuki Ward gives an example of a community in Tanzania where the majority of vegetable farmers believed that, without pesticide use, crop production would have been impossible. In a previous study carried out by the Work and Health in Southern Africa (WAHSA) team (unpublished), it was found that mixing three to five different types of pesticides in a single spray mix was a common practice in Ngarenanyuki, and that farmers did not understand what was written on the label or the meaning of the colors on the containers. They simply applied pesticides because a neighbor had applied them, and not because they had identified a particular pest problem. The farmers were also found to have mixed pesticides without following the doses recommended on the label, sometimes doubling or trebling the dosage regardless.

Retail outlets for pesticides in Ngarenanyuki were also found not to have been registered with the regulatory authority and therefore appeared to be selling pesticides illegally. It was further noted that, because the shop owners tended to repackage or dispense pesticides in other containers, they were observed on occasion to be left with empty pesticide containers, which they apparently destroyed by burning them at the marketplace. Farmers were also observed in some instances to have stocked substantial amounts of pesticides to cater for the whole year, owing to perceived shortages in the local village and the reported distances they had to travel in order to purchase pesticides in towns, frequently mentioned as Arusha or Moshi. Some of these stored pesticides were also observed to have become obsolete, which were then likely to create fresh problems of disposal as shown in Figure 1.

The unintended outcomes of pesticide exposures are difficult to reverse once they have been established and are in themselves expensive. Although advances in acute pesticide-poisoning surveillance and treatment in developed countries have led to some achievements in control, pesticide poisoning remains a public health problem globally, particularly in developing countries.[7] Those applying pesticides need to understand the effects of these chemicals to the environment and to their own health and the resulting costs. Alternative pest management strategies that are cheaper and friendlier to end users and the environment need to be promoted.

A workshop was organized for Southern Africa Development Community (SADC) registrars of pesticides in Arusha on October 13–14, 2006. Participants suggested that WAHSA-TPRI (Table 1) should pilot the tool used in the Asia Pacific to establish a systematic mechanism for pesticide monitoring and data collection, with a view to determining the extent of pesticide exposures, injuries, and diseases at the community level. WAHSA-TPRI then selected Ngarenanyuki as the study area, based on their working experience in Northern Tanzania in health hazards posed by pesticides and on the knowledge that farmers in the area were especially at risk with regard to pesticide poisoning.

FIGURE 1 Hazardous practices observed in Ngarenanyuki, 2006–2007. (left) Haphazard disposal of empty containers. (right) Dispensing/repackaging of pesticides in retail shops.

TABLE 1 The WAHSA Program Was Established in October 2004 as a Regional Initiative in Southern Africa to Build Capacity in the Region in Occupational Health

One of its key programs was its project ***Action on Health Impacts of Pesticides,*** which aimed to:

- Improve pesticide-safety materials for the SADC region
- Intervene to reduce pesticide usage
- Improve on agricultural policies and pesticide registration
- Enhance knowledge and improve surveillance about pesticide exposures and health impacts in the region
- Foster a strong regional network for information exchange and consultation

This entry reports on the process involved in the establishment of a community-monitoring team in Ngarenanyuki and on the preliminary results of the monitoring exercise. The authors hope that the findings will facilitate a process to identify those resources required to reduce pesticide use, the development of an action plan to access and mobilize these resources, and the further establishment of an effective system of communication among members of the community on pesticide use and access to any other information with regard to pesticide poisoning.

Methodology

This initiative was intended to pilot the CPAM approach that has already been used successfully in Asian countries. The WAHSA-TPRI Team was trained on the subject through their link with a non-governmental organization, AGENDA for Environment and Responsible Development, and was then employed to mobilize the community in Ngarenanyuki.

The initiative adopted a participatory research methodology by involving farmers in the collection and analysis of pesticide-related data. Data collection tools were developed by making use of Community Pesticide Action Kits (CPAKs), and training materials were developed in the regional language of Swahili. As a result of these activities, the community was sensitized and a subsequent rise in awareness was noted. CPAKs were produced by an ASEAN team of citizens' groups and farmer schools as a tool for action and advocacy, encouraging community education/empowerment. It contains modules that address various aspects of concern such as Warning! Pesticides are a Danger to Your Health; Breaking the Silence: Pesticides in Plantations; Profiting from Poisons: The Pesticides Industry; Drop Pesticides! Build a Sustainable World; Pesticides Destroy our World; Women and Pesticides; Keeping

Watch: Pesticides Laws; How to say NO! to Pesticides: Community Organizing; and Seeking out the Poisons: A Guide to Community Monitoring. The modules are not complete in themselves but need additional materials in local languages.

After securing the community's consent and the involvement of farmers' representatives and communities in capacity building, the program of community-based data collection and analysis was started and the monitoring exercise was implemented. Selected farmers worked in collaboration with the WAHSA experts to monitor and record issues related to pesticide use and exposures in the Ngarenanyuki villages.

Through a series of village meetings, the ward government in collaboration with the ward extension officer invited the farmers to participate in the training. Thirty farmers were selected by the farmers themselves from two villages (Uwiro and Olkung'wado) to represent each subvillage. No farmers were selected from Ngabobo, Kisimiri Juu, and Kisimiri Chini as communication became difficult. Ngarenanyuki as a whole is situated between Mt. Kilimanjaro and Mt. Meru, the first and third tallest mountains in Africa, respectively. The terrain thus consists of rocks, hills, valleys, rivers, and streams, which make some areas impassable during the wet season. One of the villages left out did not cooperate well with the others as they are believed to grow cannabis, a plant that is illegal in Tanzania.

A 6-day training of 25 representative farmers from the Ngarenanyuki was conducted by WAHSA-TPRI scientists, who had expertise in agricultural extension, agronomy, toxicology, entomology, plant pathology, and environmental science, and covered the following topics:

1. Pesticide use and their impacts on human health and environment, where farmers learned about pesticide use around the world, including examples of the negative impacts of pesticides on human health and the environment.
2. Pesticide identification and classification according to their acute toxicity, where farmers learned to identify the types of pesticides used and how they are classified according to their acute toxicity by the World Health Organization (WHO). One such classification the farmers learned was according to the different chemical families, such as organochlorines, organo-phosphates, carbamates, pyrethroids, and so on.
3. Pesticide label identification and interpretation, where farmers learned to read and understand pesticide labels, the various pictograms, and colored warning signs on containers, including the interpretation of the various toxicity symbols.
4. Pesticide handling and management, where farmers learned how to handle pesticides properly to safeguard themselves, their families, their neighbors, and their surroundings. They learned to observe which pesticides are used in their area, how they are used, and to observe the protective measures that are taken during mixing and application. They also learned how they might get contaminated during the handling of pesticides.
5. Pesticide storage and disposal of empty pesticide containers, where farmers learned about proper storage and disposal of surplus pesticides and their empty containers. They also learned how the improper storage of pesticides and the careless disposal of empty containers could form a risk for children, foodstuff, freshwater supplies, farm animals, and so on.
6. Recognizing the signs and symptoms of pesticide poisoning, where farmers learned the different signs and symptoms of pesticide poisoning and how to recognize them. They also learned how to distinguish these from other signs and symptoms that are simply due to poor health.
7. Pest identification and management, where farmers learned how to identify different insects, distinguishing genuine pests from more beneficial insects and symptoms of common vegetable diseases. Farmers were introduced to the basic principles of pest control methods. They were thus equipped with a practical knowledge of insects as an important component in pest management and on how to protect their crops from insect attack with a view to reducing the insecticide load on the environment.

8. Introduction to Integrated Pest Management (IPM), where farmers learned the principles of IPM as a sustainable approach to managing pests by combining biological, cultural, physical, and chemical tools in a way that minimized financial, health, and environmental risks. Farmers were further informed that one of the primary missions of IPM was to assist them in producing profitable crops, using environmentally and economically sound approaches.
9. Spraying equipment and techniques, where farmers learned about spray equipment [such as the knapsack sprayer, the motorized ultra low volume (ULV) sprayer, and so on]. They also learned about the handling, maintenance, and spraying techniques with regard to this equipment.
10. Reducing pesticide costs, where farmers learned to assess actual costs of pesticide use to include direct and indirect costs.
11. Participatory data collection methodology, where farmers learned about methods of data collection and analysis. They were introduced to the kind of data needed and data collection procedures, using different techniques with different data collection tools. Demonstration and practical sessions on how to handle and record data were also held with the farmers.

Establishment of Community Pesticide Monitoring Team

The 25 trained representative farmers were divided into teams of at least three people each, who then became the focal point for monitoring and recording of all pesticide incidences in Ngarenanyuki, and who also worked closely with the WAHSA-TPRI Team, including those who had been working with communities in the Arumeru district in research and training in their respective fields.

Data Collection

Consent forms were developed to be completed by those individuals who agreed to participate in the Community Monitoring Project. Three data collection tools were developed: a questionnaire, a checklist, and a self-surveillance form. They were designed to cover all areas of interest in community pesticide monitoring through interviews, observation, and self-examination of pesticide exposure.

The tools were pretested for validity and consistence in Mlangarini ward with a sample of 30 farmers. Adjustments and other improvements were made to the tools prior to final data collection in Ngarenanyuki. A self-surveillance form without pictograms was preferred, owing to some confusion arising from the meaning of the pictograms.

Farmers were organized into teams to conduct crop surveys and recognize damages, assess losses, and collect insect pests for identification. The farmers went out into their respective villages to collect information on pesticides used, perceptions on pesticide hazards, poisoning, and symptoms using the questionnaire. They also used the checklist to observe and record pesticides available in the area, means of storage, and use of protective equipment. Each farmer contacted by the team members was asked to do self-surveillance and record pesticide use conditions and practices, as well as poisoning signs and symptoms experienced.

The Community Pesticide Monitoring Teams needed technical support and close follow-up to ensure consistency in data collection and in transferring the knowledge gained to the entire Ngarenanyuki community. However, the teams were fully prepared in getting the message across to the community and to involve them in providing relevant information regarding pesticide issues. Moreover, the village leaders were made responsible for making a close follow-up of the team and the villagers involved.

Data Analysis

Analysis of information collected was performed using two different approaches. Structured interviews were conducted by the farmers using questionnaires, and the information was tallied, before it was tidied up and analyzed with the aid of the SPSS (Statistical Package for the Social Sciences) computer software to obtain frequencies. The data that were collected through observation on the basis of checklists were manually analyzed by the farmers themselves using flip charts and colored pens.

Results and Discussion

The training of the farmers was meant to prepare the community in taking responsibility themselves for monitoring the negative impacts of pesticides in their area. Subject matter specialists conducted the training with the aim of building the capacity of participants to make the right judgement and decisions when dealing with pest and pesticide issues. During the training sessions, farmers expressed keen interest in learning how to recognize insects (beneficial and harmful), to recognize the signs and symptoms of pesticide exposure, to practice safer pesticide handling and management, to understand proper spraying techniques and the maintenance of knapsacks, and to understand the benefits of participatory data collection techniques.

General Information

The data from the farmers in Ngarenanyuki Ward were collected between February and April 2007 by the farmers trained on pesticide monitoring and analyzed using the SPSS computer software. While the majority of the 120 farmers were males (90%), the average highest education level recorded was that of primary education (76%); hence, functional literacy was not a problem in this community. Agriculture (98.3%) was the major income-generating activity, although some farmers also kept livestock.

Pesticides Used in Ngarenanyuki

Thirty different types of pesticides commonly used in Ngarenanyuki were identified by the farmers. The major groups of pesticides used included insecticides, fungicides, and, to a lesser extent, herbicides. The most widely used insecticide and fungicide were chlorpyrifos (72.5%) and mancozeb (69.2%), respectively. Only 36.6% of the pesticides used in Ngarenanyuki had full registration, while some had provisional or experimental registration. It is mandatory for pesticides intended for use in Tanzania to go through a registration process, which involves efficacy and quality tests before they are approved for general, restricted, or experimental use. Pesticides under experimental use are not expected to be sold in retail shops. There was also the presence of one class 1b pesticide (chlorfenvinphos) and banned/restricted pesticides such as DDT.

Pesticide Availability, Affordability, and Application

The majority of pesticides (86.7%) were locally available in Ngarenanyuki, and a considerable proportion of farmers (65.8%) could afford to buy pesticides. Those unable to buy mostly obtained their pesticides on credit, and paid after harvesting. Most farmers (68.3%) claimed to have a pesticide application timetable, the most prominent approach being that of applying pesticides whenever insects or disease symptoms appeared.

Pesticide Mixing

The majority of farmers (90%) mixed more than one pesticide in a single application. The main reason given for mixing was to kill all pests and diseases at a go and to improve the quality of leaves and fruits (54%) in the field. A few (25%) said they preferred mixing to ease the workload and in order to cover larger areas with one treatment, while some (55%) said they had simply followed the pesticide retailer's advice. The mixing exercise was widely done in respective farms (89%). The common mixtures normally contained more than one fungicide and one insecticide, although some mixtures were found with around three fungicides and two insecticides.

Frequency of Pesticide Application, Number of Risk Days per Year, Spraying Equipment, and Pesticide Storage

The scale of environmental pollution was fairly evident as pesticides could be smelled all over the farms and in nearby residential areas, causing health problems (such as cough, sneezing, excessive difficulty breathing, and chest pains) to both sprayers and those who found themselves in the path of the sprays. The farmers worked out 52 risk days per year, as the majority (73%) of 120 farmers applied pesticides once a week and fewer (18%) applied the pesticides twice a week. The most common spraying equipment was the knapsack (76%), while in some cases (21%), buckets were also used.

Most respondents (57%) stored pesticides in a pesticide store, and in some cases, storage took place in sitting or living rooms (12%), in general stores (13%), and in bedrooms (7%). Pesticides were also found to be stored in toilets (1%). The choice of storage areas was often determined by their offering protection against thieves.

Adherence to Pesticide Label Instruction

The study by the farmers revealed that many of them did read the instructions on the pesticide containers, but only few actually followed the instructions as shown in Table 2. An example is the mixing of ULV formulations in water sprays while instructions given on the label are for direct application without dilution. The following were the arguments put forward for not following instructions: that some labels were only written in English, that the farmers were not familiar with conventional signs and symbols, and that some containers had no labels at all, having been dispensed from another container. The repackaging and dispensing of smaller quantities was found to be a common, albeit illegal, practice and it was felt that this needed greater attention, since this practice has negative implications for efforts to reduce the worst effects of pesticide poisoning by the implementation of proper labeling and instructions.

Disposal of Pesticide Containers

The major mode of disposal of empty pesticide containers by most of the farmers was by simply throwing the containers away in the farm surroundings and by burning. It was observed that some empty containers from the pesticide retail shops were also thrown or burnt at the marketplace. It was also revealed that some farmers did reuse empty pesticide containers for domestic purposes such as buying cooking oil and kerosene and for local brewing (Table 3).

TABLE 2 Adherence to Pesticide Label Instruction by Farmers in Ngarenanyuki during a Pevious Farming Season (December 2006 to March 2007)

Response toward Pesticide Label Instructions	Number of Farmers (N = 120)	% of Farmers
Always read instructions	72	60
Follow instructions	45	38
Sometimes follow instructions	34	28
Sometimes read instructions	28	23
Trained on pesticide issues	16	13
Get information on pesticides	7	6

TABLE 3 Modes of Disposal of Empty Pesticide Containers in Ngarenanyuki (December 2006 to March 2007)

Mode of Disposal	Number of Farmers (N = 120)	% of Farmers
Burn	41	34
Throw away on the farm	35	29
Bury in the farm surroundings	18	15
Sell back to pesticide vendors	8	7
Throw in the toilet	7	6
Use for other domestic uses	2	2

Pesticide Poisoning

The self-surveillance form was used without pictograms, to record the signs and symptoms of pesticide poisoning, owing to the confusion arising from the use of pictograms. During the pretest, farmers did not understand what the pictograms meant, and since the majority were able to read and write, it was agreed that there would be no need to include picto-grams in the surveillance form and that the list of signs and symptoms provided in the form was sufficient until proper research had been undertaken to determine what visual aid would be considered appropriate for the target audience.

The majority of the farmers (69.2%) had experienced pesticide poisoning in the previous farming season, owing to exposure, much of which had occurred more than 3 times to a single farmer. Pesticide poisoning was characterized by signs and symptoms known from previous studies to be related to pesticide exposures. Cypermethrin–profenofos mixture and profenofos were mostly associated with poisoning, and the action taken by many of those exposed (43.3%) was to drink milk, while a few respondents had attended hospitals for a proper medical examination. A considerable high proportion (57.5%) had been admitted more than 3 times, owing to pesticide poisoning (Table 4). Validation of poisoning through biological monitoring was not possible during this pilot stage but has been planned in future surveillances.

The action taken by the 25 farmers who fully participated in the pilot study was to intensify the training by initiating capacity-building sessions in all villages in Ngarenanyuki. They held community pesticide monitoring training in every village meeting, gave feedback to the WAHSA-TPRI Team on the farmers' reaction, and suggested what further input they needed from the team.

Conclusion

This pilot enabled the building of Ngarenanyuki farmers' capacities to assess their own health and environment as far as pesticides were concerned, analyze the situation, develop a plan of action, and work toward improving their condition. It facilitated the farmers' capacity so that they could take control and work with pesticides more safely and so become healthier. This program therefore works to benefit not only the farming community in the long run but also those consumers who would otherwise be forced to eat contaminated crops, and it contributes to the health of the environment as a whole.

Relevant data relating to pesticides, such as their availability, their usage, the farmers' handling practices, risk perception, and behavior, all gathered during the pilot project, enabled farmers in Ngarenanyuki and the WAHSA-TPRI Team to properly document the incidents and adverse events resulting from pesticide use. The initial evaluation of the association of the observed adverse event and pesticide exposure revealed that different pesticide-related tasks gave rise to signs and symptoms of pesticide poisoning and that skin and eye problems, for example, needed more attention during interventions.

The impact of the sensitization and awareness-raising seminars has been dramatic. The disposal site at the marketplaces vanished and the mistake of mixing ULV formulations with water has also been abandoned by the trained farmers and their associates. The farmers realized that the formulation was suspended in water and they were spraying water in some areas instead of pesticide. The formation

TABLE 4 Pesticide Poisoning, Circumstances, and Action Taken in Ngarenanyuki (December 2006 to March 2007)

Event		Number of Farmers (N = 120)	% of Farmers
Pesticide poisoning	Affected by pesticides in the last farming season	83	69
	Not sure	18	15
Occurrence of effects in the last farming season	Once	11	9
	Twice	12	10
	Thrice	9	8
	More than three times	26	22
Pesticides used	Profenofos + cypermethrin	32	27
	Profenofos	25	21
	Mancozeb (Dithane)	14	12
	Endosulfan	14	12
	Triadimenol	12	10
	Chlorothalonil	12	10
	Lambda-cyhalothrin	8	7
	Mancozeb (Ivory)	8	7
	Deltamethrin	1	1
	Copper sulfate	1	1
Action taken after pesticide Poisoning	Drank milk	52	43
	Went to the hospital	34	28
	No action taken	4	3
	Washed with water	2	2
Number of times admitted due to pesticide poisoning	Once	20	17
	Twice	23	19
	Thrice	8	7
	More than three times	69	58

of the community monitoring teams enhanced the whole process of data collection and action being taken. This has also provided a base for the sustainability of the project as the team continues to be in close contact and collaboration with the WAHSA-TPRI Team through the training of other farmers and in responding to their queries on pests, pesticides, monitoring pesticide use, their application, and the disposal of obsolete pesticides and empty pesticide containers.

The project was well received by the Ngarenanyuki community and has shown that if it is applied elsewhere, it will help in changing risk behaviors and in reducing the negative impact of pesticide exposures in communities. It is therefore recommended that the program be implemented systematically in Ngarenanyuki and be extended to other communities in Tanzania such as Mang'ola, in Karatu District, where the current use of pesticides appears to be indiscriminate.

Acknowledgments

We are indebted to the small-scale vegetable farmers in Ngarenanyuki for their cooperation. This project could not have been implemented without support from AGENDA for Environment and Responsible Development for which we are grateful. We appreciate the work done by the WAHSA-TPRI Team and the contribution of experts from Selian Agricultural Research Institute (Dr. Hussein Man-soor) and Mikocheni Research Institute (Dr. Ruth Minja) during the farmers' training.

Developing Countries: Pesticide Health Impacts

Aiwerasia V.F. Ngowi, Catharina Wesseling, and Leslie London

Introduction

The use of potentially hazardous chemicals is increasing in developing countries whose populations have the least capacity to protect themselves. Hundreds of thousands of people die annually from the effects of use, misuse, or accidental exposures to pesticides.[1,2] Developing nations in Africa, Asia, and Latin America comprise more than 75% of the total world population, use 25% of the world's pesticides, yet account for 99% of deaths caused by these toxic agents.[3]

Health Impacts

Acute Pesticide Poisoning

Two decades ago, the World Health Organization estimated that three million cases of acute pesticide poisoning resulting in 220,000 deaths occur worldwide each year, the majority in developing countries.[3] However, it is well recognized that these figures are an underestimate because of underdiagnosis and/or underreporting. Diagnostic difficulties are prominent in developing countries,[4–6] owing to insufficient medical training and high background levels of ill health.

Organophosphorus insecticides are the most common agents involved in acute pesticide poisonings, accounting for between 50% and 80% of all poisonings in Asia[7] and are a major public health concern in most African countries, where approximately 80% of the workforce is involved in agricultural work. In Central America, pesticides identified as causing most poisonings between 1992 and 2000 were paraquat; aluminum phosphide; the organophosphates methyl parathion, methamidophos, monocrotophos, chlorpyrifos, terbufos, and ethoprophos; the carbamates carbofuran, methomyl and aldicarb; and endosulfan.[8]

Part of the reason for this picture is the continued use in developing countries of pesticides no longer registered for use in the developed world, because of their high toxicity, and the substitution of persistent organochlorines with organophosphate insecticides.

Fatality rates and lifelong disability resulting from pesticide poisoning in developing countries are exacerbated by poor diagnosis and delayed treatment, resulting in both human suffering and economic losses.

High rates of unintentional poisoning, mostly occupational, have been reported in rural agricultural working and urban populations worldwide.[9,10] Nearly 66,000 cases of acute pesticide poisonings occur annually in Nicaragua.[11] Mass poisonings by pesticides in developing countries have typically resulted in high numbers of fatalities.

In the remote Andean village of Tauccamarca in October 1999, 42 children were poisoned after eating a school breakfast contaminated with the organophosphate pesticide methyl parathion, resulting in 24 deaths before the children could reach medical treatment.[12]

However, it is only a limited number of the most extreme cases in developing countries, which appear to be documented. Less high-profile cases are common but unrecorded. For example, a methomyl-poisoning incident involving 11 female flower farm workers in Arusha, Tanzania, in March 2004 was reported in the press, but absence of adequate local investigation mechanisms prevented its documentation in the peer-reviewed literature.

Deliberate self-harm is a major problem in the developing world. Pesticides are commonly used as suicidal agents throughout developing nations and are associated with high mortality rates, causing an estimated 300,000 deaths annually in the Asia Pacific.[1,2,8,9,13] In India, suicide using aluminum phosphide was reported as so common that postmortem examinations on deceased bodies were said to be routinely conducted by staff wearing respirators for personal protection from released fumes.[14]

Underlying factors that make individuals at risk for self-harm are both social (including domestic problems, poverty, social isolation, and financial hardship) and medical.[1] Farmer indebtedness, widespread in many developing countries characterized by unequal economic systems, is an important factor driving high rates of suicide. More recent findings suggest that pesticides, particularly organophosphates, may be more than agents in suicidal attempts; they are also part of the causal pathway because of their neurotoxicity and the possible links between organophosphate exposure, depression, and impulsivity, mediated through effects on neurotransmitters such as serotonin.[9] In a context where the above social risk factors for depression are common in developing countries, further exposure to neurotoxic pesticides may substantially increase the risks of suicide.

Chronic Health Impacts Unknown

Although long-term consequences of pesticide poisoning are well recognized in the literature, relatively few studies of long-term health effects of pesticide exposure have been conducted among working populations in developing countries. Underdiagnosis is accentuated for long-term health consequences that require greater diagnostic capacity. Dermal exposure routes for developing country workers are also common but are an underdocumented yet critical pathway for systemic poisonings, both acute and chronic. Consequently, the extent of chronic health impacts of pesticides in developing country workers is poorly characterized.

However, there is little reason to believe that their impact would be any less than that in developed countries. Indeed, high levels of background morbidity and poor social conditions are likely to aggravate pesticide toxicity. For example, research among South African farm workers highlighted the link between chronic lifetime undernutrition, organophosphate exposure, and impaired neurological performance on tests of vibration threshold.[15]

Azoospermia (absent sperm), oligospermia (low sperm count in semen), and low fertility have been documented in more than 26,000 workers previously exposed to 1,2-dibromo-3-chloropropane (DBCP) on banana and pineapple plantations in more than 12 countries.[16]

Weak Surveillance for Hazards and Impact

Although a critical public health tool for the control of pesticide poisoning, surveillance in developing countries is bedeviled by multiple problems such as lack of access to health care for poisoning survivors, lack of human resources, diagnostic skills and equipment to identify cases, and weak information systems. Acute poisoning rates are consequently underestimated and may selectively undercount certain types of poisoning (occupational circumstances) and certain risk groups (women and migrant workers). Lack of professional competence and conflict of interest arising from compensation system levies may also lead occupational poisonings to be misreported as suicide.[10] As a result, inferences from review of flawed data may lead to mistaken policy decisions.[17]

To improve information on the extent of pesticide poisoning in developing countries, surveillance systems for acute health effects from pesticides are being established in developing nations. In 1998, almost 6000 pesticide poisonings were reported in five of the seven Central American countries generating an estimate (corrected for underreporting) of 30,000 pesticide poisonings annually in the region.[11] Poisoning rates reported in an intensified surveillance intervention in South Africa increased 10-fold in the study area compared to a control area.[17] Recently, WHO in collaboration with partners initiated a community intervention, the Global Public Health Initiative, to prevent self-harm by pesticide poisoning.[18]

Weak Regulation and Enforcement

Vulnerable economies and weak infrastructure in developing nations hinder their ability to regulate the use of pesticides, particularly when macroeconomic pressures promote deregulation and restrict public spending required to implement regulatory controls. As a result, marketing and advertising of pesticides are often uncontrolled. Incorrectly labeled or unlabeled formulations, including readymade solutions in soft drink bottles and other containers, are commonly sold at open stands. In South Africa, the repackaging of aldicarb granules into small-volume packets sold by street vendors[19] for domestic pest control has been linked to increasing numbers of poisonings in urban areas. Low retail prices, sometimes associated with subsidy policies, promote risky pesticide use. Weaknesses in sustainable international and national agricultural and chemical management policies manifest in a reliance on "safe-use" strategies. Yet, evidence has shown that the so-called "good agricultural practices" and "safe use" are ineffective in controlling risks in developing countries, principally because many measures assumed to enable safe use are not feasible in developing countries, particularly under tropical or adverse climatic conditions.[20]

Low Levels of Worker and Community Awareness

Farmers and farm workers rarely have access to adequate training in pesticide safety or advice on the complicated management of pesticides. Hot climates are a disincentive to use of protective clothing, and many workers and farmers lack access to water for washing hands or exposed skin, increasing the risks of contamination. Recognition of pests and their predators is generally low, leading to overreliance on routine pesticide applications to control pests; knowledge of product selection, application rates, and timing is poor; different products are often combined in the belief that the effect will be greater; re-entry periods after spraying are not known; and without knowledge of alternatives, farmers often assume that the only solution to pest problems is to spray more frequently.[21]

Pesticides are often stored improperly in or around farmers' homes, increasing family member's access.[21,22] In some instances, empty pesticide containers are reused to store water and food, resulting in serious poisonings.

Import/Export of Banned and Restricted Compounds

Pesticides banned or restricted in developed countries are often easily available in developing countries. These include pesticides causing significant acute and chronic morbidity (such as class I and II organophosphates and paraquat) and organochlorines earmarked for eradication under the Stockholm Convention on persistent organic pollutants (POPs) (particularly dieldrin, lindane, and chlordane). Endosulfan, a candidate pesticide for inclusion under the POPs treaty, has been responsible for a series of poisonings in Benin[21] and developmental impacts on children in Kerala, a state in India.[21,23]

The use of *p*-*p′*-dichlorodiphenyltrichloroethane (DDT) continues to be permitted for malaria control in developing countries, where malaria remains endemic, despite its known hazards for wildlife and controversial adverse effects on human health.[24,25] Ironically, DDT use in Africa has increased since the Stockholm Convention came into effect.[26] As a result, it is still produced for export in at least three countries. Because of its ongoing usage for public health vector control, unauthorized use for agricultural purposes remains a concern in developing countries, particularly where regulatory controls are weak. The presence and persistence of DDT and its metabolites worldwide are still problems of great global relevance to public health.

Although the Prior Informed Consent (PIC) procedure, upgraded in status from a voluntary agreement to an international convention known as the Rotterdam Convention, seeks to protect developing countries from harms arising from import of chemicals banned or restricted in exporting countries, the effectiveness of the Convention has been questioned. For example, the data requirement for a Severely Hazardous Pesticide Incident report, used under the Convention to add a pesticide onto the controlled list, lacks mechanisms suited to developing country conditions. This is usually because developing countries lack the infrastructure to collect the required data. Similarly, the process of adding a pesticide onto the POPs list (e.g., endosulfan) is often met in practice with strong resistance. Even when pesticides are restricted by the POPs and Rotterdam conventions, compliance with the obligations contained in the conventions may often be poor, despite developed countries ratifying the conventions. The PIC and POP secretariat could assist local contacts such as the Designated National Authorities (DNAs) in developing simple tools that will be used to collect relevant data and help in the establishment of suitable mechanisms for the flow of data and information in member countries.

Over the past few years, pressure from non-governmental organizations and discussions within the Food and Agriculture Organization and other intergovernmental bodies has recognized that greater effort must be put into restricting the availability of pesticides based not only on their acute toxicity, traditionally measured through the WHO classification system, but also on the capacity of particular pesticides to cause long-term toxic effects with chronic exposure. These initiatives, particularly the call for a progressive ban on highly hazardous pesticides, offer some hope for better protections for developing country populations, but are still in development.

Lack of Technical and Laboratory Capacity

Many developing countries suffer from a lack of human and technical resources, aggravated by the global brain drain and weak economies. As a result, few developing countries are able to monitor pesticide residues. Most developing countries do not have laboratories capable of conducting analyses for pesticides and their residues, particularly at standards that meet good laboratory practice. Where laboratory capacity is available, it is usually to service residue testing of agricultural exports destined for consumers in developed countries. Produce grown for domestic consumption is rarely monitored.

Environmental media such as water and soil are rarely tested, and, even then, usually only on a research basis. Isolated studies of lactating women in Southern Africa have confirmed the presence of high levels of DDT metabolites in breast milk in populations living in malaria-endemic areas subject to DDT applications. Yet, despite provisions arising from the POPs treaty to undertake routine testing to monitor the impact of DDT use, there is no system for biological monitoring for DDT metabolites in place in Southern Africa. As a result, many infants in the region are substantially exposed through cross-placental transfer and breastfeeding, with potential adverse impacts on childhood neurodevelopment.

Research capacity to identify problems and develop prevention strategies is also constrained by limited investments in capacity building in relevant scientific fields in developing countries. As a result, there is neither proactive monitoring nor information systems usage to effect adequate responses to pesticide problems identified. It is critical to foster South–South learning to promote best practice because what applies in the north may be different to what happens in the south. There is a need to build southern capacity because reliance on the north at times perpetuates many of the problems. Indeed, there is much expertise in the south from which both north and south can learn.

Pest Control Policies

Unlike many developed countries, agricultural policies in many developing countries have emphasized short-term economic gains at the expense of environmental sustainability or human health. Few developing countries have adopted integrated pest management or pest reduction strategies. The dominant "pesticide culture" assumes that the use of pesticides to control pest as the first option is the norm, is reinforced by advertising and marketing practices, and is often encouraged by agricultural credit policies and development aid. Much needs to be done to enhance research and development to support pesticide reduction for agriculture and public health, and to strengthen the capacity in developing countries to develop monitoring systems and research capacity to deal with the problems of pesticides in developing nations. Reducing deaths from pesticide poisoning through restrictions on the availability of pesticides can be accomplished based on a prior evaluation of national agricultural needs and the development of a plan to encourage substitution with less toxic pesticides without loss of agricultural output,[27] bearing in mind that policies aiming towards sustainable chemical-free agriculture would be the ideal long-term solution.

Conclusions

Underestimations of acute and long-term effects of pesticide in developing countries occur due to underdiagnosis and/or underreporting. The impact of pesticide poisoning is also unknown because of weak surveillance for hazards and impact, import/export of banned or restricted compounds, lack of technical and laboratory capacity, weak regulations and enforcement, low level of worker and community awareness, and inappropriate pest control policies. Enhancing research and development to support pesticide reduction for agriculture and public health and strengthening capacity to develop monitoring systems are critically important for developing countries to deal with problems concerning pesticides.

Insulation: Facilities

Wendell A. Porter

Introduction

Insulation is rated in terms of thermal resistance, called the *R*-value, which indicates the resistance to heat flow. Although insulation can slow all types of heat flow—conduction, convection, and radiation—its greatest impact is on conduction.

The higher the *R*-value is, the greater the insulation effectiveness is.[1,2] The *R*-value of thermal insulation depends on the type of material, the thickness, and the density. When calculating the *R*-value of a multilayered installation, the *R*-values of the individual layers are added.

The effectiveness of an insulated wall or ceiling also depends on how and where the insulation is installed. For example, compressed insulation will not give its full rated *R*-value. The overall *R*-value of a wall or ceiling will also be somewhat different from the *R*-value of the insulation itself because some heat flows around the insulation through the studs and joists thermal bridging. With careful design, this short-circuiting can be reduced.

The key to an effective insulation system is proper installation of quality insulation products. A building should have a continuous layer of insulation around the entire building envelope (Figure 1). Studies show that improper installation can cut performance by 30% or more.

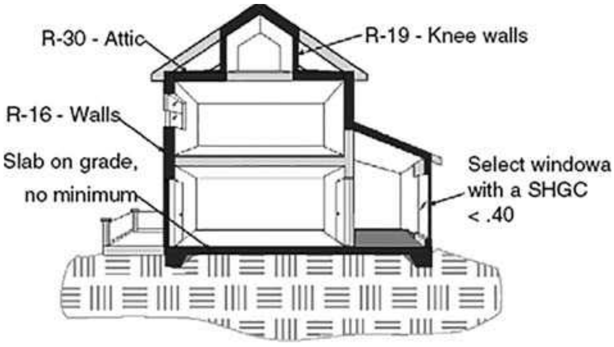

FIGURE 1 Building envelope insulation.

Insulation Materials

The wide variety of insulation materials makes it difficult to determine which products and techniques are the most cost effective (Table 1). Whatever product is chosen, install it per the manufacturer's specifications.

Here are short descriptions of a few of the insulation products available today:

- Fiberglass insulation products come in batt, roll, and loose-fill form, as well as a semirigid board material. Many manufacturers use recycled glass in the production process of fiberglass building insulation, with most using between 20% and 30% recycled glass in their product. Fiberglass is used for insulating virtually every building component—from walls to attics to ductwork.
- The term mineral wool refers to both slag wool and rock wool. Slag wool is manufactured from industrial waste product. It is primarily (~75%) produced from iron ore blast furnace slag, a by-product of smelting. Rock wool is fireproof and produced from natural rocks—basalt primarily—under high heat. Mineral wool insulation is available as a loose-fill product, batts, semirigid, or

TABLE 1 Comparison of Insulating Materials

Material	Typical R-Value (per inch)
Batts, blankets, and loose-fill insulation	
Mineral wool and fiberglass	2.2–4.0
Cellulose (loose-fill)	3.0–3.7
Cotton (batts)	3.0–3.7
Perlite (loose-fill)	2.5–3.3
Foam insulation and sheathing	
Polyisocyanurate	6.0–6.5
Closed-cell, spray polyurethane	5.8–6.8
Open-cell, low-density polyurethane	3.6–3.8
Extruded polystyrene	5.0
Molded expanded polystyrene (beadboard)	4.0
Fiberboard sheathing (blackboard)	1.3
Air-krete	3.9
OSB sheathing (3/8 in.)	0.5
Foil-faced OSB	Depends on installation
Polyicynene	3.6

rigid board. Usage of this product has decreased as more and more building codes require active sprinklering of buildings.

- Cellulose insulation, primarily made from post-consumer recycled newsprint with up to 20% ammonium sulfate and/or borate flame retardants, is installed in loose-fill, wall-spray (damp), dense-pack, and stabilized forms. Because of its high density, cellulose can help reduce air leaks in wall cavities, but air sealing other areas of air infiltration, such as under wall plates and band joists, must be performed to obtain an effective air barrier. However, given certain conditions and applications, cellulose may hold moisture.
- Molded expanded polystyrene (MEPS), often known as beadboard, is a foam product made from molded beads of plastic. MEPS is used in several alternative building products discussed in this entry, including insulated concrete forms and structural insulated panels (SIPs).
- Extruded polystyrene (XPS), also a foam product in rigid board form, is a homogenous polystyrene produced primarily by three manufacturers with characteristic colors of blue, pink, and green.
- Polyisocyanurate, foil-faced rigid board, is insulating foam with one of the highest available *R*-values per inch.
- Closed-cell, high-density spray polyurethane is used both for cavity insulation and as insulating roofing materials [often referred to as spray polyurethane foam (SPF)]. It has structural properties, good adhesive properties, and good compressive strength.
- Open-cell, low-density polyurethane foam is used primarily to seal air leaks and provide an insulating layer. Produced primarily from petrochemicals, some of these products are now manufactured in part from soybeans.
- Aerated concrete, including lightweight, autoclaved (processed at high temperature) concrete, can provide a combination of moderate R-values and thermal mass for floors, walls, and ceilings, in addition to structural framing.
- Reflective insulation is often used between furring strips on concrete block walls to reflect the heat. Note that reflective insulation products differ from radiant barriers in that they include a trapped air space as part of the product. These trapped air spaces may be a result of the way the reflective insulation is manufactured or installed.

Determine actual R-values and costs from manufacturers or local suppliers.

Note that many new types of insulation are rapidly becoming incorporated into conventional construction. However, always research a material's characteristics and suitability to a particular situation before buying any new product. For instance, many new insulation products require covering for fire rating.

Insulation and the Environment

There has been considerable study and debate about the potential negative environmental and health impacts of insulation products.[3] These concerns range from detrimental health effects for the installer to depletion of the earth's ozone layer.

- Fiberglass and mineral wool—questions about effects on health from breathing in fibers. In 2001, the International Agency for Research on Cancer changed its classification for fiberglass and mineral wool from "possible human carcinogen" to "not a known human carcinogen."
- Cellulose—concerns about dust inhalation during installation to VOC emissions from printing inks (these are now almost entirely vegetable-based) and limited evidence of toxicity of boric acid flame retardants. Long-term fire retardancy is unknown. Limited health and safety research has been performed on these products.
- Foam products and chlorofluorocarbons—for years, many foam products contained chlorofluorocarbons (CFCs), which are quite detrimental to the earth's ozone layer. The CFCs were the blowing agent that helped create the lightweight foams. Current blowing agents are

- Expanded polystyrene—pentane, which has no impact on ozone layer, but may increase the potential for smog formation.
- Extruded polystyrene, polyisocyanurate, and poly-urethane—use primarily hydrochlorofluorocarbons (HCFCs), which are 90% less harmful to the ozone layer than CFCs. Some companies are moving to non-HCFC blowing agents.
- Open-cell polyurethane, including the products made by Icynene, Inc. and Demilec, Inc., as well as the newer soy-based foams—use water, which is much less detrimental than other blowing agents (Table 2).

Insulation Strategies

In general, commonly used insulation products are the most economical. Prices can vary according to in staller and location. Review all of the choices, as they offer different *R*-values, suggested uses, and environmental and health considerations.

TABLE 2 Comparison of Insulation Materials (Environmental Characteristics and Other Information)

Type of Insulation	Installation Method(s)	R-Value per Inch (RSI/m)[a]	Raw Materials	Pollution from Manufacture	Indoor Air Quality Impacts	Comments
Fiber insulation *Cellulose*	Loose fill; wall-spray (damp); dense-pack; stabilized	3.0–3.7 (21–26)	Old newspaper, borates, ammonium sulfate	Vehicle energy use and pollution from newspaper recycling	Fibers and chemicals can be irritants. Should be isolated from interior space	High recycled content; very low embodied energy
Fiberglass	Batts; loose fill; semi-rigid board	2.2–1.0 (15–28)	Silica sand; limestone; boron; recycled glass, phenol formaldehyde resin or acrylic resin	Formaldehyde emissions and energy use during manufacture; some manufactured without formaldehyde	Fibers can be irritants, and should be isolated from interior spaces. Formaldehyde is a carcinogen. Less concern about cancer from respirable fibers	
Mineral wool	Loose fill; batts; semi-rigid or rigid board	2.8–3.7 (19–26)	Iron-ore blast furnace slag; natural rock; phenol formaldehyde binder	Formaldehyde emissions and energy use during manufacture	Fibers can be irritants, and should be isolated from interior spaces. Formaldehyde is a carcinogen. Less concern about cancer from respirable fibers	Rigid board (e.g., Roxul) can be an excellent foundation drainage and insulation material
Cotton	Batts	3.0–3.7 (21–26)	Cotton and polyester mill scraps (especially denim)	Negligible	Considered very safe	Two producers; also used for flexible duct insulation
Perlite	Loose fill	2.5–3.3 (17–23)	Volcanic rock	Negligible	Some nuisance dust

TABLE 2 (*Continued*) Comparison of Insulation Materials (Environmental Characteristics and Other Information)

Conversion Factors

R-Value Conversions	To Get	Multiply	By
Thermal resistance (R)	RSI (m2 C/w)	R (ft2 hF/Btu)	0.1761
Insulation R/unit thickness	RSI/mm	R/in.	0.00693

In the chart the heading is R-value per inch (RSI/m); to obtain this number, the RSI/mm is divided by 1000.

Foam insulation

Polyisocyanurate	Foil-faced rigid boards; nail-base with OSB sheathing	6.0–6.5 (42–45)	Fossil fuels; some recycled PET; pentane blowing agent; TCPP flame retardant; aluminum facing	Energy use during manufacture	Potential health concerns during manufacture. Negligible emissions after installation	Phaseout of HCFC ozone-depleting blowing agents completed
Extruded polystyrene (XPS)	Rigid board	5.0 (35)	Fossil fuels; HCFC-142b blowing agent; HBCD flame retardant	Energy use during manufacture. Ozone depletion	Potential release of residual styrene monomer (a carcinogen) and HBCD flame retardant	Last remaining insulation material with ozone-depleting blowing agents
Expanded polystyrene (EPS)	Rigid board	3.6–1.4 (25–31)	Fossil fuels; pentane blowing agent; HBCD flame retardant	Energy use during manufacture	Potential release of residual styrene monomer (a carcinogen) and HBCD flame retardant	
Closed-cell spray polyurethane	Spray-in cavity-fill or spray-on roofing	5.8–6.8 (40–4.7)	Fossil fuels, HCFC-141b (through early 2005) or HFC-245fa blowing agent; nonbrominated flame retardant	Energy use during manufacture, global-warming potential from HFC blowing agent	Quite toxic during installation (respirators or supplied air required). Allow several days of ailing out prior to occupancy	
Open-cell, low-density polyurethane	Spray-in cavity-fill	3.6–3.8 (25–27)	Fossil fuels and soybeans; water as a blowing agent; nonbrominated flame retardant	Energy use during manufacture	Quite toxic during installation (respirators or supplied air required). Allow several days of ailing out prior to occupancy	
Air-Krete	Spray-in cavity-fill	3.9 (27)	Magnesium oxide from seawater; ceramic talc	Negligible	Considered very safe	Highly fire-resistant; inert; remains friable

(*Continued*)

TABLE 2 (*Continued*) Comparison of Insulation Materials (Environmental Characteristics and Other Information)

.	Conversion Factors					
R-Value Conversions		To Get		Multiply		By
Radiant barrier						
Bubble back	Stapled to framing	Depends on installation	Aluminum; fossil fuels	Energy use during manufacture	Minimal offgassing from plastic	Exaggerated R-value claims have been common
Foil-faced	Stapled to framing;	Depends on installation	Aluminum; fossil	Energy use during	Minimal offgassing from	Exaggerated Æ-value claims
polyethylene foam	requires air' space for radiant benefit		fuels; recycled polyethylene	manufacture	polyethylene	have been common. Recycled content in some
Foil-faced paperboard sheathing	Stapled to framing; requires air' space for radiant benefit	Depends on installation	Aluminum; fossil fuels; recycled paper	Energy use during manufacture	Considered very safe	High recycled content. Structural sheathing available (e.g., Thermo-Ply®))
Foil-faced OSB	Most common as attic sheathing	Depends on installation	Wood fiber; formaldehyde binder in OSB; aluminum	Energy use and VOC emissions during manufacture	Formaldehyde emissions	Primary benefit is reduced heat gain

[a] RSI/m: The standard unit of measurement in the United States has been the Imperial unit. The country is converting to the International System (SI) unit—or metric standard—which predominates internationally. To differentiate like terms, you may find "SI" added to the term symbol. For example, RSI refers to the Æ-value in International System (metric) units.

Critical Guidelines

When installing any insulating material, the following guidelines are critical for optimum performance[4]:

- Seal all air leaks between conditioned and unconditioned areas
- Obtain complete coverage of the insulation, especially around doors and windows
- Minimize air leakage through the material with air sealing measures
- Avoid compressing insulation
- Avoid lofting (installing too much air) in loose-fill products

Foam Insulation Strategies

Foam products are primarily economical when they can be applied in thin layers as part of a structural system or to help seal air leaks. Examples include:

- Exterior sheathing over wall framing
- Forms in which concrete can be poured
- As part of a structural insulated panel for building walls
- Spray-applied foam insulation

Floor Insulation

Slab-on-Grade

Slab-on-grade floors consist of a concrete slab poured over at least four inches of compacted gravel or sand and a layer of 10-mil polyethylene used as a vapor barrier. In hot, humid climates, most buildings are built with concrete slab-on-grade.

For colder climates, slabs lose energy as a result of heat conducted outward toward the perimeter of the slab. Insulating the exterior edge of the slab with R-10 rigid insulation can reduce winter heating bills by 10%–20%.

Raised Floor

Raised floor systems (wood and concrete) have specific requirements depending on climate zones. Consult the local building code for specific details.

Wall Insulation

Walls are the most complex component of the building envelope to provide adequate thermal insulation, air sealing, and moisture control.

Concrete Wall Insulation

Foundation walls and other masonry walls are usually built of concrete block or poured concrete. Insulating concrete block walls is more difficult than insulating framed walls.

Insulating Concrete Block Cores

Builders can insulate the interior cores of concrete block walls with insulation such as:

- Vermiculite R-2.1 per inch (See Figure 2)
- Polystyrene inserts or beads R-4.0–5.0 per inch
- Polyurethane foam R-5.8-6.8 per inch

Unfortunately, as shown in Figure 2, the substantial thermal bridging in the concrete connections between cores continues to depreciate the overall *R*-value. This approach is only a partial solution to providing a quality, well-insulating wall. Other techniques, as explained in the next few pages, provide more cost-effective solutions.

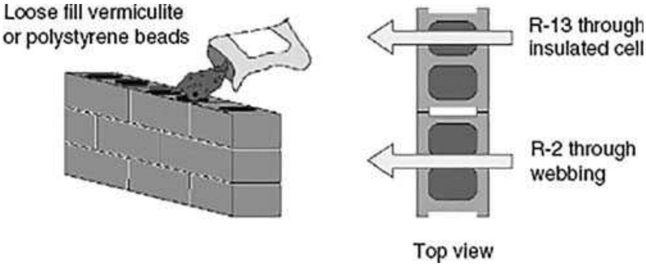

FIGURE 2 Insulating concrete block cores (R-4–R-6 overall).

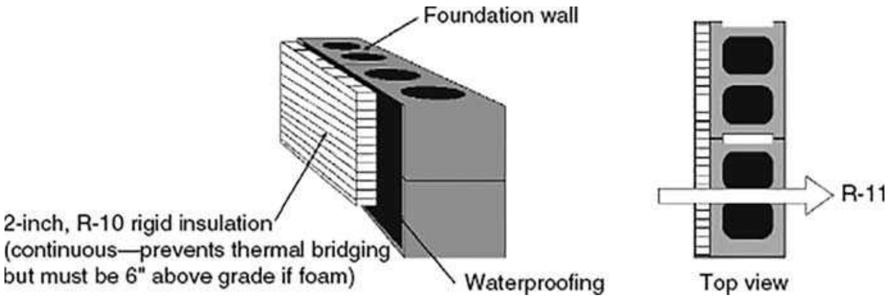

FIGURE 3 Exterior foam insulation (R-11–R-12 overall).

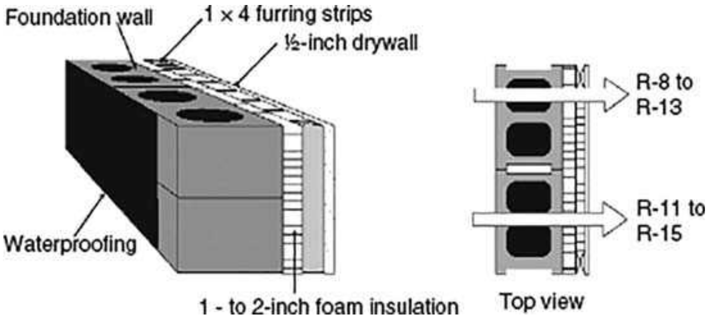

FIGURE 4 Interior foam insulation (R-10–R-14 overall).

Exterior Rigid Fiber Glass or Foam Insulation

Rigid insulation is generally more expensive per *R*-value than mineral wool or cellulose, but its rigidity is a major advantage (Figure 3). However, it is difficult and expensive to obtain R-values as high as in framed walls.

Interior Foam Wall Insulation

Foam insulation can be installed on the interior of concrete block walls (Figure 4); however, it must be covered with a material that resists damage and meets local fire code requirements. Half-inch drywall will typically comply, but furring strips will need to be installed as nailing surfaces. Furring strips are usually installed between sheets of foam insulation; however, to avoid the direct, uninsulated thermal bridge between the concrete wall and the furring strips, a continuous layer of foam should be installed underneath or on top of the nailing strips.

Interior Framed Wall

In some cases, designers will specify a framed wall on the interior of a masonry wall (Figure 5). Standard framed wall insulation and air-sealing practice can then be applied.

Insulated Concrete Form Systems

Insulated concrete forms (ICFs) are permanent rigid plastic foam forms that are filled with reinforced concrete to create structural walls with significant thermal insulation (Figure 6). The foam is typically

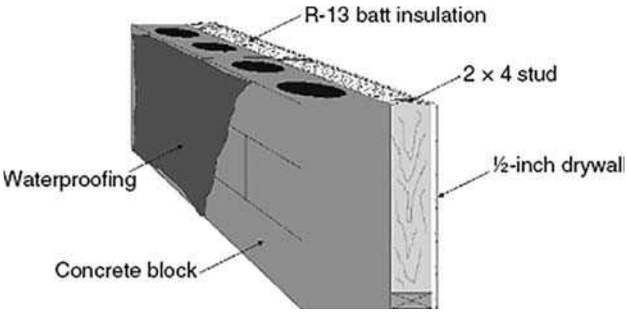

FIGURE 5 Interior framed wall insulation (R-11–R-13 overall).

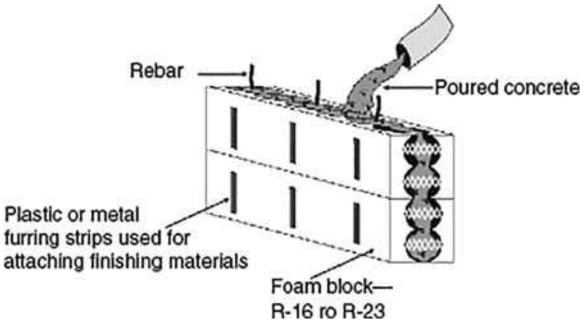

FIGURE 6 Insulated concrete foam system (R-17–R-24 overall).

either expanded polystyrene (EPS) or extruded polystyrene (XPS) and occasionally polyurethane, but it may also be made from a composite of cement and foam insulation or a composite of cement and processed wood.[5]

The concrete will be one of several shapes: flat, waffle-or screen-grid, or post-and-beam, depending on the specific form design. The Portland Cement Association (PCA) reports that in 1994, 0.1% of all new homes used ICFs in above-grade walls (about 1100 new homes). That number rose to 1.2% in 1999, 2.7% in 2001, and increased to 3.8% in 2002, which would be 50,639 homes, according to U.S. Census Data.

Above-grade ICF walls cost more to build than typical wood-framed walls. As wood-framed walls approach the thermal insulation value of ICFs, the cost differential will decrease. In most cases, materials' costs (concrete and forms) are primarily responsible for increased costs, while labor costs are often similar to wood framing. Cost premium depends on relative material prices, labor efficiency for each system, engineering necessity, and its effect on other practices or trades, among other factors.

The cost premium for ICF houses is smaller in areas such as high-wind regions, which require additional labor, time, and materials for special construction of woodframed houses. According to an NAHB Research Center study, costs are estimated to increase by 1%–8% of total house cost over a wood-framed house.

Lightweight Concrete Products

Lightweight, air-entrained concrete is an alternative wall system (Figure 7). Autoclaved aerated concrete (AAC), sometimes referred to as precast autoclaved aerated concrete (PAAC), which can be shipped either as blocks or panels, combines elevated *R*-values (compared to standard concrete) with thermal mass.

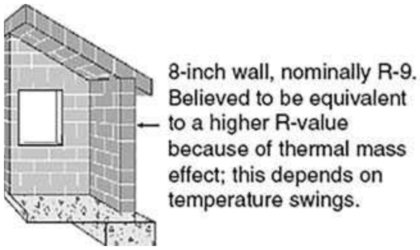

FIGURE 7 Lightweight concrete products (R-1.1 per inch plus).

TABLE 3 2 × 4 Framed Wall Problems and Solutions

Problem	Solution
Small space available for insulation	Install continuous exterior foam sheathing and medium (R-13) to high (R-15) density cavity insulation
Enclosed cavities are more prone to cause condensation, particularly when sheathing materials with low R-values are used	Install a continuous air barrier system. Use continuous foam sheathing
Presence of wiring, plumbing, ductwork, and framing members lessens potential R-value and provides pathways for air leakage	Locate mechanical systems in interior walls; avoid horizontal wiring runs through exterior walls; use air sealing insulation system

2 × 4 Wall Insulation

Throughout the United States, debates on optimal wall construction continue.[6] Table 3 summarizes typical problems and solutions in walls framed with 2 × 4 studs. In addition to standard framing lumber and fasteners, the following materials will also be required during construction:

- Foam sheathing for insulating headers.
- 1 × 4 or metal T-bracing for corner bracing (Figure 8).

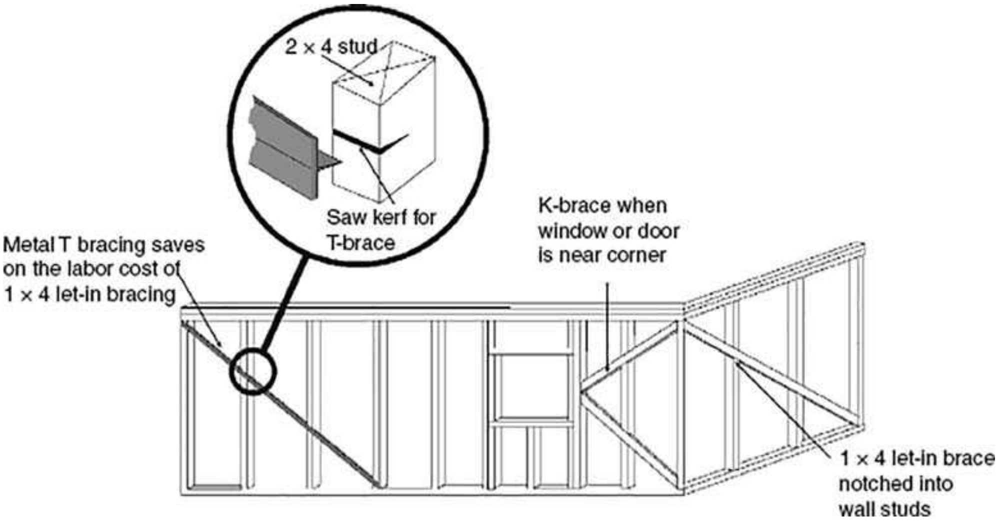

FIGURE 8 Let-in bracing.

- R-13 batts for insulating areas during framing behind shower/tub enclosures and other hidden areas.
- From the Florida Building Code, Residential (FBC-R): "R307.2 Bathtub and shower spaces. Bathtub and shower floors and walls above bathtubs with installed shower heads and in shower compartments shall be finished with a nonabsorbent surface. Such wall surfaces shall extend to a height of not less than 6 ft above the floor."
- Caulking or foam sealant for sealing areas that may be more difficult to seal later.

Avoid Side Stapling

Walls are usually insulated with batts that have attached vapor retarder facing. Many builders question whether it is best to side staple or face staple batt insulation. The common arguments are that face stapling results in less compression, while side stapling interferes less with drywall installation.

The ideal solution should focus on where the kraft paper (vapor retarder) is rather than on how it is installed.[7]

The face stapling question is an appropriate question in northern or "heating-dominated" climates. In northern areas, vapor retarders should be installed on the "warm" side of the wall cavity. In southern or "cooling-dominated" climates, the vapor retarder should be on the outside surface of the wall cavity. Because of this, the use of unfaced batts is recommended in hot-humid climates (Figure 9).

Unfaced batts are slightly larger than the standard 16-or 24-inch stud spacing and rely on a friction-fit for support. Because unfaced batts are not stapled, they can often be installed in less time. In addition, it is easier to cut unfaced batts to fit around wiring, plumbing, and other obstructions in the walls.

Blown Loose-Fill Insulation

Loose-fill cellulose, fiberglass, and rock wool insulation can also be used to insulate walls. This insulation is installed with a blowing machine and held in place with a glue binder or netting (Figure 10). This technique can provide good insulation coverage in the stud cavities; however, it is very important that excess moisture in the binder be allowed to evaporate before the wall cavities are enclosed by an interior finish. Keep in mind that insulation products are not replacements for proper air sealing technique.

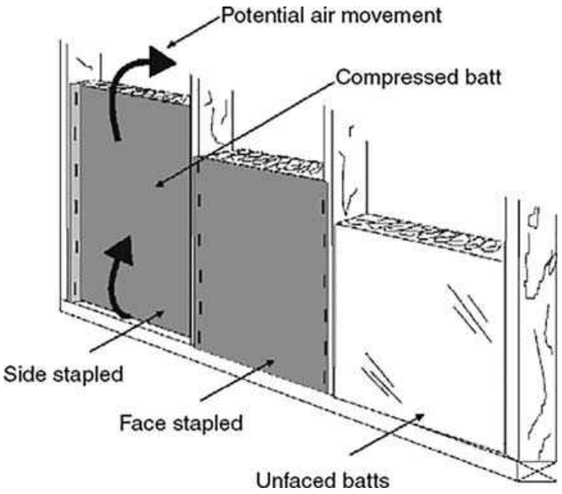

FIGURE 9 Insulating walls with batts.

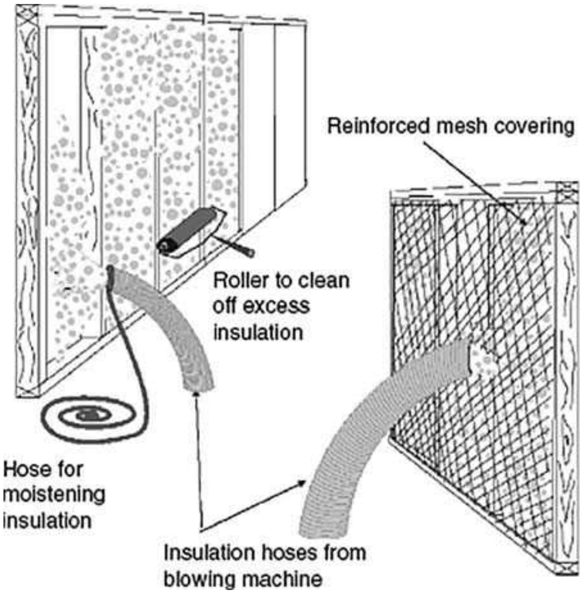

FIGURE 10 Blown sidewall insulation options.

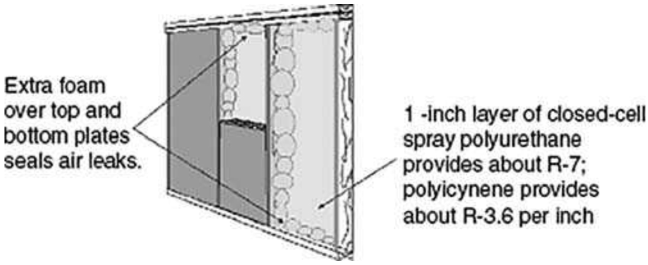

FIGURE 11 Blown foam insulation.

Blown Foam Insulation

Some insulation contractors are now blowing polyurethane or polyicynene insulation into the walls and ceilings of new buildings (Figure 11). This technique provides high *R*-values in relatively thin spaces and seals air leaks effectively. The economics of foam insulation should be examined carefully prior to their application.

Structural Insulated Panels

Another approach to wall construction is the use of structural insulated panels (SIP), also known as stress-skin panels (Figure 12).[8] They consist of 4-inch or 6-inch thick foam panels onto which structural sheathing, such as oriented strand board (OSB), cement fiber board, or various types of metal have been attached. They reduce labor costs, and because of the reduced framing in the wall, they have higher *R*-values and less air leakage than standard walls.

SIPs are generally 4 feet wide and 8 to 12 feet long. There are a wide variety of manufacturers, each with its own method of attaching panels together. Procedures for installing windows, doors, wiring, and plumbing have been worked out by each manufacturer. Some SIPs come from the factory with

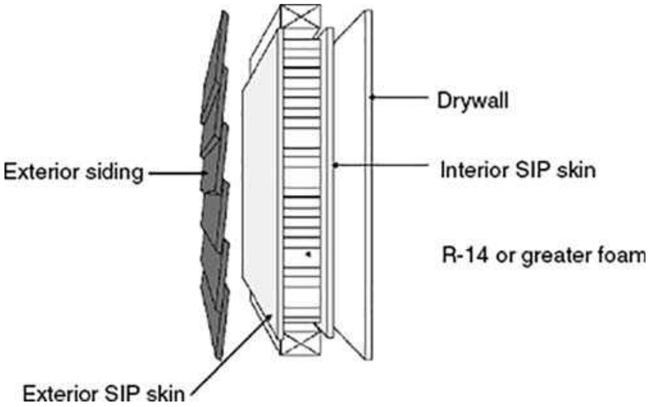

FIGURE 12 Structural insulated panels (SIP)

preinstalled windows. In addition to their use as wall framing, SIPs can also be used in ceilings, floors, and roofs.

While buildings constructed with SIPs may be more expensive than those with standard framed and insulated walls, research studies have shown that SIP-built buildings have higher average insulating values per inch than most commonly used insulation materials. Due to their typical modular style of construction, infiltration losses are also reduced. Thus, they can provide substantial energy savings. Be sure to follow local building codes with regard to termites, including leaving a 6" inspection zone above finished grade.

The performance of any SIP wall depends on its component materials and installation processes. There are a few important variables to take into consideration when building with SIP systems:

1. Panel fabrication (proper panel gluing, pressing, and curing) is critical to prevent delamination.
2. Panels must be flat, plumb, and have well-designed connections to ensure tightness of construction.
3. Though SIPs offer ease of construction, installers may need training in installing the system being used.
4. Fire rating of SIP materials and air-tightness of SIP installation affect the system's fire safety.
5. There may be potential insect and rodent mitigation issues, depending on SIP materials and construction.
6. Proper HVAC design and installation must take the SIP system being used into account.

Metal Framing

Builders and designers are well aware of the increasing cost and decreasing quality of framing lumber. As a consequence, interest in alternative framing materials, such as metal framing, has grown. While metal framing offers advantages over wood, such as consistency of dimensions, lack of warping, and resistance to moisture and insect problems, it has distinct disadvantages from an energy perspective.

Metal framing is an excellent conductor of heat. Buildings framed with metal studs and plates usually have metal ceiling joists and rafters, as well. Thus, the entire structure serves as a highly conductive thermal grid. Insulation placed between metal studs and joists is much less effective due to the extreme thermal bridging that occurs across the framing members.

The American Iron and Steel Institute is well aware of the challenges involved in building an energy efficient steel structure. In their publication *Thermal Design Guide for Exterior Walls* (Publication RG-9405), the Institute provides information on the thermal performance of steel-framed buildings. Table 4 summarizes some of their findings.

TABLE 4 Effective Steel Wall *R*-Values

Cavity Insulation	Sheathing	Effective Overall R-Value
11	2.5	9.5
11	5	13
11	10	18
13	2.5	10
13	5	14

Moisture-related problems have been reported in metal frame buildings that do not use sufficient insulated sheathing on exterior walls. Metal studs cooled by the air conditioning system can cause outdoor air to condense, leading to mildew streaks (or ghosting), where one can see the framing members on the inside and outside of a home. In winter, studs covered by cold outside air can also cause streaking. Attention to proper insulation techniques can alleviate this problem.

2 × 6 Wall Construction

There has been interest in hot, humid climates in the use of 2 × 6s for construction. The advantages of using wider wall framing are:

- More space provides room for R-19 or R-21 wall insulation.
- Thermal bridging across the studs is less of a penalty due to the higher *R*-value of 2 × 6s.
- Less framing reduces labor and material costs.
- There is more space for insulating around piping, wiring, and ductwork.

Disadvantages of 2 × 6 framing include:

- Wider spacing may cause the interior finish or exterior siding to bow slightly between studs.
- Window and door jambs must be deeper, resulting in additional costs.
- Walls with substantial window and door area may require almost as much framing as 2 × 4 walls and leave relatively little area for actual insulation.

The economics of 2 × 6 wall insulation are affected by the number of windows in the wall because each window opening adds extra studs and may require the purchase of a jamb extender. Walls built with 2 × 6s having few windows provide positive economic payback. However, for walls in which windows make up over 10% of the total area, the economics become questionable.

Ceilings and Roofs

Attics over flat ceilings are usually the easiest part of a building's exterior envelope to insulate. They are accessible and have ample room for insulation. However, many homes use cathedral ceilings that provide little space for insulation.[9] It is important to insulate both types of ceilings properly.

Attic Ventilation

In the summer, properly designed ventilation reduces roof and ceiling temperatures, thus potentially saving on cooling costs and lengthening the life of the roof. In winter, roof vents expel moisture which could otherwise accumulate and deteriorate insulation or other building materials.

At present, several research studies are investigating whether attic ventilation is beneficial. For years, researchers have believed the cooling benefits of ventilating a well-insulated attic to be negligible. However, some experts are now questioning whether ventilation is even effective at moisture

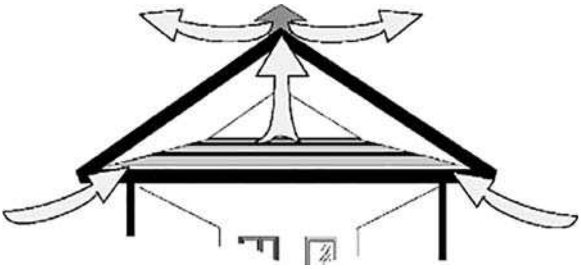

FIGURE 13 Attic ventilation through soffit and ridge vents.

removal. The Florida Building Code, Residential now provides provisions for "conditioned attic assemblies" (Section R806.4) as long as certain conditions are met. When attic ventilation is provided, ventilation openings shall be provided with corrosion-resistant wire mesh with 1/8 in. minimum to 1/4 in. maximum openings. Total net free ventilation area shall not be less than 1–150 of the area of the space ventilated. An exception for 1–300 is provided in the code.

Vent Selection

The amount of attic ventilation needed is based on state building code requirements. If ventilating the roof, locate vents high along the roof ridge and low along the eave or soffit. Vents should provide air movement across the entire roof area (Figure 13). There are a wide variety of products available, including ridge, gable, soffit, and mushroom vents.

To allow for proper airflow in attic spaces, it is common practice to install a rafter baffle at the soffit. This will prevent insulation from sealing off the airflow from the soffit vent to the attic space.

The combination of continuous ridge vents along the peak of the roof and continuous soffit vents at the eave provides the most effective ventilation. Ridge vents come in a variety of colors to match any roof. Some brands are made of plastic and covered by cap shingles to hide the vent from view.

Manufacturer or product testing is being performed by a variety of organizations to verify leak-free operation of continuous ridge vents in high wind situations. Care should be taken to ensure that the vents chosen are appropriate for hurricane-prone areas.

Powered Attic Ventilator

Electrically powered roof ventilators can consume more electricity to operate than they save on air conditioning costs and are not recommended for most designs. Power vents can create negative pressures in the home, which may have detrimental effects, such as (Figure 14):

- Drawing outside air into the home
- Removing conditioned air from the home through ceiling leaks and bypasses
- Pulling pollutants, such as radon and sewer gases, into the home
- Backdrafting fireplaces and fuel-burning appliances

Attic Floor Insulation Techniques

Either loose-fill or batt insulation can be installed on an attic floor. Generally, blowing loose-fill attic insulation is usually less expensive than installing batts or rolls. Most attics have either blown fiberglass, rock wool, or cellulose. Ceilings with a rise greater than 5 and a run of 12 (5 over 12) should not be insulated with blown-in insulation.

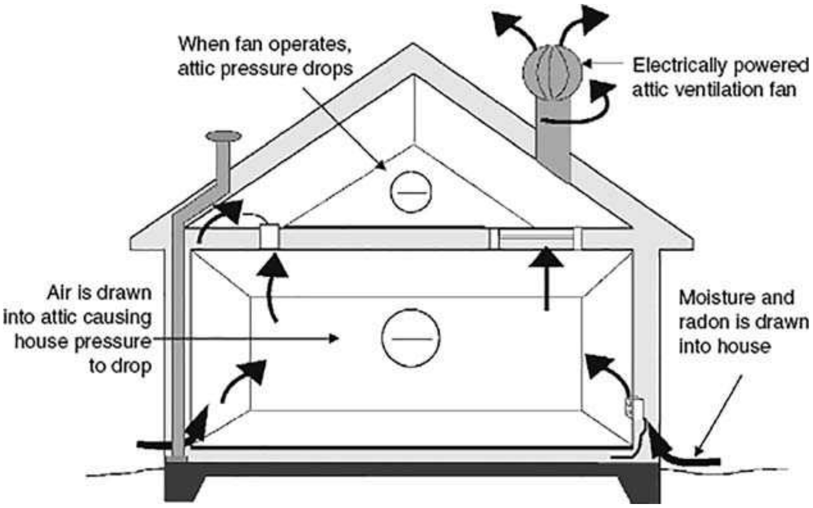

FIGURE 14 Attic ventilation through powered ventilation.

Loose-Fill Attic Insulation

Steps for installing loose-fill attic insulation[10]:

7. Seal attic air leaks, as prescribed by fire and energy codes.
8. Follow manufacturer's and state building code clearance requirements for heat-producing equipment found in an attic, such as flues or exhaust fans. One example of attic blocking is shown later in this entry.
9. Use baffles to preserve ventilation space at eave of roof for soffit vents.
10. Insulate the attic hatch or attic stair. Foam boxes are available for providing a degree of insulation over a pull-down attic stairway.
11. Determine the attic insulation area; based on the spacing and size of the joists, use the chart on the insulation bag to determine the number of bags to install. Table 5 shows a sample chart for cellulose insulation. Cellulose is heavier than fiberglass for the same *R*-value. Closer spacing of roof joists and thicker dry-wall is required for larger *R*-values. Check this detail with the insulation contractor. Weight limits and other factors at R-38 insulation levels are shown in Table 5 for the three primary types of loose fills.
12. Avoid fluffing the insulation (blowing with too much air) by using the proper air-to-insulation mixture in the blowing machine. A few insulation contractors have "fluffed" (added extra air to) loose-fill insulation to give the impression of a high *R*-value. The insulation may be the proper depth, but if too few bags are installed, the *R*-values will be less than claimed.

TABLE 5 Blown Cellulose in Attics

			2 × 6 Joists Spaced 24 in. on Center		2 × 6 Joists Spaced 16 in. on Center	
R-Value at 75°F	Minimum Thickness (in.)	Minimum Weight (lb/ft2)	Coverage per 25-lb Bag (ft2)	Bags per 1000 ft2	Coverage per 25-lb Bag (ft2)	Bags per 1000 ft2
R-40	10.8	2.10	12	83	13	77
R-32	8.6	1.60	16	63	18	56
R-24	6.5	0.98	21	48	23	43
R-19	5.1	0.67	37	27	41	24

13. Obtain complete coverage of the blown insulation at relatively even insulation depths. Use attic rulers (obtainable from insulation contractors) to ensure uniform depth of insulation.

Batt Attic Insulation

Steps for installing batt insulation:

14. Seal attic air leaks, as prescribed by fire and energy codes.
15. Block around heat-producing devices, as described in Step 2 for loose-fill insulation.
16. Insulate the attic hatch or attic stair as described in Step 4 for loose-fill insulation.
17. Determine the attic insulation area based on the spacing and size of the joists, order sufficient R-30 insulation for the flat attic floor. Choose batts that are tapered—cut wider on top—so that they cover the top of the ceiling joists. (See Figure 15).
18. When installing the batts, make certain they completely fill the joist cavities. Shake batts to ensure proper loft. If the joist spacing is uneven, patch gaps in the insulation with scrap pieces. Try not to compress the insulation with wiring, plumbing, or ductwork. In general, obtain complete coverage of full-thickness, noncompressed insulation.
19. Attic storage areas can pose a problem. If the ceiling joists are shallower than the depth of the insulation (generally less than 2 ×10s), raise the finished floor using 2 × 4s or other spacing lumber. Install the batts before nailing the storage floor in place (see Figure 16).

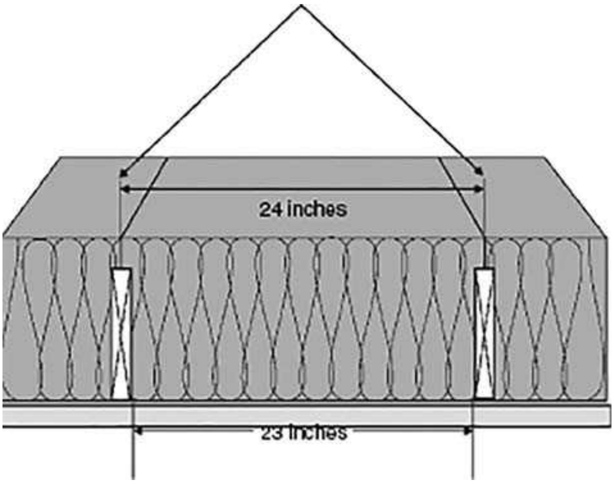

FIGURE 15 Full-width ceiling batt insulation.

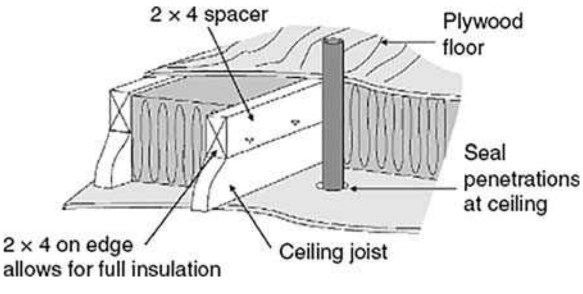

FIGURE 16 Ceiling insulation under attic storage floor.

Note that often attic framing is not designed for storage. Check engineered loads of framing before increasing loads and piggy-backing ceiling joists.

Preventing Air Flow Restrictions at the Eave

One problem area in many standard roof designs is at the eave, where there is not enough room for full R-30 insulation without preventing air flow from the soffit vent or compressing the insulation, which reduces its *R*-value. Figures. 17 and 18 show several solutions to this problem. If using a truss roof, purchase raised heel trusses that form horizontal overhangs. They should provide adequate clearance for both ventilation and insulation.

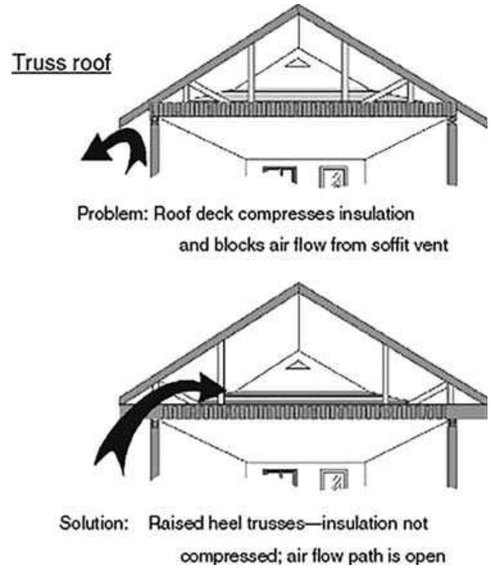

FIGURE 17 Soffit air ventilation—raised heel trusses.

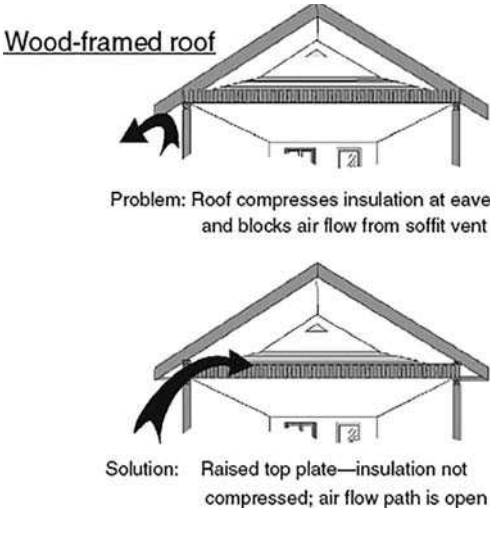

FIGURE 18 Soffit air ventilation—raised top plate.

In stick-built roofs, where rafters and ceiling joists are cut and installed on the construction site, an additional top plate that lies across the top of the ceiling joists at the eave will prevent compression of the attic insulation. Note: This needs to be a double plate for bearing unless rafters sit directly above joists. The rafters sitting on this raised top plate allow for both insulation and ventilation.

Cathedral Ceiling Insulation Techniques

Cathedral ceilings are a special case because of the limited space for insulation and ventilation within the depth of the rafter. Fitting in a 10-in. batt (R-30) and still providing ventilation is impossible with a 2 × 6 or 2 × 8 rafter (R-19 or R-25, respectively).

Building R-30 Cathedral Ceilings

Cathedral ceilings built with 2 × 12 rafters can be insulated with standard R-30 batts and still have plenty of space for ventilation. Some builders use a vent baffle between the insulation and roof decking to ensure that the ventilation channel is maintained.

If 2 × 12s are not required structurally, most builders find it cheaper to construct cathedral ceilings with 2 × 10 rafters and high-density R-30 batts, which are $8^{1/4}$ in. thick (Table 6).

Some contractors wish to avoid the higher cost of 2 × 10 lumber and use 2 × 8 rafters. These roofs are usually insulated with R-19 batts.

In framing with 2 × 6 and 2 × 8 rafters, higher insulating values can be obtained by installing rigid foam insulation under the rafters. Note that the rigid foam insulation must be covered with a fire-rated material when used on the interior of the building. Drywall usually meets this requirement.

Scissor Trusses

Scissor trusses are another cathedral ceiling framing option. Make certain they provide adequate room for both R-30 insulation and ventilation, especially at their ends, which form the eave section of the roof.

Any sized rafter; blown-in cellulose, fiberglass, or rock wool held in place; provide 1 in. ventilation space above.

Difficulties with Exposed Rafters

A cathedral ceiling with exposed rafters or roof decking is difficult and expensive to insulate well. Often, foam insulation panels are used over the attic deck, as shown in Figure 19. However, to achieve R-30, four to seven inches of foam insulation are needed. Ventilation is also a problem.

In homes where exposed rafters are desired, it may be more economical to build a standard, energy efficient cathedral ceiling, and then add exposed decorative beams underneath. Note that homes having tongue-and-groove ceilings can experience substantially more air leakage than solid, drywall ceilings. Install a continuous air barrier, sealed to the walls above the tongue-and-groove roof deck and held in place; provide 1 in. ventilation space above.

TABLE 6 Cathedral Ceiling Insulation Options

Rafter	Batt
2 × 8	R-19
2 × 10	R-25
2 ×10	Moderate density R-30
2 × 12	Standard density R-30

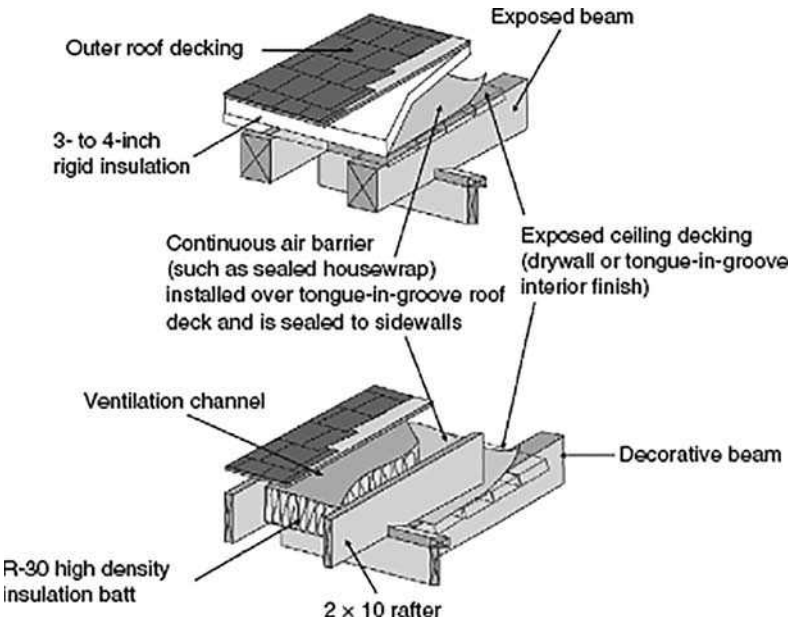

FIGURE 19 Insulating exposed rafters.

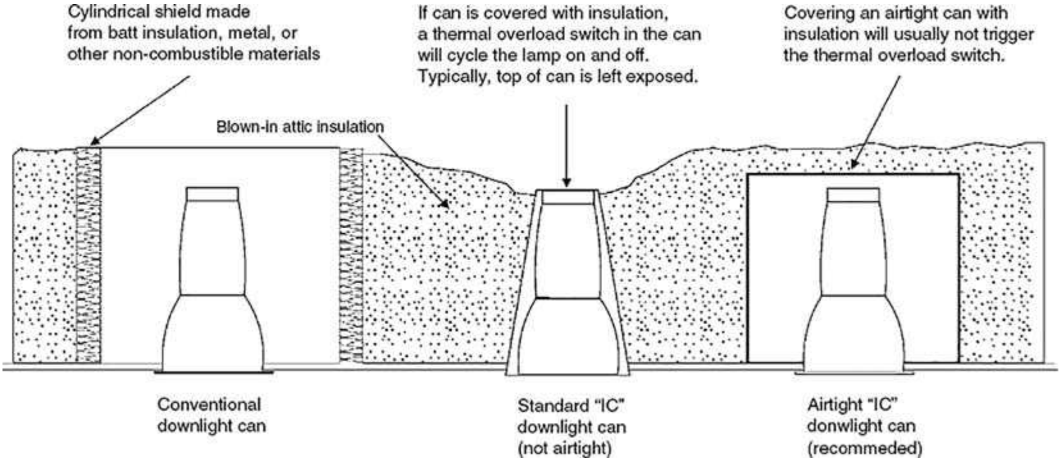

FIGURE 20 Recessed lighting insulation.

Recessed Lights

Standard recessed fixtures require a clearance of several inches between the sides of the lamp's housing and the attic insulation. In addition, insulation cannot be placed over the fixture. Even worse, recessed lights leak considerable air between attics and the home.

Insulated ceiling (IC) rated fixtures have a heat sensor switch that allows the fixture to be covered—except for the top—with insulation (see Figure 20 for the proper insulation methods for these fixtures). However, these units also leak air. If you have to use recessed lights, install airtight IC-rated fixtures. There are alternatives to recessed lights, including surface-mounted ceiling fixtures and track lighting, which typically contribute less air leakage to the home.

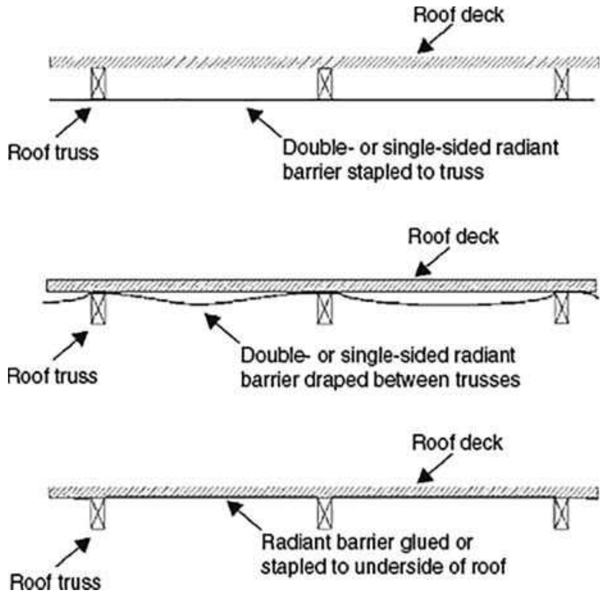

FIGURE 21 Radiant barrier configuration

Radiant Heat Barriers

Radiant heat barriers (RHB) are reflective materials that can reduce summer heat gain via the insulation and building materials in attics and walls. RHBs work two ways: first, they reflect thermal radiation well; and, second, they emit (give off) very little heat. RHBs should always face a vented airspace and be installed to prevent dust build-up. They are usually attached to the underside of the rafter or truss top chord or to the underside of the roof decking. Acceptable attic radiant barrier configurations can be found in Figure 21.

How Radiant Barrier Systems Work

A radiant barrier reduces heat transfer. Thermal radiation, or radiant heat, travels in a straight line away from a hot surface and heats any object in its path.

When sunshine heats a roof, most of the heat conducts through the exterior roofing materials to the inside surface of the roof sheathing. Heat then transfers by radiation across the attic space to the next material—either the top of the attic insulation or the attic floor. A radiant barrier, properly installed in one of many locations between the roof surface and the attic floor, will reduce radiant heat flow. Thermal insulation on the attic floor resists the flow of heat through the ceiling into the living space below. The rate at which insulation resists this flow determines the insulation's *R*-value. The amount of thermal insulation affects the potential radiant barrier energy savings. For example, installing a radiant barrier in an attic that already has high levels of insulation (*R*-30 or above) would result in much lower energy savings than an attic insulated at a low level (R-11 or less).

All radiant barriers use reflective foil that blocks radiant heat transfer. In an attic, a radiant barrier that faces an air space can block up to 95% of the heat radiating down from a hot roof. Only a single, thin, reflective surface is necessary to produce this reduction in radiant heat transfer. Additional layers of foil do little more to reduce the remaining radiant heat flow.

Conventional types of insulation consist of fibers or cells that trap air or contain a gas to retard heat conduction. These types of insulation reduce conductive and radiant heat transfer at a rate determined by their

R-value, while radiant barriers reduce only radiant heat transfer. There is no current method for assigning an *R*-value to radiant barriers. The reduction in heat flow achieved by the installation of a radiant barrier depends on a number of factors, such as ventilation rates, roof reflectivity, ambient air temperatures, geographical location, the amount of roof solar gains, and the amount of conventional insulation present.

Several factors affect the cost effectiveness of installing a radiant barrier. You should examine the performance and cost savings of at least three potential insulation options: adding additional conventional insulation, installing a radiant barrier, and adding both conventional insulation and a radiant barrier.

In 1991 (revised June, 2001), the U.S. Department of Energy (DOE) published the Radiant Barrier Attic Fact Sheet, which shows how to calculate the economics of radiant barriers and added ceiling insulation. It includes an Energy Savings Worksheet with an example. The worksheet is part of the fact sheet and can be found at http://www.ornl.gov/sci/roofs+walls/radiant/rb_05.html.[11]

Because radiant barriers redirect radiant heat back through the roofing materials, shingle temperatures may increase between 1 and 10 F (0.6 C-5.6 C). This increase does not appear to exceed the roof shingle design criteria. The overall effect on roof life, if any, is not known.

Remember, radiant barriers are most effective in blocking summer radiant heat gain and saving air-conditioning costs. Although the radiant barrier may be somewhat effective in retaining heat within a cold-climate home, it may also block any radiant winter solar heat gain in the attic.

Conclusion

Buildings are insulated to help moderate the environment that we live and work in. As utility costs rise, this aspect of our constructed environment becomes more and more important. Many new materials have entered the market in the past few years, each having their own particular advantages and disadvantages. This entry has described in detail the importance of installation practices and their effect on overall performance. Emphasis was placed on properly defining the building envelope and different methods and materials that can be used to effectively insulate and, therefore, thermally isolate the constructed environment from the daily extremes produced by local weather.

New techniques and materials will evolve; however, some guidelines will remain the same:

- Choose an insulation material with characteristics suitable for the climate region.
- Use the proper R-value for the climate region where each particular structure is being constructed.
- Apply the recommended thickness, or R-value, to each building component, such as ceiling, walls, and floors.
- Install each particular insulation product in a proper fashion, following the manufacturer's recommendations and instructions, leaving no voids, and filling each building cavity to the level required for the building site.

Insulation materials and techniques play a large part in minimizing energy consumption and maximizing human comfort. Recent advances in both materials and techniques will help further this trend.

Acknowledgments

Many thanks to Kyle Allen, an engineering student at the University of Florida, because without his persistent efforts, the publication of this entry would not have been possible.

Environmental Accounting: A Tool for Supporting Environmental Management and Nature Conservation

Pier Paolo Franzese, Elvira Buonocore, and Giovanni F. Russo

Environmental Management and Nature Conservation

Healthy ecosystems are capable of maintaining their structures and functions, ensuring the generation and maintenance of natural capital stocks and ecosystem services flows (Buonocore et al., 2018; Pauna et al., 2018).

There is a growing evidence that biodiversity increases the stability of ecosystem functioning, representing the basis for the generation of ecosystem services vital for human well-being (Teixeira et al., 2019; Vihervaara et al., 2019). Therefore, biodiversity loss represents one of the major threats to humanity with potential impacts on both nature and human economy (Cardinale et al., 2012; TEEB, 2010).

In line with the objectives of the Convention on Biological Diversity (CBD) striving to address the issue of biodiversity loss, ensure the sustainable use of natural resources, and allow an equitable share of benefits, there has been significant progress toward conservation targets (UNEP-WCMC, IUCN, and NGS, 2018). Nonetheless, efforts are still needed to increase the effectiveness of nature conservation actions (Hoffmann et al., 2018).

Many international policy processes, including the CBD and the UN 2030 Agenda for Sustainable Development, recognize protected areas as successful management tools for protecting biodiversity while ensuring the sustainable exploitation of natural resources. When effective management measures are in place, protected areas are capable of meeting the multitude of objectives they are designed for, supporting the achievement of both local and large-scale sustainability goals.

Over the past decade, there have been increasing research efforts to assess the value of natural resources, also exploring how these values can be embedded into decision making (Costanza et al., 2014; European Union, 2014; Franzese et al., 2014, 2019).

Assessing the biophysical and economic value of natural capital and ecosystem services provides a deeper understanding of ecosystems functioning while supporting managers and policy makers in charge for implementing management plans and policies rooted in the principle of sustainable development (Maes et al., 2016; TEEB, 2010).

These assessments can be particularly useful in the case of protected areas to establish a baseline to monitor changes over time, assess the consequences of management decisions and changes, and demonstrate their importance in achieving international conservation targets (Neugarten et al., 2018).

Environmental Accounting

Environmental accounting is a tool useful for exploring three main dimensions related to the exploitation of natural resources both in the context of nature and human economy: environmental costs, impacts, and benefits (Häyhä and Franzese, 2014).

In particular, when applied in the context of nature conservation, environmental accounting is useful to address multiple aspects dealing with the exploitation of natural resources, among which (1) the assessment of environmental costs sustained by ecosystems for the generation and maintenance of natural capital stocks, (2) the assessment of goods and services that humans receive from ecosystems (i.e., the ecosystem services), and (3) the assessment of the impacts generated by human activities for the exploitation of natural resources (Figure 1).

Environmental accounting takes into account both direct and indirect environmental costs as well as local and global impacts. In general, environmental accounting methods can be assigned to two broad categories: (1) upstream methods, focusing on the cumulative amount of environmental resources supporting the investigated system, and (2) downstream methods, more concerned with the potential environmental impacts due to the system's emissions.

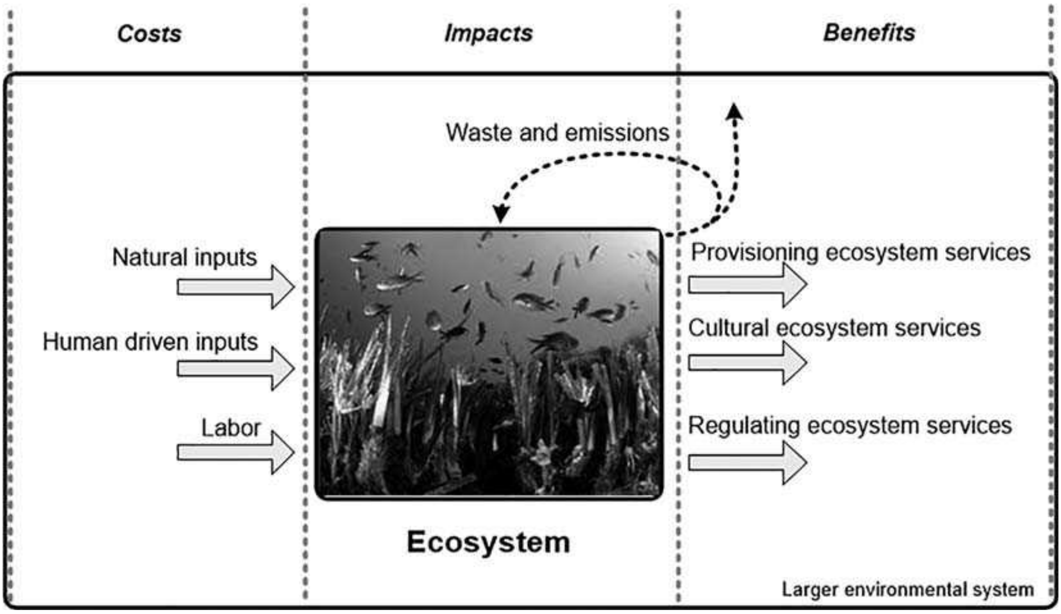

FIGURE 1 Three main dimensions of environmental accounting: assessment of environmental costs, impacts, and benefits.

The Emergy Accounting Method

The emergy accounting method (Odum, 1988, 1996) aims at calculating indicators of environmental performance and sustainability accounting for both natural and economic resources used up within ecosystems and human-dominated process.

Emergy is a "donor-side" approach assessing the value of goods and services in terms of work of biosphere invested for their generation. According to this method, the greater the cumulative environmental support to generate natural resources, the higher is their emergy value.

The emergy method takes into account: (1) natural input flows (e.g., solar radiation, wind, rain, and geothermal flow), (2) human-driven material and energy flows (e.g., machineries, fuels, chemicals), and (3) human labor and services converging to a process (Brown and Ulgiati, 2004).

According to this method, different forms of energy, materials, human labor, and economic services are accounted for in terms of their solar emergy, defined as the total amount of solar available energy (exergy) directly or indirectly required to make a given product or support a given flow, and measured in sej (solar emergy joules). The solar emergy required to generate one unit of product or service is referred to as Unit Emergy Value (UEV), expressed in sej/J in the case of energy flows or in sej/g in the case of mass flows.

The emergy method is deeply rooted in the concept of resource quality, i.e. the awareness that different energy forms have a different ability to do useful work even when their heat content is the same. Instead of only looking at what can be extracted out of a resource (exergy), the emergy accounting method focuses on what it takes for the biosphere to make and for human economy to process a given resource (Franzese et al., 2009).

The additional work provided by human activities to refine a raw resource adds up to its quality by making it more suitable to the final user. According to the emergy donor-side perspective, what makes a resource valuable is therefore both the environmental and human work investment for its production (Franzese et al., 2009).

An emergy assessment is typically implemented through the following main steps:

1. Identification of the spatial and temporal boundaries of the investigated system.
2. Modeling of the investigated system through an energy diagram drawn according to a standardized energy systems language (Odum, 1996).
3. Inventory of mass and energy flows supporting the investigated system.
4. Conversion of input flows into emergy units by using appropriate UEVs factors.
5. Calculation of the total emergy supporting the system.
6. Calculation of emergy-based indicators.

To calculate emergy-based indicators, all the input flows to a system are clustered into three main categories: the local Renewable flows (R), the local Non-renewable flows (N), and the flows Imported from outside the system (I). R, N, and I can be summed to account for the total emergy input (U) to a system.

In addition to the total emergy input (U) and the UEV of the system's output, the main emergy-based indicators used to describe the environmental performance and sustainability of the investigated system are: the Environmental Loading Ratio (ELR), the Emergy Yield Ratio (EYR), and the Emergy Sustainability Index (ESI).

The ELR compares the amount of non-renewable (N) and imported emergy (I) to the amount of locally available renewable emergy (R). In the case of a natural ecosystem, there would be no investments from outside and the system would be driven only by local renewable resources, thus having an $ELR=0$.

The EYR is a measure of the ability of a process to exploit and make available local resources by investing outside resources. The lowest possible value of the EYR is 1, situation in which the emergy converging to generate the yield does not differ significantly from the emergy invested from outside the system.

Finally, the ESI is an aggregated index calculated by the ratio of the EYR (sensitive to the outside-versus-local emergy use) and the ELR (sensitive to the non-renewable-versus-renewable emergy use) (Brown and Ulgiati, 2004).

Emergy flows can be converted into non-market "currency equivalents" by using the Emergy-to-Money Ratio (EMR) defined as the ratio between the total emergy (U) supporting a nation and its gross domestic product (GDP) in the same year (Lou and Ulgiati, 2013). This ratio represents the average amount of emergy needed to generate one unit of money in the national economy.

It is important to remark that, while the conversion of emergy units into money units can facilitate the communication of the results of emergy studies in political and socio-economic contexts, these figures expressed in money units should never be interpreted by applying a user-side perspective as they are non-market economic values.

Emergy Accounting and Marine Protected Areas

Emergy accounting has been widely applied to investigate natural, human-dominated, and man-made ecosystems. Many studies focused on the emergy assessment of natural capital and ecosystem services at local, regional, and national scales (Berrios et al., 2017; Campbell and Brown, 2012; Coscieme et al., 2014; Franzese et al., 2008, 2015; Huang et al., 2011; Lu et al., 2007, Ulgiati et al., 2011). Among them, recent studies focused on the assessment of matter and energy flows supporting the generation of natural capital stocks in marine protected areas. In particular, Vassallo et al. (2017) developed a biophysical and trophodynamic environmental accounting model based on emergy accounting and aimed at assessing the value of natural capital in marine protected areas. This model was articulated in three main steps: (1) trophodynamic analysis, providing an estimate of the primary productivity used to support the benthic trophic web within the study area; (2) biophysical accounting, providing an estimate of the biophysical value of natural capital; and (3) monetary conversion, expressing the biophysical value of natural capital into monetary units. This last step does not change the biophysical feature of the assessment, but instead it has the merit of allowing an easier understanding and effective communication of the ecological value of natural capital in socio-economic contexts.

Franzese et al. (2017) assessed the biophysical and economic value of natural capital in a Mediterranean marine protected area by using the emergy accounting method. In this study, the value of natural capital stocks in the main habitats included in the marine ecosystem was estimated in terms of work of biosphere invested for their generation and maintenance. In addition, using a GIS tool, the distribution of natural capital value in the protected area was made spatially explicit and integrated with the bionomic map and the zonation showing different protection levels.

The overlap of these different information layers allowed the identification of sites where natural capital value is more concentrated, supporting local managers and policy makers in charge for developing sustainable management strategies.

Picone et al. (2017) assessed the value of both autotrophic and heterotrophic natural capital stocks in a Mediterranean marine protected through emergy accounting. In addition, by using Marxan software, the results of the environmental accounting were integrated with spatial data on main human uses. This approach highlighted the importance of developing marine spatial planning taking into account both conservation measures and human activities devoted to resources exploitation.

Buonocore et al. (2019) jointly applied the emergy and eco-exergy methods to account for natural capital value in two marine protected areas located in Southern Italy. The emergy method allowed the assessment of natural capital in terms of direct and indirect solar energy flows invested for its generation, while the eco-exergy method accounted for the chemical energy stored in organic matter and the genetic information embodied in biomass stocks. This study showed that the sciaphilic hard bottom is characterized by a high emergy density value, confirming the high effort of nature in the formation of this habitat, suggesting the need for its proper consideration in the development of conservation strategies. Instead, *Posidonia oceanica* seagrass bed showed the highest value of eco-exergy density due to two main factors: (1) the large biomass density of *Posidonia oceanica* and (2) the high ß value of *Posidonia oceanica* reflecting its evolutionary history that involved the acquisition of key adaptations for the successful colonization of marine environments.

The integration between emergy and eco-exergy methods resulted in a useful approach to shed light on different biophysical measures of value based on different features of natural resources.

In all these studies, emergy accounting provided an alternative measure of value of natural resources complementary to more conventional economic studies. In addition, the integration of emergy accounting with other environmental accounting methods and tools allowed the generation of new scientific information useful for supporting the management of marine protected areas conceived to strike a balance between multiple human uses of the marine environment and nature conservation goals.

Concluding Remarks

Environmental accounting is a useful tool capable of addressing multiple aspects dealing with natural resources and their exploitation by human activities.

Among different environmental accounting methods, emergy accounting allows the assessment of nature's value applying a biophysical and geocentric perspective focusing on the work of biosphere supporting the generation of raw natural resources and refined products. The outcomes of emergy studies can complement those of more conventional economic analysis based on an anthropocentric perspective and on market laws.

A multicriteria approach to environmental accounting can address the plurality of nature values, supporting managers and policy makers in charge for sustaining the socio-economic development while ensuring the sustainable (long-term) management of natural resources.

Remote Sensing: Pollution

Massimo
Antoninetti

Introduction

The earth's environment is placed under constant stress by various human activities and natural processes.

Resource management activities for conservation or sustainable use rely on several critical components: accurate and up-to-date information, an understanding of "how" the environment and its components function, and an ability to continuously and constantly monitor the environment's components and processes. Consequently, there is a need for spatial information in the form of baseline mapping and inventory, monitoring programs, and predictive models. Satellite remote sensing (RS) is going to play a major role in fields related to place and space. Thanks to this innovative technology, it is possible to monitor and map rapidly changing phenomena on the surface of our planet due to its broad spectral range, affordable cost, and rapid coverage of large areas. Synergistic use of RS and ancillary data can create a geographic information system (GIS) database, which can be used to store, process, and retrieve environmental data.

This is not a comprehensive review, as many entries have been published on the topics covered. We have attempted to emphasize a few important applications, recent reviews, and recent papers that provide the reader with an overview of the main literature on each topic.

Remote Sensing

Remote sensing is generally defined as the set of techniques, instruments, and interpretative tools able to expand and improve the perceptive ability of the human eye, collecting information about an object without being in physical contact with the object itself.[1] Consequently, RS allows the obtaining of quantitative and qualitative measures from a distance of the surface of objects, and, under some specific conditions, also of the subsurface. The most frequently measured quantity is the electromagnetic energy in one or more regions of the electromagnetic spectrum reflected or emitted from the earth's surface.[2] The primary law governing radiation is the Planck radiation law, which governs the intensity of radiation emitted by unit surface area into a fixed direction (solid angle) from a blackbody as a function of wavelength for a fixed temperature. Conceptually, a blackbody is an ideal radiator of thermal radiant energy, and consequently, also an ideal absorber. The Planck law can be expressed through the following equation:

$$M_\lambda = \frac{\varepsilon C_1}{\lambda^5 \left[\exp\left(\frac{C_2}{\lambda T} \right) - 1 \right]} \tag{1}$$

where M_λ is the spectral radiant exitance (W cm^{-2} µm^{-1}); ε = emittance (emissivity), dimensionless; C_1 is the first radiation constant, 3.7413×10^8 [W (µm)^4]/m^2; C_2 is the second radiation constant, 1.4388×10^8 (µm K); λ is the radiation wavelength (µm); and T is the absolute radiant temperature (K).

Moreover, the Stefan–Boltzmann law states that the total amount of energy M emitted by a blackbody is proportional to the fourth power of its absolute temperature T, and consequently M rapidly increases with the T increasing:

$$M = \int_0^\infty M_\lambda d\lambda = \sigma T^4 \left[Wcm^{-2} \right] \tag{2}$$

where σ is the Stefan–Boltzmann constant ($\sigma = 5.67 \times 10^{-4}$ W cm^{-2} K^{-4}).

However, there is an inverse relationship between the maximum wavelength emission $\lambda_{\max}$ of a blackbody and its temperature when expressed as a function of wavelength (Wien radiation law):

$$\lambda_{max} = \frac{2898}{T} [\mu\text{m}] \tag{3}$$

The Wien law demonstrates that the $\lambda_{\max}$ moves toward lower values at the increasing of the surface temperature T of a body. For example, the maximum emission value for the sun is 0.483 µm (corresponding to the blue-green part of the visible spectrum), 0.966 µm for a incandescent bulb (near infrared [NIR]), and 9.66 µm for the surface of the earth (thermic infrared).

Consequently, for any given material, the amount of solar radiation that it reflects, absorbs, transmits, or emits varies with wavelength. When that amount (usually intensity, as a percent of maximum) coming from the material is plotted over a range of wavelengths, the connected points produce a curve called the material's spectral signature (spectral response curve) (Figure 1). For example, at some wavelengths,

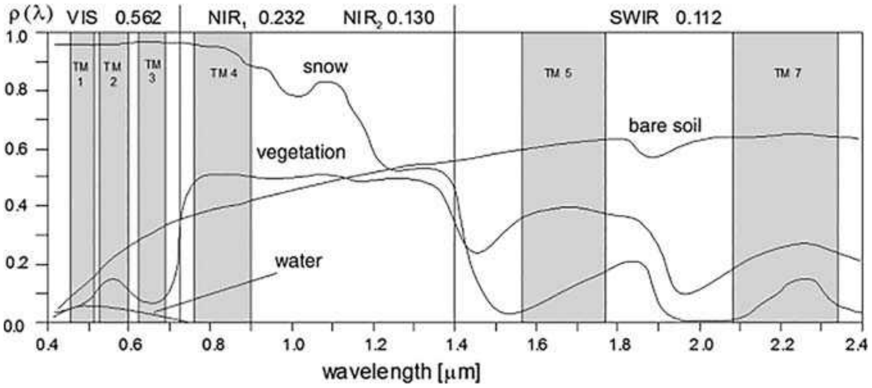

FIGURE 1 Schematization of solar radiation spectral distribution of typical surfaces' spectral reflectivity curves, and of Landsat TM spectral bands.
Source: Brivio et al.[3]

sand reflects more energy than green vegetation; however, at other wavelengths, it absorbs more (reflects less) than the vegetation.

There are two main types of RS using different sensors to register the data: passive RS and active RS. A sensor can be defined as a device that measures a physical quantity and converts it into a signal that can be read by an observer or by an instrument. This physical quantity is the radiance (W m^{-2} sr^{-1}) or the spectral radiance (W m^{-2} sr^{-1} λ^{-1}); they are radiometric measures that describe the amount of electromagnetic energy that passes through or is emitted from a particular area, and falls within a given solid angle in a specified direction. They characterize both emission from diffuse sources and reflection from diffuse surfaces.

Passive sensors detect the natural radiation emitted or reflected by the object. Reflected sunlight is the most common source of radiation measured by passive sensors. Active sensors emit energy in order to scan objects and areas, detecting and measuring the radiation that is reflected or backscattered from the target. RADAR (radio detection and ranging) is an example of active RS where the time delay between emission and return is measured, establishing the location, height, speed, and direction of an object (Figure 2). In most cases, the instruments register a raster image. The image contains a fixed number of rows and columns of pixels, as the smallest individual picture element in the image (Figure 3).

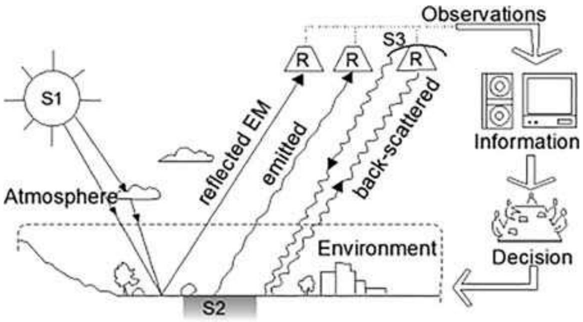

FIGURE 2 Remote sensing basic scheme. Natural energy sources are the sun (S1) and the earth (S2), while the antenna (S3) is an artificial source. Sensor R registers the information carried by electromagnetic waves. This information is stored and elaborated to be used for environmental studies.

FIGURE 3 Digital image concept and description. A digital image is formed by a matrix of $N \leftrightarrow M$ pixels, easily visible only with an enlargement in the window 5 ↔ 5. A digital number (DN) is assigned to each pixel in function of the intensity of the electromagnetic energy registered by sensors.
Source: Modified from Brivio et al.[3]

Each pixel holds a quantized value representing the amount of electromagnetic energy registered by instruments at any specific point. Consequently, the quality of RS image data consists of its spatial, spectral, radiometric, and temporal resolutions. The spatial resolution represents the size of the surface area (i.e., in square meters) being measured on the ground, determined by the sensors' instantaneous field of view, from less than 1 m to more than 1 km. A higher resolution means more image details.

The spectral resolution is the wavelength interval size (discreet segment of the electromagnetic spectrum) recorded by the instruments mounted on board, normally a radiometer, able to measure the radiant flux of electromagnetic radiation. A multispectral radiometer collects electromagnetic energy in different spectral bands, normally from the visible (0.4 μm) to the long-wave infrared (15 μm) part of the spectrum (e.g., Enhanced Thematic Mapper Plus [ETM+] mounted on board of the Landsat satellite has 8 bands recorded), while a hyperspectral imaging deals with hundreds of narrow spectral bands, producing a spectra of all pixels in the scene (e.g., Hyperion sensor on Earth Observing-1 has 220 bands with a spectral resolution of 0.10–0.11 μm per band). The radiometric resolution is the number of different intensities of radiation that the sensor is able to distinguish. Typically, this ranges from 8 to 14 bits, corresponding to the 256 levels of the gray scale and up to 16,384 intensities or "shades" of color in each band.

Finally, temporal resolution is defined as the frequency at which images are recorded/captured in a specific place on the earth's surface (National Oceanic and Atmospheric Administration Advanced Very High Resolution Radiometer [NOAA-AVHRR] capture an image every 12 hr, while Landsat ETM+ every 16 days) (Table 1).

Remote sensing data are processed and analyzed with a digital image processing system, using computer algorithms to improve the quality and quantity of the information registered. As an image is formed by an array of numbers, digital image processing uses simple or complex mathematic algorithms to obtain image restoration; to eliminate errors, noises, and distortions; to improve the information content extraction; and to recognize and classify pixels on the basis of their digital signatures.

A simple process, for example, is the "false-color" composition. Three images acquired in different spectral bands could be combined together to obtain an RGB (red–green–blue) color image where each color tone is the combination of the information contained in each band. The term "false color" identifies images whose colors represent measured intensities outside the human eye capacity.

A complex mathematical model is an artificial neural network, inspired by the structure of physically interconnected neurons in biology and able to process information using a connectionist approach through an interconnected group of artificial neurons. It provides an efficient alternative to map complex nonlinear relationships between input and output datasets without requiring a detailed knowledge of underlying physical relationships. **Table 1** List of main satellites with on-board sensors description

Finally, Geographic Information System (GIS) is a database system used for manipulating data, utilizing a data input system, data storage and retrieval, data manipulation and analysis, and data output. The data inputs are usually spatial and non-spatial data derived from a combination of existing maps, aerial photographs, and RS imagery. The data output is used to generate reports in tabular form, digital displays, or maps. Because the input data on which a GIS is based becomes obsolete quickly, it is important to update this data. Remote sensing is often the most cost-effective source for these updates. The resource database should contain as much base inventory data as possible, as well as simple layer selection and spatial and tabular query capabilities, to illustrate how this data is accessible and useful. Data manipulation is of primary concern, including the tracking of metadata that describe the legacy of the information including source, compilations scale, data of last compilation, and other information needed to qualify the usefulness of the information to support a particular application.

What goes beyond a GIS is the Spatial Data Infrastructure, tools that are interactively connected on the web for retrieving, presenting, and processing data in an efficient and flexible way, in a coordinated series of agreements on technology standards, institutional arrangements, and policies.

Remote Sensing Applications

Water

Although not all deleterious processes can be measured directly (e.g., overfishing), many environmental and ecological properties can be measured using RS. These properties include sea surface temperature (SST), chlorophyll-*a* (Chl-*a*) and suspended sediment concentration, salinity, wind speed, algal blooms, etc. Given a robust understanding of the ecosystem responses to these environmental parameters and some in situ field observations, many other biological benchmarks can often be indirectly derived (e.g., fish abundance).[4]

In the open waters, color variations chiefly depend on the presence and abundance of plankton: these waters are defined as Case I. Conversely, coastal and estuarine systems are often characterized by optically complex waters (Case II), with high concentrations of highly reflective water constituents, the color of which is also due to dissolved organic matter and suspended sediments. The constituents, characterized by variation at much smaller geographical scales, are able to modify natural equilibrium.[5]

In recent years, coastal zones, probably more than any other parts of the earth, have been exposed to pressure and processes of change caused by natural processes (waves, currents and storms, etc.), and human activities.[6] As a large percentage of the world's coastlines are poorly mapped or maps have become outdated, satellite imagery can be a useful and economic tool to overcome these constraints, producing maps containing thematic information of relevant interest in coastal environment protection: planimetric mapping of waterlines and beach and coral reef position, shallow water bathymetry, and thematic maps of cover types on adjacent land and islands. This may include mapping of bare sand, mangroves, seagrass, reef flats, wetlands, etc. The number of classes (categories) (e.g., coral reef, seagrass, sand, hard substrate) distinguishable by RS depends on many natural factors (including atmospheric clarity, surface roughness, water clarity, and water depth) and on the type of RS sensor. Very high resolution pixels (0.1–0.8 m) are required to accurately quantify the percentage of bleached corals. The most likely solution to this limitation of pixel size is the application of methods that estimate the cover of substrata within pixels. These methods known as spectral unmixing, even though they have been developed for terrestrial RS, could be adapted to aquatic environment, taking into account the interference of water column.[4]

In shallow water, the water column (including the substances dissolved or in suspension in the medium) and the seafloor contribute to the upwelling signal leaving the water body. An inverse modeling of the radiation transfer can be developed for simultaneous deriving of seafloor reflectance, depth, water-column subsurface reflectance, and diffuse attenuation coefficient from RS of coastal shallow waters.[7] This method relies on a synthetic database of subsurface irradiance reflectance-compiled field and simulated data and the use of a forward shallow-water reflectance model.[8] Uncertainties in the computation of Chl-*a* absolute values can arise primarily owing to the presence, in the water column, of optically active materials other than phytoplankton and related pigments (i.e., dissolved organic matter and suspended inorganic particles), with partially overlapping spectral signatures. Nevertheless, experience has shown that remotely sensed data can provide unique information on phytoplankton growth patterns over a range of space scales (i.e., from a few kilometers to entire basins) and of time scales (i.e., from days to years) not available by any other means.[9]

Ultraviolet (UV) radiation and high levels of photosynthetically active radiation can have a variety of negative impacts on marine phytoplankton, zooplankton, nekton, and benthos. Satellites provide global time series measurements of incident UV radiation.

Understanding the way in which cetaceans interact with the surrounding environment has become a key tool, not only in their subsequent conservation but also in the management of the ecosystems of which they form a part. Due to their high trophic status and vulnerability to anthropogenic effects, marine mammals such as cetaceans are ideally suited to act as indicator species of ecosystem change and anthropogenic threats.[10] Cetacean studies have focused on their relationships with sea temperature.

Thermal infrared SST measurements are derived from radiometric observations at wavelengths of ~3.7 μm and/or near 10 μm. Although the 3.7 μm channel is more sensitive to SST, it is primarily used only for night-time measurements because of relatively strong reflection of solar irradiation in this wavelength region, which contaminates the retrieved radiation. Both bands are sensitive to the presence of clouds and scattering by aerosols and atmospheric water vapor. For this reason, thermal infrared measurements of SST first require atmospheric correction of the retrieved signal and can only be made for cloud-free pixels. Thus, maps of SST compiled from thermal infrared measurements are often weekly or monthly composites, which allow enough time to capture cloud-free pixels over a region. Thermal infrared instruments that have been used for deriving SST include AVHRR on NOAA Polar-Orbiting Operational Environmental Satellites (POES), Along-Track Scanning Radiometer (ATSR) aboard the European Remote Sensing Satellite (ERS-2), the Geostationary Operational Environmental Satellite (GOES) Imager, and Moderate Resolution Imaging Spectroradiometer (MODIS) aboard NASA Earth Observing System (EOS) Terra and Aqua satellites.

Images supplied by the NERC Remote Sensing Data Analysis Service (RSDAS) were atmospherically corrected and provided in a Mercatore projection. Values or digital numbers (DN) associated with each pixel of the AVHRR images supplied were converted into real SST (°C) values using the following equation as supplied by the RSDAS[10]:

$$\mathrm{SST} = \mathrm{DN} \times 0.1 - 0.3 \tag{4}$$

where SST is the sea surface temperature (°C) and DN is the digital number or the value of each pixel.

Chlorophyll-*a* concentration data could be obtained from the Sea-Viewing Wide Field-of-View Sensor (Sea-WiFS) monthly composite images using the following equation, also supplied by RSDAS:

$$\mathrm{CHL} = 10^{(\mathrm{DN} \times 0.015 - 2.0)} \tag{5}$$

Where CHL is the Chl-*a* concentration (μg L^{-1}).

Higher numbers of striped dolphins were generally observed in the 21–24°C range in the Mediterranean.[11]

Environmental protection from spills of hydrocarbon compound over the sea surface is currently an important subject of increasing public concern. Oil spills, depending on the exact hydrocarbon content and type, usually involve extensive areas of film on sea surface, a fact that reduces water roughness and can therefore allow the detection by synthetic aperture radar (SAR) images, providing information on location, size, distance from the land, etc.[12,13] The automatic detection of oil slicks in SAR images is not a simple task, as objects resembling oil spills (often called look-alikes) occur frequently in SAR images, especially in low wind conditions. Most frequently, look-alikes are produced by organic film, grease, wind front areas, land, plankton formations, rain cell, current shear zones, and upwelling zones. The probability of each object extracted after image classification to be an oil spill was estimated using an artificial intelligence fuzzy logic modeling system. The fuzzy logic theory has emerged as a useful tool for modeling processes that are too complex for conventional quantitative techniques, or when the available information from the process is qualitative, inexact, or uncertain. Fuzzy logic addresses qualitative information perfectly as it resembles the way humans make inferences and decisions.[14] It fills an important gap in system design methods, which is between purely mathematical approaches (e.g., system design) and purely logic-based approaches (e.g., expert systems). While other approaches require accurate equations to model real-world behaviors, fuzzy design can accommodate the ambiguities of real-world human language and logic. It provides an intuitive method for describing systems in human terms and automates the conversion of those system specifications into effective models. Traditional set theory is based on bivalent logic, where an object is either a member of a set or not. Contrary to that, fuzzy logic allows a number or object to be a member of more than one set and most importantly it introduces the notion of partial membership.[15]

Most of the oil spill detection studies use low-resolution SAR data (quick-looks) with nominal spatial resolution of 100 m×100 m to detect oil spills. Low-resolution data is sufficient for large-scale monitoring; however, small and fresh spills cannot be detected sufficiently as they are represented in very few pixels and present brighter contrast than the bigger and older oil spills. Neural networks are able to detect and classify dark formations. A neural network's ability to successfully handle nonlinearly separable classes is a big advantage against the commonly used statistical approaches.[16] The exploitation of optical satellite images allows more frequent (sometimes daily) information if compared with SAR images. However, good weather conditions and daylight are mandatory conditions for correct detection. The physical and geometrical features of an oil spill are computed by the feature extraction module for an automatic supervised classification: geometrical features (area, perimeter, and complexity of the object) and gray level features (object standard deviation, maximum contrast, mean contrast).[17] Due to its thermal inertia (lower than the sea water), oil polluted areas have a higher brightness temperature in AVHRR thermal infrared (TIR) images collected in daytime, and the opposite during the night. In fact, materials having high thermal inertia show resistance toward a change in temperature, resulting in long-term temperature stability. In daytime, an oil spill should exhibit a relatively higher brightness temperature in AVHRR TIR images as, due to solar radiation, oil becomes warmer than the surrounding water.[18] Finally, GIS can qualitatively and quantitatively characterize not only spatial and temporal distribution of oil spills but also the environmental conditions of the sea basins as a whole. Such an environment can be created by means of integration in a GIS of different databases for seawater quality, nutrient and chemical composition, and contextual information about slick position relative to surrounding objects (ships, ship lanes, rigs, platforms, natural seeps).[19,20]

Groundwater is one of the most valuable natural resources, supporting human health, economic development, and ecological diversity. Nevertheless, it is considered to be vulnerable mainly due to anthropogenic activities such as agriculture and waste disposal. Satellite data provides quick and useful baseline information about factors controlling the occurrence and movement of groundwater, such as geology, lithology, geomorphology, soils, land use/cover, drainage patterns, and lineaments. Remote sensing helps minimize the amount of field data collection in the exploration and assessment of groundwater resources, in estimation of natural recharge distribution, and in subsurface flow and pollution modeling.[21]

A pollution risk map can be obtained combined a vulnerability map with a land use map in a GIS. The vulnerability map illustrates the potential decrease of groundwater protection as a result of the flow regime toward the aquifer, analyzing the hydrogeologic and geomorphologic conditions of the basin and the isotopic ratio$^{18}O/^{16}O$ measured in the collected water samples (springs, rivers, lakes). The updated land use map is produced by satellite image data set analysis. The socioeconomic component is introduced to integrate the whole process leading to the assessment of aquifer's pollution risk, a very important element for decision making and planning.[22]

Agricultural activities have been identified as major sources of non-point source pollutants of ground and surface waters, with nitrogen being one of the most important and problematic nutrients. The use of mathematical models is a common approach for analyzing and describing the status quo, identifying interdependencies between agriculture and hydrosphere, and investigating the effects of agricultural environmental reduction measures. Satellite imagery has been used to substitute low-resolution, outdated, and inadequately differentiated land use maps with high-resolution land cover and imperviousness maps. By applying crop-specific classified satellite imagery in a semiautomated way, the nitrogen surpluses can be transferred and spatially located to main crops on the field scale.[23]

Wetlands and lakes are very sensitive ecosystems that play a key role in maintaining ecological equilibrium and biodiversity. They provide a habitat for wildlife, support a rich biodiversity, and aid in floodwater management and water quality improvement besides having esthetic and educational benefits for humans. Moreover, local economies depend on the water and vegetation of wetlands and lakes for fisheries, reed harvesting, grazing, and recreation. Unfortunately, in many countries, the extensive loss of wetlands and trophic pollution of lakes have occurred. Imaging spectrometry is a versatile tool for assessing water quality in small lakes, monitoring the variation of submerged vegetation in coastal zones, and performing ad hoc studies on transitional ecosystems as lagoons. The Chl-a and the TSS maps, obtained by combining MIVIS hyperspectral airborne data with semi-empirical modeling, confirmed the hypereutrophic-dystrophic conditions of the lakes and the elevated load of nutrient and suspended matter transported by the tributary rivers (Figure 4). The surface temperature map also revealed the discharge of warmer waters by urbanized and industrialized areas.[24] Moreover, MIVIS data demonstrates a good capacity in evaluating variations in submerged vegetation (Figure 5). Macrophyte meadows are in fact indicators of water and sediment quality, as their disappearance from many freshwater and coastal marine environments can be attributed mainly to the phenomena of eutrophication.[25] Once the models are calibrated with in situ measurements, bio-optical models may be applicable over selected lakes. They are mathematical equations that relate radiometric variables observed above or below the water surface (e.g., satellite-derived water reflectance) to the inherent optical properties (i.e., absorption and backscattering coefficients of colored dissolved organic matter and particle).[26]

In recent decades, common reeds (*Phragmites australis*) have been monitored for various purposes, including wetland management for nature conservation. Common reeds are an ecosystem with a high value of biodiversity, ideal for fish, amphibian, and bird reproduction; moreover, they function as a cleaning filter for the lake waters as they can remove up to 10%–15% of the sediment nitrogen content and subtract significant amounts of heavy metals. Lake water eutrophication has been identified as the main reason for reed die-back, while in the hotter and drier Mediterranean area, *P. australis* seems to

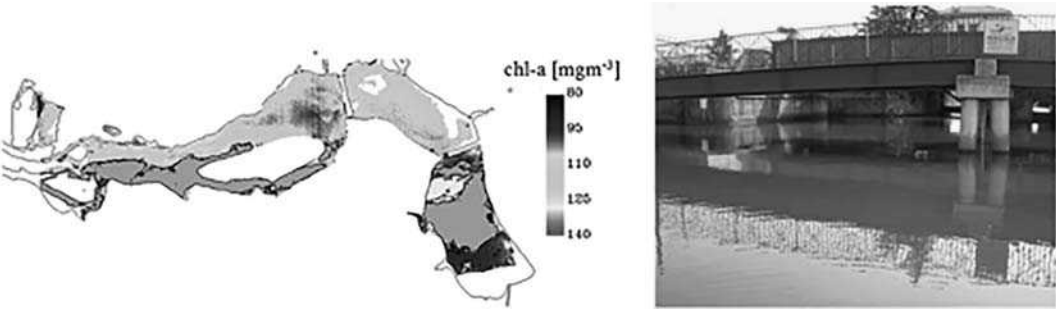

FIGURE 4 MIVIS-derived Chl-*a* maps of three lakes of Mantua, Italy. The high value concentrations are due to eutrophication caused by excessive nutrients from agricultural sources that color of green water.
Source: IREA-CNR, Milan, Italy.

grow vigorously and to expand, even in eutrophicated areas. High normalized difference vegetation index (NDVI) values highlight greater amount of reed biomass that is the result of the higher germinative capacity in optimal environmental conditions.[27]

Land

As for land, ecosystem vegetation plays a fundamental role in the energy and mass exchange between land surface and atmosphere, and can be considered a good indicator of environmental stress. Environmental health conditions, stand structure, damage levels, and other phenomena can be determined using satellite images.[28] The spectral vegetation indices are used to investigate changes in plant stress due to soil contamination. A vegetation index combines two or more spectral bands to enhance the vegetative signal while minimizing background effects; they are commonly used to measure the sensitivity of vegetation to stress. As hyperspectral RS images are increasingly becoming available, further exploration of the increased number of spectral variables is a logical step.[29]

Canopy leaf area index (LAI) is typically defined as the one-sided area of green foliage projected onto a unit area of ground. The LAI is critical in estimating terrestrial carbon sequestration, net primary production, hydrologic watershed budgets, and pollutant deposition. The LAI retrieval method is based on an analytical solution to a multiple scattering equation. The algorithm uses different input data layers to produce a single LAI map: reflectance in the red and NIR bands, satellite zenith view angle, solar zenith altitude angle, sun sensor relative azimuth, and terrain characteristics (elevation, slope, and aspect).[30] A simplified approach uses a semi-empirical regression model between ground measurements and spectral vegetation indices (VIs), such as band ratios or normalized band difference, computed from remotely sensed images.[31,32]

Atmospheric composition affects reflectivity of the spectrum and makes it difficult to compare satellite images from different seasons. To reduce impacts from the atmosphere, the normalized ratio vegetation index (NRVI) has been applied to satellite imagery to study Chl-*a* concentration.

For Landsat ETM/TM, TM3 is a main band for absorbing the spectrum from Chl-*a* and is represented by the red band with a wavelength range varying from 630 to 690 nm. TM4 is an NIR band with a wavelength range varying from 760 to 900 nm. The band is sensitive to the category of green vegetation and is therefore often used for detecting green vegetation. Based on the characteristics of the two bands, three VIs could be selected for RS analysis: NDVI, ratio vegetation index (RVI), and NRVI, all of which are relatively simple in arithmetic and widely used.

The equation of the RVI is

$$\mathrm{RVI} = \frac{\mathrm{TM3}}{\mathrm{TM4}} \tag{6}$$

The equation of the NDVI is

$$\mathrm{NDVI} = \frac{\mathrm{TM4} - \mathrm{TM3}}{\mathrm{TM4} + \mathrm{TM3}} \tag{7}$$

The equation of the NRVI is

$$\mathrm{NRVI} = \frac{\mathrm{RVI} - 1}{\mathrm{RVI} + 1} \tag{8}$$

The NRVI has a positive correlation with Chl-*a* concentration, while NDVI has a negative correlation. Correlative degrees between NRVI and Chl-*a* are also much higher than that of NDVI, showing that the obtained regressions capture the relation between the water quality parameters (nutrient pollution loaded mainly with agricultural wastewater, phosphorous pollution loaded mainly with runoff from forest areas, pollution loaded with a mixture of domestic and industrial wastewater, and agricultural runoff and natural lake water) and the band reflectance values.[33]

Change in leaf spectral reflectance is a symptom of deteriorating forest health. Increase in red reflectance due to reduced chlorophyll absorption, decrease in NIR reflectance due to reduced cell vigor, and shifts in the red edge between these two regions have been commonly used as indicators of leaf stress.[34]

Topography also plays an important role in vegetation sensitivity to air pollution. In general, elevated and wind-ward sites appear to be more affected than depressed and leeward locations. Consequently, wind direction could apparently be more important than topography.[35] Using RS techniques to achieve a detailed analysis of the type and status of vegetation can help us understand the fate of persistent organic pollutants (POPs) in the environment. These POPs are generally bioaccumulated in the food chain and affect living organisms owing to their long persistence and toxicity. Forests play a key role in the environmental distribution of POPs since they act as filters of these chemicals, trapping them in the air compartment and transferring them to forest soils, consequently decreasing their atmospheric half-lives. Therefore, it is necessary to include the vegetation compartment in multimedia models, to understand and predict the fate of these substances in the environment. Multimedia models used to study the fate of POPs and their redistribution in different environmental compartments, from the atmosphere to soil or water via vegetation interface, require foliage biomass information. Foliage biomass (FB) is estimated with the following model:

$$\mathrm{FB}_i = \mathrm{LAI}_i \times \frac{1}{SLA_i} \times \left(\frac{\mathrm{FW}}{\mathrm{DW}}\right)_i \tag{9}$$

where $\mathrm{FB}_{i;}$ is the foliage biomass of vegetation class i (kg m^{-2}), LAI_i, is the leaf area index of vegetation class i, SLA_i,· is the specific leaf area (m^2kg^{-1}) of vegetation class i, and $(\mathrm{FW/DW})_i$, is the relative ratio between fresh and dry biomass weight of vegetation class i.[36]

Natural fires and arson greatly affect forests, vegetation, and the environment in general (Figure 6) Mercury (Hg) emissions from fires may be also detected directly using reflectance spectroscopy, field

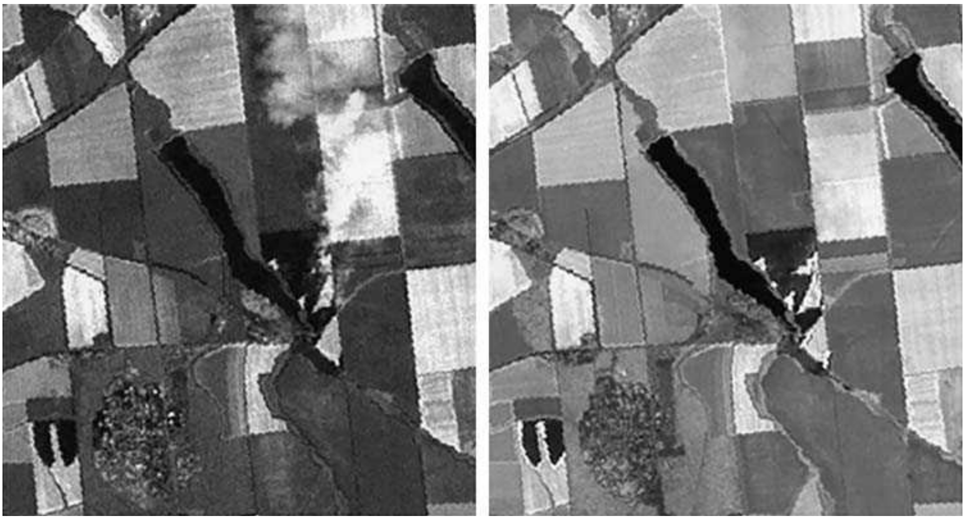

FIGURE 6 False-color Landsat-7 images taken over Ukraine on July 2001, illustrating the different possibilities in identifying agriculture fires. Left: RGB natural color composition of visible band highlights fires smoke, its intensity and direction, and burned areas. Right: RGB false color composition of visible, and infrared bands, identifies active fires and burned areas.
Source: IREA-CNR, Milan, Italy.

sampling, and laboratory analysis; however, many contaminated regions are covered by vegetation. The Hg released to the atmosphere from vegetation is primarily related to Hg concentrations in foliage. It varies with tissues of plants—predominantly leaves, bark, and root—foliar age, forest typologies, and soil characteristics.

Satellite observations were used to assess Hg emissions through the assessment of spatial and temporal distributions of forest phytomass content and forest burnt areas.[37] Plants with the greatest amount of foliar Hg showed symptoms of stress earlier than plants of other treatments. Foliar Hg appears to influence spectral reflectance at several specific regions of the electromagnetic spectrum. The red edge position is the wavelength of the maximum value of the first derivative of the spectra in the 680–740 nm region and is positively related to chlorophyll concentration and biomass of leaves and canopies.[38] Shifts in vegetation spectra, occurring in both the visible and the NIR part of the spectrum, could be metal induced due to geochemical stress or the presence of old waste deposit sites.

Mining activities, such as coal, are often responsible for environmental pollution. Consequently, the forest patches near the mining sites have been badly degraded, whereas patches away from the mining sites registered relatively less impact. The degree of degradation was based on density, canopy structure, ground flora, and soil conditions (presence of ash and pollutants). The prime reason of these changes can be attributed to the discharge of noxious/toxic gases and particulate matter during drilling, blasting, and loading/unloading operations. It has been recorded that the areas near the industrial area and affected areas hold fewer plant species than that of areas far away from these site. Variation in number of herbs per unit area was found to decrease significantly when approaching mining sites.[39]

Urban green spaces provide a variety of functions essential for improving the quality of citizen life, while urban heat island tends to aggravate the negative effects of climate over urban areas and their surroundings.

Using NDVI multitemporal image differencing it is possible to detect subtle changes and to discern "from–to" changes using a postclassification comparison.[40]

Land surface temperature (LST) retrieved by RS is an important parameter in characterizing surface energy balance and a key parameter in monitoring farming drought, and very significant in studies of global change, meteorology, hydrology, ecology, agricultural, etc. Results reveal that LST is significantly different in various types of land use, the highest is bare land; the second is built-up land; followed by cropland, grass, and forest; and at the lowest in water.[41]

City growth is increasing population and the change of land cover types from permeable to anthropogenic impervious surfaces. Impervious surface area (ISA) is defined as constructed surfaces—roofs, roads, parking lots, driveways, and sidewalks. Impervious surfaces can alter the natural hydrological condition by increasing the volume and rate of surface runoff and decreasing groundwater recharge and base flow. Pollutants either dissolved or suspended in water, or associated with sediment including nutrients, heavy metals, and oil and grease, can accumulate and wash away from ISAs. The percentage of impervious surface estimated from satellite RS data can be used to assess the spatial extent of urban land use, as well as urban development density.[42]

Building energy saving is defined as the rational use of energy and constant improvement of energy efficiency under conditions that guarantee and improve the comfort of the building. Using Landsat TM thermal data, surface radiance values for each scene pixel were calculated with the use of calibration coefficients to identify build structure, building material, vegetation, and heating methods.[43]

Night light emissions that originate mainly from large urban areas are among the main elements of environmental pollution: disturbance of biological rhythms, psychological effects, and environmental degradation. The Defense Meteorological Satellite Program, run by the NOAA, has the capability to detect faint sources of visible near infrared (VNIR) emissions on the earth's surface, making it possible to detect cities and towns. Modern GIS packages offer advanced tools for visibility analysis, including line-of-sight estimations and viewshed mapping. The viewshed identifies the cells in an input raster that can be seen from one or more observation points. Moreover, it is possible to identify areas affected with indirect light pollution.[44]

Unlike the United States, where the use of asbestos is still legal but tightly controlled, on January 1, 2005 (following the directive 76/769/CEE), the marketing and use of products containing asbestos was banned through-out the European Union. Prohibition is due to the possible diffusion of asbestos fibers into the environment constituting a health hazard leading to asbestosis (mesothelioma) cancer. Hyperspectral sensors, characterized by a high spectral and/or spatial resolution, allow reliable quantitative measurements of specific absorption features of urban materials. Spectral analyses can distinguish the asbestos spectrum shape from other roofing materials and backgrounds. Moreover, the classification of the TIR emissivity dataset permits good discrimination between buildings and open spaces and among different roof types, even though residual false positives were still present due to difficulties in the temperature/emissivity separation procedure.[45]

Around oil fields, a considerable part of lighter hydrocarbon fraction normally evaporates, while the remaining fraction in liquid form could be partially recovered. The scars of the damage caused by the spillage of oil remains as soot, tarmats, and tarcrete, which are unrecovered denser hydrocarbon fractions. The surface area covered by the "oil lakes" continues to shrink visibly, leading to the suggestion that there is a disappearance of oil-polluted surfaces. However, thermal RS data provides evidence that the spatial spread of hydrocarbon-contaminated surfaces is much more than previously reported. The addition of hydrocarbons alters soil composition, and these compositional changes are reflected as temperature variations. Landsat TM data has been processed to obtain the LST. Emissivity affects the apparent temperature due to changes in the thermal properties of materials (conductivity, density, capacity, and inertia). The effect of darkness will not affect the LST observations, so waste dumping during night-time can be easily identified for pollution control and environmental management.[46]

Kuwait's oil lakes and oil-polluted surfaces were an act of sabotage imposed on the desert environment during the 1990 to 1991 Arabian Gulf War. The oil formed networks of oil rivers and lakes that accumulated around oil wells and in relatively low areas. The majority of Kuwait's producing oil fields have high reservoir pressures that maintain natural flowing oil from the reserves to the surface. During the 10 months of oil fires, some of the oil fields, especially the Greater Burgan, were more or less inundated with crude oil. The interpretation of high-resolution satellite imagery (Landsat TM, Spot, and Indian Remote Sensing IRSI) shows that contaminated areas demonstrated remarkable resilience, in terms of vegetation growth, seven years after the burning of the oil wells, with increased rainfall from 1991 to 1995. The stabilization of the top sandy soil with tarmat and soot prevented the blowing away of plant seeds, and therefore increased the chances of vegetation growth. The soot, which later turned into black soil, did not appear to be a hindrance to vegetation growth. Oil lakes, tarmats, and black soil continue to decrease and are not always readily observed on the surface. However, harmful chemicals remain in the soil.[47]

In understanding environmental contamination/pollution, one must understand the trajectory of heavy metals in different environmental compartments, which can be seen as different morphological regions (relief forms) shown in RS images. A digital terrain model, generated from the available stereo-pair bands of the ASTER image in the VNIR system, helps aid visualization and interpretation through 3-D observation of different rock types, as well as geomorphometric information (elevation, declivity, and aspect) of the slopes, which potentially reside in, feed, and conduct the landfill wastes.[48] The GIS and RS have an important role in the linkage and analysis of changes in land use-land change (LULC) patterns data, in particular for detection (direct and indirect), extrapolation and interpretation, area calculation, and monitoring. Information on LULC changes is required to achieve environmentally sound management and decision making for future developments.[49]

Air

Over recent years, Earth observation (EO) satellite sensors sent into orbit with improved temporal and spatial resolution, together with enhanced radiometric accuracy, has led to the possibility of using satellite data within the framework of air quality analysis. In this context, the synoptic view and the daily/hourly repetition cycle of satellite observations can provide the monitoring of transboundary air pollution. Moreover, they can allow estimates of air pollutant concentration fields characterized by a more homogeneous spatial distribution and with a more complete coverage of the domain of interest with respect to those carried out by sparse in situ samplings. The processing of the radiance measured by satellite sensors in the spectral range from 0.4 to 2.1 μm supplies information on the atmospheric aerosol loading in terms of columnar aerosol optical depth (AOD) or aerosol optical thickness (AOT) as a measure of light extinction by aerosol in the atmosphere (typically at 0.55 μm), during their overpass time.[50]

Low and moderate spatial resolution satellite sensors have already shown their capability in tracking air pollution in general and aerosols particularly at a global scale. Sensors with moderate to high spatial resolution (such as MODIS and MERIS) seem also to be appropriate for aerosol retrieval at a regional scale by using the differential textural analysis (DTA) code. The DTA code quantifies the contrast reduction as local "textural degradation" on geometrically and radiometrically corrected satellite images.

The code, applied to a set of geo-corrected images, is able to retrieve and map AOT values relative to a reference image assumed to be clean of pollution with a homogeneous atmosphere.[51] As the total atmospheric optical thickness depends on molecular structure (Rayleigh scattering) and aerosols, it is possible to separate the contribution of the "natural" atmospheric molecules from "contaminants" such as aerosols. The AOT can be defined as the integrated extinction coefficient over a vertical column of unit cross section of atmosphere.

Aerosols smaller than the wavelength of satellite sensors cannot be detected, so only coarse particles more than a few micrometers can be detected by MODIS bands. Band combinations of 1, 3, and 7 of MODIS image were used to extract maps of aerosols. Bands 1 and 3, covering the optical region of the electromagnetic spectrum (0.459–0.876 μm), are used to collect information on aerosols and particulate matters, while band 7 covering the infrared region (2.105– 2.55 μm) is used for calibration purposes only.[52]

Aerosol optical thickness in the visible (or atmospheric turbidity) can be considered as an overall air pollution indicator in urban areas, among others, because during photochemical pollution episodes, light extinction is due to particles, while only the yellow-brownish coloration of smog is due to NO_2. Moreover, the presence of particles in the atmosphere always causes an increase of the extinction coefficient, which is strongly correlated with small particle concentration.

Atmospheric turbidity, which expresses overall particulate pollution levels in urban areas, can be extracted by comparing multitemporal high-resolution data. The main prerequisite to carry out this comparison is that no change has arisen in the ground intrinsic reflectance between the data sets used. The noise introduced by changes in ground reflectance is reduced by the combination of two complementary procedures based on physically independent optical effects that are induced by the aerosols in different spectral areas.[53]

Vegetation fire is a global phenomenon that affects large areas and a variety of biomes of the world, from circumboreal forests to the tropical belt through the woodland and shrubland of temperate regions.[54] Since the late 1970s, prescribed and wild vegetation fires have been recognized as a major source of atmospheric trace gases and aerosol particles that affect the composition of the atmosphere, the global climate, and air pollution.[55] In an exceptional event, large vegetation fires raged throughout the Indonesian archipelago in 1997 and 1998, causing a smog blanket that covered more than 3 million square kilometers, with economic losses estimated at over U.S. $4.5 billion.[56] Both active fires and the extent of burned areas can be observed from satellite. Fire radiative power is measured over active fires, and is provided by the MODIS sensor and by the SEVIRI (Spinning Enhanced Visible and InfraRed Imager) sensor onboard the Meteosat Second Generation satellite. Fire radiative power is a very good candidate for any assessment of emission from fires, although it relies on active fires observed by the EO systems, which are a temporal sampling of burning activity. It is consequently possible to highlight similarities and differences in the seasonality and geographical distribution of emission at the global and continental levels.[57] In addition to direct damage on vegetation, devastating fires produced large quantities of gaseous air pollutants and particulate matter (PM_{10} and $PM_{2.5}$, airborne particles smaller than 10 and 2.5 mm in size, respectively) dispersed over the surrounding region, increasing respiratory diseases, asthma, bronchitis, and eye irritation.

The MODIS sensor can measure aerosol abundance and size over land and water with nearly global coverage at moderate spatial resolutions. In addition, MISR (Multiangle Imaging SpectroRadiometer), on board the EOS satellites, is able to provide information on aerosol type and plume top heights. Particle information retrieved by satellite sensors may be suitable for monitoring the spatial and temporal trends of particle concentrations over large geographical areas.[58] The MODIS aerosol optical properties were used in a semi-empirical approach to estimate $PM_{2,5}$ content at ground level. Comparison with daily $PM_{2,5}$ sampled on the ground showed good agreement, with the satellite-based concentrations tending to underestimate the values by at most 20%.

Substantive results suggest that changes in AOD have a significant impact on infant mortality due to respiratory diseases, providing evidence that air pollution's adverse effects, although nonlinear, are not only present in large cities, but also in lower pollution settings that lack ground measures of pollution. A lack of reliable measures of air pollution across wide geographic areas hampers research on pollution's effects on health.[59] Meteorological parameters (air pressure, air temperature, relative humidity, and wind velocity) can influence the estimation of PM from MODIS AOT data. Air quality is usually monitored at fixed ground stations. Although ground measurements are able to indicate the concentration level of air pollutants and their temporal variations precisely, this method of monitoring is limited by its huge expense and sparse spatial coverage. To complement these sparse precise measurements with the estimates derived from satellite, it is more reliable to monitor PM10 from MODIS AOT data at a high temperature and relative humidity, but at low pressure and wind velocity. There is an inverse relationship between the pollution level and the accuracy at which it is monitored from the MODIS data. These findings should serve as useful guidance in selecting the appropriate meteorological conditions under which air pollution can be monitored reliably from MODIS AOT data.[60]

The problem of particulate pollution in the atmosphere has attracted new interest given the recent scientific evidence of the ill-health effects of small particles. Aerosol optical thickness in the visible (or atmospheric turbidity), which is defined as the linear integral of the extinction coefficient due to small airborne particles, can be considered an overall air pollution indicator in urban areas. Reflectance in the visible bands measured by satellite can be used to derive the PM10. In fact, the reflectance at the TOA (top of atmosphere) measured from the satellite is subtracted by the amount given by the surface reflectance to obtain the atmospheric reflectance. The atmospheric reflectance derived from Landsat TM signals can be used as independent variables in a calibration regression analysis to measure the PM10 values.[61]

Using meteorological and other ancillary datasets, an empirical relationship between AOT and $PM_{2.5}$ mass can be obtained, assessing the effects of wind speed, cloud cover, and mixing height on particulate matter air quality. The analysis shows that the $PM_{2.5}$–AOT relationship strongly depends on aerosol concentrations, ambient relative humidity, fractional cloud cover, and height of the mixing layer.[62]

Ground level observations indicated that PM concentration varies widely across different regions, which was mainly due to the difference in weather conditions and anthropogenic emissions. Results showed that MODIS AOD had a better positive correlation with the coincident hourly average PM concentration than with daily average, due to diurnal variation in PM mass measurements. After correcting AOD for relative humidity, the correlation did not improve significantly, suggesting that the humidity was not the main factor affecting the correlation of PM with AOD. The statistical regression analysis between MODIS AOD and PM mass suggested that the satellite-derived AOD is a useful tool for mapping PM distribution over large spatial domains.[63]

A recent method for multi-objective optimization of air quality monitoring systems based on satellite RS of the troposphere uses atmospheric turbidity as a surrogate for air pollution loading. The values of AOD have been extracted by images obtained by sensors on board in-polar-orbit Earth satellites (specifically SPOT 5 and Landsat 7) at the time of their daily overpass. Through an image-processing algorithm, the spatial distribution of optical depth over the whole area is obtained. Assimilating the optical depth field with the field of the mixing layer height, the scattering coefficient of the lowermost part of tropospheric aerosol was reckoned. A physico-chemical and multiphase thermodynamic equilibrium model was used to estimate the secondary aerosol formation and primary aerosol. Using non-linear multiple regression, the experiential relationship between the scattering coefficient of primary and secondary aerosol, its ambient air concentration, and relative humidity can be calculated.[64]

Ozone (O_3) is one of the most dangerous of the phytotoxic air pollutants. Its effects on plants include reductions in photosynthesis, visible leaf injury, growth limitation, and accelerated senescence. Advanced RS techniques using hyperspectral sensors demonstrated the feasibility of detecting the stress in its early phase by monitoring excess energy dissipation pathways, such as chlorophyll fluorescence and non-photochemical quenching.[65] The total ozone mapping spectrometer (TOMS) measures the reflected spectrum from the earth to estimate total column ozone thickness, including maps of erythemal (biologically damaging) UV reaching the earth's surface. Recently, TOMS has been replaced by the ozone monitoring instrument (OMI), which is on board the NASA satellite Aura. The OMI can distinguish between aerosol types such as smoke, dust, and sulfates, and can measure cloud pressure and coverage, providing data to derive tropospheric ozone.[4]

An important indicator for volcanic activity is the emission of trace gases such as sulfur dioxide (SO_2). During an eruption, SO_2 is the third most abundant gas found in volcanic plumes, after H_2O and CO_2. Changes in SO_2 flux can be a precursor for the onset of volcanic activity. In addition, SO_2 is also produced by anthropogenic activities such as power plants, refineries, metal smelting, and the burning of fossil fuels; however, its atmospheric background level is usually very low. Satellite-based instruments operating in the UV spectral region have played an important role in monitoring and quantifying volcanic SO_2 emissions. The TOMS was the first satellite instrument to detect volcanic SO_2 released during the El Chichon eruption in 1982. The detection limit to measure volcanic and anthropogenic SO_2 greatly improved for the Global Ozone Monitoring Experiment (GOME), on board the ERS-2 satellite, and the Scanning Imaging Spectrometer for Atmospheric Cartography (SCIAMACHY), on board the ENVISAT satellite. Last but not least, the Infrared Atmospheric Sounding Interferometer (IASI) on MetOp-A is also able to detect SO_2 with an excellent global coverage in combination with small footprints. Satellite-based observations provide valuable information for detecting and tracking eruption plumes, and therefore minimize the risk of aircraft encounter with hazardous volcanic clouds. GOME-2 has higher sensitivity, especially for SO_2 at lower altitudes, whereas IASI also offers night-time observations, a higher spatial resolution, and an estimation of the altitude of the plume. With commercial and freight air traffic growing globally, the risk of aircraft encounter with hazardous volcanic clouds is increasing, as many volcanoes are not regularly monitored and atmospheric winds can rapidly distribute ash and gas.[66] In fact, once aloft, winds can transport the ash and gases rapidly and in multiple directions, depending on the wind speed and wind shear (the change in wind direction with height). The ash can cause extensive damage to aircraft, stalling engines, abrading windscreens and damaging sensitive avionics equipment. Volcanic gases, specifically SO_2, may also pose a hazard to aircraft, and because gas and ash have different specific gravities they may separate and travel at different speeds and heights in a sheared atmosphere.[67] The 2010 eruptions of the volcano Eyjafjallajökull in Iceland, which, although relatively small for volcanic eruptions, caused enormous disruption to air travel across western and northern Europe. About 20 countries closed their airspace (a condition known as ATC Zero), and it affected hundreds of thousands of travelers.

Conclusion

Remote sensing is nowadays the most applicable tool not only for detection, monitoring, and tracking of pollutants, but also for damage assessment where damage is demonstrable by its effect on the environment.

There is a physical limitation that can never be overcome. Taking marine pollution as an example, it is only possible to differentiate between surfaces (i.e., oil slick and clear water) if they reflect or emit radiation in different proportions; that is, if they have different spectral signatures. This physical limitation means that toxins in water, for example, cannot be detected unless they have an effect on something that is "visible" to the sensor, such as phytoplankton. Another limitation is that electromagnetic radiation has very little power to penetrate objects; for example, it is almost entirely absorbed at the water surface for wavelengths of NIR and longer, and can only penetrate a matter of meters (approximately 15–30 m for very clear water) in the visible wavelengths. This means that RS can only operate on the surface skin of oceans and seas. Fortunately, this is where most marine pollution is focused.[68]

Recent developments in microwave RS, theory, and sensor availability have resulted in new potential and capabilities, such as the ability to extract/detect subsurface parameters and features using these techniques. More and more research is required to refine and implement these approaches. Consequently, there is a need to develop an optimal sensor system including both active and passive microwave techniques for more effective monitoring of the environment. It will allow a range of applications and the synergism of the two types of measurements to provide more useful and new information. Such studies will not only enhance and refine RS applications in environment studies, but will also significantly contribute to the sensor development program.

Finally, the integration of expert systems and spatial decision support systems with GIS is a very interesting area of research, aiding effective and timely decision making concerning the planning, design, analysis, operation, and maintenance of environmental resources systems. Moreover, these tools can greatly reduce the time and effort required in traditional approaches, automating the process of solving pollution problems and helping the selection of cost-effective management alternatives.

Solid Waste Management: Life Cycle Assessment

Ni-Bin Chang,
Ana Pires, and
Graça Martinho

Introduction

In the end of 2005, the European Commission (EC) published a proposal for a directive on waste [COM (2005) 667,[1] which resulted in the publishing of the new Waste Framework Directive[2]] that is currently under implementation in European institutions. One element of the proposal is the establishment of a hierarchy of principles (i.e., waste hierarchy principle hereafter) to be applied for waste management. The commission proposal includes the following reference to the hierarchy:

> The Member States are to take measures, as a matter of priority, for the prevention or reduction of waste production and its harmfulness and, secondly, for the recovery of waste by means of re-use, recycling and other recovery operations.

It provides for a flexible application of the hierarchy and does not explicitly make a suggestion between the d…l/l/l/l/k,ifferent recovery options such as reuse, recycling, and recovery of energy, making the policy blurred. Later on, with the publishing of the new Waste Framework Directive 2008/98/EC,[1] resulting from COM (2005) 667, a five-step hierarchy was proposed to encourage the member states in the EC to take measures, as a matter of priority, for the following: 1) prevention; 2) preparing for reuse; 3) recycling; 4) other recovery, e.g., energy recovery; and 5) disposal. The waste hierarchy principle for prioritizing waste management options has touched the base of pollution prevention and resource conservation. Yet recent climate change impacts and resource scarcity made some of these options for solid waste management (SWM) no longer risk informed and forward looking. As a consequence, another amendment was introduced that seeks to support the flexibility of the waste hierarchy principle by stating the following:

> When applying the waste hierarchy [...], Member States shall take measures to encourage the options that deliver the best overall environmental outcome. This may require specific waste streams departing from the hierarchy where this is justified by life-cycle thinking on the overall impacts of the generation and management of such waste."

Given that extensive studies are required to deviate from the hierarchy, modern sustainable SWM strategies must be tied to an all-inclusive assessment metrics covering socioeconomic aspects, cost–benefit analysis, technical feasibility, public health requirements, environmental impacts, ecological footprint, carbon footprint, and even sociopolitical considerations. Hence, sustainable SWM has been deemed as a renewed paradigm, in which understanding how sustainable decisions in association with life cycle assessment (LCA) can be reached in a societal context becomes a critical task.

Multicriteria decision making (MCDM) processes have been helpful in translating the features of real-world problems to decision-making processes. The problems of MCDM can be broadly classified into two categories: multiple-attribute decision making (MADM) and multiple-objective decision making (MODM). The main features that differentiate both methods are the type of criteria (attributes or objectives) and the number of alternatives. Whereas MADM has a finite number of alternatives, MODM has an infinite number of alternatives. With the prescribed waste management alternatives in our study by which the salient features for sustainable SWM can be retrieved distinctly, MADM was thus selected to aid in our decision analysis. To explore the decision making with respect to a suite of criteria, this entry presents a comparative study through two different MADM approaches for the purpose of demonstration. They include the simple additive weight (SAW) and the technique for order preference by similarity to ideal solution (TOPSIS). The practical implementation was assessed by a case study in Setúbal peninsula, Portugal, where there is an acute need to improve the quality of SWM to achieve a sustainable solution.

Life Cycle Assessment for Solid Waste Management

Life cycle assessment is a compilation and evaluation of the inputs, outputs, and potential environmental impacts of a product system throughout its life cycle.[3] Thus, LCA is a tool for the analysis of the environmental burden of products at all stages in their life cycle—from the extraction of resources, through the production of materials, product parts, and the product itself, and the use of the product to the management after it is discarded, either by reuse, recycling, or final disposal (in effect, therefore, "from cradle to grave").[4]

The concept of LCA was produced in the 1960s as a way to cumulatively account for energy use leading to the projection of future resource supplies and demand.[5] Since the 1990s, LCA has been applied in a broad range of different fields including SWM. The ISO 14040 standard[3] points out the main areas of application of LCA, including the identification of improvement possibilities, decision making, selection of relevant environmental performance indicators, and marketing. The most influential momentum in the context of ISO 14040 applied for SWM is to explore how the decision-making processes in a social context can make the final option different.

The salient use of LCA for SWM was conducted in Denmark, aiming to meet the need to properly manage the packaging waste embedded in the packaging materials.[6–10] Life cycle assessment may also be applicable in conducting intercomparisons among waste treatment alternatives for specific waste streams, such as recycling of cardboard[11] and recycling vs. incineration of scrap paper.[12] Earlier applications of LCA for SWM focused on the evaluation of waste hierarchy principle in some industrialized countries during 1990.[13] In the literature,[14] it is clear that waste hierarchy principle cannot be used to substitute thorough assessment in most cases. Once LCA is capable of promoting a holistic view of

SWM, several combinations of different technologies can be meaningfully applied to support essential SWM against the contradictory suggestions in early waste hierarchy paradigm. For this reason, LCA has been recommended by the European Union Waste Framework Directive[2] to verify if waste hierarchy principle is the best solution, particularly from the environmental point of view.

The applications of LCA tools for waste management appeared mainly in Europe and United States for the screening of technologies under the umbrella of the integrated solid waste management (ISWM) systems. Several LCA models were tailored specifically for ISWM systems, and examples may include but are not limited to WISARD,[15] IWM,[16] WASTED,[17] and EASEWASTE.[18] Specifically, the IWM versions 1 and 2[19,20] for SWM systems provide life cycle inventory (LCI). The models enabled decision makers and waste managers to use an LCA for assessing their specific waste management configurations without in-depth knowledge of the theory and methodology and allowed them to learn how changes in the system could affect the environmental impacts through scenario analysis.[21] However, generic models, like UMBERTO, Gabi, and SimaPro, were applied to SWM, with raising potentials concerning SWM specificities.[22] Besides, extended tools focusing specially on the possible impact of economic features on decision-making process were developed. In United States, for example, the municipal solid waste – decision support tool (MSW-DST) developed by the Research Triangle Institute and United States Environmental Protection Agency,[23,24] where the environmental methodology is based on the use of LCA and the cost methodology with respect to the full-cost accounting, became available in the 2000s.

Application of LCA in SWM systems has also been promoted through the combination with other systems analysis tools to reach a sustainable decision. In this field, LCA was combined with site-dependent and qualitative approaches to evaluate waste-to-energy taxation.[25] Life cycle assessment and strategic environmental assessment were integrated to assess economic and environmental impacts for weight-based tax in waste incineration.[26] The ORWARE model, developed by Dalemo et al.,[27] Björklund, Dalemo, and Sonesson,[28] and Eriksson et al.[29,30] combines LCA with a simulation tool and material flow analysis. Solano et al.[31,32] developed a model for ISWM to obtain the best solution through LCA and an optimization model for balancing economic and environmental considerations. From the previous review,[22] it can be summarized that LCA results have been capable of changing packaging and packaging waste management, influencing the selection of waste treatment technologies, affecting regulation assessment, challenging waste hierarchy paradigm, increasing knowledge, and developing tools and methods for decision support. Those systems analysis models can be flexibly woven to deal with SWM issues with varying features, and more discussion can be seen in the work of Harrison et al.[33] and Chang, Pires, and Martinho.[22]

Regardless of these cases above where LCA was applied in a variety of SWM systems, it is important to understand how LCA could influence the decision making in many SWM systems and, especially, the decision-making process. The methodology capable of linking different criteria is MADM, such as the applications in the work of Kijak and Moy,[34] Contreras et al.,[35] and Skordilis,[36] all of which can pro mote the understanding in decision making for SWM.

Study Area and System Description

The Setúbal peninsula is located in the district of Setúbal, covers an area of 1522 km^2, and has 714,589 inhabitants.[37] The area is divided into nine municipalities, as shown in Figure 1. The nine municipalities have associated to manage their municipal solid waste (MSW), on a regional scale. AMARSUL company is owned by the local municipalities and is responsible for managing the MSW system since 1997. The SWM system is composed of nine recycling centers, two material recovery facilities (MRFs), two landfills, one transfer station, and one aerobic mechanical biological treatment (MBT).

Nowadays, this SWM system keeps on promoting the separation of paper/cardboard, glass, and light packaging (plastics, metals, and composite packaging) waste by means of curbside recycling systems. Each type of waste is collected separately in three specific containers and then directly sent to the MRF

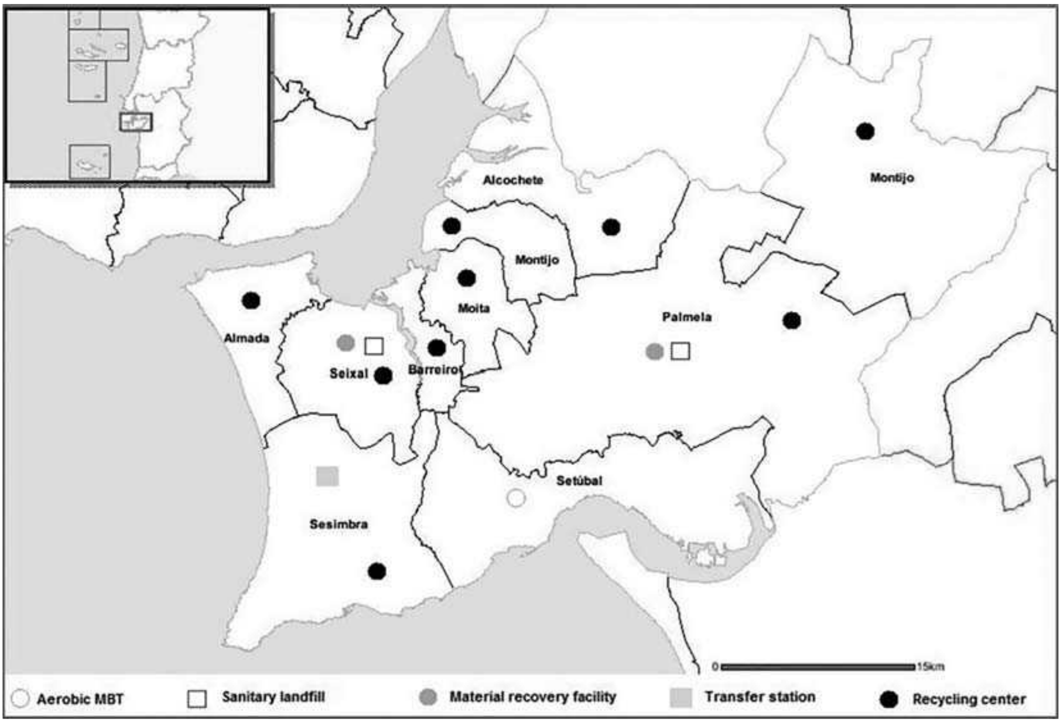

FIGURE 1 The geographical location of the Setúbal peninsula SWM system.

for recycling, recovery, and reuse. The remaining waste fractions are then collected through a door-to-door and/or bin collection scheme, which is destined for final disposal at landfills. In the case of the Sesimbra municipality, the waste stream is first sent to the transfer station, which is then followed by the final disposal at sanitary landfills. Yet the residual waste after waste separation and recycling collected from the Setúbal municipality is transported to an aerobic MBT plant, where the "stabilized residue" can be produced as fertilizer to be applied as agriculture soil-amendment materials.

Within this MSW system, there is a recent need to make some changes in order to comply with the Packaging and Packaging Waste Directive[38] and Landfill Directive.[39] The National Plan for MSW (i.e., designated as PERSU II) has decided to pursue the construction of several more MBT units. An anaerobic digestion (AD) MBT unit, with a mechanical treatment to separate recyclables and high-calorific material to produce refuse derived fuel (RDF), is predicted. It is expected that the unit will work with two separate lines, in which one is related to the biodegradable municipal solid wastes (BMW) and the other is for the residual waste streams. The RDF may be combusted in an incinerator to generate electricity. The existing aerobic MBT plant will be maintained as usual. It is expected that both MRF plants (manual sorting) will be substituted by two automated units.

The schematic of the SWM to be analyzed can be shown in Figure 2, which generally covers all stages of SWM involved, from raw waste pickup to the delivery to bins, to some intermediate processing units, and to the final disposal at landfills. Both AD MBT lines are represented as two separated processes.

These SWM processes include collection and transportation of residual waste and recyclables, waste treatment, waste transport from waste treatment facilities to final destination, energy-from-waste or waste energetic recovery (ER), and landfilling. Several final destinations for recyclables are located in Spain rather than Portugal, specifically for composite packaging and ferrous and nonferrous metal packaging materials.

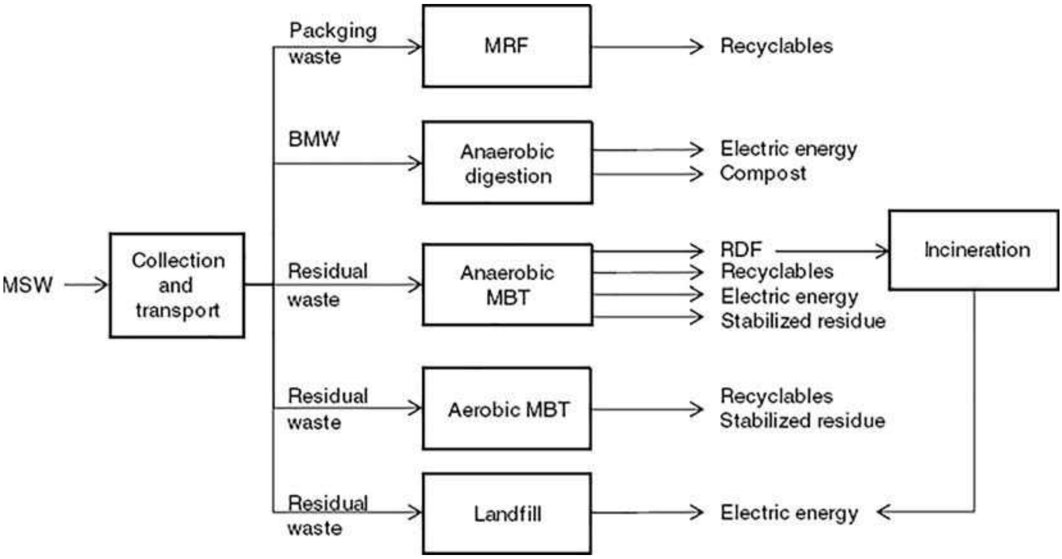

FIGURE 2 The schematic of the SWM system at Setúbal Peninsula.

Based on this system, Table 1 presents the 18 management alternatives for assessment plus the actual situation (base scenario). Those alternatives include waste collection and separate recycling of the three packaging materials through bin systems, which handle 12.4% of the current MSW in the study area. This MRF system is responsible for the compliance with the prescribed target in the Packaging Waste Directive.

Alternative 0 refers to the predicted change that will take place in the Setúbal peninsula waste management system. The remaining alternatives were designed to examine some special options for complying with the Landfill Directive. For example, alternative 1 emphasizes the inclusion of aerobic MBT; alternative 4 signifies the use of AD MBT; alternative 6 examines the specific case of using a BMW AD line. In general, alternatives 0, 3, and 5 are options for differing intermediate processing. Separation of the high-calorific fraction of waste for ER was considered through the production of RDF and the direct burning of the high-calorific fraction in municipal incinerators.

The 18 alternatives of SWM were assessed by considering two scenarios:

- *Baseline scenario*: Targets may be reached without systematic involvement and evolution, meaning that targets fulfillment can be promoted by several external agents such as government, the Green Dot Society (Sociedade Ponto Verde), and promotion campaigns that motivate a better environmental consciousness. The system may be financed by using water consumption tax for waste management to be included in the water billing system.

TABLE 1 The Distribution of Waste Streams Associated with Each Alternative in the SWM System

	Alternatives							
Fraction (%) Option	0/0[a]/0[b]	1/1[a]	2/2[a]/2[b]	3/3[a]	4/4[a]/4[b]	5/5[a]/5[b]	6/6[a]	Base
MRF	12.4	12.4	12.4	12.4	12.4	12.4	12.4	4.8
Anaerobic digestion BMW	5.4	0	0	13.3	0	7.5	28.7	0
Anaerobic digestion MBT	28.2	0	33.9	0	49.6	38.9	0	0
Aerobic MBT	13.2	49.7	15.8	32.6	0	0	0	13.8
Landfill with ER	40.8	37.9	37.9	41.7	38.0	41.2	58.9	81.4

[a] Alternatives considering RDF production plus incineration of high-calorific fraction.

[b] Alternatives not considering RDF production but considering incineration of high-calorific fraction from MBT.

- *Pay-as-you-throw (PAYT) scenario*: Targets can be reached by imposing an economic instrument— PAYT—to be implemented by various levels of MSW system managers.

The renewed interest in studying both instruments rests upon the actual billing system in Portugal, which does not comply with the philosophy of the new Waste Framework Directive due to the fact that the water billing system is dependent on the water consumption rate rather than the waste production rate. The PAYT system, being designed based on a pay-per-bag system, would fully comply with the polluter-pays principle.

Methodology

Multiattributive Decision Making

As we know, MADM is one type of multicriteria decision-making category for problem solving in decision making, by which a finite number of alternatives identified by a group of experts can be analyzed. Several MADM methods have been applied in waste management, including ELECTRE,[40] PROMETHEE[41] and GAIA,[42] AHP,[43] TOPSIS,[44] and SAW.[45] To proceed in this study, SAW and TOPSIS were selected for demonstration, both of which are well-proven techniques and make it possible to rank the solutions via a preference order for SWM with a logical procedure and a set of criteria allowing a better appliance for nonexperts, according to Cheng et al.[45] Good performance when compared with more sophisticated methods may be anticipated.[46,47]

Even though criteria of different natures might have different units, this would not be a problem in implementing SAW and TOPSIS methods, once a normalization procedure may be used to perform the criteria aggregation. In detail, SAW is a well-defined method, which is intuitive and easy to understand.[48] In SAW, the role of the decision maker is to assign weights to each attribute. The decision maker can then obtain a total score for each alternative simply by multiplying the scale rating for each attribute value by the weight assigned and summing these products over the attributes. The alternative with the highest score is the one prescribed to the decision maker. The mathematical formula of the SAW is given by Cheng et al.:[46]

$$U_j = \sum_{i=1}^{n} w_i r_{ij}, \; j = 1,\ 2,\ \ldots,\ m \tag{1}$$

where w_i is the weight of the attribute and r_{ij} is the normalized impact matrix, by which the normalization may be provided through a linear scale transformation.

TOPSIS, developed by Hwang and Yoon[44] based upon the concept that the chosen alternative should have the shortest distance from the positive ideal solution and the farthest from the negative ideal solution, was applied in this study too. A utility value $D(i)$ for each alternative i can be obtained by calculating the relative distance from i to the ideal solution, which can be described as follows:[45]

Step 1. Calculate the normalized decision matrix. The normalized value n_{ij} is calculated as

$$n_{ij} = x_{ij} / \sqrt{\sum_{j=1}^{m} x_{ij}^2}, \qquad j = 1,\ldots,m,\ i = 1,\ldots,n \tag{2}$$

Step 2. Calculate the weighted normalized decision matrix. The weighted normalized value v_{ij} is calculated as

$$v_{ij} = w_i n_{ij}, \qquad j = 1,\ldots m, I = 1,\ldots,n \tag{3}$$

where w_i is the weight of the ith attribute or criterion, and

$$\sum_{i=1}^{n} w_i = 1c$$

Step 3. Determine the positive ideal and negative ideal solution:

$$A^+ = \{v_1^+, \ldots, v_n^+\} = \left\{\left(\max_j v_{ij} \mid i \in I\right), \left(\min_j v_{ij} \mid i \in J\right)\right\}.$$
$$A^- = \{v_1^-, \ldots, v_n^-\} = \left\{\left(\min_j v_{ij} \mid i \in I\right), \left(\max_j v_{ij} \mid i \in J\right)\right\} \tag{4}$$

where i is associated with benefit criteria, and j is associated with cost criteria.

Step 4. Calculate the separation measures, using the n-dimensional Euclidean distance. The separation of each alternative from the ideal solution and for the negative ideal solution are given as, respectively,

$$d_j^+ \left\{\sum_{i=1}^{n} \left(v_{ij} - v_i^+\right)^2\right\}^{\frac{1}{2}}$$

$$d_j^- \left\{\sum_{i=1}^{n} \left(v_{ij} - v_i^-\right)^2\right\}^{\frac{1}{2}} \quad j = 1, \ldots m \tag{5}$$

Step 5. Calculate the relative closeness to the ideal solution. The relative closeness of the alternative j with respect to ideal solution is defined as

$$R_j = d_j^- / \left(d_j^+ + d_j^-\right), \qquad j = 1, \ldots, m \tag{6}$$

Since $d_j^- \geq 0$ and $d_j^+ \geq 0$, then $R_j \in [0,1]$.

Step 6. Rank the preference in descending order.

Life Cycle Assessment

According to ISO 14040,[3] LCA consists of four major stages: goal and scope definition, LCI, life cycle analysis, and interpretation of the results. Below is a detailed description of each stage to enhance comprehension.

Goal and Scope Definition

The purpose of the LCA is to assess the 18 alternatives mentioned in Table 1. The same framework was applied to both scenarios as defined by the water billing system and PAYT, respectively. The LCA provided in this study is of an attributional type. We applied the "zero burden assumption," which suggests that waste management carries none of the upstream environmental burdens into the SWM system.[49]

In an LCA system with multiple products, which is the case in our study, it is necessary to set up the methodological framework. According to ISO 14044,[50] the system boundary should be geared toward expanding the product system to include the additional functions related to the coproducts to avoid allocation. In this LCA, the material recycling, energy recovery, and fertilizer application (i.e., stabilized residue waste) of MSW were included in the LCA, which collectively resulted in an expansion of the system boundary. In this LCA, the emissions resulting from the referred operations were included as the baseline information as the emissions of those competing products and energy recovery potential resulting from those alternative operations were also included for the purpose of comparison. In this context, the system can be expanded to include additional burdens of coproduct processing and the avoided burdens of any avoided processes (i.e., substitution or avoided burden method).[4,51–53]

To ensure correct implementation of the avoided burden method through successful MSW recycling and reuse, the expanded system products should have the same function as the raw products. The substitution ratios were then applied considering closed-loop and open-loop procedures. Table 2 presents the substitution ratios for recovered materials and energy consumed. In the cases where substitution ratio is 1:1, they were considered as a closed-loop procedure with a hypothesis that no changes occurred in the inherent properties of the recycled material.[54] For example, 1 kg of recycled glass can replace 1 kg of virgin glass without considering degradation of the material during the recycling so that the quality of the secondary material may not be worse than that of the primary material.[54] The materials included in this situation in our study were glass, metals, polyethylene plastics, plastic wood, fertilizers, and

TABLE 2 Criteria Applied in Decision Making

Evaluation Criteria	Description
	Technical criteria
Landfill deviation rate	Ratio between waste not landfilled and total waste generated in a year (in percentage).
	Environmental criteria
Abiotic depletion (AbD)	Extraction of natural non-living resources. It is the difference between resources consumed during waste life cycle and resources consumption avoided from materials and energy substituted (in kg Sb eq).
Acidification	Referent to acidifying pollutants emitted during waste life cycle. The calculation is the difference between impacts from waste life cycle and the avoided impact from substituted materials and energy (in kg SO_2 eq).
Eutrophication	It is the consequence of high levels of macronutrients, such as nitrogen and phosphorus. It is the difference between eutrophication substances' potential impact during waste life cycle and avoided impacts from substituted materials and energy (in kg PO_4^{3-} eq).
Global warming potential (GWP)	Represents the impact of greenhouse gas (GHG) emissions on the radiative forcing of the atmosphere, inducing climate change. It is obtained from GHG potential impact from waste life cycle less the GHG impact from substituted materials (in kg CO_2 eq).
Human toxicity (HT)	It is the difference between impacts on human health of toxic substances emitted and the impacts from substituted materials and energy life cycle [in kg para-dichlorobenzene (p-DCB) eq].
Photochemical oxidation (PO)	Represents the formation of reactive chemical compounds, such as ozone, by action of sunlight on certain primary air pollutants. The calculation is provided from impact difference between waste life cycle and materials and energy substituted life cycles (in kg C_2H_2 eq).
Gross energy requirement (GER)	Amount of commercial energy that is required directly and indirectly by the process of making a good or service. It is the difference between energy consumed and energy produced (in kJ).
	Economic criteria
Investment costs	Represents the amount to be expended to implement the alternative (in infrastructure, equipment, vehicles, and land) (in millions €).
Operational costs	Related to the amount to be expended during alternative operation (in material, electricity, maintenance, and labor) and to financial costs like annuity (in €).
Operational revenues	The amount related to the profit obtained from selling products (energy, recyclables, compost) or
Social criteria	with the avoidance of landfilling products (RDF, recyclables) (in €).
Fee	It is the amount paid by the population to finance MSW management system (in €/t).

electricity. Specifically, 15% of the electricity consumed in Portugal was purchased from Spain, and the ratio can be taken into account too, with a proportion of 85:15, for carrying out the LCA. Polyethylene, expandable polystyrene, and plastic wood are specific cases having a 1:1 substitution ratio, since they appeared only one time in the market, such that degradation of the material was not considered.

In the cases where substitution ratio is less than 1, an open-loop allocation procedure was applied since degradation of the material should be considered, such as the cases of polyethylene terephthalate (PET), paper/cardboard, and paper from composite packaging. The calculation of substitution ratios was based on the limit number of times that a specific material can be recycled and reused repeatedly.[55] For PET, the limit number of recycling with respect to losing physical properties considered was five times.[56] Concerning paper from composite packaging, the same limit may be applied given that the proportion of paper in the packaging (0.75%) may be assumed, and the calculation procedure adopted by Rigamonti et al.[54] was applied. The substitution ratio adopted for PET was collected from the Institute for Prospective Technological Studies.[57]

Life Cycle Inventory

The LCI is the second phase of the LCA. It is an inventory of input/output data related to the SWM system that is being studied. It involves the collection of the data, which is necessary to meet the goals of the defined study.[50] In accordance with the scope of the study, an LCI was prepared for the waste management activities specified in Figure 2. The Umberto 5.5 software package was used to support the LCA.

Concerning each operational unit analyzed in the AMARSUL system, a short description of the data and assumptions considered for prescribed scenarios were provided. First of all, some of the information applied for our systems analysis was provided by the Empresa Geral do Fomento, co-owner of the SWM system at AMARSUL, which is responsible for the management of this MSW system, and the Portuguese Environment Agency. The rest of information was drawn from the Umberto software library and from the selected data sources such as the vendors of machinery features.

Life Cycle Analysis and Interpretation

Our LCA was then carried out using the Umberto 5.5 software package with the aid of the entire LCI as described in the previous section. Following the methodology suggested by the ISO 14040-44 standard,[3,50] environmental indicators were obtained for covering different impact categories. The impact categories being studied include abiotic depletion, acidification, eutrophication, global warming, human toxicity (HT), and photochemical oxidation. The characterization factors applied to each impact category are proposed by the CML 2000 method.[4]

Determination of Weighting Factors

The criteria applied to assess the alternatives in this study are partially based on some traditional criteria, which concern investment costs, operational costs, and possible revenues. Besides, the fee for waste disposal to be applied to the general public is an important criterion, which is considered as a social concern. Such a fee system is designed to increase the landfill life span, though. Due to this reason, the target of landfill space saving was considered as a technical criterion. Environmental criteria related to environmental impact categories in the context of LCA are those to be particularly tested for sensitivity analysis in this study (Table 2).

To determine the appropriate weighting factors for this application, all relevant criteria associated with different stakeholders involved in the decision-making processes were taken into account. The stakeholders involved in such decision-making processes of SWM are composed of governmental agencies, municipalities, technical groups, academics, and environmentalists. In general, governmental agencies would favor these economic criteria, whereas academia might prefer to weigh all criteria

[a] The remaining environmental impact categories will have zero weight; their contribution to decision making will not be considered.

equally. Yet municipalities would have a closer look into a delicate balance between economic and social criteria simultaneously, whereas technical groups may focus on technical criteria. With such observations, a regional survey waste conducted to obtain stakeholders' weighting factors, being the results summarized in Table 3.

As a few more environmentalists were brought into the discussion to investigate the differential views, the LCA criteria were configured, signified, and summarized in such a decision-making process. To assess in detail the effect due to the inclusion of those LCA criteria in the SWM decision-making processes, three combinations of impact categories from LCA were tested. This combination will result in the application of three environmental impact categories (Table 4).

Alternative Screening and Ranking

Ranking Based on Traditional Criteria

When choosing the traditional criteria in SAW, the best option to be applied is conformed to the current one. That is mainly due to the revenues from selling the electric power generated at the sanitary landfill since the investment made for hardware construction has been present already, resulting in a reduced fee. However, there is a need to implement some essential measures to com-ply with Landfill and Packaging Directives in the future, which drives us to look at some more management options. Alternative P.A3* is the best when considering the same weight to all criteria. From a technical point of view, the option of treating MSW in MBT plants with AD treatment and ER of high-calorific fraction is the best option. In regard to the consideration of economic criteria only, the option of collection and treatment of separate BMW streams in an AD plant, including RDF production, is the best option. In having only the social criteria, the best option is to maximize the aerobic MBT plant. The results are collectively presented in Table 5. When applying the same practices based on the TOPSIS method, the best options associated

with the prescribed weighted criteria selected are similar to those obtained from the case of SAW except when all the criteria present the same weight. These results are collectively presented in Table 6. Comparing the scenarios with PAYT (denoted as P in the context) and with water billing indicates that the best is the PAYT system except when the base alternative is taken into account.

[b] Alternatives not considering RDF production but considering incineration of high-calorific fraction from MBT.

account, applying the AD to treat a source separated from BMW followed by RDF production remains the best option, if the base case is not considered. When the TOPSIS was applied, the results, as presented in Table 8, have changed, being preferable options with AD and incineration of high-calorific fraction. However, concerning social criteria, the option of maximizing aerobic MBT is considered as the best solution. Also, at almost criteria cases, the option of applying PAYT is better than the same technological option with the water billing system.

Another concern when applying LCA criteria is that the total number and type of impact category used in the SAW and TOPSIS could impact the final options. If we reduce the consideration from seven to three criteria, the results would be changed in both SAW and TOPSIS. When looking into the case of SAW, such a change is salient as only AbD/global warming potential (GWP)/HT impact categories were applied, as shown in Table 9. In this case, the AD of BMW separated from source with the inclusion of RDF ER in an incineration plant would be the best option for more criteria. For the remaining environmental impacts the results are mostly in accordance with the total LCA criteria applied (Table 7). Such a finding suggests that there are some LCA criteria that would have a bigger influence on the ranking outcome.

The phenomenon mentioned before has also been verified via TOPSIS (Table 10). When looking into the case of TOPSIS, for LCA criteria AbD/GWP/HT, the results were changed even more than those in the counterpart. When only the technical criterion was taken into account, the option favored the use of an anaerobic MBT plant with ER from the high-calorific fraction, without producing RDF. Such an option is always advantageous no matter how many LCA criteria were included for screening and ranking. Options like the adoption of a full aerobic MBT plant to divert organic waste from landfill as well as selective collection of BMW plus RDF production with burning in an incineration plant were selected as the best options when considering the other combinations of environmental impact categories in LCA (Table 10). Yet the inclusion of a varying number of criteria in LCA might impact the preference for PAYT. It obviously leads to the conclusion that the PAYT can be a better instrument to meet the environmental targets from a sustainable point of view.

Final Remarks on the Importance of LCA

The inclusion of environmental criteria into the MADM process can result in a change of the best option when compared with the cases where only all or part of the traditional criteria are taken into account. This proves that a sustainable decision must include all elements of sustainability, or else the decision would end up a biased option. Even though LCA impact category can be considered, the results would vary when differing numbers of LCA impact category were assessed in the MADM process. Impact categories are mutually exclusive, however. When all impact categories were included, the normalization process in the MADM process might dilute the relative importance or effect of some impact categories and, therefore, distort the outcome to some extent. In any circumstance, it is not possible to implement weighted criteria to restore such an outcome. To reach a sociopolitical sustainability, the selection of an impact category should be the stakeholders' responsibility. Regardless of some discrepancies present in the selection of impact categories and normalization, the final results obtained from both SAW and TOPSIS allow improvements for SWM in Portugal complying with the new guidelines and mandatory items with respect to those sustainable principles reinforced by European policies. Overall, the option of applying PAYT has been shown to be a good option relative to the water billing system.

Conclusions

In this entry, we analyze how LCA could have an impact on the decision-making processes of SWM. A case study in Portugal clearly indicates that the inclusion of LCA for screening and ranking has shown the potential of helping SWM decision making. The inclusion of LCA impact categories, together with traditional criteria associated with economic considerations, is capable of producing relatively sustainable decisions, which otherwise would not be reached. Within the analysis, both SAW and TOPSIS were proven capable of showing which alternatives should be favored. Comparing traditional criteria, these two methods have quite-consistent outputs in terms of several weighted criteria applied. When considering only the traditional criteria, the base case is the best option, without regard to environmental regulations. With the inclusion of LCA criteria, the best solution is to adopt the AD MBT plant followed by the energy recovery at incineration plant. Overall, the option of applying PAYT has been shown to be a good option relative to the water billing system. The selection of the number and type of LCA criteria (environmental impact categories) to be included in the MADM process is flexible, depending on the stakeholders' preference during the decision analysis. Such selection must be careful, however, since it ends up making an obvious difference in the final decision analysis results.

Sustainable Development: Ecological Footprint in Accounting

Simone Bastianoni, Valentina Niccolucci, Elena Neri, Gemma Cranston, Alessandro Galli, and Mathis Wackernagel

Introduction

Since the onset, sustainable development has called for a set of suitable tools and sustainability indicators that are able to monitor the relevant aspects of systems under scrutiny. In general, sustainability indicators are required to highlight the major "hot spots" of a system and provide the most relevant elements upon which to carry out a "sustainability diagnosis." This is necessary to determine the most appropriate "sustainability therapy," which may include future action plans, programs, and strategy, to support the development of environmental management policies and the decision-making process.

In recent decades, the global increase in resource consumption, waste production, and environmental pollution has become a core aspect within the sustainable development framework. The mismatch between the earth's resource regeneration rates and humanity's consumption rates is fundamental to understanding sustainability; the importance of this discrepancy was highlighted by H. Daly through the formulation of his famous "sustainability principles." Such principles can be expressed as follows: 1) renewable resources must be used no faster than the rate at which they regenerate; 2) nonrenewable resources must be used no faster than the time it takes for renewable substitutes to be implemented; and 3) pollution and wastes must be emitted no faster than the speed with which natural systems can absorb them, recycle them, or render them harmless. Assessments are therefore needed to account for both the ecosystem's capacity to provide ecological assets to support human activities and the subsequent effects human use has on the environment. A solution could be to focus upon careful management of natural capital with the long-term aim to preserve the integrity of ecosystems and improve human well-being.

The "life-supporting" natural capital upon which humans depend is generated by the negentropic capacity of the planet to convert, via photosynthesis, low-quality forms of energy (e.g., solar energy) into high-quality forms of energy that can be used by living organisms among which are humans. As such, the Ecological Footprint Analysis (EFA) can be considered a resource accounting framework, with a biophysical and thermodynamic basis, providing reliable measures of both (biosphere) supply of and (human) demand for the photosynthetic capacity of the planet.

Ecological Footprint analysis is not able to answer all aspects of sustainability but instead provides an account of the flows and overuse of resources by humanity. The imbalance between human demand and nature's capacity is one part of the sustainability issue, and the Ecological Footprint is able to answer the key question of how much of the earth's regenerative capacity does humanity demand.

The Ecological Footprint is a highly versatile tool with a wide range of applications and functions ranging from territorial levels (cities, regions, nations, etc.), to a wide set of systems. Ecological Footprint analyses help governments, businesses, and individuals to manage resources available and plan on how to use them in a sustainable way.

This entry consists of seven main sections. After a general introduction, the first section details the conceptual background underpinning the Ecological Footprint methodology. There are two fundamental aspects to the methodology—Ecological Footprint and biocapacity—both of which are introduced and described. In the section "The Mathematics of the Ecological Footprint," the mathematics behind Ecological Footprint and biocapacity calculations is explored. This section also discusses the topic of ecological balances (the comparison between Ecological Footprint and biocapacity) and focuses on the concept of biocapacity remainder and deficit. The section "Toward a Multiindicator Approach" offers a joint discussion of the Ecological Footprint with other indicators like human development index (HDI), gross domestic product (GDP), and index of sustainable economic welfare (ISEW). The section "New Insight in Footprint Theory: Toward a ThreeDimensional Ecological Footprint Geography" presents a new theoretical insight: a three dimensional representation of the Ecological Footprint based on the distinction between depletion of natural capital stocks and use of natural capital flows. An overview of existing applications of the Ecological Footprint to environmental management practices is then provided in the section "Applications of Ecological Footprint," from territorial to products and services. The section "Weakness and Limitations of EFA" acknowledges the limitations of the methodology and provides final conclusions.

Fundamentals of EFA

The EFA was introduced as an environmental accounting and management tool able to provide either static snapshots or temporal trends of human demand on ecological assets (i.e., natural resources and ecosystem services).[1,2] The EFA introduced two relevant spatial parameters:[3–5] Ecological Footprint and biocapacity. The Ecological Footprint tracks the amount of biologically productive area directly and indirectly demanded on a continuous basis by humanity to provide the energy and material resource flows used and to assimilate the wastes generated (i.e., CO_2 emissions), given prevailing technologies and resource management practices.

Biocapacity represents the maximum regenerative capacity of the biosphere, which is annually available for human use. Therefore, biocapacity is an intrinsic property for any given area (where the population lives or the product is produced). Ecological Footprint and biocapacity have some common properties—both can be divided into six major land-use categories according to the World Conservation Union classification:[6] cropland, pasture land, forest, fishing ground, built-up land, and carbon uptake land. The first four land types are required to make animal-, plant-, and fish-based food and fiber and wood products available for human consumption. The built-up land is required for shelter and other physical infrastructure such as roads and cities. The last land type represents a sink, the bioproductive space required to absorb the wastes emitted from human economies. Given global data limitations, national footprint assessments currently consider only carbon dioxide emissions from fossil fuel burning as a waste. Other waste streams would also be included, if the data became available. CO_2 emissions from fossil fuel burning are converted into an equivalent forested area needed to remove the excess CO_2 from the atmosphere, given forest sequestration rates. On the demand side, this area is called the carbon footprint; on the biocapacity side, land for CO_2 sequestration is forest (forest can serve either timber and fuel wood production, or carbon sequestration—but these services are typically in competition for space). Due to data limitation about forests with long-term carbon sequestration commitments, current Ecological Footprint accounts do not distinguish between forests for forest products, long-term carbon uptake (or "carbon uptake land"), or biodiversity reserves.

It should be noted that the term "carbon footprint" used in the context of the Ecological Footprint methodology is not to be confused with the "Carbon Footprint" methodology itself. The latter term refers to a different methodology and aims to measure the total amount of all greenhouse gas emissions that are directly and indirectly caused by an activity or are accumulated over the life stages of a product or an activity. Further information on the differences between the carbon footprint component of the Ecological Footprint methodology and the Carbon Footprint methodology can be found in the work of Galli et al.[7]

Ecological Footprint and biocapacity are both expressed in a standardized unit, global hectares (gha);[3,8] the global hectare represents a hectare with world-average biological productivity.[9] Global hectares are normalized so that the number of actual hectares of biologically productive land and sea on the planet is equal to the total worldwide budget of global hectares in any given year.[10] Because of international trade and the dispersion of carbon dioxide wastes, hectares demanded can be physically located anywhere in the world.[11] While the global hectare is the unit recommended by Global Footprint Network, world-average hectares (*w*ha) and nation-specific hectares (*n*ha) are also possible units,[9,12] and results can be easily converted from one unit of measure to the other. Global hectares are needed to measure bioproductivity rather than surface area. Each global hectare has world-average productivity for all land types and provides more information than simply weight (which does not capture the extent of land and sea area used) or physical area (which does not capture how much ecological production is associated with that land). Global hectares are particularly useful for ranking different products based on their total ecological demands. World-average hectares are areas of a specific land type with world-average productivity for that land type (e.g., 1ha of forestland with the ecological production of the average forest hectare globally). Nation-specific actual hectares are physical areas of a specific land type located within a specific country and characterized by the bioproductivity of that country.

The choice of the unit of measure depends on the posed research question. The main advantage of using global hectares lies in the possibility to compare the ecological demands of nations and/or products across the globe. A productivity-based normalization is necessary to convert actual hectares into global hectares: yield and equivalence factors (EQFs) are used for this purpose. The yield factor (YF) captures the difference between local and global (world-average) productivity.[9,10] It is calculated as the ratio between the yield for the production of each product in a specific nation and the average yield for the production of the same product in the world. In each year, every country has its own set (one for each of the six land types) of YFs.

The EQF captures the difference between the productivity of a given land type and the world-average productivity of all biologically productive land types.[9,10] Equivalence factors are currently calculated by Global Footprint Network by using the Global Agro-Ecological Zones model, which provides data on potential agricultural suitability. The EQF for a land type depends on its level of potential agricultural suitability relative to world-average suitability. A set of EQFs is calculated on a yearly basis. The EQF for marine area is calculated such that a single global hectare of pasture will produce an amount of calories of beef equal to the amount of calories of salmon that can be produced by a single global hectare of marine area. The EQF for inland water is set equal to the EQF for marine area. The set of YFs and EQFs is annually updated and released by Global Footprint Network.

Mathematics of the Ecological Footprint

The EFA may have various purposes and be applied in different contexts. Here we refer to the Ecological Footprint within a geographically delineated area, e.g., a nation and the Ecological Footprint of a product.

Ecological Footprint of a Nation

The Ecological Footprint of a nation, EF_N, is a function of the number of inhabitants, Pop, and the footprint of consumption of a single inhabitant, $EF_{C,\,i}$, associated with the ith product and/or waste:

$$\mathrm{EF_N} = \mathrm{Pop}^* \sum_{i=1}^{n} \mathrm{EF}_{C,\,i} \tag{1}$$

where the per capita footprint of consumption is the sum of the per capita footprint of production ($EF_{P,\,i}$) and imports ($EF_{I,\,i}$) minus the footprint of exports ($EF_{E,\,i}$) for the ith product and/or waste.

$$\mathrm{EF}_{C,\,i} = \mathrm{EF}_{P,\,i} + \mathrm{EF}_{I,\,i} - \mathrm{EF}_{E,\,i} \tag{2}$$

In calculating footprints of production, imports, and exports for each ith product and/or waste. the reference formula is

$$\mathrm{EF}_i = \sum_{j=1}^{6} \frac{T_i}{Y_{N,\,i}} * YF_{N,\,j} * EQF_j = \sum_{j=1}^{6} \frac{T_i}{Y_{W,\,i}} * EQF_j \tag{3}$$

where

- T_i is the produced, imported, or exported amount of each product i (in tonnes).
- $Y_{\mathrm{N},\,i}$ is the annual yield (t ha^{-1} yr^{-1}) for the production of each product, i, in the nation, N. This is calculated as the tonnes of product, i, produced annually divided by all areas in the nation on which this product is grown.
- $Y_{\mathrm{W},\,i}$ is the world-average (W) annual yield (t ha^{-1} yr^{-1}) for the production of each product, i, given by the tonnes of product, i, produced annually across the world divided by all areas in the world on which this product is grown.
- $YF_{\mathrm{N},\mathrm{j}}$ is the YF specific to nation, N, and land type, j.
- EQF_j is the EQF for land type, j.

From these equations, it can be derived that the Ecological Footprint of a population is a function of four main factors:[9,10] 1) population size; 2) average standard of living; 3) the average productivity of land and water ecosystems; and 4) the efficiency of resourcing, harvesting, processing, and use.

Biocapacity is an aggregate measure of the amount of bioproductive land available, which is weighted by the productivity of that land. It represents the ability of the biosphere to produce crops, livestock (pasture), timber products (forest), and fish as well as to take up carbon dioxide in forests. It is calculated as reported in Eq. 4:

$$\mathrm{BC_N} = \sum_{j=1}^{6} A_{N,\,j} * YF_{N,\,j} * EQF_j \tag{4}$$

where $A_{N,\,j}$ represents the estimated bioproductive area expressed in nation-specific hectares that is available. $YF_{N,\,j}$ and EQF_j have been defined above.

Biocapacity represents the maximum theoretical rate of resource supply that can be sustained by a territory under prevailing technology and management schemes. Thus, biocapacity depends on natural conditions as well as on prevailing land-use practices in, for example, farming and forestry.[10]

The Ecological Footprint of a population can be directly compared with the biocapacity of the area where the population resides in the same way that expenditure is compared against income in financial terms.[4,10] The resulting "biocapacity balance" reveals whether that population is living, in net terms, within or beyond its local ecological means. This ecological balance has significance at both the global and national level, though it has to be noted that living within one's ecological means does not yet guarantee ecological sustainability.[13,14] Additional criteria such as biodiversity conservation, soil preservation, decreased release of toxic elements, and the like should be tracked in a comprehensive and multidisciplinary sustainability assessment. Further, countries with a biocapacity reserve (where biocapacity > Ecological Footprint) may use their available biocapacity to satisfy their own domestic consumptions or export ecological resources to other nations. This is generally the case for low-income countries that use only a fraction of their locally available resources, like some African and Latin America countries.[13,15,16]

Conversely, countries with a biocapacity deficit (where Ecological Footprint > biocapacity) must rely on biocapacity from outside their own borders or draw down their own natural budget. Many high-income countries (like the United States, Canada, and some western European countries such as Italy, the United Kingdom, and France) have footprints several times larger than their domestic biocapacity.[13,15,16] Such a biocapacity deficit is becoming an increasing economic risk for countries, particularly in a world of growing global overshoot. It highlights a country's dependence on additional external goods and ecological services, which are provided through one or more of the three following mechanisms:[10,13] 1) the biocapacity trade deficit, which consists of net import of biocapacity from other regions of the world; 2) the biocapacity deficit due to depletion, due to an overuse of local resources; and 3) the demand on biocapacity due to occupation of global commons, such as emissions of greenhouse gases into the global atmosphere (rather than domestic absorption) or fishing in international waters.[17]

The analysis of biocapacity and Ecological Footprint trends reveals how human consumption is changing over time. At the global level, the latest data released[13,16] show that humanity is currently operating in a state of overshoot: in other words, demand for natural resources exceeds the regenerative capacity of existing natural capital by at least 50% according to calculations of Global Footprint Network.[15] Furthermore, the gap between Ecological Footprint and biocapacity globally has been continuously increasing since the mid-1970s (Figure 1).

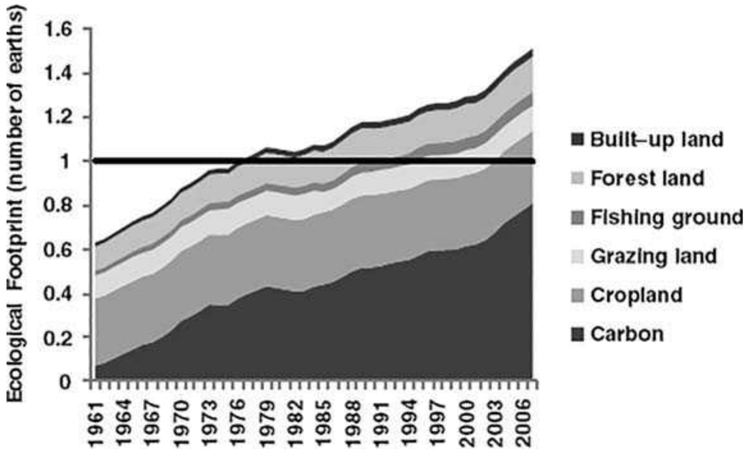

FIGURE 1 Humanity's Ecological Footprint, 1961–2007.

In 2007, humanity's total Ecological Footprint worldwide was 18 billion gha; with world population at 6.7 billion people, the average person's footprint was 2.7 gha.[13,16] However, there was only 11.9 billion gha of biocapacity available that year, equivalent to 1.8 gha per person. This overshoot of approximately 50% means that in 2007, humanity used the equivalent of 1.5 earths to support its consumption. In other words, it would have taken the earth approximately a year and a half to regenerate the resources used by humanity in that year. The largest Ecological Footprint component was the carbon footprint. This has increased by 35% since 1961 and currently accounts for more than half of the global Ecological Footprint.[13,16]

Even if the earth has a high resilience, prolonged biocapacity deficit is not possible since vital ecosystems and nonrenewable stocks would be depleted due to insuperable ecological and thermodynamic constraints. Also, it is not obvious that high-input agriculture can maintain its yields in the long run, particularly in the face of soil loss and potential phosphate limitations. It has become an urgent task to reduce our consumption levels back within the limits of our ecological budget.[14]

The growing global trends, however, hide significant regional variation (Figure 2).

Both demand on and supply of biocapacity are unevenly distributed across the world. Ecological Footprint and biocapacity values can therefore be used to develop new criteria for distinguishing among world nations. For instance, an alternative approach can be used to look at countries, based on their "biocapacity balances" (Figure 3), which helps to identify where resources are located and who uses what and to what extent. While in 1961, approximately 80% of the world population was living in countries characterized by a biocapacity remainder, in 2007, most of the world population was living in countries running a biocapacity deficit situation.

The total Ecological Footprint demanded by a country is strongly related to GDP[18,19] and changes accordingly, in both its extent and its composition, among high-, middle-, and low-income countries (Figure 4).[13]

Generally, high-income countries have per-capita Ecological Footprint values nearly 3 times higher than the world average, the majority of which is from the carbon footprint (approximately 65% of the total value). Conversely, middle- and low-income countries have average Ecological Footprint values that are equal to and lower than the world average, respectively. These countries are frequently characterized by transition economies, in which the carbon footprint component, although increased over the last decades, still constitutes less than 50% of the overall demand (Figure 5).

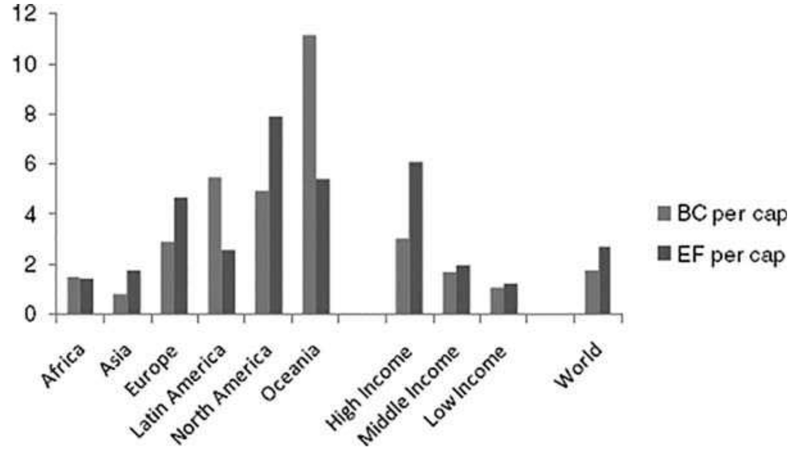

FIGURE 2 Ecological footprint (EF) and biocapacity (BC) by income level and country. The unequal distribution of human demand on bioproductive lands was also investigated by White.[20]

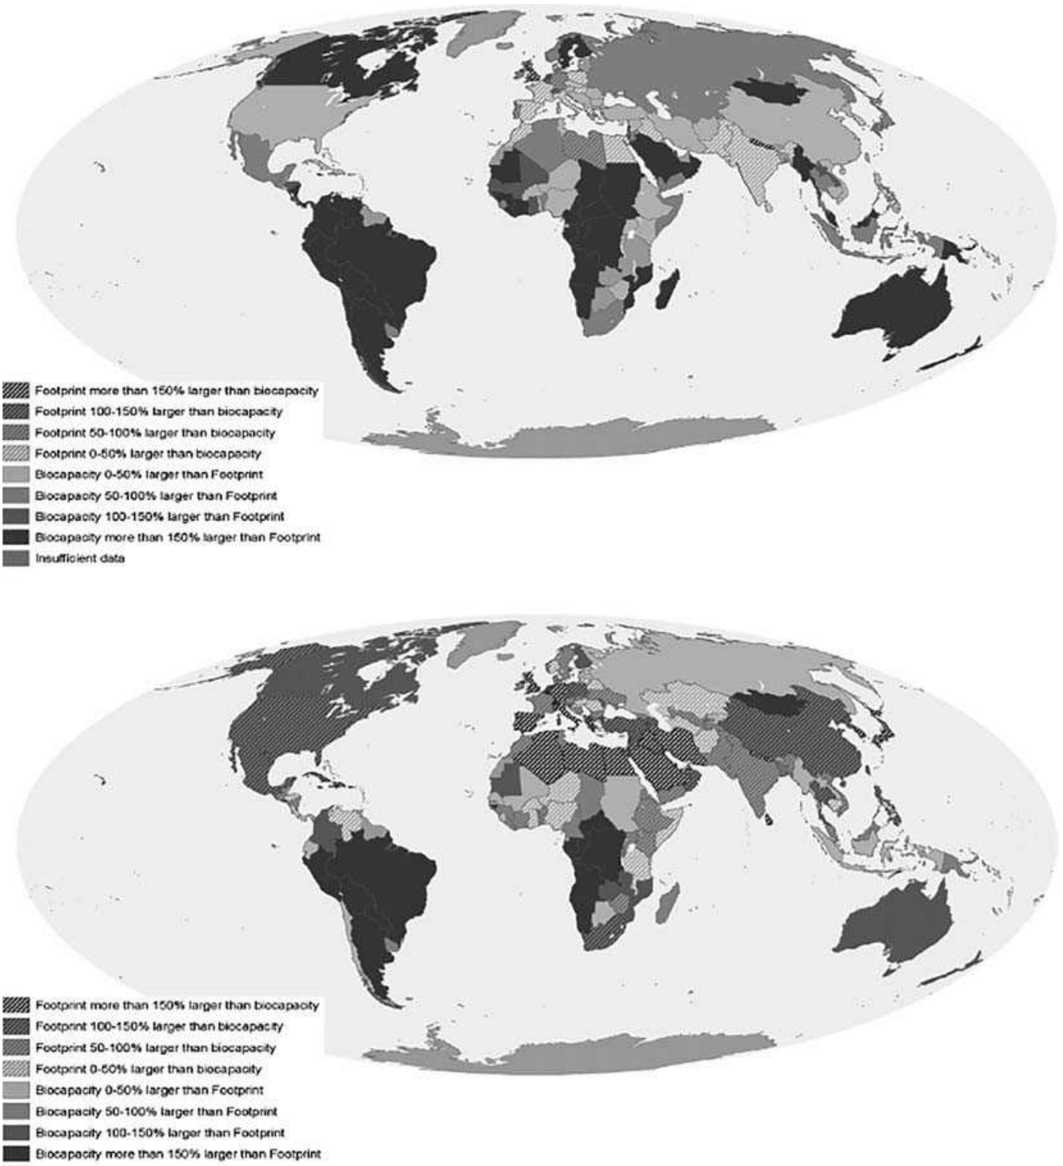

FIGURE 3 Biocapacity reminder/deficit status for world countries in 1961 and 2007. Green nations represent countries where the local biocapacity is greater than their residents' footprint (biocapacity reminder countries); red represents countries where the footprint is greater than local biocapacity (biocapacity deficit countries).

Ecological Footprint of a Product

The Ecological Footprint of a final or intermediate product is defined as the total amount of resources and waste assimilation capacity required in each of the phases required to produce, use, and/or dispose of that product.[8] The lifecycle boundaries can be flexible and changed according to the aim and scope of the analysis i.e., from cradle to gate (production to distribution) or cradle to grave (production to destruction). The Ecological Footprint is evaluated by considering all the direct and indirect inputs that are associated with the analyzed system for its entire life cycle. Each of these inputs is converted in terms

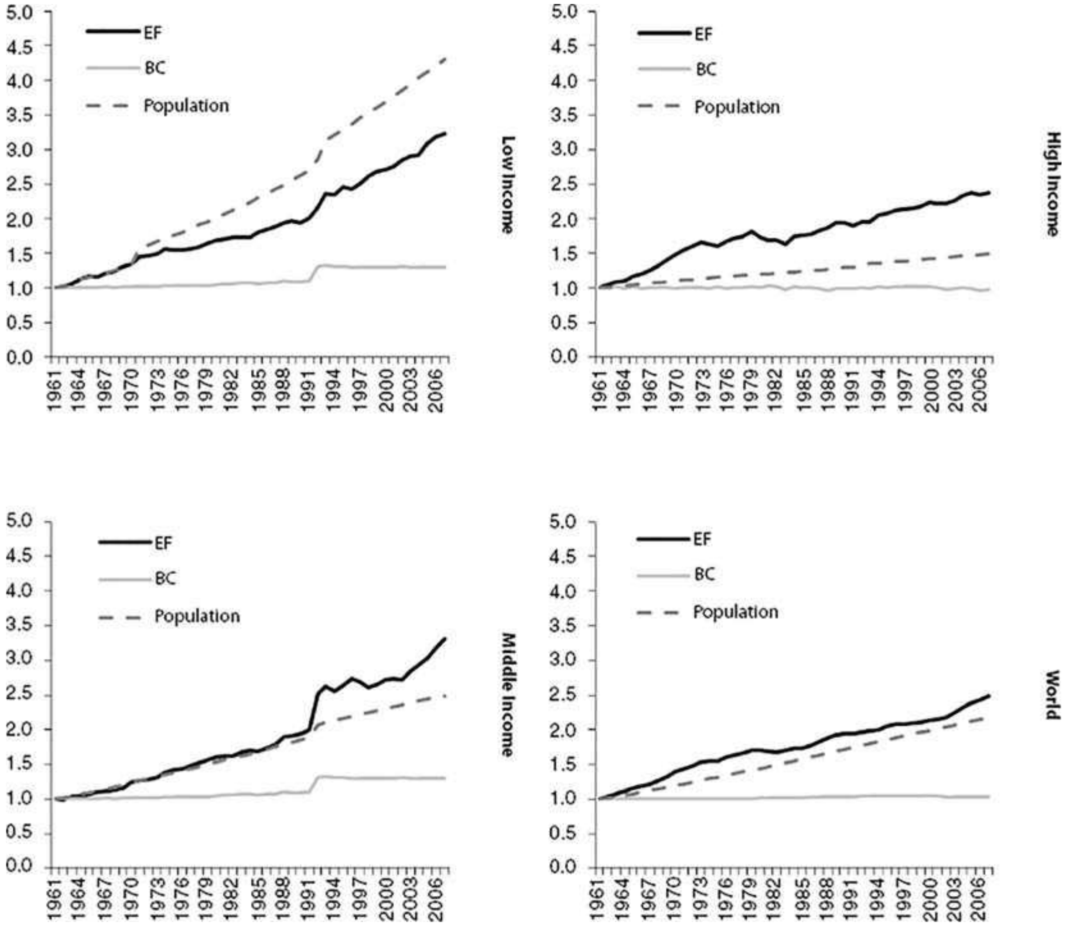

FIGURE 4 Variations on Ecological Footprint (EF), biocapacity (BC), and population for the world and low-income, middle-income, and high-income countries, indexed to 1961.

of the global hectares needed to support their production The EFp is expressed in units of global hectare years (gha yr), not just global hectares.[8] As the Ecological Footprint is strictly related to the production system, the way a product is produced should be clear and identifiable. The functional unit for the analyzed system should be also defined as well as the temporal and spatial boundaries.

There are two widely used approaches for calculating the Ecological Footprint of a product, both standards compliant: process-based life-cycle assessment (P-LCA) and environmentally extended input-output life-cycle assessment.[8] Process-based life-cycle assessment has the advantage of a large amount of detail, as individual product types and even brands can be analyzed, with the general disadvantage of lacking complete upstream coverage of the production chain (e.g., truncation error). Extended input-output life-cycle assessment has the advantage of full upstream coverage but the disadvantage of generality, as input-output tables typically do not disaggregate down to the level of individual product types (e.g., homogeneity assumption).

Following the P-LCA, Ecological Footprint of product ($\mathrm{EF_P}$) is given by the sum of the footprints of each input consumed and disposed within the life cycle of the production process as reported below.

$$\mathrm{EF_P} = \sum_{j=1}^{6}\sum_{i=1}^{n}\frac{T_i}{Y_{N,i}} * \mathrm{YF}_j * \mathrm{EQF}_j$$

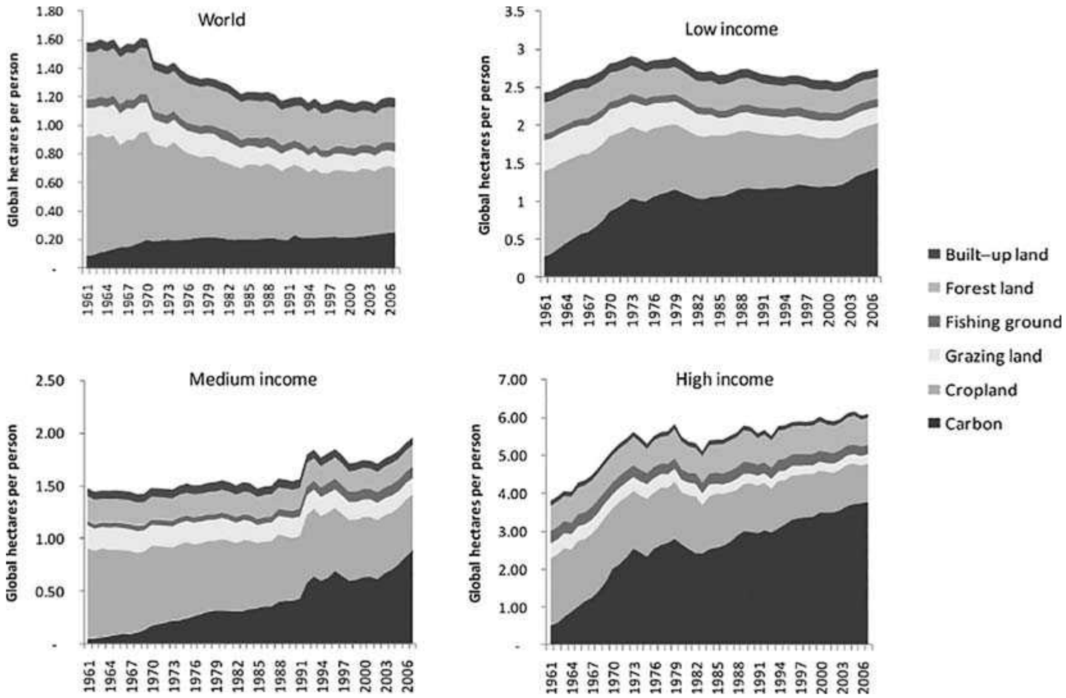

FIGURE 5 Per-capita Ecological Footprint for the world and high-, middle-, and low-income countries by land type, 1961–2007.

$$= \sum_{j=1}^{6}\sum_{i=1}^{n} \frac{T_i}{Y_{W,i}} * \mathrm{EQF}_j \tag{5}$$

where the variables are as follows:

- i refers to the n-input needed
- j refers to the six different land-use types (cropland, grazing land, fishing grounds, forest area, built-up land, and carbon uptake land)
- YF_j is the YF of the jth land type
- EQF_j is the EQF of the jth land type

Toward a Multi-Indicator Approach

Building on the premise that no single indicator is able to provide a full sustainability diagnosis and indicators should rather be used and interpreted jointly (i.e., the joint use of more than one indicator), this section reports some of the most interesting applications.

For instance, the HDI[21] can be used together with the Ecological Footprint to provide important insights on whether a high level of consumption is necessary for a high level of human development.[15] The HDI is a composite indicator used to rank countries by level of “human development” and then of well-being. It is a comparative measure of life expectancy, literacy, education, and standards of living for countries worldwide. The relationship between Ecological Footprint and HDI has two different categories (Figure 6).

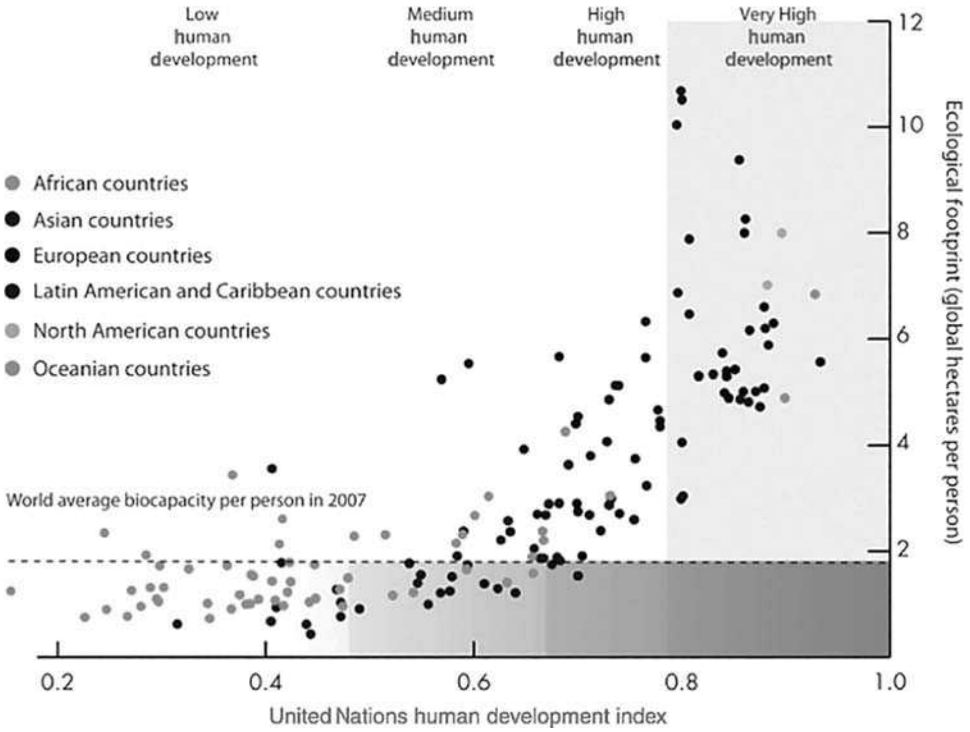

FIGURE 6 Human development index vs. Ecological Footprint, 2007.

While countries with a low level of development (HDI <0.8) report small variations in Ecological Footprint per capita, countries with a higher HDI value than the threshold show significant variations in Ecological Footprint per capita (for example, from Peru with 1.5 gha per person to Luxembourg with over than 9 gha per person). However, as development increases beyond a certain level, so does per-person Ecological Footprint; this is up to a point where small gains in HDI come at the cost of very large Ecological Footprint increases. Moreover, several countries with a high level of development have a similar per-capita Ecological Footprint to countries with a much lower level of development. Together with the breakdown in connection between wealth and well-being above a certain level of GDP per capita, this indicates that a high level of consumption is not necessarily required for a high level of development or well-being.

Ecological Footprint and biocapacity temporal trends have been compared with economic indicators such as GDP and the ISEW.[22] In particular, it has been shown that some (western) countries are characterized by increased economic wealth (measured by GDP) and growing environmental pressure (documented by Ecological Footprint trend) at the expense of a decrease in environmental sustainability (as shown by the increasing gap of Ecological Footprint and biocapacity) and a stagnation or even decrease in welfare (as ISEW demonstrates; Figure 7).[22]

A comparison between Ecological Footprint and life satisfaction—used as a subjective measure of well-being— was performed to understand the nature of their relationship and to test whether it could be possible for humans to reduce their levels of resource consumption without compromising well-being and life satisfaction and, at the same time, protecting the environment.[23,24] The relationship between Ecological Footprint and life satisfaction has two different paths. While countries with an Ecological Footprint of less than 4 gha per capita report significant variations in life satisfaction, countries with higher values (Ecological Footprint >4 gha per capita) report small variations in life satisfaction (Figure 8).

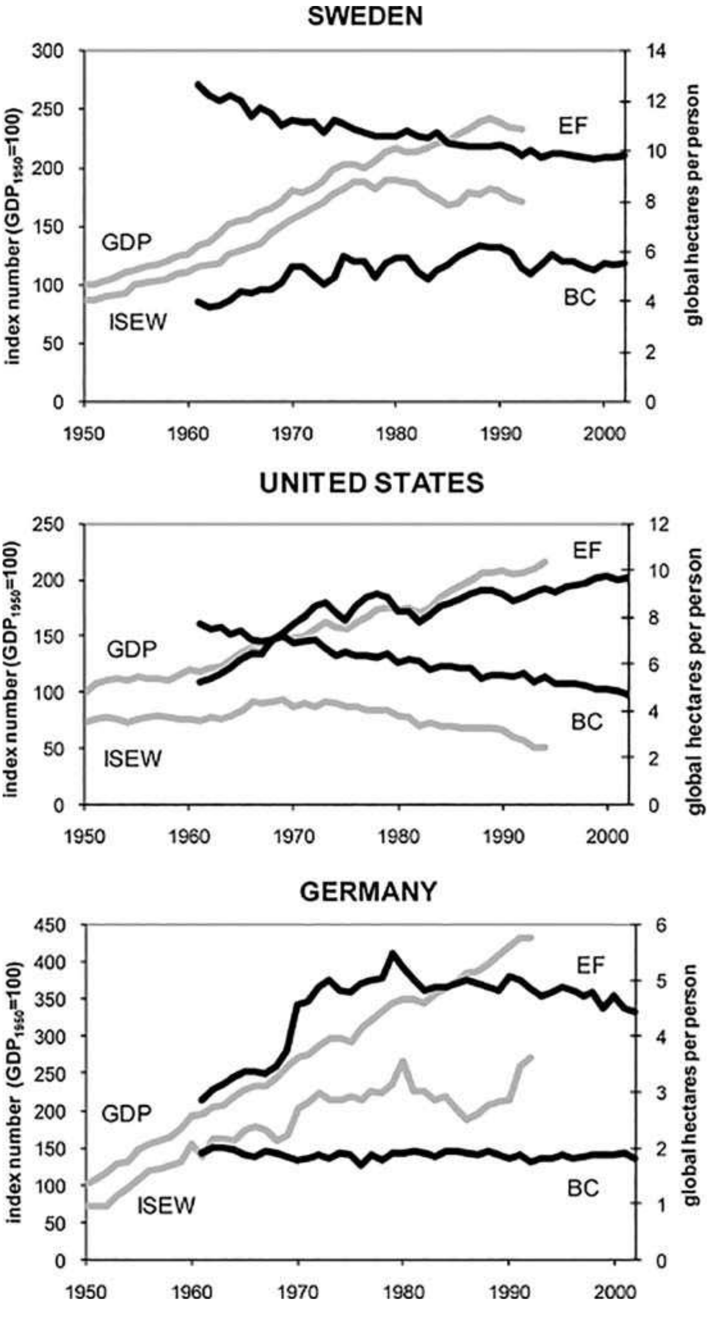

FIGURE 7 The comparison among temporal trends of GDP vs. ISEW (left scale) and Ecological Footprint (EF) vs. biocapacity (BC) (right scale) for Sweden, United States, and Germany.

In general, people with high consumption and income levels are more satisfied with life than people with lower consumption and income levels despite the differing levels and patterns of consumption that are necessary to obtain the same level of satisfaction. On the contrary, people with low consumption and income levels are less satisfied, but the same unit of consumption produces different perceptions of satisfaction (life satisfaction values are more unpaired).

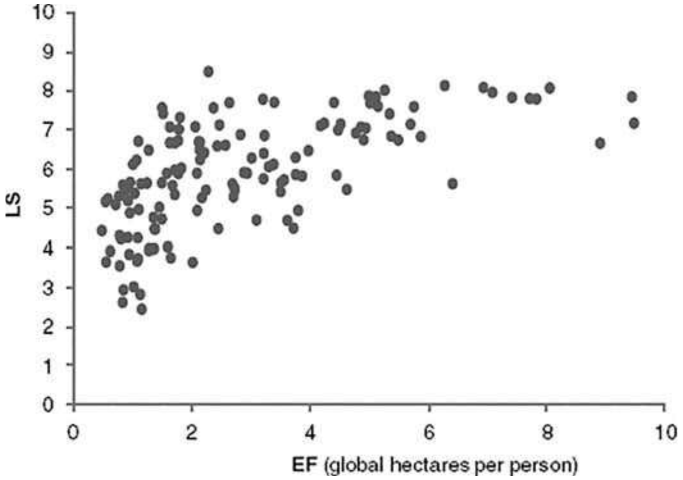

FIGURE 8 Life satisfaction (LS) vs. Ecological Footprint (EF) for 130 world countries.

Biocapacity and Ecological Footprint temporal trends have recently been used to develop alternative interpretations of the geopolitical context of nations around the world.[25,26] Based on their development paths, Ecological Footprint and biocapacity trends for nations around the world can be grouped into four main dynamic typologies: parallel, scissor, wedge, and descent.[25] Each typology corresponds to a particular environmental situation, the implications of which could have extreme relevance for environmental management, economic, and social prosperity as well as the development of sustainability policies. In particular, the role of biocapacity is highlighted in maintaining healthy economies, in offering an acceptable quality of life, and as an essential asset to ensure national competitiveness.[27]

Finally, under the recent EU-funded One Planet Economy Network Europe (OPEN:EU) project, three indicators have been identified as useful and complementary in assessing environmental issues—ecological, carbon, and water footprints—and therefore grouped together to form a suite of indicators called "footprint family."[7] Although not yet comprehensive, this suite provides a quantifiable platform for discussions regarding the limits to biotic resource and freshwater consumption and greenhouse gas emissions, as well as how to address the sustainability of natural capital use across the globe, thus enabling decision makers to more easily understand the environmental consequences of economic activities.

New Insight in Footprint Theory: Toward a Three-Dimensional Ecological Footprint Geography

The presence of global overshoot proves that the current human economy partially relies on natural capital depletion rather than just on sustainable flow consumption.[4] Considering natural capital and its limits, differentiating between these two components is fundamental for environmental planning and management. Recently, a variant of the classical Ecological Footprint model has been proposed, where a distinction between depletion of natural capital stocks and use of natural capital flows is operated.[28] The Ecological Footprint was redesigned as a three-dimensional model (^{3D}EF) with two relevant components, called size (EF_{size}) and depth (EF_{depth}), related to the two different uses of natural capital. The EF_{size} regards the appropriation of the so-called "income" of natural capital, i.e., the consumption of flows of resource yearly regenerated by natural cycles. It is the spatial component expressed in global hectares and plotted in the (x, y) plane. By definition, its value ranges from zero to biocapacity.

On the other side, the EF_{depth} regards the depletion of natural capital, which is the use of stocks of resources requiring a regeneration time longer than the flows. It is the intensity component plotted on the z-axis. In particular, the EF_{depth} component arises when overshoot is present and expresses the number of years it would theoretically take to regenerate the natural capital used in one year. By definition, its value ranges from 1 (the reference value called "natural depth") upward (additional depth).

It should be remarked that the two approaches, classical and three-dimensional, are simply two different ways of representing the same footprint values. The ^{3D}EF originates from the fact that flow and stock are technically incommensurable and cannot be summed up because the former is consumed each year and regenerated the following year, whereas the latter represents the irreversible erosion of natural stocks that add up from year to year into an accumulated "environmental debt."

Footprint size and depth have been characterized by opposite trends:[17] 1) EF_{size} grew continuously until mid-1970s, when it reached the asymptote (i.e., the earth biocapacity), and has remained constant ever since; and 2) EF_{depth} has remained equal to the natural depth until the appearance of overshoot, and it has subsequently been growing. Recently, the ^{3D}EF model has been theoretically applied to national case studies with the aim of enhancing the significance and potential usefulness of the Ecological Footprint in tracking relevant issues in the sustainability debate, such as the differentiation between resource stocks and flows.[17] Moreover, EF_{size} can be used as a proxy to highlight the existing intragenerational (in)equity in the appropriation of resources and ecological services by the residents of different nations. At the same time, EF_{depth} enables the relationships between current and future generations to be examined.

Although several questions remain to be addressed, the implementation of both a multilateral trade framework and the ^{3D}EF model in the National Footprint Accounts could form the basis for a new Ecological Footprint-based geography able to differentiate pressures on flows and stocks and identify the spatial/geographical location of such pressures.[4]

Applications of Ecological Footprint

Territorial Systems

Examples of national Ecological Footprint studies can be found in the literature,[29,42] although the most comprehensive set of national Ecological Footprint assessments is represented by Global Footprint Network's National Footprint Accounts.[16]

As of today, more than 35 nations have engaged with the Global Footprint Network directly, 17 nations have completed reviews of the Ecological Footprint, and a few have formally adopted it. Wales has adopted the Ecological Footprint as its headline indicator for sustainability. The Swiss government has incorporated the footprint into its national sustainable development plan. Japan includes the footprint as a measure in its environmental plan, the United Arab Emirates is using the Ecological Footprint as a tool to recommend and assist in the development of longterm science-based policies,[43] and Ecuador has set official footprint reduction targets in its 2009–2013 National Development Plan. There are several other countries that are currently collaborating with Global Footprint Network.[44]

Among nongovernmental organizations, WWF (World Wide Fund for Nature) International, one of the world's most influential conservation organizations, uses the Ecological Footprint in its communication and policy work for advancing conservation and sustainability. WWF has recently established a target of bringing humanity out of overshoot by 2050 and is actively pursuing this goal through its One Planet programs.

Numerous applications have also been performed at various subnational scales.[45–53] Currently, there are two suggested methodologies for subnational Ecological Footprint evaluations: component (or bottom-up) and compound (or top-down) approaches. The component method starts from specific individual consumption and waste production data to then calculate the total Ecological Footprint. While the method is detailed and flexible, several problems, including double counting, the lack of detailed data, and specific conversion factors, make this approach less acceptable. The compound approach evaluates the subnational Ecological Footprint by scaling the national Ecological Footprint value according to differences in consumption and life style. This is the widest used and more complete method.[54,8]

Products and Services

Despite its diffusion and popularity, product Ecological Footprint applications are still scarce, though a few interesting case studies exist. Studies on cultivation of tomatoes,[55] conventional vs. organic wine farming,[56] nectarine production,[57] shrimp and tilapia aquaculture,[58] marine aquaculture of reef fish,[59] and fisheries products[60] have been performed to highlight appropriation of natural capital, efficiency of natural resource use, and environmental pressure. Evaluations of the environmental impact of farms[61] and dairy production[62] as well as assessment of economic and ecological carrying capacity of crops[63] have been proposed via the combined use of the Ecological Footprint with other methods, such as life-cycle assessment, emergy analysis and economic cost, and return estimation.

In the context of product, Ecological Footprint has been used as a basis for the elaboration of the model of the double pyramid, which flanked the food pyramid with the environmental pyramid.[64] This model highlights that, in general, modern lifestyles produce a growing impact on the planet; it tries to promote eco-sustainable life and eating styles.

In the context of industrial processes, the potential of using EFA as an environmental indicator for the textile sector has been considered, although the contribution of wastes other than carbon dioxide should be included in the footprint methodology.[65]

The EFA has also been applied to the tourism sector. Starting from some pioneering studies,[66,67] the EFA has received attention as a key environmental indicator of sustainable tourism,[68] and several studies have been published at different scales.[69–72]

Over time, several tools and software have been developed for Ecological Footprint assessment for both territorial systems and products, although only a few are standard compliant. Most of them are freely downloadable from Web sites such as the footprint calculator (available at http://www.footprintnetwork.org/en/index.php/GFN/page/personal_footprint/). The REAP (Resource and Energy Analysis Programme) software (available at http://www.sei.se/reap) is a scenario based, integrated resource–environment modeling tool developed by the Stockholm Environment Institute to help local authorities in the U.K. make decisions about how to reduce their Ecological Footprint.

The Footprinter software (available at http://www.foot-printer.com), developed by Best Foot Forward, is comprehensive and powerful analytical software for carbon and Ecological Footprint assessment for products and organizations. It is based on the use of EcoIndex database.

Role of Business

The Ecological Footprint has been used to evaluate the environmental pressure of production processes; this type of investigation is becoming increasingly important to integrate sustainability issues (as natural capital consumption) into industrial and business decision-making processes. In a recent World Business Council for Sustainable Development project (WBCSD), several companies and industries came together to assess their role in helping to shape a future sustainable society for mankind.[73] With the help of Global Footprint Network, the consequences, in Ecological Footprint and biocapacity terms, of the hypothetical scenarios (up to the year 2050) envisioned by WBCSD were estimated. Results from this study showed that humanity will likely require the equivalent of 2.3 planets' worth of resources upon following a business-as-usual scenario or, conversely, 1.1 planets' worth of resources by implementing all the envisioned actions and activities, such as 50% reduction in CO_2 emissions compared with 2005 levels; enhanced forest productivity using better management techniques and an extension of their acreage between 2030 and 2050; increased crop productivity (+2% each year over past trends) due to technological advances and the diffusion of best practices; and changes to the average global nutritional regime, in terms of both diet and calorie content.[74]

Weakness and Limitations of EFA

Despite its popularity, EFA, like most indicators, is not exempt from criticisms regarding philosophical as well as methodological issues. In this section, a brief summary of the main weaknesses and limitations is offered. For further details on this topic see, for example, Best et al.,[75] Fiala,[76] Kitzes et al.,[77] and van der Bergh and Verbruggen.[78]

The first criticism is that the EFA cannot be fully defined as a measure of sustainability. The EFA research question is limited to identify the extent to which humanity is consuming bioproductive land compared with the available biocapacity.[21] We believe consuming resources within the capacity of the planet is a first necessary although not sufficient criterion for sustainability; as such, in order to depict a comprehensive picture of the system analyzed, it is strongly recommended to combine the Ecological Footprint with other complementary indicators (environmental as well as social and economic).

The use of a spatial unit makes some impacts difficult to determine.[75] Ecological Footprint is not able to directly account for all resources that cannot be referred to in spatial terms. This is the case for the depletion of nonrenewable deposits, such as metals, minerals, or fossil fuel reserves. For processes of extraction and refining, only the CO_2 emissions related to these processes are accounted for. The use of fossil fuels is evaluated in an indirect way, considering the amount of forestland required for the absorption of the CO_2 that is emitted. To date, carbon dioxide is the only greenhouse gas accounted for, and its associated footprint relies on the assumption that all emissions are absorbed only by forests and the oceans, neglecting carbon uptake by other biomes.

Other missing elements in EFA are freshwater consumption and soil erosion, even if the latter could be accounted for, at least theoretically. A possible way to include the overexploitation phenomena possible in agricultural land as well as in other land types into the classical Ecological Footprint framework was proposed by Bastianoni et al.[79] As EFA is unable to show unsustainable practices and their consequences, when agricultural EFA is performed, there can be some misunderstanding and misinterpretation of the results. Sometimes, it seems that EFA encourages more intensive farming, as this increases agricultural intensities, resulting in a higher biocapacity. The Ecological Footprint shows pressures that could lead to degradation of natural capital (e.g., reduced quality of land or reduced biodiversity) but does not predict this degradation.

Furthermore, multifunctional land-use patterns are not considered, in order to prevent double counting.[79] Each hectare is counted only once, even though it might provide multiple services. Counting them multiple times would produce an overestimation on Ecological Footprint.

Finally, EFA also is not able to capture the impacts due to the release of long-life toxic materials (e.g., pollution in terms of waste generation, toxicity, eutrophication, etc.), for which no regenerative capacity exists.

Conclusion

This entry offers a comprehensive insight to the EFA. Based on its simple logic and unit of measure, the Ecological Footprint has become a very popular sustainability indicator preserving scientific rigor on an ecological and thermodynamic basis.

By tracking a wide range of human activities, the Ecological Footprint is able to monitor the combined impact of anthropogenic pressures that are more typically evaluated independently and can thus be used to understand, from multiple angles, the environmental consequences of human activities.

The main strength of this methodology is its ability to explain, in simple terms, the concept of ecological limits, thus helping to safeguard the long-term capacity of the biosphere to support mankind and understand how resource issues are linked with economic and social issues.

One of the positive characteristics of this methodology is its ability to make visible aspects that are traditionally invisible for conventional economic analyses. For instance, the choice of an area as a unit of measure reflects the fact that many basic ecosystem services and ecological resources are provided by surfaces where photosynthesis takes place. Unfortunately, these surfaces are limited by physical and planetary constraints: reporting results in terms of an area helps to better communicate the existence of physical limits to the growth of human economies.

Currently, the Ecological Footprint is a robust method widely used to give a measure of the (un)sustainability of consumption patterns at different scales as well as to establish the natural capital requirement of products, services, and activities.

Due to the growing number of applications, Global Footprint Network has released the Ecological Footprint Standards[8] in order to enhance the consistency and quality of footprint assessments. This standard contains a list of mandatory requirements for standards compliance. The document also suggests the best way to present the results avoiding distortion and misinterpretations. The National Footprint Accounts are updated and improved every year, and the annual release of the newest version ensures that the method is more robust, reliable, and detailed than previous versions, though some shortcomings still exist and remain to be addressed. The Ecological Footprint Standards are also periodically updated. The information derived from Ecological Footprint assessments could be included in the environmental management and future planning of territories to promote more competitive lifestyles, resource-efficient strategy, and a more effective management of our ecological assets.

Environmental Legislation: Asia

Wanpen Wirojanagud

Introduction

The 21st century has been dubbed "The Asian Century." The region's economic growth is unprecedented, with the rise of China and India as the next economic superpowers.[1] China is the second largest economy and is predicted to take over after the United States as the largest economy in the world by 2020. India is one of the fastest-growing economies and is expected to become the world's third largest economy in the near future.[2–3] More than 58% of the world's population live in Asia and the Pacific region, and Asia is categorized both as the factory of the world as well as the booming market with tremendous growth potential. As a result, natural resources, which are the capital for development of both economic and social sectors, have been remarkably exploited, with a consequent substantial increase in environmental pollution. Without proper environmental management, the ecosystem continues to suffer, resulting in loss of biodiversity, depletion of ecosystem services, desertification, loss of fertile land, atmospheric pollution, aquatic and marine pollution, etc. The consequences of environmental degradation have become more and more acute and chronic over the years. Moreover, natural disasters are more frequent and more severe. As indicated in the Asia-Pacific Disaster 2010 Report of the United Nations (UN), "while the region generated one quarter of the world's GDP, it accounted for a staggering 85 per cent of deaths and 38 per cent of global economic losses due to natural disasters over the last three decades." The report concludes that Asia is the most disaster-prone region in the world.[4] The change in climate patterns has also become more severe.

Environmental status in Southeast Asia, as summarized in Table 1, evidently indicates that over the last decades pressure mostly from anthropogenic activities (rapid population growth, urbanization, economic growth, and consumptive lifestyle) has had a substantial impact on the plentiful natural resources and the environment. Natural resources depletion results in impact on agricultural

TABLE 1 Key Environmental Issues and Causes in ASEAN

Country	Shared Issues	Key Causes
Brunei	Seasonal smoke and haze; solid wastes	Transboundary pollution from land and forest fires; inadequate waste management facilities and practices
Cambodia	Soil erosion; sedimentation; water pollution; deforestation; loss of biodiversity; and threats to natural fisheries	Unmanaged waste and effluent discharge into Tonle Sap Lake; destruction of mangrove wetlands through extensive industrial and aquaculture development
Indonesia	Deforestation; loss of biodiversity; water pollution; air pollution in urban areas; national and transboundary seasonal smoke and haze; land degradation; pollution of Malacca Straits	Deficiencies in urban infrastructure—unmanaged industrial wastes and municipal effluents and waste; vehicle congestion and emissions; extensive land clearance and forest fires for pulp wood and oil palm production; extensive and unmanaged mining activities; national and transboundary industrial pollution; tourist developments in coastal regions beyond carrying capacity
Laos	Deforestation; loss of biodiversity; soil erosion; limited access to potable water; water-borne diseases	Land clearance; shifting cultivation; inadequate water supply and sanitation infrastructure
Malaysia	Urban air pollution; water pollution; deforestation; loss of biodiversity; loss of mangrove habitats; national and transboundary smoke/haze	Vehicle congestion and emissions; deficiencies in urban infrastructure industrial and municipal effluents; extensive land clearance and forest fires for pulp wood and oil palm production; unmanaged coastal developments; tourist developments in coastal regions beyond existing carrying capacity
Myanmar	Deforestation; loss of biodiversity; urban air pollution; soil erosion; water contamination and water-borne diseases	Land clearance; excessive mineral extraction; vehicle congestion and emissions; deficiencies in urban infrastructure—unmanaged industrial and municipal effluents
Philippines	Deforestation in watershed areas; loss of biodiversity; soil erosion; air and water pollution in Manila leading to waterborne diseases; pollution of coastal mangrove habitats; natural disasters (earthquakes, floods)	Illegal forest cutting; land clearance; rapid urbanization and deficiencies in urban infrastructure—unmanaged industrial and municipal effluents, inadequate water supply and sanitation; tourist developments in coastal regions beyond existing carrying capacity
Singapore	Industrial pollution; water shortages; waste disposal problems	Seasonal smoke/haze; limited natural fresh water resources; limited land available for waste disposal
Thailand	Deforestation; loss of biodiversity; land degradation and soil erosion; shortage of water resources in dry season and flooding in rainy season; conflict of water users; coastal degradation and loss of mangrove habitat; urban air pollution; pollution from solid waste, hazardous materials and hazardous waste	Sporadic development and destruction of watersheds; unmanaged aquaculture; tourist growth exceeding growth in carrying capacity; deficiencies in urban and rural infrastructure; freshwater resources polluted by domestic/industrial wastes, sewage, and contaminated runoff
Vietnam	Deforestation and soil degradation; loss of biodiversity; loss of mangrove habitat; water pollution and threats to marine life; groundwater contamination; limited potable water supply; natural disasters (e.g., floods)	Land clearance for industry; forest clearance and chronic impact of Agent Orange; extensive aquaculture and overfishing; growing urbanization and infrastructure deficiencies; inadequate water supply and sanitation (particularly in Hanoi and Ho Chi Minh City)

Source: Data from Nguyen.[5]

productivity; increased frequency of disasters such as floods, landslides, and soil erosion[5]; depletion of aquifers; deterioration of diversity; increased loads from municipal, industrial, and hazardous wastes; atmospheric pollution; and marine and aquatic pollution.[6]

Hence, the key policy question facing Asian governments is how to reconcile economic development and environmental protection. In other words, how to make a transition from the "grow first, clean later" approach to the policy of "sustainable development"—a holistic integration of economic, social, and environmental dimensions.[7] More importantly, the main driving forces in the development of environmental management tools in Asia are international agreements, the occurrence of environmental disasters, and non-harmonized legal framework. Asian countries have shown increasing interest in environmental management by which environmental legislation has been used as one of the important tools in this complex task of integrating environmental protection and economic development. Environmental legislation is among the most determined elements in environmental management toward sustainable development.[8] "Legislation is an important element of the institutional framework for environmental management. The role of legislation is to implement and enforce policy and to provide effective administrative and regulatory mechanisms."[9]

Relevantly, development and implementation of environmental law may involve interaction with legislation and administrative practices and institutions. Thus, environmental laws are undeniably increasingly important in Asia. Environmental law is defined as a body of state and federal statutes intended to protect the environment, wildlife, land, and beauty; prevent pollution and overcutting of forests; save endangered species; conserve water; develop and follow general plans; and prevent damaging practices.[9] The particular law gives individuals and groups the right to bring legal actions or seek court orders to enforce the protection, or demand revisions of private and public activity that may have detrimental effects on the environment.

In terms of the evolution of environmental legislation, two different types of statutes can be distinguished, referred as to the "first generation" and the "second generation" of environmental laws. Although there is no total agreement about how to characterize each generation, generally, the first generation of environmental legislation refers to "command-and-control statutes and regulations administered with technology-based standards and enforced by rule-of-law litigation."[10] Then arrived the "second generation" in the late 1980s with the new concept of "sustainable development" aimed at reconciling environmental protection and economic development.[11] The role of the people, particularly local communities, is highlighted, and compliance incentives and market-based mechanisms have been developed to encourage compliance and provide flexibility.[12]

In the Asia-Pacific region, environmental legislation began to emerge in the 1970s, the same period as the growing global interest in environmental protection. Examples of the early framework laws and regulations for environmental protection are presented in Table 2. Noticeably, there is no lack of environmental legislation in Asia. However, there is a wide gap between law and practice. The countries have to put an emphasis on ways and means to increase the effectiveness of the implementation and enforcement of environmental law.

This entry aims to provide a comparative overview of environmental law and legislation in Asia. It should be noted, however, that the development of environmental legislation in Asia has been uneven and reflects the equally uneven socioeconomic development in the region. In some cases, differences may not be significant in written laws, but lie in the effectiveness of their implementation and enforcement. Due to a wide range of environmental issues and the number of countries in Asia, it is impossible to cover all of them. The entry spotlights four themes—biodiversity conservation, electronic waste (e-waste) management, environmental assessment, and climate change—because of their significance in the Asian context. The choice of countries as case studies aims to demonstrate the uneven development of environmental legislation. Thus, Japanese law serves as a reference of a well-developed body of environmental law, with the second-generation of legislation. China, Korea, Malaysia, Indonesia, Singapore, Hong Kong, Cambodia, Thailand, Laos, and Vietnam are at various stages of development ranging from the first-generation statutes, to development of second-generation environmental laws, and implementation and enforcement.

TABLE 2 Early Laws and Regulations on Environment in the Region

Country	Law or Regulation	Year
Cambodia	Environmental Protection and Natural Resource Management Law	1996
China	Environmental Protection Law	1978
Hong Kong	Water Pollution Control Ordinance	1980
Indonesia	Environmental Management Act No. 4	1982
Japan	Cabinet Directive	1972
Korea	Environmental Preservation Act	1977
Lao PDR	Lao PDR Constitution	1991
Mongolia	Environmental Protection Law	1996
Philippines	Environmental Policy Presidential Decree No. 1151	1977
Singapore	Environmental (Public Health) Act	1969
Thailand	Enhancement and Conservation of the National Environmental Quality Act	1992
Vietnam	Environmental Protection Law	1994

Law on Biodiversity Conservation

Asia-Pacific is one of the richest regions in terms of biodiversity and 60% of the world's species are found in this region. As of 2008, the Asian and Pacific regions had the highest number of threatened species in any of the world's regions, almost one-third of all threatened plants and more than one-third of all threatened animal species.[13] The first generation of biodiversity law consisted mainly in establishing protected areas where human intervention is curtailed or prohibited. However, this exclusionary approach has caused notable socioeconomic impacts, in particular to local communities who used to live in the areas before the establishment of national parks. Therefore, more inclusive approaches have been proposed, such as community-based conservation (comanagement of a protected area by the government and local communities) and payments-based conservation (individuals are paid for their activities to conserve biodiversity). Biodiversity conservation capability is thus a function of a sound legislation in both international and national levels.

Recent Development in International Law and Its Potential Consequences on National Legislations

The international legal instruments, together with agreements that initiate the legislative framework of individual countries for biodiversity conservation, include The Convention on Biological Diversity (CBD) that entered into force on December 29, 1993, the Convention on Wetlands of International Importance Especially as Waterfowl Habitat (Ramsar 1971), the Convention Concerning the Protection of the World Cultural and Natural Heritage (Paris 1972), the Convention on International Trade in Endangered Species of Wild Fauna and Flora (Washington 1973), the Convention on the Conservation of Migratory Species of Wild Animals (Bonn 1979), etc.[14] However, an effective implementation for the international legal agreements is largely dependent on the actions taken by individual countries. Consequently, the most important of all is to establish the legal systems for biodiversity conservation at state level.

Very recently, on February 2, 2011, the Nagoya Protocol on Access to Genetic Resources and the Fair and Equitable Sharing of Benefits Arising from their Utilization was opened for signature by Parties to the Convention of Biological Diversity. Many Asian countries are in the process of amending their legislation to implement the provisions under this new protocol. As most Asian countries are resource-providing countries, the Nagoya Protocol will allow better control of their genetic resources and ensure fair financial compensation among various stakeholders, including local communities.[15]

As for forestry, the new market-based mechanism of "Reducing Emission from Deforestation and Degradation (REDD)," which is under discussion in the UN Climate Change negotiations, should provide additional impetus to the improvement of forest law in Asian developing countries, particularly in the areas of monitoring, reporting, and data collection. Cambodia, Indonesia, Papua New Guinea, the Philippines, and Vietnam are among the first countries to receive support from the UN REDD Program.[16]

Development of Biodiversity Laws at National Level

At present, the biodiversity conservative laws of Asian countries like Japan, Thailand, Indonesia, and Laos contain more or less elements of public participation that characterize the second generation of legislations. Except for Japan, however, communities' rights are still very limited and difficult to enforce. The payment-based conservation approach has generally only been implemented through small-scale projects and not adopted by Asian legislators yet.

China. China covers an enormous land area of 9,600,000 km^2, including complex and varied geomorphology, climate, and natural conditions. That creates a country rich in ecosystems, which can be categorized into five types, namely forest, grassland, desert, inland wetland and other freshwater ecosystems, and ocean and coast. Due to a massive and distinct diversity of flora and fauna, China is regarded as one of the most important biodiversity countries. It is ranked among the top 10 nations in the world diversity of its mammal, bird, amphibian, and plant species. China has been considered to have one of the most important stocks of genetic diversity in the world. It is very important to protect and conserve this biodiversity for the national and international heritage.

China has promulgated a series of laws and regulations. The main domestic laws are Forest Law (1984), Grassland Law (1985), Fishery Law (1986), and Wild Animal Conservation Law (1988). Examples of regulations related to biodiversity include Reproduction and Conservation of Aquatic Resources (1979), Regulation on Forest and Wild Animal Nature Reserves Management (1985), Regulation on Forest Fire Prevention and Control (1988), Regulation on Seed Management (1989), Regulation on Conservation of Terrestrial Wild Animals (1992), Regulation on Nature Reserves (1994), etc.

Regarding the enforcement of the statutes, great progress for in situ and ex situ biodiversity conservation has been achieved. There are, however, still some gaps in the legislation. Based on the current status of conservation legislation in China and in accordance with the Convention on Biological Diversity, more attention should be paid to the conservation legislation for genetic resources, wild plant species, and various natural ecosystems.

Korea. Ecosystems in Korea comprise forest, mountain, freshwater, coastal and marine, and agriculture ecosystems. The total forest area covers 6.394 million hectares, estimated as about 64% of the country's land area. Forests are mainly coniferous, deciduous, and mixed forests. The variety of habitats creates a rich biodiversity of plants, animals, and other living organisms (fungi, protista, prokaryotes, etc.). Some species are considered to be extinct, such as the tiger and Siberian leopard, fox, wolf, and sitka deer. The decline of biodiversity in Korea is associated with its economic development. The main threats to biodiversity include overexploitation of land and biological resources, and environmental pollution.

Under the guiding principles of the Framework Act on Environmental Policy 1990 and the Constitution, the Natural Environment Conservation Act 1991 administered by the Ministry of Environment is Korea's basic law for biodiversity and nature protection. It defines categories of protected areas and provides for species and habitat protection. The law serves as a common framework for nature conservation and strengthens the provisions of other nature laws administered by government agencies. Several government agencies share the responsibility of conservation and sustainable use of biodiversity, in accordance with various laws. The Ministry of Environment is responsible for general biodiversity conservation under the Law of Natural Environment Conservation, Law of Wildlife Protection and Hunting, Law of Wetland Conservation, Law of Natural Parks, and Law of Ecosystem Conservation for Uninhabited Islands. The Ministry of Environment is also responsible for preventing inappropriate uses of natural resources through the Environmental Impact Assessment (EIA) process by the Law of Environmental Impact Assessment. The Forestry Administration, part of the Ministry of Agriculture and Forests, which manages forests under the Law of Forests.

Japan. The country is 3000 km long in the north–south direction, with a vertical range from coasts to mountains, with thousands of islands, and a geological history of intermittent connection to and separation from the continent, and various disturbances such as eruption of volcanoes, flooding of precipitous rivers, and typhoons. Those geological characteristics, together with four definite seasons due to the monsoon climate, create diverse habitats. It is such rich biodiversity that makes Japan one of the 34 biodiversity hotspots identified worldwide. A biodiversity hotspot refers to a region that is originally rich in biological diversity and endemic species but is now exposed to a serious threat of loss of such diversity. Besides the original local geohistorical and natural conditions, the tradition of wet-paddy rice agriculture and the rural lifestyle, which rely on a secondary natural environment known as "satochi-satoyama," or simply "satoyama," as well as the way the land has been used for agricultural purpose, have also contributed to the area's biodiversity richness. As in other countries, biodiversity loss in Japan is due to high economic growth with industrial development, and also natural disasters. It can, however, be said that the Japanese law on biodiversity is regarded as one of the best laws in the field. It goes beyond the protected area–based approach by mainstreaming biodiversity conservation into the daily life of the people. The law defines not only the responsibilities of national government and local governments but also those of businesses, citizens, and private bodies. The elaboration of the National Biodiversity Strategy and regional biodiversity strategies are mandatory. The 4th National Biodiversity Strategy, which was adopted in 2010, sets a long-term goal of 100 years, mid-and short-term targets for 2020 and 2050, and indicates about 720 measures with 35 targets.[17] The results of the implementation have to be reported to the Diet every year in the Annual Report on the State of Biodiversity. The law puts emphasis on preventive and adaptive approaches, including land use planning, research and technology development, EIA, and prevention of global warming. The role of the public is also highlighted with mandatory public consultation before formulation of policies and support of voluntary activities by businesses and citizens for the conservation of biodiversity.

Other relevant legislations are the Nature Conservation Law, Natural Parks Law, Law for the Promotion of Nature Restoration, Law for the Promotion of Biodiversity Conservation Activities, Law for the Conservation of Endangered Species of Wild Fauna and Flora, Wildlife Protection and Proper Hunting Law, Invasive Alien Species Act, and Law Concerning the Conservation and Sustainable Use of Biological Diversity through Regulations on the Use of Living Modified Organisms.

Malaysia. Malaysia has been identified as one of the world's mega-diversity areas with extremely rich biodiversity. Covering much of the country are the tropical forests, the oldest and most biologically diverse ecosystem on Earth. With ratification of the CBD, Malaysia is working toward incorporating into its national policies and planning a set of commitments under the treaty as well as setting the goal to become a world leader in conservation, research, and sustainable utilization of tropical biodiversity by 2020. To accomplish the ratification and goal, Malaysia has enacted a spectrum of legislation aimed at protecting biodiversity. Examples of law relevant to biodiversity conservation are as follows: Environment Quality Act 1974, Fisheries Act 1985, Pesticides Act 1974, Plant Quarantine Act 1976, Protection of Wildlife Act 1972, National Parks Act 1980, National Forestry Act 1984, Parks Enactment 1984, Forest Enactment 1992, Fauna Conservation Ordinance 1963, etc.[18,19]

Malaysia has enacted a number of laws and regulations to protect the nation's environment but, while adequate, there was no single overarching statute (or policy?) that relates to biodiversity conservation and management until the just approved National Policy on Biodiversity. Much of the present legislation is sector based. As stated above, the attainment of biodiversity conservation is significantly dependent on implementation and enforcement of the legislation. The effectiveness of legislation can be accomplished by the dedication of government agencies as well as public participation for accountability.[18,19]

Indonesia. Indonesia is a rich and diversified archipelagic nation. With the topographical characteristics of approximately 13,500 islands and extensive reef system, Indonesia has a wide range of natural habitats, with a wealth of fauna and flora, corals, fish, and other reefs; thus, it is recognized as a major world center for biodiversity. However, that substantial biodiversity is decreasing in the country owing to illegal clearing and deforestation, including large-scale burning in oil palm plantations and small-scale slash and burn for shifting farming, as well as illegal logging and trade in timber. Indonesia has one of the world's worst deforestation rates. In addition, illegal poaching, trade in protected species, and illegal and unsustainable fishing have threatened the country's biodiversity.[20,21]

Regarding the domestic legal framework, as the result of 1972 UN Stockholm Conference on the Environment, Indonesia promptly established of the Office of the State Minister for the Environment and enacted the Environmental Management Act (EMA) No. 4 of 1982 replaced in 1997 by the EMANo. 23 of 1997. This act and its implementing regulations are set in the broader context of the state policies passed every 5 years by the People's Consultative Assembly, which have since the early 1970s progressively entrenched the concepts of sustainable development and natural resources management. The EMA must also be read in the context of other natural resources management acts, such as the Forestry Act No. 41 of 1999, and the Fisheries Act No. 31 of 2004, and associated regulations and decrees transferred to the local governments' agencies. Laws and regulations related to biodiversity conservation are exampled as follows: Act on the Conservation of Biological Resources and their Ecosystems (Act No. 5 of 1990), Decree No. 1 of the Minister of Agriculture on the Conservation of the Riches of the Fish Resources of Indonesia, and Decree of the Ministry of Forestry No. 424/ KPTS-VI/1994 on the Guidelines on Crocodile Management in Indonesia, Fisheries Law (No. 9 of 1985). Similarly to other countries, law enforcement is still not an effective function. Indonesia has no specialized environmental law courts. Environmental cases are heard by the general and administrative courts as well as the Supreme Court on appeal.[21]

Furthermore, a multitude of biodiversity laws in Indonesia tend to be conflicting and uncoordinated. Also, in the forestry sector, the power to manage forests is shared between the central government and regional governments with no clear division of powers and responsibilities. It is believed that the Regional Autonomy Law, which entered into force in 1999, has been abusively used by local authorities to issue their own logging concessions, thus resulting in massive deforestation and forest fires.[22] The Indonesian case shows that a legislation that transfers power from center to periphery has to be carefully drafted to ensure that the power is put in the hands of local communities whose livelihood depends on the forests and biodiversity, and not in the hands of local officials known for corruption and nepotism. Some main legislations of Indonesia relating to biodiversity are the Conservation of Biodiversity and Ecosystems Law (1990) and the Basic Forestry Law (2000). These laws include provisions on participatory forestry planning, people's economic empowerment, partial transfer of authority to regional governments, and community-based forest monitoring.

Philippines. The Philippines is a tropical archipelago of 7100 islands located off the southeast coast of mainland Asia. It occupies a land area of 299,400 km^2, and territorial waters covering around 2,200,000 km^2, that create precious terrestrial and aquatic ecosystems and habitat types. As a consequence of rapid loss of biodiversity, as well as widespread destruction of the country's environment, a strong effort has been put into biodiversity conservation, including the formation of the multisector Philippine Council for Sustainable Development (1992), ratification of the Convention on Biological Diversity (1993), and preparation of the Philippine Biodiversity Assessment Report and the National Biodiversity Strategy and Action Plan (NBSAP) (1995–1997). The NBSAP proposes a wide range of strategies and actions, including information generation, in situ and ex situ conservation, legislative and policy development, institutional capability building, information, education and communication, and strengthened international cooperation.[23]

Regarding ecosystem and habitat conservation in the Philippines, it was innovated through the National Integrated Protected Areas System Act of 1992, a landmark piece of legislation that provides the framework for a decentralized, community-based reserve management strategy. The legislation relevant to biodiversity conservation include the following: Act No. 2590 (1916), An Act for the Protection of Game and Fish; RA 7586 National Integrated Protected Areas System Act of 1992; RA 7900, High-Value Crops Development Act of 1995; PD 1433, Plant Quarantine Decree of 1978; Proc. No. 926, Establishing Subic Watershed Forest Reserve; DAO 20, s 1996, Implementing Rules and Regulations on the Prospecting of Biological and Genetic Resources; DAO 24, s 1991, Shift in Logging from the Old Growth (Virgin) Forests to the Second Growth (Residual) Forests; DAO 20, s 1996, Implementing Rules and Regulations on the Prospecting of Biological and Genetic Resources; etc.[24]

Singapore. The Republic of Singapore, situated off the southern tip of the Malay Peninsula, comprises one major and more than 50 adjacent islands, with a total area of 648 km^2. The main island is separated from Malaysia by the narrow Johor Strait on the north, and from Indonesia's Riau Archipelago by the Singapore Strait on the south. It is a small country with an urbanized character. Forest land and coastal areas have been cleared to provide land for residential and commercial sites and other developments, resulting in a substantial depletion of flora/fauna and deterioration of natural habitats. At present, the environmental policy states that 5% of the land area should be set aside for nature reserves, national parks, catchment areas, bird sanctuaries, and gardens. Some of the environmental laws related to biodiversity conservation are Fisheries Act 1966, Wild Animals and Birds Act 198, Parks and Trees Act (for parks not gazetted as national parks) 1985, Endangered Species Act 1989, National Parks Act 1990, Animals and Birds Act (Revised) 2002.[25]

To accomplish the vision of *Singapore Today,* which is to be "A Garden City, A Haven for Biodiversity," the Singapore Green Plan (SGP) 2012 was established to provide the direction for protected area management in the next decade. One of the SGP objectives is to ensure the quality of the living environment, including the enhancement of the country's environmental heritage. SGP 2012 also recaps the state's commitment to maintain the 5% of land set aside for nature areas, and provides the direction.[26]

Hong Kong Special Administration Region. Like Singapore, Hong Kong SAR (or Hong Kong in short) experienced very rapid growth and development, to become urbanized and industrial in character. This would have jeopardized the biodiversity of the area, which is recognized as part of the natural heritage of Hong Kong. The most common causes of biodiversity loss in Hong Kong now are habitat destruction associated with infrastructure development, population growth, hillside fires, unsustainable exploitation of wild species, introduction of alien species, pollution, and global environmental change. Possible relevant factors contributing to such causes are lack of a comprehensive legal framework to protect areas of high conservation value and poor enforcement of existing conservation, environmental, and planning laws.[27]

Environmental protection in Hong Kong is constituted by 16 ordinances. Nonetheless, overall environmental laws in Hong Kong are still short of an unambiguous conservation objective. Only the 1995 Marine Parks Ordinance (Cap. 476) and the 1997 Protection of the Harbour Ordinance (Cap. 531) enclose evidently expressed conservation principles. Other legislations protecting flora and fauna are focused on conserving particular species; however, they fail to address the values and principles that lie beneath these objectives. Regarding the Country Parks Ordinance (Cap. 208) originally enacted in 1976, a revision is needed, "To provide for the designation, control and management of country parks and special areas for the purposes of conservation of biological diversity, countryside recreation and education." Additionally, the Environmental Impact Assessment Ordinance (EIAO) is the newest piece of legislation that seeks to protect the environment. The EIAO requires certain designated projects (generally major infrastructure projects) to undertake an EIA before they can be granted an environmental permit for development to proceed. A Technical Memorandum contains guidance on the criteria and guidelines to use for ecological, fisheries, landscape, and visual impact assessment.[27]

As well as domestic laws, Hong Kong is obligated to protect its natural and cultural heritage by international treaties, including the 1973 Convention on International Trade in Endangered Species of Wild Fauna and Flora, the 1979 Convention on the Conservation of Migratory Species of Wild Animals, the 1971 (Ramsar) Convention on Wetlands of International Importance, and the 1972 Convention for the Protection of World Cultural and Natural Heritage. Seemingly, application of the 1992 Convention on Biodiversity in Hong Kong remains limited as there is no sign that the treaty will be formally applied to accomplish the CBD's biodiversity objectives after the government's endorsement.[27,28]

Thailand. Thailand has a total land area of 513,115 km^2, lying in a hot and humid climatic zone in the middle of Southeast Asia. Much of Thailand is situated in the Mekong River basin, and it is one of the Greater Mekong Subregion (GMS) countries. Thailand also has an extensive coastline. With such a location, it is enriched with biodiversity associated with terrestrial and aquatic (both freshwater and marine) ecosystems. It also covers agricultural ecosystems (about one-fifth of the country), which include biodiversity components of rice, farm crops, and livestock. Similarly to other countries, the major threat to biodiversity is human disturbance through overexploitation of natural resources/ habitat, illegal logging and trading of animals, overhunting of wildlife, deforestation, urban expansion and pollution, etc. Such disturbances cause an adverse reduction of bio-diversity.[29]

Biodiversity in Thailand is safeguarded by a number of laws and regulations. Some of the important ones are the National Park Act 1961, National Forest Reserve Act 1964, Wild Animal Reservation and Protection Act 1992, Plant Quarantine Act of 1964 and Plant Quarantine Act (second issue) 1994, Animal Species Maintenance Act 1966, Importing and Exporting of Goods Act 1979, Enhancement and Conservation of National Environmental Quality Act 1992, and Plant Varieties Protection Act 1999.[30]

In addition, Section 66 Paragraph 1 of the Thai Constitution of 2007 guarantees the right of an individual and communities to participate in the preservation and exploitation of natural resources and biological diversity. However, out of 35 pieces of legislation relating to natural resources, biodiversity and environment, only 4 provides for public participation, namely, the National Promotion and Conservation of Environment Quality Act, B.E. 2535 (1992); the Private Irrigation Act, B.E. 2482 (1939); the Plant Varieties Protection Act, B.E. 2542 (1999); and the Protection and Promotion of the Thai Traditional Medicine Act, B.E. 2542 (1999). Moreover, the rights given to individuals are still very limited, and the authorities retain most of the control in natural resources management.

Lao People's Democratic Republic. Lao PDR, situated in the Mekong River basin, is counted as one of the GMS countries. For Southeast Asia, Lao PDR is one of the countries with a large proportion of land covered with undisturbed forest. It covers a land area of 236,800 km^2, where the topography is largely mountainous, with elevations above 180 m typically characterized by steep terrain, narrow river valleys, and low agricultural potential. Lao PDR is rich with natural resources such as forestry, minerals, and hydroelectric power. Due to the country's still abundant forestry resources, it thus generates a prosperous biodiversity.[31,32] Similarly to other GMS countries, Lao PDR has enacted laws for biodiversity conservation, but the enforcement is ineffective. Illegal logging and wildlife hunting have been frequently found. Mining and hydropower developments might also cause loss of biodiversity.[31,32]

In Lao PDR, biodiversity conservation is provided for in the Forest Law of 1996, a 1993 decree that designated the first national biodiversity conservation areas, logging ban, decree on (PM Decree No. 67/PM, 1991) protecting trees by logging, decision on adoption of (PM Decree No. 66/PM, 1991) forest conservation, and seed material import regulation (quarantine regulation) that controls importation of plant material.[32]

Cambodia. Cambodia is a tropical country in mainland Southeast Asia with a territory of 181,035 km^2. It is adjacent to the Gulf of Thailand on the south and shares borders with Thailand (west and north), Laos (north), and Vietnam (east). Cambodia is in the Mekong River basin. The country is dominated by the Mekong River, known as the Tonle Thom or "great river," and the Tonle Sap or "fresh water lake." The Mekong River basin is one of the most biodiverse regions in the world. As situated in the Mekong River Basin, Cambodia has an abundance of terrestrial and aquatic ecosystems that are significant habitat for plants and aquatic organism, fishes in particular. Such ecosystems are invaluable resources for economic development and human well-being.[33,34]

To protect and sustain the country's biodiversity, Cambodia enacted the framework for the Law on Environmental Protection and Natural Resources Management in 1996. Subsequently, the Ministry of Environment was created in 1998, which manages natural resources along with the Ministry of Water Resources and Meteorology and the Ministry of Land Use Management, Urbanization, and Construction. Cambodia has continued to enact more environmental and conservation laws. Examples of the relevant laws are as follows: Environmental Protection and Natural Resources Law 1996, Law on Commune

Administration (part of the decentralization process) 2001, Land Law 2001, Forestry Law 2002, and Wildlife Law 2002. Important subdecrees include Subdecree on Concession Management (moratorium on logging and log transport), Subdecree on Community Forestry, Subdecree on Environmental Impact Assessment, Subdecree on Industrial Agricultural Concessions, Subdecree on Social Concessions, and Royal Decree on Protected Areas 1993.

Cambodia is party to a number of important international conventions of which those stated here are relevant to biodiversity conservation. The Ramsar Convention on Wetlands has been ratified, and Cambodia has identified three wetland sites for recognition: BoengChhmar in the Tonle Sap floodplain, KohKapik on the coast, and a portion of the middle Mekong river north of Stung Treng. In addition, the Tonle Sap is recognized as a UNESCO Biosphere Reserve. Cambodia ratified the Convention on Biological Diversity in 1995. In 1997, the government prepared a biodiversity prospectus and in 2002 completed a National Biodiversity Strategy and Action plan.[19,33]

Vietnam. Vietnam is situated at the eastern side of a peninsula that protrudes into the Eastern Sea, which is a bay of the Pacific Ocean. Within the Mekong River Basin, Vietnam is at the most downstream length of the Mekong River. Due to the country occupied with land, river, and sea, Vietnam is enriched with a variety of ecosystems, including tropical rainforests and monsoon savannah, marine life, and mountainous subalpine scrubland. Additionally, a specific feature of Vietnam is its length of more than a thousand miles from north to south, with a width of only 30 miles from east to west at its narrowest point, thus generating an abundance of natural resource along the coast and sea, and a richness of biodiversity. The threats tobiodiversity are mainly due to transformation of forest and wetland areas to other uses, infrastructure construction, urbanization, industrialization, and environmental pollution.

Vietnam's environmental law is based on its constitution. The Law on Environmental Protection was initially promulgated in 1993; subsequently, Vietnam has enacted a variety of laws and decrees on conservation issues. These laws affect, directly or indirectly, the conservation of biodiversity. Examples of the direct laws are the Decree on the Conservation and Development of Wetlands, the Decree on Protection of the Environment (which details rare and precious flora and fauna), and a related decree that determines methods for regulating their protection and management. The indirect laws include decrees regulating wastewater, controls on businesses creating environmental damage, the 2003 Land Law, etc. Regarding the protected areas, Vietnam has two laws concerning the establishment and management of protected areas. The two statutes are the Law on Forest Protection and Development of December 2004 (revised from the 1991 original), and the Law on Biodiversity that became effective starting July 2009. The Law on Forest Protection and Development provides the guiding principles for the development and use of special-use forests, while the Law on Biodiversity focuses on protected area concerns such as categorization and decentralization of protected area management.

Challenges to Effective Implementation and Enforcement of Biodiversity Law

Evidently, the countries presented here have enough laws and regulations to protect their environment; however, much of the present legislation is sector based. Moreover, the achievement of biodiversity conservation is not a function of the number of laws and regulations but of the implementation and enforcement of such legislation. The effectiveness of legislation can be accomplished by the dedication of government agencies as well as public participation for accountability.[19]

As partly demonstrated through the case studies mentioned above, challenges facing Asian governments in the implementation and enforcement of biodiversity law lie in corruption, weak institutional capacity, lack of reliable data and budget, high demand for alternative land use, and traditional beliefs.

With regard to weak institutional capacity, in most Asian countries, forestry staffs are not adequately trained and are underpaid. To address this shortcoming, governments such as China and Vietnam have raised the pay and living conditions for forest personnel.[19] Inter-agency coordination is another serious institutional problem. There are usually many agencies involved in forest management with overlapping areas of responsibilities or, on the contrary, areas where no agency is in charge.

Economic development has put pressure on forest protection. The construction of hydropower dams and roads, and agricultural activities have often encroached on protected lands. In an effort to reconcile forest protection and economic development, Lao PDR has piloted hydropower levies that support the management of protected areas affected.[34]

Forests and wildlife statistics are often out of date, inaccurate, and incomplete. The remoteness of the forest areas and the reluctance of officials to report forest crimes (as they may be seen as a sign of failed forest management on their part) are among factors that contribute to the lack of reliable data and information sharing among relevant agencies. The use of satellite imagery has helped improve the data collection system to a certain extent.

Traditional beliefs may sometimes come in the way of forest and wildlife protection. In many Asian countries such as China, Vietnam, Thailand, Laos, and Cambodia, the consumption of rare wildlife, such as bear's paw and monkey brains, is seen as status symbols or medicines.

Regional Cooperation

Regional cooperation has played an important role in promoting sustainable forest management. Examples of regional initiatives are the East Asia Forest Law Enforcement and Governance process (EAFLEG) and the Asia Forest Partnership (AFP). Both the EAFLEG and the AFP aim to bring together various stakeholders in forest management, including governments, non-governmental organizations (NGOs), and the private sector. They serve as an informal forum for information sharing, dialogue, and joint action. Within the Southeast Asian Nations Association (ASEAN), the ASEAN Senior Officials on Forestry (ASOF) was entrusted with the task of policy coordination and decision making on regional cooperation in the forest sector.

Law on E-Waste Management

The quantity of e-wastes in Asia has exploded in recent years with the exponential growth in the use of electronic equipment (computers, mobile phones, televisions, refrigerators, etc.) coupled with the consumers' behavior of regularly replacing their devices in order to stay up-to-date with the latest technology. E-wastes often end up in incinerators and/or landfills. Toxic substances such as mercury and lead that are commonly used in electronic products can contaminate the environment, including land, water, and air. E-waste is commonly characterized as hazardous waste. As of July 2008, among 46 countries in the Asia-Pacific region, there are 32 countries that have ratified the Basel Convention on the Control of Transboundary Movements of Hazardous Wastes and Their Disposal and some of them have also ratified the Ban amendment.[35] However, there are some countries in Asia that still lack regulations for controlling hazardous wastes including e-waste. An effective regulatory framework on the management of such wastes is urgently needed. A new legal concept created to deal with e-waste management is the Producer Extended Responsibility (PER) where producers are held liable for the costs of managing their products to end of life of the product. In this way, producers are encouraged to design environmentally friendly products to reduce disposal costs. Only a few countries, such as Japan, Korea, and Taiwan, have a well-established legislation on e-waste management based on the concept of PER and many years of experience in implementation. Some Asian countries such as China have recently enacted a law on the matter; however, the effectiveness of the implementation remains to be seen. Other countries have already passed similar laws, but the laws have yet to enter into force (Thailand and India) or are still at the drafting stage. An adaptation period is usually granted for businesses before the entry into force of the law. Other actors in a product's life cycle such as distributors, repair and customer service providers, consumers, and recyclers may also be required to bear some of the treatment and disposal costs. E-waste discussed herein includes used and waste electrical and electronic equipment (UEEE/WEEE).

China. The Ministry of Environment and Protection is responsible for regulating and controlling e-waste management. At the end of February 2006, China promulgated the law entitled "Administration on the Control of Pollution Caused by Electronic Information Products," which is simply called as China RoHS in the industry.[36] Import of WEEE has taken place since 2002 under the existing laws, including Law of the People's Republic of China on Prevention of Environmental Pollution Caused by Solid Waste, Interim Provisions on Administration of Environmental Protection on Import of Waste and its supplementary provisions, List of Wastes Prohibited against Import (Notice No. 25, 2002), and Catalogue of Solid Waste Forbidden to Import in China (Announcement No. 11, 2008). Regarding UEEE, it is allowed except used TVs; UEEE requires 3C certification. Applicable laws for UEEE are as follows: Administrative Method on Inspection and Supervision of Imported Used Mechanical and Electrical Products, Measures for Administration of Import of Specified Used Mechanical and Electrical Products (Order No. 5, 2008), and Catalogue of Import of Specified Used Mechanical and Electrical Products (Announcement No. 37, 2008). A new law on the management of e-waste has established higher standards for recycling processes and allows only certified recyclers to engage in the e-waste recycling business. To support recyclers to improve their equipment and facilities, a centralized mandatory fund has been established with contributions from domestic producers and sellers of imported electronic devices. The law also places responsibility on manufacturers, distributors, repair and consumer service providers, and recycling companiesto collect and responsibly handle e-waste. One shortcoming of the law, however, is that the scope of their responsibility and the penalizing measures for non-compliance remains vague.[35]

Hong Kong, China. The regulation of e-waste management is under the responsibility of the Environment Protection Department. Hong Kong has begun its waste import and export control through the Waste Disposal Ordinance in 1996. For the purpose of import, WEEE and UEEE (that is classified as WEEE) have been controlled through a permit system in accordance with guidelines on "import and export of hazardous waste including electrical and electronic appliances containing hazardous constituents or components."[35]

Republic of Korea. The Resource Recirculation Policy Division, Ministry of Environment, is responsible for regulating and controlling e-waste management. Specific regulations applicable to UEEE and WEEE do not currently exist; however, in general, e-waste management falls under the "Waste Control Act" of December 1986 and later amendments. Import control of WEEE is performed through application for a license from the Ministry of Environment in accordance with the Act on the Control of Trans-Boundary Movement of Hazardous Wastes and Their Disposal (Basel Convention) and Act on Resource Recycling of Electrical and Electronic Equipment and Vehicles. Import of UEEE is allowed; no specific law is applicable.[35]

Japan. The Ministry of Environment is responsible for regulating e-waste management. Since 2001, Japan has enforced the Fundamental Law for Establishing a Sound Material-Cycle Society to promote comprehensively and systematically the policies for realizing a Sound Material-Cycle Society, providing an umbrella framework for the relevant waste management laws of the country. Regarding the import and export control of WEEE, the Law for the Control of Export, Import, and Others of Specified Hazardous Wastes and Other Wastes was entered into force in 1993. This law stipulates the necessary import/export procedures of hazardous waste to comply with the requirements of the Basel Convention. The Waste Management and Public Cleansing Law of 1970 was amended in 1993 to regulate import and export of waste. None of these laws is applicable for the management of UEEE. With the specific purpose to complement to the Basic Act on Establishing a Sound Material-Cycle Society (2000), the following two specific e-waste recycling legislations have been established: the Law for the Promotion of Effective Utilization of Resources (LPUR), and the Law for Recycling of Specified Home Appliances (LRHA) (1991). The LPUR applies to used computers and small-sized secondary batteries and encourages manufacturers' voluntary efforts to take part in collection and recycling. Recycling costs are borne by both manufacturers and consumers. The LRHA is a stricter regulation. It covers television sets, refrigerators, washing machines, and air conditioners. Manufacturers and retailers have an obligation to take back used products and recycle them. Consumers are required to pay for the cost of transportation and recycling. The LRHA also sets up a procedure that allows tracking a product from the beginning until the end of its life cycle.[35]

Malaysia. The Department of Environment, Ministry of Natural Resources and Environment, is responsible for regulating e-waste management. Under the Environmental Quality Act, 1974, several regulations for the control of scheduled wastes (hazardous wastes) management in Malaysia have been enacted. The principal regulation on e-waste management is the Environmental Quality (Schedule Waste) Regulation of 2005, enforced by Department of Environment, and in which specific categories of e-waste are defined and coded. The Guidelines for the Classification of Used Electrical and Electronic Equipment entered into force in January 2008, which prohibits the import of WEEE and export for the purpose of disposal. Waste generators are allowed to export waste for recycling, recovery, or treatment provided prior written consent are obtained from the importing state. The Ministry of Local Government and Housing has the jurisdiction over households and business entities/institutions and has enacted the Solid Waste Management and Public Cleansing Act of 2007. The Royal Malaysian Customs enforces transboundary movements of hazardous waste under the Customs Act 1967, Customs (Prohibition of Import) Order 2008, and Customs (Prohibition of Export) Order 2008.[35]

Indonesia. The Environmental Impact Management Agency, Ministry of Environment, is responsible for regulating e-waste management; however, neither specific criteria on e-waste nor specific regulations on e-waste management have been established. The existing laws have been employed for WEEE and UEEE. WEEE is only allowed for export, but prohibited for import to Indonesia under Act No. 23 of 1997 on Environmental Management, Articles 20 and 21, Presidential Decree No. 61/1993 Basel Convention Ratification, and Ministerial Decree No. 231/ MPP/Kp/07/1997 Regarding Import Procedure of Waste. Import of UEEE and e-waste for direct consumption by consumers is prohibited under Decree No. 756/MPP/ Kep/12/2003 on Import of Non-New Capital Goods and Decree No. 610/MPP/Kep/10/2004 Regarding Amendment of No. 756/MPP/Kep/12/2003.[35]

Philippines. The Department of Environment and Natural Resources (DENR) is responsible for regulating e-waste management. Import of WEEE and UEEE requires permit. Laws applicable to WEEE are the Toxic Substances and Hazardous and Nuclear Wastes Control Act of 1990 (Republic Act No. 6969), DENR Administrative Order 200–6 (Implementing Rules and Regulations for RA 6969), DENR Administrative Order 1994-28 (Interim Guidelines for the Importation of Recyclable Materials Containing Hazardous Substances), DENR Administrative Order 1997-28 (Amending Annex A of DAO 1994-28), and DENR Administrative Order 2004–27 (Amending Annex A of DAO 1994-28). The law applicable to UEEE is DENR Administrative Order 1994-28 (Interim Guidelines for the Importation of Recyclable Materials Containing Hazardous Substances). DAO-94-28 allows the import of electronic assemblies and scrap with the condition that residuals from recycling of materials that contain hazardous substances without any acceptable method of disposal in the Philippines must be shipped back.[35]

Singapore. Export, import, or transit waste requires a permit from the Pollution Control Department of Singapore in accordance with the Hazardous Waste (Control of Export, Import, and Transit) Act. Import/export of UEEE are allowed if there are documents to support that the appliances for import/export are in working condition and suitable for reuse. Export of UEEE that are not suitable for reuse is prohibited. Import of UEEE for the purpose of dismantling and re-export of the dismantled components are prohibited.[35]

Thailand. The Ministry of Natural Resources and Environment and the Ministry of Industry are the administrative authorities for hazardous waste and e-waste management. Both UEEE and WEEE are controlled under the Hazardous Substance Act B.E. 2535 (AD 1992) in Thailand. UEEE can be imported only under a subordinate law for import control of UEEE. Import of UEEE is allowed only for reuse, repair/refurnish back to its original purposes, disassembly and recycle/recovery under certain conditions. Thirty-two UEEE items require import permits from the Ministry of Industry. WEEE can be imported and exported under a subordinate law and following Basel Convention procedures. The e-waste management act will only enter into force in 2014 and will seek to regulate the entire life cycle of an electronic product. At the beginning of its life cycle, importers and producers will be taxed, and the tax money collected will be used for e-waste management. At the end of the product's life cycle, the law will promote construction of an integrated waste management facility at production sites and other areas throughout the country.[35]

Lao People's Democratic Republic. Lao PDR does not have legislation discretely mentioning e-wastes; however, e-waste is considered hazardous waste by defining that hazardous and toxic wastes include batteries, old paint cans, aerosol, and other refuse. Such wastes are mixed with municipal solid wastes that are disposed at landfills. Accordingly, there are no specific laws or regulations directed to e-wastes. For solid waste disposal itself, a decree on waste management is planned in connection with the finalization of the revision of the Environmental Protection Law of 1999. Nonetheless, some laws have implications for solid waste management in Lao PDR, for example, the Environmental Protection Law (Article 22), the Decree on Implementing the Environmental Protection Law (Article 9.4), and in addition some of the provinces and the Capital City of Vientiane have issued specific regulations on urban environmental management including solid waste management. Thus, Lao PDR is encountering solid waste problems due to several reasons, as follows: inadequate legal framework, ambiguous institutional responsibilities and lack allocation of responsibilities on solid waste management to specific institutions, insufficient budget allocation to carry out functions in accordance with the law, etc.[37]

Cambodia. At present, Cambodia does not produce EEE products. Regulation on e-wastes is the responsibility of the Ministry of Environment. Specific law and/or regulation to properly manage, recycle, and dispose EEW does not yet exist. Cambodia, however, uses the following existing laws for WEEE management: Subdecree on Solid Waste Management and the Inter-Ministerial Declaration on SWM in Cities and Provinces. Import of WEEE to Cambodia is banned, while import of both new EEE and UEEE is allowed for domestic consumption. Export of household waste and hazardous waste from Cambodia requires approval from the Ministry of Environment, export license from the Ministry of Trade, and permit from the import country (BCRC China, 2009).

Vietnam. Regulating e-waste management is the responsibility of Hazardous Waste Management Division, Waste Management and Environment Promotion Agency, Vietnam Environment Administration, Ministry of Natural Resources and Environment. In January 2006, Vietnam promulgated the Implementation Rules for the Law on Trade (No. 12/2006/ND CP), which bans import of waste materials (both WEEE and UEEE), toxic chemical substances, and second-hand commodities, including electronic, cooling, and home appliances. Other applicable laws are the Regulation of Management of Hazardous Waste (Decision No. 155/1999/QD-TTg), and Decision No. 23/2006/QD-BTNMT on the List of Hazardous Waste. In Circular No. 12/2006/TT-BTNMT, export of hazardous waste shall follow Basel Convention procedures.[35]

Transboundary Movements of Hazardous Waste

Since the entry into force of the Basel Convention on the Control of Transboundary Movements of Hazardous Wastes in 1992, most Asian countries have acceded to the Convention and enacted national laws banning import of waste into their territories. However, despite the legal prohibition, China and India continue to be the world's largest waste dumping yards. One of the reasons is that there are loopholes in the laws that provide for some exceptions to the ban. For example, in India, the law allows for imports of secondhand computers and laptops if they are intended for donations to educational institutions or NGOs. Due to several arrests for e-waste smuggling recently, the government is considering a complete ban on e-waste.[38] In China, some recyclable wastes such as poly-silicon and artificial fiber continue to be allowed into the country. To prevent the smuggling of prohibited waste, all solid waste imports are required to undergo electronic inspections.[39]

Challenges to Effective Implementation and Enforcement of E-Waste Management Law

Barriers to effective implementation and enforcement of e-waste management laws, like other pollution-control laws, are as follows: 1) lack of specific legal frameworks; 2) complexity of institutional arrangements; and 3) lack of technological, financial, and human resources.

Lack of specific legal frameworks. As the above-mentioned case studies show, many Asian countries have yet to enact a specific e-waste management law.

Complexity of institutional arrangements. Agencies involved in pollution control are often numerous with overlapping areas of responsibilities as well as gray areas where the institutional responsibilities are unclear or lacking. Lack of coordination is not only an issue between ministries but also between central governments and local authorities, as well as between the administration and the industrial sector.

Lack of technological, financial, and human resources. E-waste management requires considerable investments in planning, staff training, purchasing technology, and building new facilities. The laws need to provide funding or economic/fiscal incentives to manufacturers and local authorities in order to allow them to comply with environmental standards. Or else, many would prefer to pay a little extra money to officials who would turn a blind eye on their polluting practices. How to raise sufficient resources for pollution control remains a big challenge for Asian governments. Thus far, taxation is the most commonly adopted method in resource raising (property taxes, sewerage charges, and vehicle taxes, for instance). However, taxation is never popular. International assistance by means of finance, technology transfer, and capacity building is also essential to help improve the capacity of developing countries in addressing pollution problems.[40]

Law on Environmental Assessment

Environmental assessment considered herein includes EIA and strategic environmental assessment (SEA). EIA and SEA are related methods with the purpose to prevent, mitigate, and compensate adverse environmental impacts that may be caused by a proposed activity. EIA focuses on projects such as construction of a dam, industry, mining, etc., whereas SEA is applied to policies, plans, programs, and macro projects (in some countries) such as a transportation development plan, energy development plan, international airport project in Hong Kong, etc. EIA regulations were established in most Asian countries in the 1980s and 1990s. In terms of legislation, they are varied ranging from none (Myanmar), to very recent and not widely applied legislation (Laos and Cambodia), to moderately to highly applied legislation (Thailand, Malaysia, the Philippines, Indonesia), and to extensively applied EIA regulation within a broader planning framework (Japan, Hong Kong, South Korea, China).[41,42] Accordingly, EIA has been practiced throughout Asia with varying degrees of rigor and effectiveness. However, SEA is a relatively new method and, thus far, few Asian countries have incorporated SEA into their legislation.[42]

In 2006, the World Bank released a report called "Environmental Impact Assessment Regulations and Strategic Environmental Assessment Requirements: Practices and Lessons Learned in East and Southeast Asia." The report divides countries in the region into three categories: 1) Hong Kong SAR, Japan, and Korea, which have the most advanced EIA/SEA legislations and effective implementation; 2) China, the Philippines, Indonesia, and Thailand, which have less strict EIA/SEA legislations and have encountered difficulties in their implementation; and 3) Vietnam, Mongolia, Lao PDR, and Cambodia, which have recently established EIA/SEA legislations and are at an early stage of implementation. Some countries are exampled for discussion herein with the content is mostly drawn from such mentioned report.

China. The EIA system has been in place since 1979, which was the year that China enacted the Environmental Protection Law. This law contained broad elements requiring EIA, particularly for construction projects. Later in 1986, the first legal document on EIA in China was issued by the

Ordinance of Environmental Protection of Construction Projection (1986). A series of regulations on construction projects were issued, including Environmental Protection Procedures for Construction Project (SEPA, 1990), Regulation of Environmental Protection of Construction Projects (State Council No. 253, 1998), and Environmental Management Catalogue for Construction Projects (SEPA, 1999). To broaden environmental assessment, the current EIA law has been modified and extended to cover plans, and has become SEA inclusive. A new law on EIA was approved by the National People's Congress in 2002, and has functioned since September 1, 2003. The new EIA law incorporates the concept of SEA for plans and programs, but not for policies. Subsequently, the EIA law covers two large areas: plans and construction projects. Plans are divided into two categories: 1) plans for land use, regional, watershed, and offshore development; and 2) "specific plans," which include agriculture, industry, livestock breeding, forestry, natural resources, cities, energy, transportation, tourism, etc. However, enforcement in legislation, public participation, and capacity building should be undertaken for applications of policy-and plan-based SEA.[42]

Hong Kong SAR. To solve environmental problems encountered in the country, the Hong Kong government has put forth effort to mitigate, control, and prevent such problems. Environmental assessment is considered an important tool in preventing environmental pollution. It is applied not only to individual projects but also to strategic policies and proposal that facilitate the country moving toward sustainability. The EIA process has been applied to projects since 1986, to plans since 1988, and to strategies and policies since 1992. Hong Kong's EIAO was enacted in 1997 in order to formalize the 15 years experience with EIA, environmental monitoring, and auditing, and came into force in April 1, 1998. The EIA in Hong Kong is considered SEA inclusive. With a successful application of EIA/SEA tools with proven records in legal provision, technical capacity, training and implementation, Hong Kong has become one of the most transparent EIA systems in the world.[42]

Japan. The EIA concept was introduced in Japan in the 1960s and implemented through various administrative guidelines, sector legislation (such as the Public Water Area Reclamation Law), and ordinances and guidelines issued by local authorities. The unified law called "the Environmental Impact Assessment Law" was finally adopted in 1997 and took effect in 1999. The law adopts a listing method by scale to identify projects for which environmental impact statement (EIS) is required.[42] Legal requirements that make the Japanese EIA system more strict and comprehensive than those of many other countries in the region are, for instance, EIA requirements for small-scale projects with potential adverse impacts on the environment and emphasis on public participation. Therefore, public opinion is requested at both the scoping stage and the EIA conduction stage, and a period of 100 days is provided for public hearings and information display before submission of EIA report.

Although Japan has yet to make SEA into law, there is a strong political will at both the national and regional level to integrate SEA in the policy-making process. The Ministry of Environment and other ministries have adopted SEA guidelines such as the Ministry of Environment's preliminary guideline on SEA in the formulation of municipal waste management plans. Local governments are also active in implementing SEA.

Republic of Korea. The development of the EIA system was initiated in 1977 through the Environmental Preservation Act, and put into effect by the legislation of "Regulations on the Preparation of EIA" enacted in February 1981. After the Environmental Administration was upgraded to the ministerial level in 1990, the previous Environmental Preservation Act was divided into a number of separate laws. One of those is the Basic Environmental Policy Act enacted in August 1990. The Environmental Impact Assessment Act was enacted as a separate law on June 11, 1993, and was put into effect on December 12, 1993. To increase efficiency of the system, the EIA Act was further revised in 1997, and became the EIA law of 1997. The current EIA system is considered as SEA exclusive. Nonetheless, an SEA type of system was applied in the late 1990s known as the Prior Environmental Review System (PERS), which is mainly implemented for various plans and programs. The current PERS has been amended as an SEA type in general, but not to cover policy level. Thus, EIA in Korea includes two types, the PERS conducted at a planning stage and EIA carried out at the project-development stage. In this system, a decision on whether to execute a development project will be made at the planning stage, taking into account environmental concerns.[42]

Malaysia. The Environmental Quality Act (EQA) was enacted in 1974 as the major federal environmental statute. It was not until 1987 that EIA procedures were introduced under the EQA as a control preventative mechanism. The EIA is well established in Malaysia under the responsibility of the federal government.[43] The situation is currently changing by delegation of EIA powers to the state level. The states of Sarawak and Sabah have adopted independent impact assessment procedures for natural resource management, and it is possible that other states may follow. However, the EIA at state level has faced some problems due to insufficiency of skilled staffs, low institutional capacity, and an absence of effective monitoring of mitigation measures.[43] Therefore, there is a need to strengthen the state capability on EIA implementation. EIA in Malaysia is considered SEA exclusive. However, there is now evidence of an up-and-coming commitment to SEA in the country. Government objectives in environmental protection and management are moving forward, although the regulatory framework to achieve these objectives is not, as yet, fully developed.[44]

Some major infrastructure projects, such as roads and power facility development, could be subject to SEA procedures in the future. Integration of SEA into policy, plan, and programs is necessary to secure a more environmentally sustainable development in the country.

Indonesia. The development of the EIA system was initiated by Government Regulation No. 29 (1986) in compilation with the provisions of Article 15 of the former Environmental Management Act No. 4/1982. Later, Government Regulation No. 51 (1993) concerning EIA imposed significant revisions to the assessment system. Currently, Regulation No. 27/1999 is a revision of EIA regulation No. 51/1993. The new regulation is expected to be improved and provide a more democratic basis. The EIA system is the responsibility of the Environmental Impact Management Agency. The EIA in Indonesia is project based and SEA exclusive. However, the government has realized the importance of SEA in the decision making process, but its application is not compulsory. The Ministry of Environmental published a book on Strategic Environmental Assessment that provides the fundamentals, procedures, and benefits of applying SEA in the policy, plan, and program process.[42]

Philippines. Originally, the EIS system, which is equivalent to the EIA system, was conceived in Philippines Environmental Policy (P, D, No 1151). The actual establishment of the EIA system began with Presidential Decree (P.D.) No. 1586 in 1978. After issuance of some respective decrees, the EIS was adopted in the document *DAO No. 30 of 2003 Implementing Rules and Regulations (IRR) for the Philippine Environmental Impact Statement (EIS) System,* which was issued in 2003. The EIS system is the responsibility of the DENR. The EIS system is well established in the Philippines, including a legal mandate, administration, procedure, and guidelines. It is regarded as extremely comprehensive and perhaps entails the most stringent requirements in the whole Southeast Asia region.[45] The current EIA system in the Philippines is still project based and SEA exclusive. However, some SEA initiatives have been undertaken. In DAO 30/2003, it was stated that, “The EMB shall study the potential application of EIA to policy-based undertakings as a further step toward integrating and streamlining the EIS system” (Article II, Section 7). The SEA covering policy and plan are being considered to be contained in a new EIA Act.[46]

Singapore. Implementation of EIA in Singapore has been operated through the Environmental Pollution Control Act 2000 and the Land Planning process. Regarding EIA through Pollution Control, an EIA may be required for particular projects specified by the Ministry of Environment and Water Resource that have potential to cause pollution affecting public health; for example, petrochemical works, gasworks, and refuse–incineration plants; foreign investment projects using or storing large quantities of hazardous substances; etc. This is likely a project-based EIA. By EIA through Land Planning, Singapore established a document called the *Concept Plan,* which broadly outlines land-use policies in the country, of which the policies are translated into detailed proposals for local areas called “Development Guide Plans” (DGPs). The basic environmental concerns are considered in the DGPs. This is an SEA-like approach for spatial planning. With the provision of relatively effective laws and efficient centralized planning mechanisms, the lack of an EIA law does not appear to obstruct environmental management endeavors. Not only the comprehensive planning and effective pollution control mechanisms but also, more importantly, a stringent enforcement system makes it possible for Singapore to move toward sustainable development.[42]

Thailand. The EIA system was established in Thailand through the Improvement and Conservation of the National Environmental Act (1975), followed by the Enhancement and Conservation of Environmental Quality Act (1992). Although the EIA system is well established in Thailand with a good number of qualified personnel, the law remains vague on many issues and public hearing is optional for some projects. The recent EIA procedures for projects identified as having potential adverse impacts to natural resources, environment, and health legally require public involvement through a strict and specific process. EIA for such listed projects is named as Environmental Health Impact Assessment.[47,48] Regarding SEA implementation by law, Thailand has not made SEA mandatory yet. However, SEA has been performed for some projects specified by line agencies for certain areas of interest, such as SEA for Economic Zone at Border Territory at Chiang Rai Province by the Office of Natural Resource and Environment Policy and Planning (2005).[49] SEA legislation is now under development. At this moment, it can be stated that EIA in Thailand is project based and SEA exclusive.

Lao PDR. Lao PDR enacted the regulations on EIA back in 2000, and these regulations were revised and upgraded to decree with the Prime Minister Decree on Environmental Impact Assessment No. 112 of 2010. The Ministry of Natural Resource and Environment is responsible for administrating the EIA system, approving EIAs, and for issuing Environmental Compliance Certificates Related legislation on social impacts, including the Decree on the Compensation and Resettlement of Development Projects, 192/PM of 2005, and the Regulations for Implementing Decree 192/PM on Compensation and Resettlement of People Affected by Development Projects.

Since the EIA system of Lao PDR is quite recent, it sets relatively high legal standards and requirements, particularly focusing on social aspects. EIA reports in Lao PDR are called Environmental and Social Impact Assessment. Despite a relatively good legal basis, many barriers to effective implementation persist in Lao PDR, particularly the lack of qualified professionals in EIA. Thus, many capacity building programs for EIA personnel have been funded by international organizations and donor countries most prominently the long-term development cooperation with Sweden (Strengthening Environmental Management Phase I and II) and the assistance from the Government of Finland (Environmental Management Support Programme). At this time, EIA is legally implemented as project based and SEA exclusive; however, through the above-mentioned support, the Ministry of Natural Resources and Environment is revising the Environmental Protection Law and developing a decree and guidelines on SEA. This is combined with comprehensive capacity building and case studies on SEA.[42]

Cambodia. In 1996, the National Assembly of Cambodia enacted the Law on Environmental Protection and Natural Resource Management (EPNRM) as a framework law governing environmental protection and natural resources management. The law requires the Royal Government to prepare national and regional environmental plans. In addition, there are subdecrees concerning a wide range of environmental issues, including EIAs, pollution prevention and control, public participation, and access to information (SIDA). Cambodia has subsequently established an EIA system under the EPNRM law through the EIA Subdecree on Environmental Impact Assessment issued in 1999, which mandates general requirements, procedures, and responsibilities. The subdecree instructs the Ministry of Environment to formulate implementing rules and guidelines.[50] This EIA system covers only projects and is SEA exclusive.

Vietnam. EIA was first mentioned in the Law on Environmental Protection (LEP) 1994 Article 18, which stipulates that organizations and individuals must submit EIA reports to be appraised by the state management agency for environmental protection. The *Government Decree on Providing Guidance for the Implementation of the Law on Environmental Protection* (Government Decree No. 175/CP, 1994) is an important legal document on EIA in Vietnam.

The implementation of the EIA system is the responsibility of the Ministry of Natural Resources and Environment. The current EIA system in Vietnam is basically consistent with international practice.[51] SEA has already been adopted conceptually in the Vietnamese legislative framework, for example, in the LEP, GD 175/CP, and Circular No. 490/TT-BKHCNMT, where "EIA not only must be carried out at project level, but also for master plans for development of regions, sectors, provinces, cities and industrial zones." There are several cases of applying SEA in Vietnam in recent years. As plans are covered by the EIA system, the system is conceptually SEA inclusive. The government is considering accommodating SEA in the new environmental legislation.

Conclusion

Development of environmental law in the region began about four decades ago. However, it has been uneven depending on the economic development of each country. According to the level of development of environmental legislation and effectiveness of the implementation, Asian countries may be divided into three categories: 1) countries with advanced economy, comprehensive environmental legislations, capable and well-coordinated institutional framework, and relatively effective implementation, such as Japan, Korea, Hong Kong, and Singapore; 2) countries with a developing economy, relatively well-established legislations but ineffective implementation due to problems such as institutional complexity and lack of qualified personnel, such as China, Malaysia, Indonesia, the Philippines, and Thailand; 3) countries that have recently emerged from conflict and are rebuilding, and therefore are at an early stage of developing environmental legislations and institutions, such as Laos, Cambodia, and Vietnam.

Environmental legislation in Asia is incorporating more and more elements of the "second generation of environmental legislation," which are public participation, compliance incentives, and market-based mechanism. However, regarding the role of the people, in many cases, the law recognizes rights of local communities in natural resource management but does not provide for procedure or institutional framework that would enable the effective exercise of such rights. In addition, environmental legislations in Asia are struggling to keep pace with the rise of the emerging environmental problems and the level of environmental degradation. The problem of e-waste is one good example. For environmental assessment including EIA and SEA, all the countries presented herein have enacted with Environmental Protection Law that include EIA. However, SEA implemented by law is limited. The EIA systems of most countries by law are project based and SEA exclusive. Only some countries such as China, Hong Kong, and Vietnam have environmental assessment system by law for EIA with SEA inclusion.

To ensure effective implementation, a good environmental legislation must be complemented with a capable and coordinated institutional framework, qualified personnel, and an adequate budgetary allocation. Regional and international cooperation are of utmost importance in the development and implementation of environmental legislations in Asia, particularly in the areas of capacity building, technical cooperation, and funding.

Acknowledgments

This entry could not have been completed without the great help of Miss JinjutaManotham, Second Secretary, Ministry of Foreign Affairs, Thailand, for searching some meaningful environmental legislation-related topics; Mr. Brian J D'Arcy, Environmental Expert, Scotland, U.K.; Mr. Peter Gammelgaard Jensen, Chief Technical Advisor, Grontmij, Denmark, for editing the manuscript; and Miss SriratSuwannakom, my research assistant, for formatting the document. I would like to thank the Research Center for Environmental and Hazardous Substance Management, KhonKaen University, National Excellence Center for Environmental and Hazardous Substance Management for supporting me on the relevant research and academic services. I would also like to thank the *Encyclopedia of Environmental Management,* Taylor & Francis Group, for giving me the opportunity to write this entry.

V

ELE: Focuses on the Use of Legislation or Policy to Address Environmental Problems

29

Environmental Policy

Sanford V. Berg

Introduction

When economic activity leads to pollution and over-use of common property resources, government intervention can improve social welfare. Pollution involves a market failure in which damages caused by a producer or consumer are imposed on third parties. These damages can involve personal health, the physical deterioration of buildings, and foregone options for the future. Of course, if transaction costs are low, those that are causing pollution damage can be taken to court if the liability rules are clear. Destruction of common property resources such as losing unique ecological habitats, endangering particular species, or destroying valued scenic vistas is another form of market failure affecting the environment. Because there may not be clear property rights to such elements of the environment, these common property resources can be overutilized. Given the lack of well-defined property rights, government enacts environmental laws to address these market failures. However, identifying and quantifying the damage caused by pollution sources or inflicted upon sensitive ecosystems can be difficult, making any determination of the benefits and costs a contentious exercise. Consequently, choosing policies that define the extent of the environmental protection can be both contentious and problematic.

The next section describes the multidisciplinary inputs that are incorporated into environmental policy analysis, selection, and implementation. Other topics addressed here include policy impacts, the burden of proof, economic evaluation, and the strengths and limitations of policy options.

Multidisciplinary Approach to Developing Environmental Policy

Environmental economics is the study of how economic and environmental issues interact. Issues addressed by environmental economists include but are not limited to evaluating ways to reduce pollution, analyzing the trade-offs between using renewable and nonrenewable resources, or estimating monetary values for ecosystems or habitat. While no single field of study contains all the insights needed to develop and implement sound environmental policies, the focus here will be on economics because it provides a system for incorporating many perspectives and it is the framework by which environmental policy is designed and evaluated. Depending on the burden of proof, the resulting policies might be excessively stringent (costly relative to their benefits) or inadequate for the protection and preservation of environmental features that affect human health and welfare and have intrinsic value.

We know from materials balance that human activity does not create matter but only changes its form, concentration, and location, thus there is a need for physical sciences such as chemistry, physics, and biology to help inform environmental policy. While all societies affect natural systems, the scale of potential impacts has grown with economic development. There is evidence that as incomes rise, citizens are willing to devote relatively more resources to controlling environmental impacts. Moreover, many citizens would like to see much more attention given to reducing current damages and limiting the risks for future harm, hence an understanding of societal and political dynamics is also important for informing environmental policy.

The development and implementation of sound environmental policy draws upon information and procedures from many fields of study. Here, economics is utilized as the framework for integrating the concepts, measurements, and values required for the steps:

1. Determine appropriate regulatory objectives (through citizen participation in political processes and community consensus-building)
2. Balance those objectives to determine regulatory priorities
3. Identify and legislate oversight responsibilities for environmental agencies
4. Develop (a) mechanisms for monitoring environmental impacts (such as ambient air and water quality) and (b) methodologies for integrating new scientific understandings of environmental impacts into the policy prioritization process
5. Define the appropriate targets for different types of pollutants and the protection of biodiversity
6. Determine (and then apply) the appropriate policies for meeting objectives
7. Analyze environmental indictors on a regular basis, checking for noncompliance
8. Evaluate the impacts, recognizing potential biases in the measures and the ways impacts are valued
9. Establish an effective process for monitoring and reviewing the framework, including the penalties and sanctions applied when there is noncompliance

These steps require input from a number of disciplines that shape the way we see things. Although technical training allows analysts to delve deeply into subjects in a consistent manner, awareness of other disciplines' perspectives can be important for constructive environmental policy-making, including:

- Engineers look to technology for solutions to environmental problems. They are able to incorporate new (often expensive) control technologies into energy extraction, production, consumption (energy efficiency), and pollutant disposal and storage (as with nuclear waste).
- Meteorologists and hydrologists analyze pollution transport in air and water systems. They have a deep understanding of the impacts of discharges under different conditions. In conjunction with demographers and epidemiologists, they can estimate the doses received by different population groups.
- Medical scientists and toxicologists analyze the dose response relationships for citizen health, conducting exposure and risk assessments.

- Ecologists study the impacts of pollutants on the local and global environment, assess the value of ecosystem services, and track invasive species and biodiversity. Climate scientists help assess the causes and consequences of changes in local and global temperatures and other weather patterns.
- Materials scientists look at damages caused by air and water pollution. The associated impacts include cleaning and painting buildings, treatment costs, and shorter life spans for affected equipment.
- Political scientists focus on issues of power, legitimacy, social cohesion, and the roles of different stakeholder groups in influencing environmental policies. Consensus is critical because ultimately, in a democratic system, there needs to be widespread agreement on the desired outcomes if the system is to avoid instability.
- Economists emphasize the importance of efficiency in resource allocation. They apply benefit-cost analysis and tend to depend on price signals to provide incentives for the adoption of appropriate control technologies and conservation measures.
- Planners deal with land-use and zoning issues, given population growth projections. Planners integrate legal constraints with historical experience, bringing topological, aesthetic, and geographical elements to the analysis.
- Archeologists and anthropologists provide insights on the impacts of dams, mines, and their related economic activities on unique historical sites, local populations, and indigenous groups. Such impacts create difficult valuation issues.[1,2]
- Lawyers spotlight the institutions of policy implementation. For example, rules and regulations attempt to pay significant attention to procedural fairness. Due process contributes to the legitimacy of outcomes. If different parties perceive that there is no transparency and no opportunity for participation, environmental policy will be perceived as unreasonable and the laws will either be changed or they will be disobeyed in a variety of ways.
- Environmentalists advocate sustainability and environmental equity. The by-products of energy production affect public health and have environmental outcomes. Those impacts have economic value, but often that value is nonmonetary or difficult to quantify. For example, generation and transmission siting decisions incorporate impacts on biodiversity and sustainability.
- Ethicists help society understand personal values and notions of stewardship. Humans have a clear responsibility to leave future generations with a legacy of sound institutions and a clean environment, though the best means to this end are often not obvious.

Thus, physical, biological, and social scientists attempt to uncover patterns and identify lessons to help us improve policy. Given the complexity of environmental issues, most environmental problems are managed, not solved.

Impacts

Energy production and consumption impact people and the environment in a number of ways. For example, activities can damage ecosystems in the extraction phase (oil drilling or coal mining) or involve cross-media emissions in the consumption phase that can lead to further ecosystem damage. Emissions can be from a single point or a mobile source. In addition, they can be continuous or intermittent (with exposure and impacts depending on wind and other weather conditions or the presence of other chemicals). The transport mechanism can be complicated and involve multiple jurisdictions (as with SO_2 and NOx—emissions lead to "acid rain" or ozone problems in downwind areas).

Air

Issues range from local concentrations of particulate matter in the atmosphere to concerns over anthropogenic climate change. Consequences for health, ecosystems, agriculture, coastal settlements, species survival, and other impacts make atmospheric change a serious policy issue. For example, long-range transport means pollutants cross national boundaries and require coordination. Other pollutants—such as greenhouse gas emissions of CO_2—require coordination not due to transport, but because the effects are global in nature regardless of where emissions occur.

Water

Effects of contaminants vary in surface waters and groundwater. The United States has primary standards to protect public health (with maximum contamination levels [MCLs] for toxic wastes). Secondary standards and associated MCLs are meant to protect public welfare (for example, ensuring that the taste, odor, and appearance of groundwater do not result in persons discontinuing water use). Other environmental issues include species loss and dealing with nonindigenous, invasive species.

Land Use

Siting is an issue for electricity generators, transmission lines, and distribution systems (other aspects of land use include urban sprawl and availability of land for agriculture. The focus here is on the environmental impact of energy systems. For example, social investments in mass transit affect emissions from mobile sources (autos). However, environmental policy addresses many other issues, such as the use of pesticides and fertilizers by agriculture or deforestation). The problem of not in my back yard (NIMBY) is universal: we like the convenience of electricity but do not want its production or transport to affect our own property. Surface coalmines are an eyesore, but restoration can be costly. Hydroelectric dams can affect fisheries, flood unique canyons (causing a loss of scenic vistas), damage ecosystems (as in the Amazon), or displace human populations (as with China's Three Gorges Project). Solar collection stations and wind generators require space and have impacts on aesthetics. For some, viewing large windmills along the crest of a lovely mountain range is an eyesore. For others, the same scene is a symbol of hope.

Environmental policy-makers must be aware of the relationship between changes in impacts in one medium and changes in impacts in other media. For example, reducing airborne emissions of mercury will also lead to reduced mercury concentrations in rivers and lakes. However, it may also be the case that reducing ozone precursors from auto emissions by using methyl tert-butyl ether (MTBE) leads to increasing harm to bodies of water as the MTBE precipitates out in rain. Finally, there may be policy and impact trade-offs that must be evaluated with reducing CO_2 emissions through a greater use of nuclear energy. The policy reduces greenhouse gases but raises issues and associated risks of waste storage and protection. In all cases, the links between different environmental media and different environmental policy must be understood for society to properly evaluate the trade-offs.

Burden of Proof

Because environmental issues tend to be complex, delays in responding to citizen concerns and new scientific information can lead to negative impacts or a local crisis. What is more problematic: erring on the side of environmental protection or erring on the side of development? When science is unclear or when studies yield conflicting outcomes, the issue of burden of proof arises. Two types of errors are possible. In a Type I error, a hypothesis is rejected when it is in fact true (e.g., deciding that a pollutant causes no health damages when in fact it does). Rejecting the hypothesis of a health link would lead to more emissions (and citizen exposure) than otherwise would be the case.

A Type II error occurs when the decision maker fails to reject a hypothesis that is in fact false (e.g., not rejecting the hypothesis that low doses of a pollutant have no damaging side effects for certain types of citizens, such as asthmatics, who are viewed as potentially sensitive to a particular pollutant). If in fact at low doses the pollutant does not have negative health impacts, environmental regulators might have imposed standards that induced costly compliance strategies that were based on the Type II error.

Dose-response models that do not reject linear functions when the actual relationships are non-linear would fall into this category.

Both types of errors have costs. However, the political implications may depend on the type of error, leading decision-makers to prefer making errors that are difficult to detect. Thus, it can be argued that environmental regulators will tend to avoid making Type I errors. When evidence accumulates and shows conclusively that a pollutant has health impacts, those responsible for environmental policy do not want to be blamed for acting too slowly. Furthermore, citizens might prefer excessive caution (labeled a "precautionary bias"). On the other hand, Type II errors can result in regulators imposing high abatement costs onto polluters (and those purchasing associated products) in a manner that is not cost effective.

A related issue is whether or not the environmental impact is irreversible. If it is not reversible, a case can be made that the burden of proof should be assigned to those who assert that relatively higher levels of pollution are not problematic. On the other hand, if abatement costs are systematically underestimated and the benefits of pollution reduction are overestimated, it is possible to devote excessive resources to limiting environmental impacts.

Economic Framework

Economists are aware that it is difficult to place monetary values on many impacts of pollution but argue that environmental amenities must be balanced against other valued goods and services.[3] Some view economists as overemphasizing the efficacy of market incentives to the exclusion of other instruments. However, because economics offers a consistent framework for integrating insights from other fields, it will be described here.

Cost-Benefit Analysis (CBA)

The most fundamental economic analysis looks at how pollution impacts (reflected in "external costs") cause excessive consumption of polluting goods in the absence of government intervention. These external costs are the negative spillover effects of production or consumption for which no compensation is paid (e.g., a polluted stream that damages the health of those living along the stream). Producers consider the environment to be a free input; hence they only minimize private costs. If these external costs are added to the private costs (reflected in the supply curve), this is the total social cost.

Figure 1 shows how a competitive product market yields an equilibrium price ($4) and quantity (80 units per week). However, in the absence of public intervention, the price only reflects the private costs of production, not damages imposed on others (amounting to $2 when the 80th unit is produced, but this is assumed to be less if only 65 units of the good are produced. The external costs are higher at

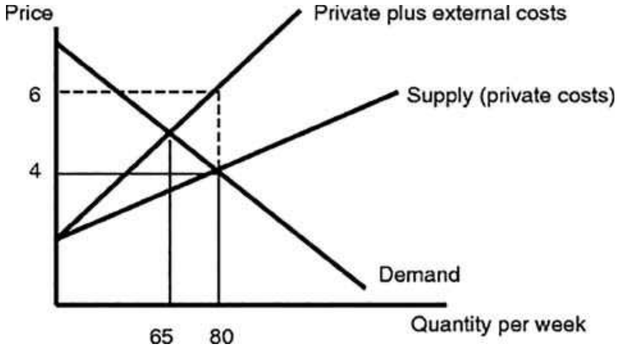

FIGURE 1 Private costs and external costs.

higher levels of output presumably because damages rise dramatically when there are very high concentrations of the pollutant in the atmosphere). Determining the extent of those damages requires some valuation metric.

For now, let us assume that the analysts "got it right" in estimating both benefits and costs. This is a strong assumption because environmental services are notoriously hard to price. This problem can limit the ultimate effectiveness of CBA because the abatement costs tend to be short-term and quantifiable, but the benefits (avoided damages) are often long-term and difficult to quantify. For now, consider the impacts of environmental regulation within the CBA framework. Regulation requires pollution abatement activity, raising production costs but reducing the pollution and associated damages (as shown in Figure 2).

The imposition of environmental regulation raises production costs (shifting the supply curve up) and reduces equilibrium consumption of the polluting good (from 80 to 75 per week) because the price has risen (from $4.00 to $4.40). In addition, external costs are reduced (so the sum of private and external costs is now $5 when 75 units of the good are produced). Emissions are reduced (though this particular figure only indicates the reduction in damages, not the precise reduction in emissions).

The next question is how much pollution abatement makes economic sense, since control costs rise rapidly as emissions are cut back towards zero. Continuing with our illustrative example, Default three depicts the total benefits of abatement and the total cost of abatement. The latter depends on the abatement technology and input prices and the interdependencies among production processes (for retrofitting control technologies). It is relatively easy to compute abatement costs from engineering cost studies, although predicting future control costs is not easy because innovations will create new control technologies. The benefits from abatement (or the reduction of pollution damages—the cost of pollution) depend on the size of the affected population, incomes (indicating an ability to pay for environmental amenities), and citizen preferences (reflecting a willingness to pay). The benefits can be very difficult to estimate. Consider, for example, the health benefits of reduced particulates in the atmosphere, habitat values, and citizen valuations of maintaining a habitat for a particular species. Physical benefits can be found from dose-response studies. Various survey methods and market proxies for computing willingness to pay to avoid experiencing the impacts of pollution have methodological problems. However, if the dollar metric is to be used for determining the benefits of environmental improvements, techniques can at least establish rough benchmarks (as shown in Figure 3) (Some argue strongly against the use of CBA.[4]).

The total benefits and costs to the marginal benefits and costs can be related because, for economists, the issue is not zero emissions versus unlimited emissions. In the former situation, if 80 units of the good results in 80 tn of emissions, then zero emissions reduced would be characterized as having no abatement costs (but also, no benefits from abatement). When the total benefits equal the total cost of abatement (at 65 tn of emissions reduced per week in Figure 3), the last reductions in emissions were very

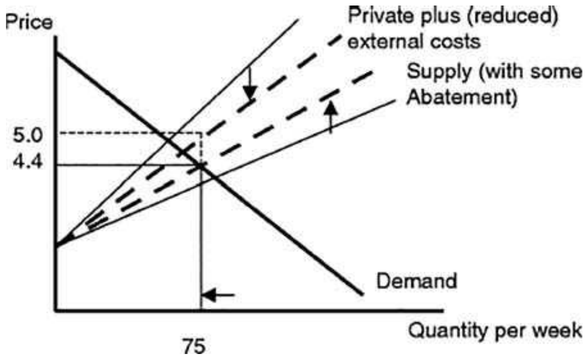

FIGURE 2 Reducing external costs.

costly and the additional benefits were fairly small. Zero abatement activity would also be inefficient in this example because the marginal damages are very high and marginal abatement costs are quite low. Economics tries to determine the optimal amount of emissions. In the hypothetical example, the "optimal" quantity of reduced emissions is about 25, where the marginal abatement cost is just equal to the marginal benefits of $2. These are depicted in Figure 4.

This outcome means that there are still 55 tn of emissions per week. If the estimated benefits and costs of pollution abatement are correct in this illustration, economic efficiency would be violated if additional resources were devoted to abatement activity. For example, if 50 tn of emissions were reduced (so only 30 tn of the pollutant are released), the marginal benefit would be about $1, but the marginal cost would be greater than $5. From the standpoint of economic efficiency, those resources could be used to create greater value in other activities.

Of course, the difficulty of obtaining a common dollar metric for all the impacts of different pollutants means that benefit-cost analysis must incorporate a range of values. The range could be incorporated in Figure 4 as a band around the marginal benefit curve indicating one standard deviation from the calculated values. A conservative approach would recognize that the marginal benefit function could be above that depicted in Figure 4, which would lead to optimal emission reduction of more than 25 tn per week (improving the ambient air quality).

Further complicating the analysis are production and exposure interdependencies. For example, the marginal cost of abatement associated with one type of emission may depend on the level of treatment (or abatement) for another contaminant. A joint optimization problem results, with the basic principles

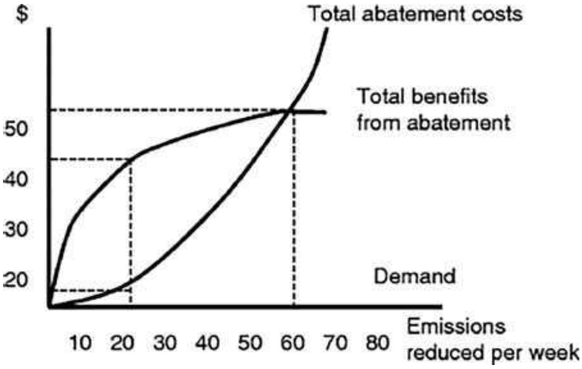

FIGURE 3 Total benefits and total cost of abatement.

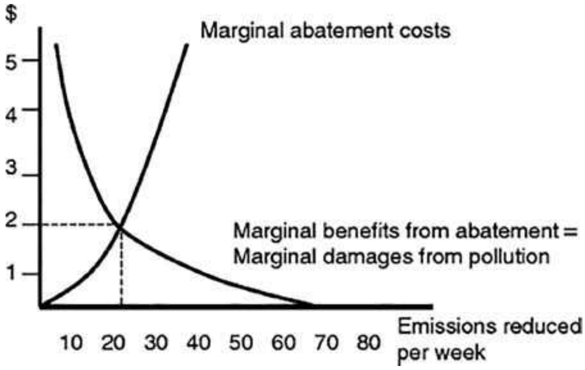

FIGURE 4 Marginal benefits and marginal cost of abatement.

unchanged. Many investments in abatement equipment have this characteristic: once one set of contaminants is being reduced from a discharge flow and the cost of dealing with additional contaminants can be relatively low. For example, in the case of water discharges, if iron or manganese is removed via the precipitation method, total dissolved solids (TDS) is reduced and there may be an improvement in water clarity.

Interdependencies can also arise on the benefit side when the dose-response relationship for a particular contaminant is influenced by the presence of other contaminants. Again, in the case of secondary groundwater standards, perceptions of odor and color will be affected by whether or not they occur in combination. Such considerations must be factored into the analysis when comparing the benefits and costs of different treatment options.

Cost-Effective Analysis

Instead of trying to estimate the dollar benefits of saving a human life (or reducing the incidence of asthmatic attacks), one can compare the number of lives saved per dollar spent in abatement activity across programs. Thus, cost-effective analysis involves finding the least-cost method of achieving a given economic or social objective such as saving lives or retaining unique ecological settings. No dollar value (or explicit measure of avoided damages) is placed on that objective.[5] One advantage of this approach is that the focus is on minimizing the cost of meeting the (politically determined) target. It promotes consistency across a range of programs that might be designed to address a particular problem, whether that involves health impacts or a loss of habitat. Cost-effective analysis facilitates comparisons across programs, leading to reallocations of resources devoted to meeting such targets as new information is gathered over time.

Policy Instruments

Political systems have passed legislation and created agencies to apply laws to improve environmental performance. For example, in the United States, the Water Pollution Control Act of 1956 and the Clean Air Act of 1963 and subsequent amendments to both pieces of legislation have focused on achieving ambient standards. The U.S. Environmental Protection Agency is responsible for implementing these laws, and in other nations agencies have also been established to reduce emissions and improve environmental outcomes. A number of policy options can lead to emission reductions.[6,7] These instruments have different economic efficiency implications. In addition, some of these approaches are difficult to implement (due to being information-intensive), some are not cost effective (in that other approaches achieve the same outcome at lower cost), and the distributional implications can differ across these approaches (tax burdens differ or some groups obtain valuable assets).

Tax on the Polluting Good

An excise tax could be imposed on the good, cutting back consumption to 65 units per week (Figure 1). Of course, the problem is not with the product but with the emissions associated with its production. Thus, this option does not provide incentives for developing new technologies that reduce abatement costs—it represents a static approach to the problem because it does not promote technological innovation.

Tax on Emissions

A penalty or charge for each ton of emissions would lead suppliers to cut back on emissions—to the extent that the abatement is less expensive than the tax. Thus, in Figure 4, a tax of $2/tn would lead to the optimal reduction of pollutants. In addition, it provides incentives for innovation in the control technology industry. Firms will seek ways to reduce abatement costs, thus reducing their pollution taxes. This strategy is likely to be opposed by polluters who will be passing the taxes on to customers (where the ultimate incidence depends on supply and demand elasticities in the product market).

Tradable Emissions Permits

The same result (and incentive) is obtained if "allowances" of 25 tn are allocated to polluting firms, limiting emissions (the situation is not completely identical—a tax has certain costs to firms but yields uncertain overall abatement because regulators will not have precise estimates of abatement costs; the allowances have certainty in terms of overall abatement but uncertain cost. Of course, with monitoring, the tax can be varied over time to achieve a desired ambient condition). This approach provides an incentive for those with low abatement costs to reduce emissions and sell their permits (allowances) to others whose abatement costs would be very high. This places entrants at a disadvantage because incumbent firms are "given" these valuable allowances. The SO_2 regime in the United States has this feature. Of course, the initial allocations raise political issues (because permits represent wealth). In establishing a tradable permit regime, an environmental agency must determine the allowed level of emissions (here, 25 tn) and whether additional constraints might be applied to local areas with particular circumstances. In addition, the energy sector regulator has to make decisions regarding the treatment of cost savings from the regime. For example, savings might be passed on to consumers or retained by firms. The latter situation provides an incentive for utilities to participate in the emissions trade markets. A sharing plan can also be utilized so customers benefit as well.

Tighten Liability Rules

An alternative approach would utilize a court-based system, where fees would be assessed against those responsible for damaging the health of others, for reducing the economic value of assets, or for reducing the amenity values of ecosystems. Of course, this approach requires a well-specified set of property rights and clear causal links between specific emitters and affected parties. The transaction costs of such a system (resources devoted to negotiations and legal activity) could be prohibitive for many types of pollutants.

Emission Reduction Mandates (Quantity-Based Command-and-Control)

Although equal percentage cutbacks sound "fair," this strategy is not cost-effective because abatement costs can differ widely across pollution sources. If there are scale economies to emission reductions, it would be most efficient to have a few firms reduce emissions. The least-cost way to achieve a given overall reduction in emissions will involve differential cutbacks from different firms.

Mandate a Specific Control Technology (Technology-Based Command-and-Control)

This "command and control" strategy is not cost-effective because production conditions and retrofitting production processes differ across firms (based on the age of the plant and other factors). However, this policy option has been utilized in a number of situations as a "technology-forcing" strategy.

Other Policy Issues

The above instruments have been utilized in different circumstances. Additional issues include intrinsic benefits, income distribution, sustainability, and renewable resources.

Intrinsic or Nonuse Benefits

Some people take a more expansive view of environmental amenities as they attempt to separate economic values from inherent values. However, this might be partly accounted for in terms of the perceived benefits to future generations. Intrinsic benefits from environmental programs include option values, existence values, and bequest values.[8] The first value represents a form of insurance so future access to a potential resource is not eliminated due to current consumption. The rationale behind option values is closely related to the "margin for error" argument noted earlier. Existence values reflect a willingness to pay for the knowledge that the amount of contaminant in the environment does not exceed particular levels or that a particular species (or level of biodiversity) is retained. The resource or ecological system is available for others. The bequest values can be interpreted as the willingness to pay for preserving a resource (or a geographic site) for future generations.

Redistributive Effects

It is important to note that citizens being harmed by emissions are not necessarily the same as those who are consuming the polluting good (such as electricity). Even if a particular program has positive net benefits, some parties are likely to be losers. They are seldom compensated and left better off, raising concerns about the distributional consequences of alternative policies. Furthermore, those harmed may have lower incomes (and thus, a lower willingness to pay to avoid damages due to the lower ability to pay). This point underscores the role of fairness as a factor that might outweigh efficiency considerations in some circumstances. Some agencies have been forbidden to use CBA on the grounds that the numbers are too speculative and that social concerns should be given priority. Intergenerational concerns can be interpreted as reflecting redistributive considerations.

Sustainable Development

Some of the issues associated with energy involve the use of nonrenewable resources (irreversibility). Some citizens argue that sustainability requires development that can be supported by the environment into the future. These people wish to ensure that resources are not depleted or permanently damaged. However, since sustainability depends on technology and innovations change resource constraints, defining the term with precision is quite difficult.

Renewable Energy Resources

Generating electricity without fossil fuels (e.g., hydro, wind, solar, biomass) is sometimes referred to as using green options. Green options are often limited in the amount (and reliability) of energy produced in a given time period. Utility applications for renewable resources include bulk electricity generation, on-site electricity generation, distributed electricity generation, and non-grid-connected generation. A number of regulatory commissions have required utilities to meet renewable portfolio standards. Such strategies reduce dependence on a particular energy source (to reduce the region's vulnerability to supply disruptions or rapid price run-ups). In addition, such requirements imply that managers are not making the most efficient investments in long-lived assets. Also, note that demand reduction through energy-efficient technologies is a substitute for energy, whatever the source.

Conclusions

The three main trends in environmental regulation in recent years have been shifting from command-and-control regulation towards a greater use of economic instruments (such as emissions trading), seeking more complete information on the monetary value of environmental costs and benefits, and a tendency for addressing environmental objectives in international meetings, as with the Kyoto Protocol.[9]

The interactions between economic and environmental regulation raise important policy issues. If energy sector regulation and environmental regulation remain separate, some means of harmonization may be necessary to promote improved performance. Collaboration would involve clarifying the economic duties of the environmental regulator and the environmental duties of the economic regulator. To avoid regulatory competition, agencies sometimes establish task forces or other mechanisms for identifying and resolving issues that might arise between jurisdictional boundaries (across states or between state and federal authorities). Such cooperation can serve to clarify the division of responsibilities and identify regulatory instruments that will most effectively meet economic and social objectives.

In summary, policy-makers respond to domestic political pressures by devising institutions and instruments to address pollution and environmental sustainability.[10] Although no single field of study contains all the tools necessary for sound policy formulation, economics does provide a comprehensive framework for evaluating the strengths and limitations of alternative policy options. Because of the pressures brought to bear by powerful stakeholders, adopted policies and mechanisms are not necessarily cost minimizing. The resulting inefficiencies may partly be due to considerations of fairness, which places constraints on whether, when, how, and where environmental impacts are addressed. As emphasized in this survey, citizens want to be good stewards of the land. We appreciate the adage: “The land was not given to us by our parents; it is on loan to us from our children.” How to be good stewards—through the development and implementation of sound environmental policies—has no simple answer given the complexity of the issues that need to be addressed.

Environmental Policy: Innovations

Alka Sapat

Introduction

Over the past three decades, American environmental policy management has often entailed the search for new solutions and innovative ways of managing environmental problems. These solutions have taken the form of environmental policy innovations (EPIs), which have frequently been pioneered and adopted by local and state entities, at times with the help of citizen groups and non-profit organizations. They have become an important means of managing environmental problems, particularly for intractable, multimedia, multijurisdictional environmental issues. While policy innovations have been studied in a number of areas at the state level,[1–19] less attention has been paid to policy innovations in environmental management.[20–24] The focus of this entry is to shed light on these environmental policy initiatives, termed here as EPIs.

To provide an understanding of these policy initiatives, I begin by defining and discussing EPIs and supply some understandings of the concept. Next, I discuss the nature and type of a large majority of EPIs; in particular, I focus on their reliance and inclusion of collaborative forms of environmental management and provide some examples. The fourth section of the entry analyzes some of the main factors affecting the adoption of EPIs, including determinants such as institutional commitment, resources, the severity of the problem, and the role of interest groups. The effect of neighboring entities in spurring innovation adoption and diffusion is also considered in this section. The entry ends with a conclusion that summarizes the main points of the entry, provides some considerations for further research, and discusses the policy implications of adopting environmental policy initiatives as a strategy for managing the environment.

Environmental Policy Innovations

EPIs here are defined in this entry as government-sponsored initiatives to protect the environment. This is based in part on the original definition of a policy innovation originally espoused by Walker[1] who examined the adoption of new policies by states, which he termed as "innovations." Walker's work also differentiated between states that were "leaders" and those that are deemed to be "laggards," along with examining the diffusion or the spread of these innovations from leading states to other states. Thus, he analyzed the amount of time that elapsed between the invention of an innovative program and a state's adoption of it. Based on 88 different state programs, he concluded that larger, wealthier, and more industrialized states adopt new programs more rapidly than do small, less-developed states. He also found strong regional relationships among states that were thought to reflect conditions of emulation and competition among proximate states. Walker's research lead to further investigation into state policy innovations. Gray[3] undertook a more detailed analysis and rejected Walker's contention that leading states lead no matter what the policy area; in a study of education, welfare, and civil rights policies, Gray found that innovativeness was not a pervasive factor. She concluded that based on the issue and the era, different states would comprise the leading, "middle-adopting," and lagging clusters.

During the next two decades, there were numerous other studies of state innovation that were published in a variety of policy areas. These included studies of innovation in juvenile corrections,[12] consumer affairs,[13] technology,[14] energy,[15] tort law,[16] judicial administration,[17] and human services.[18] These studies explored various determinants of innovativeness in different policy areas. However, while they expanded the scope of policy areas subject to innovation analysis, they did not lead to major advances in the conceptualization of state innovations or in the empirical approaches to its investigation.

In the 1990s, however, significant advances were made in the field of state innovations research. Research on state innovation was tested with sophisticated empirical methods in the area of state lottery adoptions[4] and state taxation.[5] In both these studies, the authors extended theories of innovation to different policy areas and made a substantial methodological contribution to the literature by refining the empirical analysis of state innovation with the employment of event history analysis (EHA), a pooled cross-sectional time-series technique. Berry and Berry[4,5] also analyzed the importance of internal determinant explanations (which posit that the factors causing a state government to innovate are the political, economic, and social characteristics of a state) and regional diffusion explanations (which point toward the role of policy adoptions by neighboring states in prompting a state to adopt).

An interesting twist on the diffusion aspect of state innovations was presented in a study of state living will laws.[19] In this study, Glick and Hays argued that as policy innovations diffuse across states, a process of "policy reinvention" occurs.[19] Policy innovations, in their view, are not adopted in their original form; rather, they are changed or selectively adapted as innovations by other states. The contribution of this study lay in refinements that added to earlier understandings of innovation diffusion.

Another variation on state innovation research was the study undertaken by Berry.[6] In this study, Frances Stokes Berry[6] extended the original research undertaken by Berry and Berry[4,5] to state innovations in strategic planning by various regulatory agencies. This extension was interesting as it was one of the first studies to empirically evaluate an innovation adopted by state bureaucracies as opposed to legislatures. This research was followed by more sophisticated understandings of the catalysts and actors behind the adoption of innovations; in his analysis, Mintrom[7,8] focused specifically on the importance of policy entrepreneurs at the state level. Using both secondary data sources and primary data gathered from a 50-state survey of state education officials in an EHA, Mintrom examined both the consideration of school choice and its adoption by states across time. He focuses in particular on the role of policy entrepreneurs by developing a theory of policy entrepreneurship and testing that theory with respect to school choice. Using EHA, he concluded that policy entrepreneurs act as catalysts in the policy innovation process by promoting ideas for dynamic policy change, persuading legislators, and networking with others in government.

In the area of environmental policy, state policy innovations has been the subject of research by Rabe,[20–23] Sapat,[24] and others. For instance, in a comparison of Canada and the United States, Rabe[21] found that despite the relatively decentralized Canadian institutional framework and more centralized and "bureaucratic" framework in the United States, the latter had been much more active and effective in devising innovative policy approaches. Comparing four U.S. states and four Canadian provinces, he concluded that within those sample jurisdictions, the United States was clearly ahead of Canada in cross-media permit integration, pollution prevention, disclosure of information on toxic substances, and achieving greater refinement and use of environmental outcome indicators. Similarly, in later research analyzing state experimentation in the realm of climate change, Rabe[22] analyzed the factors prompting successful state initiatives in reducing greenhouse gases. He finds that some states did succeed in cutting through traditional partisan divides and that agent- based entrepreneurs helped to develop policy ideas and form viable coalitions.

State EPIs adopted by administrative agencies (rather than by legislatures) have also been the subject of past research. In a study of state policy innovations adopted by agencies in the areas of hazardous waste and groundwater contamination, Sapat[24] found that state agencies are more likely to adopt innovations to deal with problems created by hazardous waste contamination than for groundwater contamination. Further, she finds that state environmental managers are not directly influenced by interest groups and that the inclusion of all stakeholders is likely to lead to greater support for new policy initiatives.

EPIs as defined here are drawn from and are based on this past research. An EPI as defined here can be one that is initiated by an agency or government institution (such as a state legislature, county government, or city) or it can be one that is borrowed from another government entity/ institution. Thus, EPIs can be adopted by legislatures or administrative agencies. Also, as defined in prior research by Sapat,[24] EPIs are defined as initiatives that protect the environment. The emphasis on the positive aspects of EPIs is important, because initiatives can have both positive and negative benefits. The term EPI as used in this entry is positive, i.e., it refers to laws, regulations, and policies that are beneficial to the environment. In other words, the goals of these EPIs are to regulate pollution problems and protect the environment.

At this point, a caveat is necessary. Clearly, policy choices can be subjectively interpreted; they may be viewed as being positive for the environment by some and as bad for the environment by others. This is particularly true within the realm of environmental politics.[25–27] For instance, the use of economic incentives, such as fees, pollution taxes, or offsets, is viewed as being beneficial by some and negative by others.[25] Even environmental organizations are divided on this issue. For instance, large environmental interest groups such as the Environmental Defense Fund, which utilize the services of economists and scientists, view economic incentives as being beneficial for the environment.[28] However, a number of smaller environmental interest groups are more suspicious about the environmental benefits of adopting market-based incentives.[29] Moreover, the problem of clearly defining an environmentally "positive" policy solution is also compounded by the fact that for some environmental issues, even scientific experts cannot come to an agreement on what the best technical solution is to a pollution problem.[30] Hence, there is extensive debate about the benefits of particular environmental policies, because of conflicting perspectives regarding policy outcomes and because of incomplete and inconclusive technical knowledge of solutions to environmental problems. To overcome some of these problems, the EPIs discussed here are those that are deemed as being beneficial for the environment by the United States Environmental Protection Agency (USEPA).[31,32] These assessments are arguably less subjective than those carried out by environmental or industry interest groups.

The Nature of EPIs: Conflict to Collaboration

Following the definition given above, EPIs can be categorized in various ways. For instance, they may be categorized according to their function; the USEPA provides a portfolio for instance, in which various environmental innovations are characterized by the core agency function that they address, such as helping in improving service delivery, enhancing regulatory outcomes, supporting superior environmental performance, designing targeted geographic solutions, etc. While it is useful to categorize environmental innovations thus, other ways of classifying environmental innovations may provide a broader and deeper understanding of these initiatives.

In this entry, I contend that rather than categorizing EPIs purely by function, it is also useful to classify such innovations by the underlying regulatory and managerial premises of such policy innovations. More specifically, it is instructive to understand the extent to which such innovations rely on collaborative as compared to non-cooperative, more conflict-based approaches to environmental management. This perspective would be useful because there has been growing evidence in both practice and theory about the usefulness of collaborative approaches to managing the environment and natural resources.

Reasons for the emergence of these collaborative approaches have been many and varied, but the primary reasons for the growth in collaborative forms of environmental management have been ascribed to the problems stemming from command and control measures.[33–39] These traditional forms of regulation have often resulted in failure to achieve key goals and/or protracted conflict. Traditional forms of environmental regulation that rely on bureaucratic, adversarial, and often technology-based regulatory approaches are also seen as being far too rigid and, more importantly, ineffective, in that they fail to address multimedia and multijurisdictional environmental hazards, particularly those stemming from non-point pollution.[33,36] Furthermore, traditional hierarchical approaches do not allow for more democratic forms of participation and often rely on unrealistic models of individual and administrative rationality.[37,40]

To overcome such problems, a search for alternative solutions to managing environmental problems began to evolve and grow. For instance, a study by John in 1994[40] found that states and local governments were increasingly turning away from “top–down command-and-control” regulation to a bottom–up style, which he termed “civic environmentalism.” Civic environmentalism relies primarily on the use of non-regulatory tools, which encompass market-based incentives to regulation.

Civic environmentalism or collaborative environmental approaches or similar interchangeable terms that can be used to describe a more cooperative, less adversarial form of environmental management are to be found in a number of EPIs that are undertaken by environmental agencies at different levels of government. Indeed, some EPIs were initially pioneered and adopted because of the failure of conflict-based approaches to manage environmental problems. For instance, environmental permitting processes engender a high level of stakeholder frustration and conflict due to permitting backlogs, long lead times, costs, and uncertainty. To improve these processes and reduce conflict and backlog times, some state and local agencies adopted EPIs to shift away from media-specific permitting for individual facilities and also to improve internal agency permitting processes. For instance, Massachusetts shifted away from a facility permitting approach to a multimedia, sector-based regulatory approach, targeting sectors with large numbers of small sources, as an alternative to facility-specific state permits with industry-wide environmental performance standards and annual self-certifications of compliance.[31,41]

Similarly, other EPIs take a collaborative approach by helping to enhance partnerships to resolve environmental problems that cannot be effectively solved without the participation and collaboration of multiple actors. Leveraging such partnerships enables environmental agencies to solve complex problems by harnessing energies and resources of stakeholders to achieve mutually desirable outcomes. An example of an EPI that does this is the effort undertaken in South Carolina to reduce neighborhood contamination. This initiative enlists the support of numerous community organizations and local businesses to provide education and outreach to reduce community exposure to lead and other hazardous substances as part of the Charleston–North Charleston Community-Based Environmental Partnership (CBEP).[42]

Other examples of collaboration-based EPIs[43] are provided in Table 1.

To summarize, EPIs are initiatives adopted to protect the environment and a number of them have been adopted at the local, state, and federal level by both legislative and administrative agencies. These EPIs are characterized by more collaborative approaches to environmental management. To understand EPIs further, we can try to ascertain which factors are likely to affect the adoption of these innovations. It is to this issue that I turn to in the next section.

TABLE 1 Examples of EPIs

Neighborhood Contamination Reduction—South Carolina	Enlists numerous community organizations and local businesses to support education and outreach to reduce community exposure to lead and other hazardous substances as part of the Charleston–North Charleston Community- Based Environmental Partnership (CBEP). (http://www.epa.gov/Region4)
Northeast Ohio Initiatives—Ohio	Responds to regional economic, sprawl, ecosystem and infrastructure challenges through a 15-county, community-based approach. (http://www.epa.gov/glnpo/lakeerie/leneohio.htm)
Urban Environmental Program—Boston, Massachusetts	Adopts a community-based approach including the city of Boston, Massachusetts DEP, and community organizations to improve the quality of life in urban settings by targeting issues such as asthma and indoor air quality, lead poisoning, vacant lots and green spaces, and pollution prevention. (http://www.epa.gov/boston/eco/uep/boston/)
Pollution Complaint Response—Indiana	Coordinates an agency-wide, multimedia response to citizen inquiries and complaints using Web-based information, enabling the agency to reduce costs and increase public trust. (http://www.in.gov/idem/5274.htm)
Ford Good Neighbor Dialogue—Illinois	Brings together stakeholders, academics, and agency representatives in a collaborative process to periodically discuss a large manufacturing facility's environmental management and performance. (http://www.delta-institute.org/)
Community Environmental Awareness Project—Michigan	Develops an approach to improve the way environmental information is presented and made available to the public; the goal of the CEAP is to improve the public's access to and understanding of how major industries are performing under environmental laws and regulations. (http://www.deq.state.mi.us/ceap)

Resources, Needs, Politics, and Other Determinants

The factors that lead to the adoption of EPIs can be many and varied. Prior research on innovation adoption in other areas, as well as on EPI adoption is useful here. The following factors are some of the most influential determinants of innovation adoption as seen in extant research.

Need/Problem Severity

Keeping in with the adage that "necessity is the mother of invention," researchers have traditionally regarded problem severity as a significant influence on the adoption of innovations.[1,3,44,45] For innovations adopted at the state and local level, the expectation is that states and local governments rather than the federal government are likely to understand local problems more clearly and are hence likely to be responsive to the needs and problems present in their jurisdictions.[27,45] For instance, in a study of state innovation, ranging from state testing on teacher competency and rail passenger service to state regulation on sodomy, Nice[45] found that the problem environment was prominent in explaining five of eight policy innovations analyzed in this study. For EPIs, the severity of the pollution problem itself has been regarded as one of the most important reasons for innovation adoption. To deal with intractable environmental problems, several entities (local, state, non-profit, and even private institutions) have come up with new ways to solve old problems.[20,31]

Institutional Factors: The Importance of Commitment and Capacity

While necessity can often drive innovation, institutional commitment and capacity have also been found to be important for the adoption of policy innovations.[24,40,46] The theoretical origins of the role of institutional actors may be found in ideas related to roles of institutional elites and theories of institutionalism and neo-institutionalism.

Elites: The importance of elites in the policy-making process is theoretically supported by the elite perspective of policy analysis. Elite theorists argue that power is concentrated in the hands of elites who use the resources of their respective organizations to manage and impose order on society.[47] Societal stability, according to this perspective, rests not on a common political culture and a set of values, but on a forced consensus created and reinforced by the elite. Pluralist politics can coexist with the governmental elite; however, key decisions regarding policy are made by elites. Popular and electoral politics are, for the most part, mainly symbolic and concerned with middle-level policy issues, according to the elite perspective.[47]

The elite theory of the policy process is close to the neopluralist view: neo-pluralists, such as Lindblom,[48] challenged the pluralist notion that power was diffuse and argued instead about the privileged position of business. Similarly, others such as E.E. Schattschneider pointed out, “the flaw in the pluralist heaven is that the heavenly chorus sings with a strong upper-class accent.”[49]

Institutionalism and Neo-institutionalism: The motivation of institutional actors and elites is also stressed in theories that emphasize the importance of institutions in policy and governance.[50–54] Institutional theories hold that government actors can act independently of interest group pressures and other factors. According to this view, government actors are not just simply “pawns” of various interest groups; rather, the perceptions and attitudes of these actors shape the way they process information and affect independently the choices they make.[52,54] Institutional theories also recognize that informational constraints and computational limitations of political actors prevent actors from making purely “rational decisions” that are independent of the actor’s subjective representation of the decision problem.[52,55] Thus, the attitudes and ideological views of institutional actors can influence their choices in innovation adoption.

Based on the theories discussed above, it is likely that pro-environmental policy actors will likely push for adoption of EPIs. Related to that issue is the importance of resources. Adoptions of EPIs require both the motivation and the commitment of key institutional actors in terms of time, money, and other resources. Typically for most policy adoptions, resources are required. For this reason, wealthier and larger states and local governments are more likely to be innovation adopters.[11,56] Resource provision by third- party institutions, such as non-profits, or by higher levels of government, such as by the federal government to state and local governments, can also help spur innovation adoption and diffusion. For instance, the USEPA provides State Innovation Grants to spur innovation adoption; these grants are typically provided to states with projects in three areas: environmental results programs, environmental management systems and permitting, and environmental leadership programs such as EPA’s Performance Track.[31]

However, while institutional resources may be required for innovation adoption, some EPIs are adopted to economize on resources or to raise revenues. For instance, EPIs in pesticide regulation adopted by certain states helped raise fees, adding to revenue sources.[24] The role of resources or the importance of economic factors can also be played out in other ways. That is, objectives of economic development by states could deter their willingness to adopt strict environmental regulations.[57–60] For instance, states with a higher percentage of economic activity relying on manufacturing or industrial activities with negative environmental consequences are less likely to favor the adoption of innovative laws and programs that would negatively affect revenue-generating industries. This raises the issue then of interest group support and its importance for EPI adoption.

Interest Group Support

Interest groups have always played an important role in the American policy process, due in part to constitutional provisions for pluralism. Theoretically, the pluralist perspective of policy making argues that public policy is the product of democratic participation by individuals who are represented by organizations such as interest groups. Theories of interest group influence on legislators and bureaucrats range from narrow views of interest group influence[61–63] to those that posit interest groups as not exercising any more influence over regulatory policy than other actors or bureaucrats.[64,65]

Pluralist theorists, such as Truman[ZS] and Dahl[67] argued that group exchange (pluralism) was the dominant (and desired) method of political decision making. In their view, this was possible because the decentralization of American institutions and the relative openness of the political system guaranteed competing groups access and some degree of power. Pluralism thus presents a view of the political system in which multiple centers of power compete to shape policy. Power is diffuse, fluid, multifaceted, and dispersed among a number of groups. Political participation is largely a goal- oriented activity in which citizens take part in order to obtain some benefit from the government.[68]

Pluralist group theory was questioned by a number of scholars, mainly neo-pluralists, who argued that dominant groups and interests had the ability to control the political agenda, preventing pluralist discourse over a full range of policy options.[47,48,69] Group theory was also evaluated in part in analyses of regulatory policies.[62,70,71] A number of scholars argued that regulatory policies emerged from a political equilibrium produced by coalitions of regulated industries and their customer groups, leading to "agency capture."[62,72,73] This narrow interest group perspective is based on the assumption that certain groups of people, who are organized and powerful in terms of possessing economic resources, will have the capability to dominate policy at the subnational level.

While this view is compatible with the Madisonian perspective of private parochial interests modifying policy outcomes, it has been modified considerably to account for characteristics of interest groups such as size and density that could affect their capabilities to exert influence over state regulations.[74] Moreover, the motivations and actions of other political actors, bureaucrats, and other interest groups themselves have also been found to be important in influencing policy outcomes.[75] Further, the narrow view of interest groups adduced by scholars such as Stigler[62] and Posner[73] have been more successful in explaining economic regulation as opposed to social regulation, such as consumer protection and regulation of the environment. The traditional "iron triangle" or "agency capture" theory does not adequately account for the emergence and power of newly organized and motivated consumer, environmental, and other "public interest" groups, which seek social benefits.

With respect to environmental policy, past studies have found environmental interest groups to be important in influencing policy outcomes. For instance, Ringquist[76] and Hird[27] analyzed the influence of environmental interest groups that countered the regulatory priorities advocated by industry groups. Ringquist[76] found environmental interest groups to have a significant influence on state water quality regulation in a group influence model of state policy influence.

With regard to EPIs, the presence and activities of environmental interest groups are likely to be important as well. However, industry interest group opposition to EPIs may be tempered by the nature of these policy innovations. As discussed above, a number of EPIs rely on collaborative nonadversarial approaches to solve environmental problems. Past research has also shown that some EPIs provide new ways to work with such industries to improve compliance with regulations and do not burden them with any additional regulatory costs.[24] Interest group opposition may also be mitigated by public support for certain EPIs, which provide broader benefits than they do costs to the public at large.

Regional Diffusion

Previous empirical studies on the diffusion of innovations have found that external influences by other neighboring entities are important. For instance, adoption of innovations by neighboring states can affect a state's adoption of a policy innovation.[1,4,11,56,77] Policy adoptions by neighboring states can decrease the information costs regarding the possible consequences, including the electoral consequences, of the adoption of a policy.[4] State officials can view the relative success/failure of programs in these adjacent states and decide whether such programs are suitable for their own state. Moreover, if a policy has been successful in a neighboring state, then state officials, in particular state legislators, can, by using the experiences of neighboring states as an example, boost public and legislative support for similar legislation in their own state. This allows them then to selectively utilize the experiences of neighboring states for their own political gain. The decrease in information costs and political uncertainty can thus increase the motivation of state policy makers to initiate or adopt a policy innovation.[24]

While early research on policy innovation diffusion focused on regional influences primarily with respect to policy innovations adopted by states,[8,11,24] later work has also studied factors affecting diffusion at the country level[78] and the local level.[11] On a related note, there has also been research on examining the mechanisms of policy diffusion,[79–82] which has moved away from looking simply at the effects of neighboring states to analyzing the more complex and multiple factors affecting diffusion, such as the presence of competition, learning, imitation, and coercion; this research has found that policy mimicry is often tempered by the size of the state and by the presence of other third-party institutions that may aid diffusion.[11] Thus, while regional effects or "external determinants" may be important, it is also necessary to understand the mechanisms of diffusion, which may be varied and complex.

There are thus, a number of factors that can influence the adoption and implementation of EPIs; need or the type of problem alone may be a necessary but not a sufficient determinant of innovation adoption. Institutional commitment and capacity, the role played by interest groups, and the effects of innovation adoption by neighboring institutions and entities are also important influences affecting the espousal of EPIs.

Conclusion

Complex environmental problems require innovative solutions for effective management. The focus of this entry has been on such initiatives or EPIs. In doing so, this entry began by defining and explaining the nature of such initiatives, including a discussion on past research on state policy innovations. I contend that a number of environmental initiatives have pioneered and are symptomatic of a shift in environmental management to more collaborative ways of solving environmental problems. Need or the severity of the problem has been one of the reasons affecting the adoption of EPIs, but institutional commitment and capacity are also critical to adoption and implementation of policy innovations in general and for EPIs. Given that interest groups are critical in the American policy process, the support or opposition of key groups is also vitally important to innovation adoption. Since a number of EPIs provide new ways to work in partnership rather than in conflict with industries to improve compliance with regulations and do not burden them with any additional regulatory costs,[24] industry opposition to such EPIs may be lessened. Interest group opposition may also be mitigated by public support for certain EPIs, which provide broader benefits than they do costs, to the public at large. Finally, innovation adoption may also be affected by the presence or adoption of innovations by neighboring entities, the external determinants. However, the mechanisms of such diffusion need further study and research.

Future research could also address the policy implications and long-term outcomes of innovation adoption. For instance, do the adoptions of EPIs lead to better environmental outcomes in terms of solving environmental problems and improve environmental quality? Do EPIs foster better outcomes in terms of increasing stakeholder participation and provide for more democratic and innovative means of achieving environmental goals? Preliminary evidence does suggest that EPIs have positive outcomes, but more research is needed on this issue. Given that the environmental problems facing us in the coming century are only likely to grow and be exacerbated by the slow-moving yet devastating effects of more large-scale problems such as climate change, the need for innovative environmental solutions is likely to be critically important.

Food Quality Protection Act

Christina D. DiFonzo

Tolerances

FQPA fundamentally changed the way EPA sets tolerances for pesticide residues in food. EPA must review all (nearly 10,000) pesticide tolerances under new FQPA guidelines. The tolerance assessment schedule developed by EPA called for examining 33% within 3 years after August 1996, 66% within 6 years, and 100% within 10 years. EPA initially took a "worst-first" approach, to review the pesticides it considered to be of greatest risk, particularly to children, by August 1999. Three major pesticide groups, organophosphates (OPs), carbamates, and probable human carcinogens (B2s), were targeted under the worst-first approach. OPs and carbamates, the majority of which are insecticides, are neurotoxins structurally related to nerve gas. They affect the enzyme acetylcholinesterase in animals, including humans. B2 carcinogens are pesticides classified by EPA as having sufficient evidence for causing cancer in lab animals (usually at very high dose levels), but human evidence is lacking. Several important fungicides, plus a few herbicides and insecticides, are classified in this category.

Before FQPA, a single tolerance was established for each pesticide/crop combination, based only on dietary exposure to pesticide residue. Under FQPA, EPA must consider the combined (aggregate) exposure to a pesticide through dietary, drinking water, and nondietary sources (for example, structural, turf, garden, and pet uses) as well as the cumulative exposure to related pesticides with a common mechanism of toxicity. Furthermore, FQPA directs EPA to consider sensitive subpopulations, especially children, when setting tolerances. To insure that sensitive groups are adequately protected, EPA can require a safety factor of up to 10-fold on existing tolerances.

The Risk Cup

An analogy of a "risk cup" is used by EPA to explain changes in the establishment of tolerances under FQPA. Before FQPA, there was a separate risk cup for each pesticide/crop combination, containing only dietary exposure to residue. FQPA creates a separate risk cup for *each group* of related pesticides with common toxicity. Multiple pesticides, as well as multiple residues from all sources—food, water, and nonfood—of each pesticide, go into the same cup. Under this scenario, the cup gets crowded, and individual tolerances for each pesticide/crop combination in the group must get smaller. Furthermore, safety factors for children may reduce the overall size of each cup, potentially by a factor of 10.

Endocrine Disruption

Under FQPA, all pesticides and pesticide additives must be tested for effects on the endocrine system. This may require in vitro and in vivo screening for three different types of endocrine effects: estrogenic (mimics or blocks estrogen), androgenic (mimics or blocks androgens), and thyroid. Of the potential targets of a screening program, these three hormone groups are important in human development, are fairly well studied, and some laboratory methodology is already available to detect changes in level and function. Estimates are that up to 70,000 pesticides and other chemicals will be screened under FQPA and a second law, the Safe Drinking Water Act.

Consumer Right-to-Know

Another issue addressed in FQPA is consumer right-to-know about pesticide residues in food. FQPA mandated that EPA create a brochure to inform consumers about pesticide risks and benefits, and ways to remove residues from food they purchase. The brochure was completed and distributed to supermarkets in early 1999. However, FQPA did not mandate that stores actually display the publication.

Potential Impacts of FQPA

Pesticides that do not meet FQPA standards must either be mitigated (use patterns changed) or eliminated (some or all uses dropped). Thus, as FQPA is implemented, it potentially will have a tremendous impact on American agriculture.

- Changes in labeling or use patterns (number, frequency, and timing of applications) of pesticides to mitigate residue.
- Loss of critical pesticide uses, particularly for so-called minor (specialty) crops. These commodities represent smaller markets for pesticide manufacturers and thus are often “expendable.”
- Increases in production costs. Traditional broad-spectrum products might be replaced by more expensive, reduced-risk alternatives that control a narrower range of pests.
- Increased complexity of production and pest management systems. Broad-spectrum pesticides will be replaced by narrower spectrum tactics that require better knowledge and more intense management of the production system on the part of the producer.
- Potential for pesticide resistance. Loss of certain classes of pesticides could lead to resistance to remaining products, which are being relied on too heavily.

Food: Cosmetic Standards

David Pimentel
and Kelsey Hart

Introduction

The American marketplace features nearly perfect fruits and vegetables. Gone are apples with an occasional blemish and fresh spinach with a leaf miner. This increase in the "cosmetic standards" of fruits and vegetables has resulted from the efforts of the Food and Drug Administration (FDA) and the U.S. Department of Agriculture (USDA) to limit the levels of insects and mites in produce, and new standards established by food wholesalers, processors, and retailers. Meeting more stringent standards has led to significant increases in the amounts and toxicity of pesticides used in crops. Increased pesticide use has negative environmental and public health consequences. In comparison, the health risks from consuming herbivorous insects/insect parts in food do not exist and certainly do not justify the increase in pesticide use and the associated problems. Recent research indicates that pesticide use can be reduced by 35% to 50% without any substantial increase in food prices or loss of crop yields.[1] Surveys suggest that the public would support relaxation of cosmetic standards if it decreases pesticide residues in its food.

History of Cosmetic Standards

The FDA sets defect action levels (DALs) for insects and mites allowed in fruits and vegetables and in products made from them. These DALs were established to reduce insect and mite infestation in foods to a reasonable and safe level, because their presence in food products was thought to indicate that crops had insufficient insect and mite control, were improperly washed, were unsatisfactorily inspected, and contained insects and mites harmful to health. Besides visual prejudice against insects in food, there is the well- placed concern that insects such as nonherbivorous houseflies and cockroaches may transmit disease.

During the past 40 years, the FDA has steadily lowered DALs.[2] For example, a fivefold decrease in the number of leaf miners permitted in spinach occurred from 1930 to 1974. As tolerance levels for insects in food have fallen, wholesalers, processors, and retailers have increased their "cosmetic standards" for produce and other food products so that most marketed U.S. produce is visually perfect. Produce distributors encourage high cosmetic standards because their contracts enable them to visually inspect produce before buying and reject it when the supply is excessive. Growers are motivated to produce cosmetically perfect produce to ensure its sale.

However, to meet these increasingly stringent regulations, farmers have had to use greater amounts of increasingly toxic pesticides and implement other pest control strategies. Synthetic pesticide use in

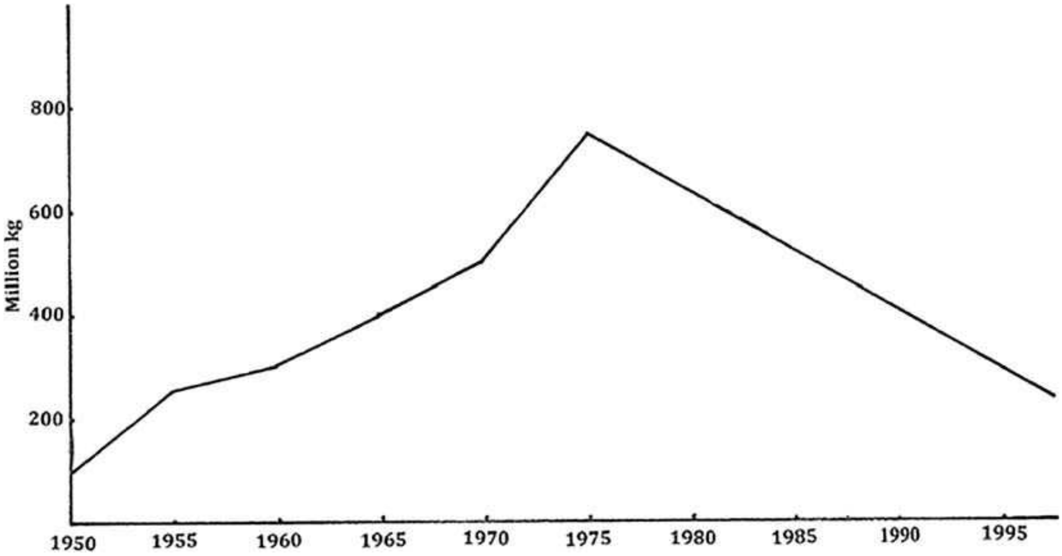

FIGURE 1 The amount of synthetic pesticides produced in the United States. About 90% is sold in the United States. The decline in total amount produced since 1975 is in large part due to the 10- to 100-fold increased toxicity and effectiveness of the newer pesticides.[1,3]

the United States has increased about 33-fold since 1945, and the toxicity of pesticides used has increased 10- to 100-fold in the past 25 years (Figure 1). More pesticides need to be used to produce the blemish-free produce distributors and consumers expect.

There is little evidence that eating herbivorous insects or insect parts is hazardous to human health.[4] However, solid data suggest that the adverse health and environmental impacts of pesticide exposure are substantial.[5] Given the direct correlation between increases in cosmetic standards and increases in pesticide use, why are cosmetic standards and DALs growing increasingly severe and perpetuating further increases in pesticide use?

The increase in cosmetic standards and more stringent DALs are based on the premise that consumers demand unblemished, insect-free food. Clearly, cosmetic appearance of produce is a primary factor consumers use in assessing the quality of produce. Unfortunately, this assessment is often made without more substantive quality information, such as nutritional values or pesticide residue levels. Recent evidence suggests that when consumers are aware of the trade-offs between blemish-free produce and pesticide use, they will purchase produce that is not cosmetically perfect because it has less pesticide residue.[6]

Environmental and Health Effects of Pesticide Exposure

An estimated 617,000 tons of more than 600 different kinds of pesticides are used annually in the United States, at a cost of approximately $9 billion.[7] Still, pests such as insects, plant pathogens, and weeds destroy 37% of all potential food and fiber crops.[8] Typically, each dollar invested in pesticides returns about $4 in crops saved.

However, this economic evaluation does not take into account the impacts of pesticide use on public health and the environment. Approximately 0.1% of applied pesticides reach target pests, leaving 99.9% of the pesticides to impact the environment.[8] Environmental effects of pesticides can be significant: Domestic animals and wildlife can be poisoned or adversely affected by pesticide exposure; beneficial natural enemies of harmful pests can be destroyed by pesticide use; heavy pesticide use can result in pesticide resistance and subsequently even heavier or more toxic pesticide use; and already limited natural resources such as soil, groundwater, and surface water can be contaminated by pesticide residues or drift.[5]

The human health effects of pesticide exposure through food are also diverse and significant. About 35% of foods purchased by American consumers have detectable levels of pesticides, and about 1%–3% of these foods have residue levels over the legal tolerance level 8. These estimates are conservative because detection methods currently detect only about one-third of the pesticides now in use in the United States. The contamination rate is undoubtedly higher for fruits and vegetables because they receive the highest levels of pesticides. One USDA study indicates that some pesticide residue remains in produce even after it is washed, peeled, and cored.[9]

Both the acute and chronic health effects of pesticide exposure are significant. Worldwide, about 26.5 million acute pesticide poisonings occur each year, resulting in about 3 million hospitalizations, approximately 220,000 fatalities, and 750,000 cases of chronic pesticide-related illness.[10] Chronic effects can adversely affect most systems of the human body. U.S. data indicate that 18% of all insecticides and about 90% of all fungicides are carcinogenic.[11] Many pesticides are also estrogenic, linked to increased breast cancer among some women in the United States. Pesticide exposure can also damage the respiratory and reproductive systems, leading to conditions like asthma and infertility.[12–14] In the United States, EPA[15] reports that 300,000 non-fatal pesticide poisonings occur each year.

The negative health effects that pesticides can have are more significant in children. Children have higher metabolic rates than adults, and their ability to detoxify and excrete toxic compounds is different. Also, because of their smaller size, children are typically exposed to higher levels of pesticides than adults. Finally, certain types of pesticides, such as carbamates and organophosphates, are more dangerous for children than adults.[10]

Given the significant environmental and public health impacts that pesticides can have, it appears desirable to limit pesticide exposure to minimize these adverse effects. However, the increasingly stringent DALs and cosmetic standards have resulted in considerable increases in pesticide use. Do the health effects of eating herbivorous insects, insect parts, or blemished produce warrant the risks and the substantial health consequences of increasing pesticide exposure to meet these standards?

Health Effects of Eating Insects/Insect Parts in Food

Even under the current stringent DAL regulatory guidelines, a few insects and mites do remain in or on produce. For instance, the DAL for apple butter is an "average of 5 whole insects or equivalents per 100 grams not counting mites, aphids, thrips, or scale insects." DALs for many other food products are similar. Many insects commonly found in foods and food products are so minute in size that they are practically impossible to eliminate. Although the numbers of insects are strictly limited by FDA regulations, some do remain and are eaten.

This, however, is not a cause for concern. In contrast with the well-documented acute and chronic negative health effects resulting from pesticide exposure, there is not one known case of human illness from ingesting insects and mites in or on foods. In addition, though some insects do carry disease or present health risks—houseflies, for example—all herbivorous insects/mites found on harvested produce are harmless to humans.

While ingesting insects or insect parts in our food may seem distasteful to many Americans, many cultures eat insects by choice. Insects are a substantial source of protein, with digestible protein content ranging from 40% to 65%,[16] and insects, shrimp, lobster, and crawfish are all arthropods; the latter three are often considered food delicacies.

Given that herbivorous insects found on produce are not a health hazard, consumers must decide whether they are willing to tolerate the presence of a few insects rather than insisting on visually "perfect" produce that requires high levels of pesticides.

Conclusions and Future Directions

If the health effects of herbivorous insects found on or in food products are not cause for concern, then the need for strict DALs might be relaxed. Relaxing cosmetic standards for some fruits and vegetables might be feasible. Approximately 10% to 20% of pesticides applied to fruits and vegetables are used only to comply with the current strict cosmetic standards established by the FDA, USDA, wholesalers, and retailers that result in blemish-free pro-duce. Rigorous cosmetic standards are probably unnecessary, since surface blemishes on fruits and vegetables generally do not affect nutritional content, storage life, or flavor. However, will the American public purchase produce that appears less than perfect?

Research on public preferences shows that 97% of Americans prefer food without pesticide residues. In addition, 50%–66% are willing to pay more for food with less pesticide residue.[17] It is estimated that in the United States, pesticide use can be reduced by about 50% without reducing crop yields. The estimated increase in the consumer's food costs would be only 0.6%.[10] This marketplace cost increase does not take into account the positive environmental and health benefits that would be realized if pesticide use were reduced. Sweden, for example, has reduced pesticide use 68% and reduced pesticide poisonings 77%.[18] The small increase in consumer cost would be more than offset by these benefits.

Therefore, given the environmental and health tradeoffs related to high cosmetic standards for produce, it appears that human health and the environment would be best protected by less stringent DALs and relaxed cosmetic standards for produce, to minimize unnecessary pesticide use and related adverse effects.

Laws and Regulations: Food

Ike Jeon

Tolerance Limits for Pesticide Residues

The responsibility for ensuring that pesticide residues in foods are not present above the limits is shared by three major government agencies.[1] The Environment Protection Agency (EPA) determines the safety of pesticide products and sets tolerance levels for pesticides. The Food and Drug Administration (FDA) enforces the tolerances in all foods except meat and poultry products. The U.S. Department of Agriculture's Food Safety and Inspection Service (FSIS) regulates commercially processed egg, meat, and poultry products including combination products (e.g., stew, pizza). In addition, any products containing 2% or more poultry or poultry products, or 3% or more red meat or red meat products are also under jurisdiction of the FSIS. The pesticides of concern usually include insecticides, fungicides, herbicides, and other agricultural chemicals. Table 1 illustrates examples of tolerance levels for pesticide residues in several food categories.[2,3] These tolerance levels are extremely low, usually below parts per million, but do not represent permissible levels of contamination where it is avoidable. In addition, blending of a food (or feed) containing a substance in excess of an action level or tolerance with another food (or feed) is not permitted, and the final product from blending is unlawful, regardless of the level of the contaminant.

Regulatory Inspection and Enforcement

The FDA monitors the levels of pesticide residues in processed foods. For imported products, the FDA checks a sample of the food at entry into the United States and can stop shipments at the entry. If illegal residues are found in domestic samples, FDA can take regulatory actions, such as seizure or injunction.

The U.S. Department of Agriculture also monitors pesticide residues in food.[4] The Department was charged in 1991 with implementing a program to collect data on pesticide residues on various food commodities. The program has become a critical component of the Food Quality Protection Act of 1996 and currently is known as the Pesticide Data Program. The data on pesticides in selected commodities are used by the EPA to support its dietary risk assessment process and pesticide registration and by the FDA to refine sampling for enforcement of tolerances.

If a product is in violation of the tolerance limits, it is *adulterated* under the food law. The product may be destroyed or recalled from the market by the manufacturer or shipper. The recall may be initiated voluntarily by the manufacturer (or shipper) or at the request of the regulatory agency. The responsible agency also may seize the product on orders obtained from the Federal courts and may prosecute persons or firms responsible for the violation.

Tolerance Limits for Insect Fragments

Many food materials may contain natural but unwanted debris that cause no health hazards for humans. These debris may include insects, insect fragments, and rodent hairs and are considered unavoidable defects in foods with the current agricultural practices. In fact, the use of chemical substances to control insects, rodent, and other contaminants has little, if any, impact on natural and unavoidable defects in foods. The FDA contends that the use of pesticides does not effectively reduce the presence of these food defects. This has led the regulatory agencies to establish maximum levels of natural or unavoidable defects allowable in foods for human use. The FDA currently lists over 100 products from fruits to fish,[5] and Table 2 shows only several examples. If no defect action level exists for a product, the FDA evaluates and decides on a case-by-case basis using criteria of reported findings such as length of hairs and size of insect fragments.

The FDA sets these action levels under the premise that it is economically impractical to grow, harvest, or process raw products that are totally free of nonhazardous, naturally occurring, unavoidable defects. It is incorrect, however, to assume that because the FDA has an established defect action level for a food, the manufacturer needs only keep defects just below that level. The defect levels do not represent averages of the defects that occur in any of the products. The levels represent limits at which FDA will regard the food product as *adulterated* and, therefore, subject to enforcement action. Like pesticide residues, blending of food with a defect at or above the current defect action level with

TABLE 1 Examples of Tolerance Limits for Pesticide Residues in Human Food

		Action Level	
Substance	Commodity	(Parts per Million)	Remark
Aldrin and dieldrin	Asparagus	0.03	
	Fish	0.3	Edible portion
	Peanuts	0.05

Source: FDA[2] and USDA.[3]

[a] Dichlorodiphenyltrichloroethane.

another lot of the same or another food is not permitted. That practice renders the final food unlawful regardless of the defect level of the finished food.

Responsibility of Food Manufacturers

Food manufacturers are required to follow the standard manufacturing procedures under a federal regulation, known as good manufacturing practice (GMP), during food production.[6] The GMP guidelines imply that all food materials used must not exceed the tolerance limits set for pesticide residues or any other poisonous or deleterious substances. The GMP also calls for the same regulatory requirement for natural or unavoidable defects in all food materials. The food materials susceptible to contamination may be tested for compliance or relied on a supplier's guarantee or certification that they are in compliance. In addition, the GMP regulation stipulates that food manufacturers and distributors must utilize at all times quality control operations that reduce natural or unavoidable defects to the lowest level feasible with the current technology.

Potential Consumer Benefits

Through conducting a monitoring program, the federal government agencies work together to improve consumer protection. The EPA will continue to review scientific data on all pesticide products, while the FDA and U.S. Department of Agriculture will closely monitor levels of pesticide residues in all foods including both domestic and imported products. The U.S. Department of Agriculture's data for 1998 suggest that violation of the pesticide tolerance limits was very low in all raw products including fruit and vege, wheat, and milk samples. In 1993, the FDA reported that no pesticide residues were found in infant formulas, and no residues over EPA tolerances or FDA action levels were found in any of the foods that were prepared as consumers normally would prepare them at home.[7]

Laws and Regulations: Pesticides

Praful Suchak

Introduction

Why Regulate Pesticides?

Chemical or biological pesticides have target specific toxicity that controls or eradicates pests falling under different groups. These products, though developed for specific usage, could have adverse effects on living beings and the environment and unchecked use can cause havoc. Regulating pesticides, therefore, would assure reasonable safety in use of these toxic substances and ensure that risks from pesticides to humans and their environment are minimized and are consistent with the benefits achieved by their use in terms of reduced losses.

Regulating pesticides at the international and national level should consider social costs in line with social benefits. Pesticides impose costs on society, such as health risks and environmental degradation, which are not borne by the user. The available policy remedies include bans on individual or classes of chemicals that prohibit the introduction of hazardous compounds into the environment, and economic instruments such as taxes, registration fees, and import duties that work to redistribute and adjust the social costs occurring for pesticide use and also provide the government with revenues that can be used to cover health costs and environmental clean-up activities.

History

The United States in 1910 introduced the Federal Pesticide Act that underwent complete metamorphosis to become the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA) in 1947, which since 1970 is under the auspices of the Environmental Protection Agency.

Australia initiated pesticide legislation with one state in 1925 and by 1945 all states had their individual laws. The Industry Association brought law common to all states in 1995. By the end of 1999 about 95% of the countries in the world had adopted full/partial regulatory systems.

Early in-depth studies were not carried out on the long-term effects of: 1) repeated exposures, 2) residual toxicity, 3) accumulated toxicity, and 4) the impact on environment. With additional knowledge on the cumulative toxicity of chlorinated hydrocarbons such as DDT having come to light, the regulating authorities have started demanding the generation of additional critical toxicological data to assess short-term, long-term, and environmental toxicity of earlier registered pesticides. The European Union has already undertaken reviews of 90 molecules in the first phase by a Commission regulation dated December 11, 1992, to be completed in 12 years, and a further 148 molecules in the second phase effective March 1, 2000. The remaining substances in the European Union would be included in third phase.

Regulatory requirements for pesticides have undergone a change over the past half a century. With the advent of highly sophisticated testing equipment, more knowledge about harmful effects of the toxic chemicals has come to light. Consistent watch by environmentalists and organizations like the Pesticides Action Network (PAN), Greenpeace, Save the Planet groups, and other nongovernmental organizations has resulted in added awareness resulting in hosts of data requirements for registration/reregistration of pesticides.

Although all developed countries and most of the developing countries have their own legislation to regulate pesticides, there have been vast variations in data requirements for registrations between these countries. With globalization it has became imperative to have harmonized data requirements so that the registrant can hope for faster registration in different (pesticide consuming) countries.

Implementation Problems

Although FAO took the lead to harmonize data requirements in participating nations for registrations of pesticides, certain problems and practical difficulties have occurred such as

7. The original registrant, having invested huge amounts in data generation, is unable to protect the data
8. Absence of confidentiality assurance by the registering country, creating difficulties in multiple country registrations
9. Recommended uses differ from country to country, resulting in difficulties
10. Unchecked dumping of unsafe or banned pesticides in less-developed countries
11. New registrations by a company other than the original registrant by providing data generated by such a company could not be checked

Steps Undertaken

Although though PIC entry of banned pesticides could be prevented, this instrument has not been fully effective. Once it becomes fully operational legally things should improve.

With the United States implementing the Food Quality Protection Act and fixing maximum residue limits for 3000 toxic compounds, countries worldwide would need to harmonize their registrations on toxic chemicals so as to meet the residue levels in food.

The formation of the European Union with 15 member countries, OECD with 29 members, and the Technical Working Group having EPA, Canada, and Mexico, has accelerated the pace towards harmonization. However, since a vast disparity exists between developed countries on one side and developing countries on the other side, it is rather difficult to have a unified data requirement, particularly in case of risk assessment.

Acceptance of electronic data submission and dossier/ monograph submissions and joint reviews by EU would also pave the way toward harmonization and would address questions in the nondietary exposure area.

Apart from studies related to bioefficiency of the product, the toxicological studies of the toxicant, its analogues, impurities and breakdown products, residual toxicity, etc., as listed in Appendix 1 would help understanding and regulating pesticides.

Present Scenario and Probable Remedies

Substantial evidence exists that pesticides are being applied in a technically and economically inefficient manner. Many developing countries subsidize pesticides and equipment, resulting in excessive use of pesticides.

Also in developing countries, the current legal environment and enforcement capabilities have been inadequate and dysfunctional, thus exerting a significant impact on current levels of pesticide use. This is partly due to lack of resources and partly due to manipulation by vested interests.

The inadequacies of the existing regulatory framework, institutional rigidities, and a bias in favor of pesticide-dependent paths also contribute to improper use of pesticides.

A major problem confronting many countries is the absence of well-established procedural mechanisms for public involvement in the decision making process including crop protection policy. Competing interests with a stake in the process, including farmers, the pesticide industry, and policy makers responsible for food security, argue for a more liberal regulatory stance. On the other hand, environmentalists, public health workers, and consumers demand strict regulation and reduced pesticide volumes.

To be more effective, pesticide regulation and implementation should be handled by a neutral agency like the Ministry of Environment or similar organization and not the Ministry of Agriculture or other interested ministry.

Pesticide policy needs to be integrated into the broader public policy debate concerning the nations' agricultural, environmental, and health strategies.

Nevertheless, two general principles should apply. First, dispassionate analysis of the costs and benefits of pesticide use would provide a useful tool for the formulation of normal policies; and second, the broader and more inclusive the debate, the more likely it is that the outcome will serve the public rather than specific private interests.

Future Global Policy

A uniform global regulatory system needs to ensure

1. Agricultural chemical use increases agricultural output
2. Food supplies are safe from harmful toxicants/ residues
3. Reduced-risk chemical pesticides, biopesticides, and nonchemical alternatives are encouraged
4. Uniform MRLs to eliminate trade barriers
5. Uniform health-based safety standards for pesticide residues
6. Special provisions for certain groups of the population including infants and children

Appendix 1

Toxicological and Other Data Requirements for Pesticide Registration

7. Identity of active substance
   Chemical name
   Empirical and structural formula
   Molecular mass
   Method of manufacture (synthesis pathways)
   Purity
   Identity and content of isomers
   Impurity and additives

8. Physical and chemical properties
   Melting point
   Boiling point and relative density
   Vapor pressure
   Volatility
   Appearance
   Absorption spectra-molecular extinction at relevant wavelength
   Solubility in water/organic solvents
   Partitioning coefficient N-octanol/water
   Stability and hydrolysis rate in water
   Photochemical degradation on surface, in water, and in air
   Thermal stability and stability in air

9. Analytical method
   Analytical method for the determination of the pure active substance in the technical grade.
   For breakdown products and additives in plant products, soil, water, animal body fluids, and tissues.

10. Toxicological and metabolism studies
    Studies on acute toxicity—oral, percutaneous, inhalation, intraperitoneal, skin and, where appropriate, eye irritation, and skin sensitization.
    Short-term toxicity—oral, cumulative toxicity, and other routes inhalation or dermal.
    Chronic toxicity—oral, long-term toxicity, and carcinogenicity.
    Mutagenicity—reproductive toxicity-teratogenicity and multigeneration studies in mammals. Metabolism studies in mammals—absorption, distribution, and excretion studies, elucidation of metabolic pathways.
    Supplementary studies—neurotoxicity studies— toxic effects of metabolites from treated plants and toxic effects on livestock and pests.
    Medical data—medical surveillance on manufacturing plant personnel, clinical cases, poisoning incidents from industry and agriculture sensitization/ allergenicity observations, observations on exposure of the general population, and epidemiological studies if appropriate. Diagnosis and specific signs of poisoning, clinical tests, and prognosis of expected effects of poisoning. Proposed treatment: first aid measures, antidotes, and medical treatment. Summary of toxicological studies and conclusions, critical scientific evaluation with regard to all toxicological data, and other information concerning the active substance.

11. Residues in or on treated products, food and feed metabolism in plants and livestock
    In treated plants (distribution, metabolism, binding constituents, etc.).
    In livestock (uptake, distribution, metabolism, binding constituents, etc.).

12. Fate and behavior in the environment
    Studies on aerobic and anaerobic degradation under laboratory conditions in different soil types. Adsorption and desorption in different soil types including metabolites.
    Mobility of the active ingredients in different soil types.
    Behavior in water and air, rate and route of degradation.
13. Ecotoxicological studies
    Effects on birds, fish, aquatic organisms such as Daphnia magna, algae, honeybees, earthworms, other nontarget macroorganisms and microorganisms.
14. Information concerning the labeling including indication of danger and safety measures.

Laws and Regulations: Rotterdam Convention

Barbara Dinham

Introduction

When chemical pesticides were introduced 50 years ago, little attention was paid to the environmental and health impacts. With the rapid expansion of use in the 1950s, understanding gradually increased of the consequences of exposure to certain chemicals. Wide-ranging impacts began to be identified, including: environmental persistence and effects on birds and wildlife; residues in soil, water, and air; residues in food; human poisonings from acutely toxic pesticides or long-term health impacts such as cancer; and pest resistance, often leading to dramatic crop losses.

With almost 1000 different pesticides and thousands of formulations on the market to control insects, diseases, weeds, and other pests, action was clearly needed to protect human health and the environment. International standards recommended that governments establish a registration system to authorize each formulation of a pesticide for each specific crop or other use. Concern with some pesticides led governments to ban or restrict them to a limited number of uses. Few developing countries can fully implement a registration scheme, and they are often unaware of bans imposed elsewhere. Recognizing these problems, in the early 1980s, governments, international organizations, and public interest groups began to demand action to provide a warning system to help developing countries regulate or ban the use of hazardous pesticides.

The Rotterdam Convention on Prior Informed Consent Procedure for Certain Hazardous Chemicals and Pesticides in International Trade[1] is the outcome of 15 years of activity on trade in hazardous chemicals. Adopted on 10 September 1998 in Rotterdam, the Netherlands, the Convention was signed by 73 countries[2] and by June 2001 had been ratified by 14 parties. It will become legally binding after 50 countries have ratified.

The Convention takes an important step toward protecting humans and the environment from highly toxic chemicals. For the first time, it will help monitor and control trade in dangerous substances, circulate better information about health and environmental problems of chemicals, and prevent unwanted imports of certain hazardous chemicals.

Central to the Rotterdam Convention is the system of Prior Informed Consent (PIC), a means of obtaining and disseminating decisions of importing countries about their willingness to receive shipments of certain chemicals, and ensuring compliance to these decisions by the exporter. To be included in PIC, a pesticide must be banned or severely restricted for health or environmental reasons by two countries in two different regions of the world—indicating that its adverse effects are a "global concern."

But focusing on banned or severely restricted pesticides may only touch the tip of the iceberg. Industrialized countries rely on trained and informed users able to apply good practice as safeguards: in developing countries where pesticides are often used under conditions of poverty, these measures cannot be applied. Furthermore, older—and often more hazardous—pesticides are often cheaper, making them attractive to poorer farmers. The Convention recognizes that "severely hazardous pesticide formulations" should be included in PIC if they cause health or environmental problems in developing countries or in Eastern Europe—termed "countries with economies in transition"— in the Convention.

History of PIC

A PIC system was first proposed in the early 1980s as part of the International Code of Conduct on the Distribution and Use of Pesticides, negotiated by governments in the Food and Agriculture Organization (FAO) of the UN. Some governments resisted the concept, and the Code was adopted in 1985 without any reference to PIC. But intense pressure from nongovernmental organizations (NGOs) and others won support, and the principle was accepted in 1987. It took until 1989 to establish the wording and issue a revised version of the Code.[3] That same year, the UN Environment Programme (UNEP) included an identical provision in the London Guidelines on the Exchange of Information on Chemicals in International Trade, and a voluntary system was put in place with the FAO acting as the Secretariat for pesticides and UNEP for industrial chemicals. The first pesticides were added in 1991, and by 1995, 22 pesticides and five industrial chemicals were included.

From Voluntary to Legally Binding

The issue of transforming the voluntary scheme into a legally binding international Convention was first mooted in 1992 at the United Nations Conference on Environment and Development (UNCED).[4] In November 1994, the FAO Council meeting agreed to proceed, and this was followed in May 1995 by a decision of the UNEP Governing Council. The two organizations convened an Intergovernmental Negotiating Committee (INC) to draft and agree international legally binding instrument.

Banning Exports of Banned Pesticides

An alternative to PIC strongly advocated at the time was to stop all exports of banned pesticides. However, unless action to limit the market for a banned pesticide could be taken, banning exports could encourage companies to relocate production, possibly in a country with less stringent controls. Preventing the export of banned pesticides would have no effect on severely restricted chemicals. Without a PIC system, a developing country could unwittingly allow the import of banned or severely restricted pesticides, ignorant of action taken by some governments. Many developing countries maintained that an export ban could limit their development, as alternatives were more expensive, and that import decisions should rest with them. PIC does not prevent individual countries from deciding that their banned pesticides should not be exported, but does ensure that regulatory actions are widely shared.

How the Convention Is Operated

In negotiating the text of the Rotterdam Convention, governments built on the experience gained in the voluntary PIC. As a mark of its importance, the Convention began immediately on a voluntary basis, with FAO and UNEP continuing as an interim Joint Secretariat.

Designated National Authorities

To participate in PIC, governments must appoint a Designated National Authority (DNA). By December 2000, 170 governments had appointed a DNA or a focal point. When ratifying the Convention, DNAs must be authorized to carry out administrative functions such as receiving, transmitting, and circulating information.

Notifying Regulatory Actions

When a government bans or severely restricts a pesticide, it must notify the Joint Secretariat within 90 days. Governments need to demonstrate that their action is final and that it was based on a risk evaluation, including a review of scientific data, and the Secretariat will validate the notification. Once two valid notifications from different PIC regions have been received for the same pesticide, it becomes a candidate for PIC.

Chemical Review Committee

The Convention set up a Chemical Review Committee to consider notifications, and advise the Conference of the Parties (CoP—this will replace the INC after ratification). A parallel structure operates in the voluntary phase, with an Interim Chemical Review Committee (ICRC). The Committee will review PIC notifications, and—when they meet the agreed criteria—draft a Decision Guidance Document (DGD).

Two Routes to Be "PIC-ed"

Pesticides in the voluntary PIC were carried forward, and new pesticides continue to be added. By June 2001, the process included 26 pesticides and five industrial chemicals (Table 1).

There are two routes for adding pesticides to the Convention. Under Article 5, a ban or severe restriction in any two regions triggers PIC if the action is taken for health or environmental reasons. Governments have decided that the PIC regions would be: Africa (48 countries), Latin America, and the Caribbean (33 countries), Asia (23 countries), Near East (22 countries), Europe (49 countries), North America (2 countries: Canada and US), Southwest Pacific (16 countries).

The second route is covered in Article 6, and addresses "severely hazardous pesticide formulations." This category applies only to pesticide formulations found to be causing health or environmental problems under conditions of use in developing countries, or countries with economies in transition. These pesticides may not have been banned, but—generally because of high toxicity— cause poisonings and deaths when used without extreme caution. Governments must submit evidence based on a "clear description of incidents related to the problem, including the adverse effects and the way in which the formulation was used." Nevertheless, this kind of evidence is rare, and collecting information is difficult: incidents take place far from medical facilities; many farmers are unaware of the active ingredients of pesticides they use; and it is common to use mixtures of several pesticides. The ICRC is investigating how to deal with these problems.

TABLE 1 Pesticides Covered by the Interim PIC Procedure, November 2000

Banned or severely restricted pesticides[a]
2,4,5-T (dioxin contamination)
Aldrin
Binapacryl (INC6)[a]
Captafol
Chlordane
Chlordimeform
Chlorobenzilate
DDT
Dieldrin
Dinoseb and dinoseb salts
1,2-Dibromoethane (EDB, or ethylene dibromide)
Ethylene dichloride (INC7)[a]
Ethylene oxide (INC7)[a]
Fluoroacetamide
HCH, mixed isomers
Heptachlor
Hexachlorobenzene
Lindane
Mercury compounds
mercuric oxide
mercurous chloride, Calomel
other inorganic mercury compounds
alkyl mercury compounds
alkoxyalkyl/aryl mercury compounds
Pentachlorophenol
Toxaphene (INC6)[a]
Severely hazardous pesticide formulations[b]
Monocrotophos
Methamidophos
Phosphamidon
Methyl parathion
Parathion

[a] Indicates that these four pesticides were added to the PIC list at the 6th and 7th International Negotiating Committee meetings.

[b] Only certain formulations of these severely hazardous pesticides are included.

Source: http://www.pic.int/[5]

Import Decisions, Information, and Website

Once a pesticide is included in PIC, the DGD is circulated to all governments who must decide whether to consent to or prohibit its import. Import decisions are posted on the PIC website, and circulated biannually. Governments in exporting countries must ensure that their exporters comply. Of course, many countries are both importers and exporters and under the rules of international trade, a country cannot ban the import of a pesticide that is manufactured and used nationally.

An important tool is the PIC Circular, updated every six months by the Secretariat. Circulated in hard copy and on the website,[5] it includes new bans and severe restrictions, importing country responses, and general progress reports. For the first time, it is easy to access sound information on government regulatory actions, even if these do not meet all the full PIC criteria.

The Convention—More than PIC

Information exchange is an important principle promoted under Article 14 of the Convention. Developing countries lack resources to undertake extensive evaluations of pesticides and governments are encouraged to share scientific, technical, economic, and legal information on chemicals within the scope of the Convention, as well as other information on their regulatory actions.

Building Capacity/Improving Regulations

The process of identifying problem pesticides through PIC will be slow, and there are limitations. In some cases, for example, governments will have no easy substitute, although this may increase the incentive to seek safer and more appropriate alternatives, including Integrated Pest Management strategies.

Financial resources are needed, not only to allow the Secretariat to meet its obligations, but also to ensure that regulators in developing countries can participate in workshops and training sessions. In poorer countries, with competing demands on scarce resources, chemical regulation is not always a priority. The status of an international Convention gives PIC the attention it requires to be effective, and should help attract the necessary funds.

PIC is just one tool, although an important one, in the regulation of pesticides. With good training and additional resources, PIC can play a central role as part of capacity building initiatives to help governments improve their ability to regulate pesticides, and to look for products and strategies that reduce the dependence on hazardous chemicals.

Laws and Regulations: Soil

Ian Hannam
and Ben Boer

Introduction

At a national level, soil law means a body of law to promote soil conservation enacted by a legislature, e.g., an act, decree, regulation, or other formal legal instrument that is legally enforceable. Soil law, or "soil legislation" as it may also be referred, includes those laws that have primary responsibility for soil conservation, soil and water conservation, and land rehabilitation. They are generally characterized by provisions to mitigate and manage soil erosion and soil degradation and methods to conserve soil resources. Internationally, the legal framework for the conservation of soil can include conventions, protocols, agreements, and covenants, which are expressed to be legally binding. Worldwide, soil law is managed by a variety of legal and institutional systems, which are the individual organizational and operational regimes that have the administrative authority over soil.

Why Law for Soil?

Soil bodies are effectively large ecosystems and comprise fundamental components of the earth's biodiversity. Soil is thus seen as the basis for the conservation of terrestrial biological diversity and the sustenance of all terrestrial organisms, including people. The ongoing and widespread soil degradation as a result of human use of soil provides the imperative for enactment of soil law. The ever-increasing demand for food by rapidly growing populations in many countries in the past few decades has exerted increasing environmental stress on the soil leading to widespread soil degradation.[1] The following definitions provide the context for soil law.

Soil

Soil forms an integral part of the earth's ecosystems and is situated between the earth's surface and bedrock. It is subdivided into successive horizontal layers with specific physical, chemical, and biological characteristics. From the standpoint of history of soil use, and from an ecological and environmental point of view, the concept of soil also embraces porous sedimentary rocks and other permeable materials together with the water that these contain and the reserves of underground water.[2]

Soil Degradation

Soil degradation is a loss or reduction of soil functions or soil uses. It includes aspects of physical, chemical, and biological deterioration, including loss of organic matter, decline in soil fertility, decline in structural condition, erosion, adverse changes in salinity, acidity, or alkalinity, and the effects of toxic chemicals, pollutants, or excessive flooding.[1]

Sustainable Use of Soil

The sustainable use of soils preserves the balance between the processes of soil formation and soil degradation while maintaining the ecological functions and needs of soil. In this context, the use of soil means the role of soil in the conservation of biological diversity and the maintenance of human life.[3]

International Law and Soil

International environmental law is an essential component for setting and implementing global, regional, and national policy on environment and development. There is an increasing recognition of the role of international environmental law to overcome the global problems of soil degradation, including its ability to provide a juridical basis for action by nations and the international community.[4] A number of international and regional instruments introduced in the past 10 years contain elements that can contribute to achieving sustainable use of soil. None are sufficient on their own. Some of the instruments could assist by promoting the management of some of the activities that can control soil degradation. However, this role is not readily apparent except for those that include provisions specifically directed to soil (e.g., see Article IV "Soil"— 1968 *African Convention on the Conservation of Nature and Natural Resources,* final revision text adopted by the African Union Assembly on July 11, 2003).

Declarations

A number of nonbinding declarations and charters draw attention to the fact that soil degradation and desertification are reaching alarming proportions and seriously endangering human survival. They call on states to cooperate and develop the tools to conserve soils. Key declarations relevant to soil include the 1972 *Stockholm Declaration on the Human Environment,* the 1981 FAO World Soil Charter, the 1982 *World Charter for Nature*, the 1982 *Nairobi Declaration,* the 1992 *Rio Declaration on Environment and Development,* and the 2002 *Johannesburg Declaration on Sustainable Development*. Also of relevance is the Programme for the Development and Periodic Review of Environmental Law for the First Decade of the 21st Century, known as the Montevideo Programme; this program includes provisions to improve the conservation, rehabilitation, and sustainable use of soils.[5]

International Conventions, Covenants, Treaties, and Agreements

Many multilateral agreements include provisions that could be used to promote sustainable use of soil, but the provisions are generally tangential to the needs of soil as such. Key global instruments relevant to soil include the 1992 *Convention on Biological Diversity,* the 1992 *United Nations Framework Convention on Climate Change* and the 1997 *Kyoto Protocol,* and the 1994 *United Nations Convention to Combat Desertification*. Relevant regional instruments include the 1968 *African Convention on the Conservation of Nature and Natural Resources* (Revised July 2003), the 1985 *ASEAN Agreement on the Conservation* *of Nature and Natural Resources*, the 1986 *Convention for the Protection of the Natural Resources and Environment of the South Pacific Region,* the 1986 *European Community Council Directive,* the 1995 *Convention Concerning the Protection of the European Alps,* and the 1998 *Protocol for the Implementation of the Alpine Convention of 1991 in the Area of Soil Protection.*[6]

National Soil Law

Legislation has been used for some 60 years in many countries to control soil degradation problems and to manage soil. A worldwide examination of national legal and institutional frameworks indicates that most countries approach the management of soil in a fragmented manner. The term "soil law" also covers those situations where comprehensive provisions for soil protection and management have been integrated in legislation that protects other aspects of the environment, such as forests, water, biodiversity, and desertification. In general, soil law thus provides for farm planning, implementation of soil erosion control measures, establishing community groups, planning catchment schemes, and compliance and enforcement. Some jurisdictions, such as the United Kingdom, have multiple soil legislation mechanisms that cover a broad range of functions including soil planning, access to sensitive land types, organic farming practices, nitrate sensitive areas, and soil restoration. On the other hand, federally organized countries often have a system where each state or province has its own soil legislation and supportive legal mechanisms. Hybrid situations also exist, such as in the People's Republic of China, which has enacted the *Water and Soil Conservation Law 1991* and the *Desertification Law 2002* at a national level, but causes them to be implemented through a comprehensive provincial system of law and regulations.

There is a wide variety of types of legal mechanisms used to protect and manage soil, including acts, decrees, resolutions, ordinances, codes, regulations, circulars, decisions, orders, and bylaws. Whereas these are generally appropriate, many need to be applied in more inventive ways to effectively manage the soil in an ecosystem context.[3]

Effectiveness of Soil Law

The effectiveness of international and national soil law is generally dependent on two matters: first, the capacity of a legal and institutional framework to manage soil—which is measured by the ability of a legislative and institutional system to achieve sustainable use of soil—and second, by the number and type of essential legal and institutional elements present in a soil statute in a format that enables soil degradation issues to be identified. These need to be backed by the legal, administrative, and technical capability in the particular instrument as a basis of some form of effective action. Capacity is also represented in the form of legal rights, the type of legal mechanisms, and importantly, the number and comprehensiveness of the essential elements and their functional capabilities. Legal and institutional "elements" for soil are the basic, essential components of a legal and institutional system. An individual law can include a number of legal mechanisms in a well thought-out structure that gives an organization the power it needs, through its executive and administrative structure, to address soil degradation. It is also possible that the necessary elements may be distributed among a number of individual laws within a comprehensive national legal and institutional system.[7]

Most key soil management issues are multifactorial (i.e., many include a sociological, a legal, and a scientific component), so it is obvious that generally more than one piece of environmental legislation (along with detailed regulations) and many types of legal and institutional elements will be needed to effectively manage soil degradation issues.[7] Legal and institutional elements can be used to assist in the evaluation of an existing law or legal instrument to determine its capacity to meet certain prescribed standards of performance for the sustainable use of soil. They can also be used to guide the reform of an existing soil law or to develop new legislation for the sustainable use of soil. The manner and degree in which an "essential element" is applied will vary according to the particular type of legal mechanism concerned and its expected role in a particular jurisdiction. For example, an international legal instrument may include a provision for dispute resolution, but the actual implementation of this provision between states might not rely on, or be influenced by, the existence of similar provisions within a law of either of the disputing states.[7]

IUCN Commission on Environmental Law

The Commission on Environmental Law of IUCN (The World Conservation Union) has carried out extensive investigation into the options for a new international instrument focusing on soil. The commission has also identified a variety of ways available for states to approach the task of a detailed legal and institutional analysis and the design of appropriate legal and institutional systems that provides for the effective management of soil. Arising from this work, in which the authors have been centrally involved, two principal strategies can be considered for the development of legal and institutional arrangements for soil. These are:

- A nonregulatory strategy which is characterized by elements for education, participatory approaches, soil management, and incentive schemes
- A regulatory approach that is characterized by statutory soil use plans that prescribe legal limits and targets of soil and land use, issue of licenses or permits to control soil use, and the use of restraining orders and prosecution for failure to follow prescribed standards of sustainable soil use.

These strategies can be approached on a short-term time frame for implementation or a longer-term time frame, which involves substantial reform of existing laws, policies, and institutional and sectoral change.[7]

Conclusions

Soil law in the past has been neglected at the international level and, in many of the world's regions, at the domestic level. However, the growing recognition of soil degradation as a major international environmental issue in the context of the conservation of biological diversity is gradually being addressed, and this is starting to change attitudes toward the benefits of improved international and national legal and institutions for soil.[8] Soil bodies represent complex terrestrial ecosystems. They require careful management of their ecological characteristics through the medium of soil law at a national and international level. This approach is essential for the long-term sustainable use of soil and to meet the food production requirements of the expanding human population of the world, as well as to meet the needs of all flora and fauna that depend on the soil for sustenance.

LEED-EB: Leadership in Energy and Environmental Design for Existing Buildings

Rusty T. Hodapp

Introduction

Existing buildings comprise a significant proportion of the total building stock in the United States and building operations consume large amounts of resources (energy, water, building materials, land, etc.), while generating great amounts of waste. For example, in the United States, commercial and industrial buildings alone are estimated to be responsible for the following[1]:

- 38.9% of primary energy use
- 38% of all CO_2 emissions
- 72% of all electricity use
- 13.6% of all potable water use
- 170 million tons of construction and demolition debris
- Using 40% of raw materials globally

Furthermore, because the average person spends 90% of their time indoors, the quality of a building's interior environment impacts virtually everyone. This suggests a very personal interest in better buildings in addition to the national implications of large-scale resource consumption. Issues such as these have driven government, corporate, and personal interest in sustainability and “green” topics. Applied to the building industry, this interest is forcefully seen in the rise of green building certification programs and, in particular, the Leadership in Energy and Environmental Design (LEED) Green Building Rating System™ of the United States Green Building Council (USGBC). Intended to guide the development and verify the performance of green buildings, LEED rating systems have become well accepted as a national standard. Consisting of a number of products, the LEED Green Building Rating System largely focuses on design and construction of new buildings. One rating system, however, known as LEED for Existing Buildings: Operations and Maintenance (LEED-EB O&M) is oriented at the operation, maintenance, and management of existing buildings. LEED-EB O&M is of particular interest to facility managers, energy managers, owners, or others interested in reducing operating costs, improving indoor environmental quality, and minimizing the environmental impact of buildings as a growing body of case study and research evidence suggests that these outcomes are linked to green building practices.

This entry presents an overview of the LEED-EB O&M Green Building Rating System, its benefits and distinctions from other LEED rating systems, how it is organized and implemented, and the value of high-performance green buildings.

Introduction to LEED

LEED stands for the USGBC’s family of standards for rating “green buildings.” The LEED Green Building Rating System is USGBC’s effort to provide a national standard to define a green building. Used as guideline for design, construction, operation, and maintenance and with third-party certification, LEED provides a consistent, credible means of developing and operating high-performance, environmentally sustainable buildings.

United States Green Building Council

Formed in 1993, the USGBC has become perhaps the most prominent “green building” organization in America. With more than 18,000 member organizations, a network of 78 local affiliates, and more than 140,000 LEED Professional Credential holders, the non-profit organization works through leaders in all sectors of the building industry to advance buildings that are environmentally responsible, profitable, and healthy places to live and work. Driving its mission to transform the building marketplace to sustainability is the Council’s LEED Green Building Rating System and related training and professional accreditation programs. USGBC also supports education, research, and advocacy programs as well as strategic alliances with key industry, research organizations, and federal, state, and local government agencies to transform the building market.[2]

LEED Green Building Rating System

The LEED Green Building Rating System is a voluntary, consensus-based, market-driven building rating system. LEED assesses sustainability from a whole-building perspective by evaluating five key areas of a building’s performance in terms of economic, environmental, and human health impact: sustainable site development, water savings, energy efficiency, materials selection, and indoor environmental quality. Buildings are awarded different levels of certification (Certified, Silver, Gold, Platinum) based upon the amounts of credits satisfied and points earned. These credits are performance oriented and intended to address specific impacts inherent in the design, construction, operation, and maintenance of buildings.

The initial LEED rating system (referred to as LEED Version 1.0) was released in August 1998. LEED 1.0 was extensively modified and released as Version 2.0 in March 2000 with LEED Version 2.1 following in 2002 and Version 2.2 in 2005. LEED has continued to evolve, undertaking new initiatives and expanding into a family of products.

As of April 2009, the portfolio of LEED rating systems consists of several products targeting specific sectors of the buildings market:

- LEED 2009 for New Construction and Major Renovation
- LEED 2009 for Commercial Interiors
- LEED 2009 for Core and Shell Development
- LEED 2009 for Existing Buildings: Operations and Maintenance
- LEED 2009 for Schools
- LEE 2009 for Retail
- LEED for Healthcare
- LEED for Homes
- LEED 2009 for Neighborhood Development

With new products, technologies, and design innovations coming into the green building marketplace daily, the Rating Systems and Reference Guides will continue to evolve as necessary to stay current and relevant.[3]

Benefits of Green Building Certification

LEED provides a guidebook for the design, construction, operation, and maintenance of green buildings, the general benefits of which will be described in more detail later in this entry. The LEED rating system is flexible in order to provide owners and design teams the ability to accommodate circumstances or goals specific to their project. The rigorous and independent certification process provides firm and compelling proof that the building has achieved the sustainable goals established for it and is performing as intended. The credible assurance that a building is in fact green can be valuable to owners, occupants, investors, and other key stakeholders in the industry as well as the public at large.

LEED and Existing Buildings

With the exception of LEED-EB O&M, the LEED family of products is intended to address the design and construction phases of buildings. The primary users of these products are architects, engineers, construction contractors, and building owners. A building designed and constructed to LEED standards has verifiably incorporated green or sustainable features and, therefore, should perform better in the key impact areas (economic returns, environmental impact, and occupant health and comfort) than a typical building built to basic code standards. Addressing the design and construction phase of a building's life is extremely important because it is in these phases that many irreversible decisions with long-term impacts on the building's performance are made.

Figure 1 depicts graphically what has become well established regarding the life-cycle cost of buildings: 1) the majority (75% or more) of total life-cycle costs occur after construction (i.e., during the O&M phase); and 2) many of the decisions that drive long-term cost occur during programming and design.[4]

However, the fact is that new buildings represent a very small percentage of the total commercial building stock in the United States. According to some sources, new construction amounts to 2% of the total stock of buildings in any one year.[5] No doubt it is safe to assume that the majority of these existing buildings were not designed or are being operated and maintained to green standards. In order to improve the building sector's performance in terms of sustainability, clearly the existing stock must be addressed in addition to new construction. Similarly, since the post-construction phase of a building's life cycle contributes disproportionately to its total cost, resource consumption, and impact on users, standards for operations and maintenance are necessary to maximize the benefits of green practices in the building sector. This is exactly the focus of the LEED-EB O&M Rating System.

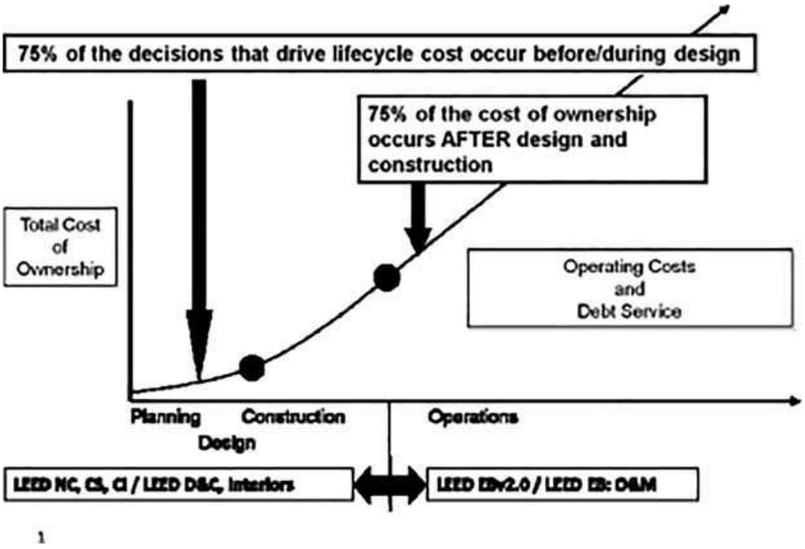

FIGURE 1 Building life-cycle cost curve.

LEED for Existing Buildings: Operations and Maintenance

The LEED-EB O&M Rating System is a set of performance standards for sustainable operations and maintenance of existing buildings of various types and all sizes. It is intended to advance high-performance, healthy, durable, affordable, and environmentally sound practices in existing buildings. LEED-EB O&M provides an entry point into the LEED certification process for the existing building stock. It can be used for buildings new to LEED certification as well as those previously certified under LEED-NC. The USGBC began developing LEED-EB in 2000 and it was tested in a pilot phase involving more than 100 buildings in 2002. The final version (Version 2.0) was released in October 2004. The current version, LEED-EB O&M, was released in April 2009 under the suite of 2009 LEED rating systems and has been further updated in April 2010. The introduction to the LEED 2009 for Existing Buildings: Operations and Maintenance Green Building Rating System states “LEED for Existing Buildings Operations and Maintenance encourages owners and operators of existing buildings to implement sustainable practices and reduce the environmental impacts of their buildings over their functional life cycles.” To achieve this, LEED-EB O&M addresses exterior building site maintenance, water and energy use, environmentally preferred products and practices for cleaning and alternations, waste stream management, and ongoing indoor environmental quality.[6]

Issues Addressed by LEED-EB O&M

LEED-EB O&M addresses all the key facets of building operations and maintenance that impact total cost of ownership, the environment, and building occupants. Some examples include the following:

- Energy use
- Water use
- Building operations and maintenance
- Building systems (e.g., mechanical, electrical, plumbing) performance
- Maintenance of building exterior and site
- Ventilation and indoor air quality
- Lighting quality

- Thermal comfort of spaces
- Green cleaning
- Recycling programs
- Green product purchasing programs
- Management of indoor pollutants and toxic substances
- Systems upgrades[7]

LEED-EB O&M seeks to address sustainability on an ongoing basis. This largely falls under the scope of those involved in managing and operating buildings, and clearly, their involvement and expertise are necessary to successfully certify a building under LEED-EB O&M. To the extent the benefits of green buildings and popularity of standards like LEED continue growing, market forces will create new opportunities for facility managers, energy managers, etc., demand for their services, and highlight the overall value of their contributions.

Key Distinctions between LEED-EB O&M and Other LEED Products

Although sharing many common features in terms of structure and process with other LEED products, LEED-EB O&M is fundamentally distinct in three key ways. LEED-NC (and the other new building-oriented products) is essentially a onetime event whereas LEED-EB O&M represents an ongoing process. Second, with LEED-NC, the green building process ends after the design and construction phase. For LEED-EB O&M, the green building phase is a continuous process that deals with ongoing operations, maintenance, and upgrades of a building over its life cycle. Buildings certified under LEED-EB O&M require recertification at least once every 5 years. Finally, given their focus on different phases of a building's life cycle, LEED-NC is primarily a capital budget event while LEED-EB O&M deals with operating budgets.[8]

Overview of LEED-EB O&M

In the same manner as all LEED products, the LEED-EB O&M Rating System is based on evaluations of a building in seven categories:

1. Sustainable sites
2. Water efficiency
3. Energy and atmosphere
4. Materials and resources
5. Indoor environmental quality
6. Innovation (in this case, in operations)
7. Regional priority

Minimum Program Requirements

All projects must meet certain minimum program requirements (MPRs) to be eligible for certification under the LEED 2009 rating systems. MPRs define the minimum characteristics that a project must possess in order to be certified and are intended to: 1) provide clear guidance to users; 2) protect the integrity of LEED program; and 3) reduce challenges during the certification process. The LEED 2009 MPRs for EB O&M are as follows:

1. Must comply with environmental laws
2. Must be a complete, permanent building or space
3. Must use a reasonable site boundary
4. Must comply with minimum floor area requirements

5. Must comply with minimum occupancy rates
6. Must commit to sharing whole-building energy and water usage data
7. Must comply with a minimum building area-to-site area ratio

The ongoing performance data from buildings required as part of the certification will be compiled and used to establish benchmarks for building performance and provide operators an idea of how their building compares on water and energy use. To further its commitment to improving building performance, the USGBC launched the Building Performance Initiative (BPI) in August 2009 to complement the MPR for ongoing performance data. The BPI will make the data collected available to building owners for analysis and feedback.

Prerequisites

Also consistent with other LEED rating systems, LEED-EB O&M requires every project to meet certain prerequisites in order to be considered for certification (see the list of prerequisites by category in Table 1). All prerequisites must be satisfied for a project to be eligible for certification.

The prerequisites include such items as minimum levels of water and energy efficiency, building commissioning, no CFC refrigerants, no-smoking policy, and other basic elements of a high-performance, green building operation. A key prerequisite involves a minimum performance period for the building. LEED-EB O&M requires buildings to be in operation for a minimum of 12 continuous months before certifying (3 months for all prerequisites and credits except Energy and Atmosphere Prerequisite 2 and Credit 1, which require a minimum of 12 months).

Credits and Points

Buildings achieve certification under all LEED products by accumulating a certain number of credit points. Points can be obtained in any combination within and among the credits and categories (see Table 2 for the credit and point breakdown for LEED-EB O&M). All LEED rating systems have 100 base points, and up to 10 bonus points can be earned through Innovation and Regional Priority credits.

TABLE 1 LEED 2009 for EB O&M Prerequisites

Category	Prerequisites
Sustainable sites	0
Water efficiency	1
Energy and atmosphere	3
Materials and resources	2
Indoor environmental quality	3
Total	9

TABLE 2 LEED-EB O&M Credits and Points

Category	Credits	Points
Sustainable sites	9	26
Water efficiency	4	14
Energy and atmosphere	9	35
Materials and resources	9	10
Indoor environmental quality	15	15
Innovation in operations	3	6
Regional priority	1	4
Total	50	110

Each LEED rating system uses the same format for prerequisites and credits. The sections include the following:

- *Intent*—describes the main goal of the prerequisite or credit.
- *Requirements*—specifies the criteria needed to satisfy the prerequisite or credit.
- *Submittals*—specifies the documentation required to demonstrate compliance with the prerequisite or credit.
- *Potential Technologies and Strategies*—identifies means and methods that project teams may consider to achieve the prerequisite or credit.

Certification Levels

LEED rating systems allow buildings to achieve various levels of certification based on points achieved (see Table 3 for the certification levels for LEED-EB O&M).

Registration Process

With the launch of LEED Version 3 in 2009, USGBC implemented a new certification model. LEED v3 consists of three components:

- LEED 2009 rating systems.
- An upgrade to LEED Online to make it faster and easier to use.
- New building certification model—an expanded infrastructure based on ISO standards, administered by the Green Building Certification Institute (GBCI) for improved capacity, speed, and performance.

LEED Online is the primary resource for managing the LEED documentation process. It allows project teams to manage project details, complete documentation requirements for LEED credits and prerequisites, upload supporting files, submit applications for review, receive reviewer feedback, and ultimately earn LEED certification. The GBCI is an independent, third-party organization that has assumed administration of LEED certification for all commercial and institutional projects registered under any of the LEED rating systems.

The process of certifying a building under any of the LEED rating systems is essentially the same—the project is first registered with GBCI using LEED Online. Once a project is registered, access to software tools, supplemental resources, sample documentation, credit interpretation rulings, and other essential information is provided. For LEED-EB O&M, the initial application (application for standard review) must be submitted within 60 calendar days of the performance periods used. The application has to include complete documentation for all prerequisites and enough points for certification. GBCI reviews the application and designates each credit and prerequisite as anticipated pending or denied. This preliminary standard review is targeted (but not guaranteed) for completion within 25 business days of receipt of the application. Within 25 days of receiving GBCI's preliminary standard review, the owner may submit a response including any revised documentation. GBCI will then review and return comments for all credits and prerequisites in response to the preliminary Standard Review and

TABLE 3 LEED-EB O&M Certification Levels

Certification Level	Points Required
Certified	40–49
Silver	50–59
Gold	60–79
Platinum	80+

designate each as awarded or denied. This final Standard Review is targeted for completion within 15 business days of receipt of the completed application. The owner then accepts or appeals the final review. Following acceptance of the final certification review, LEED projects:

1. Will receive a formal certificate of recognition
2. Will receive information on how to order plaque and certificates, photo submissions, and marketing
3. May be included (at the owner's discretion) in the online LEED Project Directory of registered and certified projects
4. May be included (along with photos and other documentation) in the U.S. Department of Energy High Performance Buildings Database[9]

Implementation Process

From a practical standpoint, the process of implementing LEED-EB O&M should generally involve the following steps:

1. Become familiar with the LEED-EB O&M Rating System
2. Gain the support of key decision makers and stakeholders
3. Form a project team
4. Conduct a preliminary building audit and identify corrective actions required to meet prerequisites and/ or opportunities
5. Establish project goals related to target certification level, credits to be pursued, and budget
6. Register the project
7. Create and adopt policies and procedures, implement upgrades, make operational changes, etc., in accordance with the project goals
8. Track performance
9. Assemble and submit required documentation (preliminary and any required corrections or resubmittals)
10. Achieve certification

The minimum performance period for initial certifications under LEED-EB O&M is 12 months. During this period, actual operational performance must be tracked and reported. The performance tracking period can be as long as 2 years depending upon the project goals and/or implementation strategy.

The USGBC provides project teams with numerous resources including the LEED Online system for managing and preparing the certification application, credit templates that define supporting documentation needed and compliance calculations, credit interpretation rulings that can help answer questions on credits and implementation strategies, and the LEED Reference Guides.[10,11]

Benefits of Green Buildings

The premise inherent in the LEED rating systems is that "green" buildings provide superior value to owners, occupants, and other stakeholders. Typically, the value proposition construct for sustainability, green buildings, etc., is the well-known triple bottom line of economic returns, environmental impact, and social benefit. Green buildings, also known (perhaps more accurately) as high-performance buildings, are premised as providing superior economic returns, reduced environmental impact, and enhanced social benefits. Such buildings in theory:

- Were properly built and/or are well operated and maintained
- Use resources (e.g., energy, water, building materials, O&M supplies) more efficiently
- Provide a safer, more comfortable, and productive working environment for occupants

In fact, there is a robust and growing body of evidence in research and case study that supports these claims. The following examples are illustrative.

A report commissioned by California's Sustainable Building Task Force found that energy savings alone exceeded the average cost increase associated with 33 different LEED buildings studied. When adding the life-cycle cost benefits of water savings, reduced emissions, operations and maintenance efficiencies, and improved occupant productivity and health, the 20 years net present value of the financial benefits of green buildings exceeded the implementation costs by as much as 10–15 times.[12] Case studies on commissioning alone show that construction and operating costs can be reduced from 1 to 70 times the initial cost of commissioning.[13] Improved thermal comfort, reduced indoor pollutants, enhanced ventilation rates, and other characteristics of green buildings have been found to have positive impacts on occupant productivity, student test scores, absenteeism, and incidences of various sicknesses.[14]

Other benefits continue to be demonstrated in case studies and research, including the following:

- Increased building value
- Risk mitigation
- Employee loyalty and recruitment
- Brand image and public relations
- Environmental stewardship[15]

Energy Efficiency Potential of Green Buildings

In LEED 2009, points are allocated among credits based on the potential environmental impacts and human benefits of each credit. As a result, the allocation of points significantly changed in comparison to previous versions of the LEED rating systems. These changes increased the relative importance of reducing energy consumption and building-related greenhouse gas emissions. Reflecting this, one credit in LEED 2009 EB O&M comprises the largest potential amount of points—Energy and Atmosphere Credit 1 Optimize Energy Efficiency Performance provides the opportunity for 18 possible points. Furthermore, with its emphasis (and associated requirements) on demonstrated performance, LEED-EB O&M presents tremendous potential to reduce energy consumption throughout the commercial building sector. When considering the fact that existing buildings comprise some 95% of the commercial building stock in the United States, the magnitude of potential reduction is immense. To put this potential in context, consider U.S. Energy Information Administration (EIA) projections of the impact of energy efficiency on per capita commercial energy consumption. In their *Annual Energy Outlook 2010,* EIA estimates per capita commercial energy consumption in 2035 could be decreased by as much as 17.5% depending upon the degree to which technology-based efficiency improvements are deployed throughout the sector.[16] McKinsey and Company estimates that, by 2020, the United States could reduce annual energy consumption by 9.1 quadrillion British thermal units (BTUs) (23%) of end-use energy (18.4 quadrillion BTUs in primary energy) from a business-as-usual baseline by deploying an array of energy efficiency measures with the commercial sector accounting for 25% of this potential. At full potential, the projected efficiency improvements could reduce greenhouse gas emissions by as much as 1.1 gigatons of CO_2 by 2020 and serve as a bridge to low-carbon energy sources.[17] Similarly, the Electric Power Research Institute (EPRI) estimates that the combination of energy efficiency and demand response programs has the potential to reduce summer peak electric demand in the United States by 157 GW to 218 GW (14% to 20%) by 2030.[18] Finally, consider the potential national impact of LEED energy savings presented in the Green Building Market and Impact Report 2009. This report projects that given the acceleration of LEED adoption, energy savings in the United States could reach 1.75 quadrillion BTUs by 2020 and 3.9 quadrillion BTUs by 2035 (8.3% and 17.3%, respectively, of national annual commercial building energy use). A best-case scenario could see those savings rise to 22.3% by 2030.[19]

Conclusion

The USGBC's LEED Green Building Rating System has become a well-recognized standard for guiding the development of green, high-performance buildings and for verifying that established green building goals have been accomplished. The LEED family of rating systems is focused on the design and construction process for new buildings. However, one rating system—LEED-EB O&M— focuses on operations and maintenance of existing buildings. LEED-EB O&M is of particular interest to facility managers, energy managers, and other professionals involved in building operation and management. LEED-EB O&M provides a guidebook for those interested in "greening" their existing building stock. Implementing these green processes and practices can be an effective means of reducing a building's life-cycle costs, reducing its environmental impact, and improving occupant health and productivity.

LEED-NC: Leadership in Energy and Environmental Design for New Construction

Stephen A. Roosa

Introduction

Land development practices have yielded adverse environmental consequences, urban dislocation, and changes in urban infrastructure. Urban development in particular has long been associated with reduced environmental quality and environmental degradation.[2] The rate at which undeveloped land is being consumed for new structures—and the growing appetite of those structures for energy and environmental resources—has contributed to ecosystem disruption and has fostered impetus to rethink how buildings are sited and constructed. While urban developmental patterns have been associated with environmental disruptions at the local and regional scales, the scientific assessments of global impacts have yielded mixed results. In part as a reaction to U.S. development patterns that have traditionally fostered suburbanization and subsidized automobile-biased transportation infrastructure, design alternatives for structures with environmentally friendly and energy efficient attributes have become available.

According to the United Nations Commission on Sustainable Development, "air and water pollution in urban areas are associated with excess morbidity and mortality … Environmental pollution as a result of energy production, transportation, industry or lifestyle choices adversely affects health. This would include such factors as ambient and indoor air pollution, water pollution, inadequate waste management, noise, pesticides and radiation."[3] It has been demonstrated that a relationship exists between the rates at which certain types of energy policies are adopted at the local level and select indicators of local sustainability.[4] As more urban policies focus on the built environment, buildings continue to be the primary building blocks of urban infrastructure. If buildings can be constructed in a manner that is less environmentally damaging and more energy efficient, then there is greater justification to label them as "green" buildings.

The concept of sustainability has evolved from considerations of land development, population growth, fossil fuel usage, pollution, global warming, availability of water supplies, and the rates of resource use.[5] Thankfully, a vocabulary of technologies and methodologies began to develop in the 1970s and 1980s that responded to such concerns. Driven by ever increasing energy costs, energy engineers began to apply innovative solutions, such as use of alternative energy, more efficient lighting systems and improved electrical motors. Controls engineers developed highly sophisticated digital control systems for heating, ventilating and air conditioning systems. With growing concerns about product safety and liability issues regarding the chemical composition of materials, manufacturers began to mitigate the potential adverse impacts of these materials upon their consumers. Resource availability and waste reduction became issues that began to influence product design. In the span of only 25 years, local governments made curbside recycling programs in larger U.S. cities nearly ubiquitous. Terms and phrases such as "mixed use planning," "brownfield redevelopment," "alternative energy," "micro-climate," "systems approach," "urban heat island effect," "energy assessments," "measurement and verification," and "carrying capacity" created the basis for a new vocabulary which identifies potential solutions. All of these concerns evolved prior to the 1992 U.N. Conference on the Environment and Development, which resulted in the Rio Agenda 21 and clarified the concept sustainability.

In regard to the built environment, architectural designers renewed their emphasis on fundamental design issues, including site orientation, day lighting, shading, landscaping, and more thermally cohesive building shells. Notions of "sick building syndrome" and illnesses like Legionnaires' disease, asthma and asbestosis, jolted architects and engineers into re-establishing the importance of the indoor environmental conditions in general and indoor air quality (IAQ) in particular when designing their buildings.

The decisions as to what sort of buildings to construct and what construction standards to apply are typically made locally. Those in the position to influence decisions in regard to the physical form of a proposed structure include the builder, developer, contractors, architects, engineers, planners, and local zoning agencies. In addition, all involved must abide by regulations that apply to the site and structure being planned. The rule structure may vary from one locale to another. What is alarming is that past professional practice within the U.S. building industry has only rarely gauged the environmental or energy impact of a structure prior to its construction. Prior to the efforts of organizations like the U.S. Green Building Council (USGBC) (established in 1995), the concept of what constituted a "green building" in the United States lacked a credible set of standards.

Concept of Green Buildings

Accepting the notion that sustainable, environmentally appropriate, and energy efficient buildings can be labeled "green," the degree of "greenness" is subject to multiple interpretations. The process of determining which attributes of a structure can be considered "green" or "not green" is inconclusive and subjective. Complicating the process, there are no clearly labeled "red" edifices with diametrically opposing attributes. While it is implied that a green building may be an improvement over current construction practice, the basis of attribute comparison is often unclear, subjective, and confusing. It is often unclear as to what sort of changes in construction practice, if imposed, would lead the way to greener, more sustainable buildings. If determinable, the marketplace must adjust and provide the technologies and means by which materials, components, and products can be provided to construction sites where greener buildings can arise. Since standards are often formative and evolving, gauging the degree of greenness risks the need to quantify subjective concepts.

There are qualities of structures, such as reduced environmental impact and comparatively lower energy usage, which are widely accepted as qualities of green construction practices. For example, use of recycled materials with post-consumer content that originates from a previous use in the consumer market and post-industrial content that would otherwise be diverted to landfills is widely considered an issue addressable by green construction practices. However, evaluation of green building attributes or standards by organizations implies the requirement that decisions be based on stakeholder consensus.

This process involves input to the decision-making processes by an array of representative stakeholders in often widely diverse geographic locations. For these and other reasons, developing a rating system for green buildings is both difficult and challenging.

Rating Systems for Buildings

Rating systems for buildings with sustainable features began to emerge in embryonic form in the 1990s. The most publicized appeared in the United Kingdom, Canada, and the United States. In the United Kingdom, the Building Research Establishment Environmental Assessment Method (BREEAM) was initiated in 1990. BREEAM™ certificates are awarded to developers based on an assessment of performance in regard to climate change, use of resources, impacts on human beings, ecological impact, and management of construction. Credits are assigned based on these and other factors. Overall ratings are assessed according to grades that range from pass to excellent.[6]

The International Initiative for a Sustainable Built Environment, based in Ottawa, Canada, has its Green Building Challenge program with more than 15 countries participating. The collaborative venture is geared toward the creation of an information exchange for sustainable building initiatives and the development of "environmental performance assessment systems for buildings."[7] In the United States, agencies of the central government co-sponsored the development of the Energy Star™ program, which provides "technical information and tools that organizations and consumers need to choose energy-efficient solutions and best management practices."[8] Expanding on their success, Energy Star™ developed a building energy performance rating system which has been used for over 10,000 buildings.

Entering the field at the turn of the new century, the USGBC grew from an organization with just over 200 members in 1999 to 3500 members by 2003.[9] The LEED™ rating system is a consensus-developed and reviewed standard, allowing voluntary participation by diverse groups of stakeholders with interest in the application and use of the standard. According to Boucher, "the value of a sustainable rating system is to condition the marketplace to balance environmental guiding principles and issues, provide a common basis to communicate performance, and to ask the right questions at the start of a project."[10] The first dozen pilot projects using the rating system were certified in 2000.

LEED-NC Rating System

The USGBC's Green Building Rating System is a voluntary, consensus-developed set of criteria and standards. This rating system evolved with a goal of applying standards and definition to the idea of high-performance buildings. The use of sustainable technologies is firmly established within the LEED project development process. LEED loosely defines green structures as those that are "healthier, more environmentally responsible and more profitable."[1]

LEED-NC 2.1 is the USGBC's current standard for new construction and major renovations. It is used primarily for commercial projects such as office buildings, hotels, schools, and institutions. The rating system is based on an assessment of attributes and an evaluation of the use of applied standards. Projects earn points as attributes are achieved and the requirements of the standards are proven. Depending on the total number of points a building achieves upon review, the building is rated as Certified (26–32 points), Silver (33–38 points), Gold (39–51 points) or Platinum (52 or more points).[11] Theoretically, there are a maximum of 69 achievable points. However, in real world applications, gaining certain credits often hinders the potential of successfully meeting the criteria of others. While achieving the rating of Certified is relatively easily accomplished, obtaining a Gold or Platinum rating is rare and requires both creativity and adherence to a broad range of prescriptive and conformance-based criteria.

The LEED process involves project registration, provision of documentation, interpretations of credits, application for certification, technical review, rating designation, award, and appeal. Depending on variables such as project square footage and USGBC membership status, registration fees can range up to $7500 for the process.[12]

LEED Prerequisites Categories and Criteria

To apply for the LEED labeling process, there are prerequisite project requirements which earn no points. For example, in the Sustainable Sites category, certain procedures must be followed to reduce erosion and sedimentation. In the category of Energy and Atmosphere, minimal procedures are required for building systems commissioning. Minimal energy performance standards must be achieved (e.g., adherence to ANSI/ASHRAE/IESNA Standard 90.1–1999, Energy Standard for Buildings Except Low-Rise Residential Buildings, or the local energy code if more stringent), and there must be verification that CFC refrigerants will not be used or will be phased out. In addition, there are prerequisite requirements outlining mandates for storage and collection of recyclable material, minimum IAQ performance (the requirements of ASHRAE Standard 62–1999, Ventilation for Acceptable Indoor Air Quality must be adhered to), and the requirement that non-tobacco smokers not be exposed to smoke.

In addition to the prerequisite requirements, the LEED process assigns points upon achieving certain project criteria or complying with certain standards. The total points are summed to achieve the determined rating. Projects can achieve points from initiatives within the following sets of categories: Sustainable Sites (14 points), Water Efficiency (5 points), Energy and Atmosphere (17 points), Materials and Resources (13 points), and Indoor Environmental Quality (15 points). Use of a LEED Accredited Professional (1 point) to assist with the project[13] earns a single point. Additional points are available for Innovation and Design Process (maximum of 4 points).

Within each category, the specific standards and criteria are designed to meet identified goals. In the category of Sustainable Sites, 20.2% of the total possible points are available. This category focuses on various aspects of site selection, site management, transportation and site planning. The goals of this category involve reducing the environmental impacts of construction, protecting certain types of undeveloped lands and habitats, reducing pollution from development, conserving natural areas and resources, reducing the heat island impacts, and minimizing light pollution. Site selection criteria are designed to direct development away from prime farmland, flood plains, habitat for endangered species and public parkland. A development density point is awarded for projects that are essentially multistory. If the site has documented environmental contamination or is designated by a governmental body as a brownfield, another point is available. In regard to transportation, four points are available for locating sites near publicly available transportation (e.g., bus lines or light rail), providing bicycle storage and changing rooms, provisions for alternatively fueled vehicles and carefully managing on-site parking. Two points in this category are obtained by limiting site disturbances and by exceeding "the local open space zoning requirement for the site by 25%."[14] In addition, points are available by following certain storm water management procedures, increasing soil permeability, and attempting to eliminate storm water contamination. Potential urban heat island effects are addressed by crediting design attributes such as shading, underground parking, reduced impervious surfaces, high albedo materials, reflective roofing materials, or vegetated roofing. Finally, a point is available for eliminating light trespass.

Water efficiency credits comprise 7.2% of the total possible points. With the goal of maximizing the efficiency of water use and reducing the burden on water municipal systems, points are credited for reducing or eliminating potable water use for site irrigation, capturing and using rainwater for irrigation, and using drought tolerant or indigenous landscaping. This section of the LEED standard also addresses a building's internal water consumption. Points are available for lowering aggregate water consumption and reducing potable water use. Reducing the wastewater quantities or providing on-site tertiary wastewater treatment also earns points.

Energy and Atmosphere is the category that offers the greatest number of points, 24.6% of the total possible. The intents of this category include improving the calibration of equipment, reducing energy costs, supporting alternative energy, reducing the use of substances that cause atmospheric damage, and offering measurement and verification criteria. Optimizing the design energy cost of the regulated energy systems can achieve a maximum of ten points. To assess the result, project designs are modeled against a base case solution which lacks certain energy-saving technologies. Interestingly, the unit of measure for evaluating energy performance to achieve credits is not kilocalories or million Btus, but dollars. Points are awarded in whole units as the percentage of calculated dollar savings increases incrementally. In addition to the ten points for energy cost optimization, a maximum of three additional points is available for buildings that use energy from onsite renewable energy generation. Purchased green power is allocated a single point if 50% of the electrical energy (in kWh) comes from a two year green power purchasing arrangement. This category provides points for additional commissioning and elimination of the use of HCFCs and halon gases. Measurement and Verification (M&V) is allowed a point, but only if M&V options B, C, and D, as outlined in the 2001 edition of the International Measurement and Verification Protocol (IPMVP), are used.

The Materials and Resources category represents 18.8% of the total possible points. This category provides credit for material management; adaptive reuse of structures; construction waste management; resource reuse; use of material with recycled content; plus the use of regionally manufactured materials, certain renewable materials and certified wood products. A point is earned for providing a space in the building for storage and collection of recyclable materials such as paper, cardboard, glass, plastics and metals. A maximum of three points is available for the adaptive reuse of existing on-site structures and building stock. The tally increases with the extent to which the existing walls, floor, roof structure, and external shell components are incorporated into the reconstruction. LEED-NC 2.1 addresses concerns about construction waste by offering a point if 50% of construction wastes (by weight or volume) are diverted from landfills and another point if the total diversion of wastes is increased to 75%. A project that is composed of 10% recycled or refurbished building products, materials, and furnishings gains an additional two points. Another two points are available in increments (one point for 5%, two points for 10%) if post-consumer or post-industrial recycled content (by dollar value) is used in the new construction. To reduce environmental impacts from transportation systems, a point is available if 20% of the materials are manufactured regionally (defined as being within 500 miles or roughly 800 km of the site), and an added point is scored if 50% of the materials are extracted regionally. A point is available if rapidly renewable materials (e.g., plants with a ten year harvest cycle) are incorporated into the project, and yet another point is earned if 50% of the wood products are certified by the Forest Stewardship Council.

The category of Indoor Environmental Quality allows 21.7% of the possible total points available. The goals include improving IAQ, improving occupant comfort, and providing views to the outside. With ASHRAE Standard 62–1999 as a prerequisite, an additional point is available for installing CO_2 monitoring devices in accordance with occupancies referenced in ASHRAE Standard 62–2001, Appendix C. A point is also available for implementing technologies that improve upon industry standards for air change effectiveness or that meet certain requirements for natural ventilation. Systems that provide airflow using both underfloor and ceiling plenums are suggested by LEED documentation as a potential ventilation solution. Points are available for developing and implementing IAQ management plans during construction and prior to occupancy. The requirements include using a Minimum Efficiency Reporting Value (MERV) 13 filter media with 100% outside air flush-out prior to occupancy. There are points available for use of materials that reduce the quantity of indoor air pollutants in construction caused by hazardous chemicals and by volatile organic compounds in adhesives, sealants, paints, coatings, composite wood products, and carpeting. A point is offered for provision of perimeter windows and another for individual control of airflow, temperature, and lighting for half of the non-perimeter spaces. Points are available for complying with ASHRAE Standard 55–1992 (Thermal Environmental Conditions for Human Occupancy), Addenda 1995, and installing permanent temperature and humidity control systems. Finally, points are gained for providing 75% of the spaces in the building with some form of daylighting and for providing direct line of-sight vision for 90% of the regularly occupied spaces.

In the category of Innovation and Design Process, 7.2% of the total possible points are available. The innovation credits offer the opportunity for projects to score points as a result of unusually creative design innovations, such as substantially exceeding goals of a given criteria or standard.

Assessing LEED-NC

The LEED-NC process has numerous strengths. Perhaps the greatest is its ability to focus the owner and design team on addressing select energy and environmental considerations early in the design process. The LEED design process brings architects, planners, energy engineers, environmental engineers, and IAQ professionals into the program at the early stages of design development. The team adopts a targeted LEED rating as a goal for the project. A strategy evolves based on selected criteria. The team members become focused on fundamental green design practices that have often been overlooked when traditional design development processes were employed.

Furthermore, the LEED program identifies the intents of the environmental initiatives. Program requirements are stated and acceptable strategies are suggested. Scoring categories attempt to directly address certain critical environmental concerns. When appropriate, the LEED-NC program defers to engineering and environmental standards developed outside of the USGBC. The components of the program provide accommodation for local regulations. Case study examples, when available and pertinent, are provided and described in the LEED literature. To expedite the process of documenting requirements, letter templates and calculation procedures are available to program users. The educational aspects of the program, which succinctly describe select environmental concerns, cannot be understated. A Web site provides updated information on the program with clarifications of LEED procedures and practice. The training workshops sponsored by the USGBC are instrumental in engaging professionals with a wide range of capabilities.

These considerations bring a high degree of credibility to the LEED process. Advocates of the LEED rating system have hopes of it becoming the pre-eminent U.S. standard for rating new construction that aspires to achieve a “green” label. To its credit, it is becoming a highly regarded standard and continues to gain prestige. Nick Stecky, a LEED accredited professional, firmly believes that the system offers a “measurable, quantifiable way of determining how green a building is.”[15]

Despite its strengths, the LEED-NC has observable weaknesses. The LEED-NC registration process can appear to be burdensome, and has been perceived as slowing down the design process and creating added construction cost. Isolated cases support these concerns. Kentucky’s first LEED-NC school, seeking a Silver rating, was initially estimated to cost over \$200/ft^2 (\$2152/m^2) compared to the local standard costs of roughly \$120/ft^2 (\$1290/m^2) for non-LEED construction. However, there are few comparative studies available to substantially validate claims of statistically significant cost impact. Alternatively, many case studies suggest that there is no cost impact as a result of the LEED certification process. It is also possible that the savings resulting from the use of certain LEED standards (e.g. reduced energy use) can be validated using life-cycle costing procedures. Regardless, LEED-NC fails as a one-size-fits-all rating system. For new construction, Kindergarten to 12th-grade (K-12), school systems in New Jersey, California, and elsewhere have adopted their own sustainable building standards.

There are other valid concerns in regard to the use of LEED-NC. In an era when many standards are under constant review, standards referenced by LEED are at times out of date. The ASHRAE Standard 90.1–1999 (without amendments) is referenced throughout the March 2003 revision of LEED-NC. However, ASHRAE 90.1 was revised, republished in 2001, and the newer version is not used as the referenced standard. Since design energy costs are used to score Energy and Atmosphere points, and energy use comparisons are baselined against similar fuels, cost savings from fuel switching is marginalized. In such cases, the environmental impact of the differential energy use remains unmeasured, since energy units are not the baseline criteria. There is no energy modeling software commercially available that has been specifically designed for assessing LEED buildings. LEED allows most any energy modeling software to be used, and each has its own set of strengths and weaknesses when used for LEED energy modeling purposes. It is possible for projects to comply with only one energy usage prerequisite, applying a standard already widely adopted, and still become LEED certified.

In fact, it is not required that engineers have specialized training or certification to perform the energy models. Finally, LEED documentation lacks System International (SI) unit conversions, reducing its applicability and exportability.

A number of the points offered by the rating system are questionable. While indoor environmental quality is touted as a major LEED concern, indoor mold and fungal mitigation practices, among the most pervasive indoor environmental issues, are not addressed and are not necessarily resolvable using the methodologies prescribed. It would seem that having a LEED-accredited professional on the team would be a prerequisite rather than an optional credit. Projects in locations with abundant rainfall or where site irrigation is unnecessary can earn a point by simply documenting a decision not to install irrigation systems. The ability of the point system to apply equally to projects across varied climate classifications and zones is also questionable and unproven.

While an M&V credit is available, there is no requirement that a credentialed measurement and verification professional be part of the M&V plan development or the review process. Without the rigor of M&V, it is not possible to determine whether or not the predictive preconstruction energy modeling was accurate. The lack of mandates to determine whether or not the building actually behaves and performs as intended from an energy cost standpoint is a fundamental weakness. This risks illusionary energy cost savings. Finally, the M&V procedures in the 2001 IPMVP have undergone revision and were not state-of-the-art at the time that LEED-NC was updated in May 2003. For example, there is no longer a need to exclude Option A as an acceptable M&V alternative.

The LEED process is not warranted and does not necessarily guarantee that in the end, the owner will have a "sustainable" building. While LEED standards are more regionalized in locations where local zoning and building laws apply, local regulations can also preempt certain types of green construction criteria. Of greater concern is that it is possible for a LEED certified building to devolve into a building that would lack the qualities of a certifiable building. For example, the owners of a building may choose to remove bicycle racks, refrain from the purchase of green energy after a couple of years, disengage control systems, abandon their M&V program, and remove recycling centers—yet retain the claim of owning a LEED certified building.

Conclusion

The ideal of developing sustainable buildings is a response to the environmental impacts of buildings and structures. Developing rating systems for structures is problematic due to the often subjective nature of the concepts involved, the ambiguity or lack of certain standards, and the local aspects of construction. While there are a number of assessment systems for sustainable buildings used throughout the developed world, LEED-NC is becoming a widely adopted program for labeling and rating newly constructed "green" buildings in the United States. Using a point-based rating system, whereby projects are credited for their design attributes, use of energy, environmental criteria, and the application of select standards, projects are rated as Certified, Silver, Gold, or Platinum.

The LEED-NC program has broad applicability in the United States and has been proven successful in rating roughly 150 buildings to date. Its popularity is gaining momentum. Perhaps its greatest strength is its ability to focus the owner and design team on energy and environmental considerations early in the design process. Today, there are over 1700 projects that have applied for LEED certification. Due to the program's success in highlighting the importance of energy and environmental concerns in the design of new structures, it is likely that the program will be further refined and updated in the future to more fully adopt regional design solutions, provide means of incorporating updated standards, and offer programs for maintaining certification criteria. It is likely that the LEED program will further expand, perhaps offering a separate rating program for K-12 educational facilities. Future research will hopefully respond to concerns about potential increased construction costs and actual energy and environmental impacts.

Nanomaterials: Regulation and Risk Assessment

Steffen Foss Hansen,
Khara D. Grieger,
and Anders Baun

Introduction

The topics of regulation and risk assessment of nanomaterials have never been more relevant and controversial in Europe than they are at this point in time. As the first major piece of legislation to be amended in Europe, the cosmetics legislation was adopted in 2009 requiring all nanomaterial-containing cosmetics to be labeled after 2013 and producers to provide a safety assessment of the nanomaterial used.[1,2]

Concurrently with the recasting of various pieces of legislation, such as the Novel Foods Regulation, the European Commission has commissioned an expert-/multistakeholder investigation of whether nanospecific amendments are needed to the current technical guidelines on substance identification and chemical safety assessment, which lie at the core foundations of the European Chemical legislation known as REACH—Registration, Evaluation, Authorization, and Restriction of Chemicals.[3,4] It is the major piece of legislation concerning regulating the manufacturing and applications of nanomaterials, although the text in REACH itself has only been subject to minor changes thus far. A number of other pieces of legislation relevant to the manufacturing, use, and disposal of nanomaterial and products have furthermore not been subject to any nanospecific changes, although they might be revised in the future.

In the following, some of the major pieces of legislation relevant for the regulation of nanomaterials in Europe will be presented. Examples of both horizontal regulation as well as subject-specific legislation will be given. Some of these have yet to take nanospecific issues into consideration, and the focus will therefore be at explaining the limitations of these in handling nanomaterials. For others, nanospecific aspects have recently been taken into consideration and for these the focus will be at explaining how this has been done and what kinds of challenges still need to be addressed.

Chemical risk assessment plays a crucial role in many of these pieces of legislation, and hence a short introduction and discussion of the applicability of chemical risk assessment to nanomaterials will be included.

Registration, Evaluation, and Authorization of Chemicals (Reach)

One of the key pieces of European legislation affecting nanomaterials is the European chemical regulation known as REACH, which went into force in mid-2007.[5] REACH prescribes

1. The registration of chemicals commercialized by manufacturers and importers in Europe as well as the collection of data on their use and toxicity.
2. The evaluation and examination by governments of the need for additional testing and regulation of chemicals.
3. That authorization has to be sought and given to manufacturers in order for them to use chemicals of high concern.
4. European Union (EU)-wide restrictions or complete ban of certain chemicals that cannot be used safely.

The REACH regulation replaced more than 40 other directives and subsequently shifted the responsibility in the registration and authorization process of REACH onto manufacturers and importers (including downstream users of chemicals) to provide data of uses and hazard information. Industry, furthermore, has to show that chemicals of high concern can be used safely. The evaluation and restriction process is still the responsibility of the national authorities, the newly established European Chemical Agency, and the European Commission.

Registration of all the commercialized chemicals in the European market is a tremendous task that is expected to occur gradually. Substances produced or imported in the highest volumes or of the greatest (known) concern are to be registered first. Substances produced or imported in more than 1000 tonnes per year per manufacturer or importer had to be registered by November 30, 2010, by the latest date. This was also the case for substances marketed in 100 tons/yr that have been classified as very toxic to aquatic organisms and for substances produced/imported in more than 1 ton/yr and which have been classified as Category 1 or Category 2 carcinogens, mutagens, or reproductive toxicants. Furthermore, substances entering the European market in yearly quantities above 100 tons, and 10 tons per producers or importers have to be registered by June 1, 2013, and June 1, 2018, respectively.[5]

REACH does not specifically mention nanomaterials, but does cover chemicals in all their physical–chemical states, using the following definition of a substance: "a chemical element and its compounds in the natural state or obtained by any manufacturing process, including any additive necessary to preserve its stability and any impurity deriving from the process used, but excluding any solvent which may be separated without affecting the stability of the substance or changing its composition."[5] Therefore, REACH is formally the relevant legislative frame for industrially used nanomaterials, and the exemption registration of carbon and graphite was redrawn in 2008 to address concerns raised about carbonaceous nanomaterials.[6,7] Companies will now have to register these materials if produced in quantities above 1 ton per producer or manufacturer per year. However, for a number of nanomaterials, it is not evident whether a nanoequivalent of a substance with different physicochemical and (eco)toxicological properties from the bulk substance would be considered as the same or as another substance under REACH.[8]

If a nanomaterial is considered to be a different substance under REACH, hazard information specifically related to the nanoform of the substance would have to be generated for the registration, if produced in more than 1 ton/yr. On the other hand, if a nanomaterial is considered to be the same as a registered bulk material, hazard information data generated for the registration might not be directly relevant for the nanoform of the substance and hence open to discussion.[8,9] In response to these concerns, the European Commission has launched a multistakeholder project on nanomaterials to look into substance identification under REACH in order to get recommendations on whether the nanoform of a substance should be considered different from the bulk form of the substance.[3,4]

If manufacturers and importers produce or import nanomaterials in volumes of more than 10 tons/yr and if it meets the criteria for classification as dangerous or a PBT (persistent, bioaccumulative, and toxic) or vPvB (very persistent and very bioaccumulative), a chemical safety assessment is required that includes information about uses, (eco)toxicological information, exposure assessment, and risk characterization(s).

Thus far, no nanomaterial has been classified as PBT or as vPvB, but if it was to be it is highly unclear how companies should do a chemical safety assessment. Both the Commission of the European Communities[10] as well as the its Scientific Committee on Emerging and Newly Identified Health Risks (SCENIHR)[11] have pointed out that current test guidelines in REACH are based on conventional methodologies for assessing chemical risks and may not be appropriate for assessing risks associated with nanomaterials.

It should be noted that a chemical safety assessment can also be required if a nanomaterial is selected for further evaluation by a member state or by the European Chemicals Agency due to specific concerns; or if a substance is a CMR (carcinogenic, mutagenic, or toxic for reproduction), PBT, vPvB, ED (endocrine disrupting), or substance of equivalent concern.

EU Water Framework Directive

Whereas REACH deals with the manufacturing and import of chemicals, the EU Water Framework Directive (WFD) deals with improving water quality and reducing dangerous chemicals in European river basins. The key aim of the WFD, which was adopted in 2000, is to promote long-term sustainable water use, preventing further deterioration of surface waters, transitional waters, coastal waters, and groundwater, and to protect and enhance the status of aquatic ecosystems with regard to their water needs, terrestrial ecosystems, and wetlands directly depending on the aquatic ecosystems,[12] Article 1.

The WFD establishes water management by a river basin approach with cooperation and joint objective setting across member state borders and even in some cases beyond the EU territory. Geographical and hydrological formation of each river basin determines which member states need to establish and implement a so-called river basin management plan. The river basin management plan, which needs to be updated every 6 years, specifies the measures to be taken to meet the environmental objectives for surface waters, for groundwater, and for protected areas. The WFD prescribes the setting of the environmental quality standards ensuring the general protection of the aquatic ecology, specific protection of unique and valuable habitats, and protection of drinking water resources and bathing water. For instance, for surface waters, member states shall implement necessary measures to prevent deterioration, and promote restoration of artificial and heavily modified water bodies with the aim of achieving "good ecological potential" and "good surface water chemical status" in 2015 by the latest. This has to be done along with a progressive reduction of pollution from a set of "priority substances" and discontinue emissions of priority hazardous substances,[12] Article 4.

For all surface waters, the WFD set a number of "general requirements for ecological protection" as well as a "general minimum chemical standard" and defines "good ecological status" and "good chemical status" in terms of the quality of the biological community, the hydrological characteristics, and the chemical characteristics,[12] Article 4.

The definition of "good chemical status" is especially relevant in regard to nanomaterials as it is defined in terms of compliance with all the quality standards established for chemical substances at the European level. For "priority substances," member states are required to set environmental quality standards (EQSs) to monitor the chemical status of a water body (European Parliament and the Council of the European Union (EP & CEU),[12] Article 16). Thus, the EQS is taken as concentration below which the chemical status is referred to as "good" in the WFD terminology (European Parliament and the Council of the European Union (EP & CEU),[12] Article 2). Even for the so-called priority hazardous substances, only a few EQSs have been set, but more substances will follow with a specific focus at substances that are toxic toward humans and/or aquatic organisms, compounds with a widespread environmental distribution, and those that are discharged in significant quantities.

A key question in regard to WFD is whether nanomaterials are possible candidates as priority substances.[13] In favor of this speaks the widespread and diffuse use of nanoparticles in a range of consumer products along with the hazard characteristics of some nanomaterials such as functionalized carbon nanotubes (CNTs), nanoscale silver, and zinc oxide. Some applications of nanomaterials furthermore involve direct contact with the water cycle, e.g., in relation to their use for water disinfection[14] and wastewater treatment,[15] as well as in regard to the direct use for treating soil and groundwater contamination.[16]

If a given type of nanoparticles is included in the list of priority substances in the future based on environmental occurrence or hazard information, an EQS will have to be defined.[12] To derive an EQS for a priority substance, the WFD outlines that test results from both acute and chronic ecotoxicological standard tests should be used for the "base set" organisms, i.e., algae and/or macrophytes, crustacean, and fish. Estimating EQS for nanoparticles is currently hampered by lack of ecotoxicological data even for the most tested nanoparticles such as C60, CNTs, TiO_2, ZnO, and Ag. For instance, the degradability of C60 and CNTs and their ability to bioaccumulate in the aquatic environment remains to be studied, making it virtually impossible to set an EQS for these two kinds of nanoparticles.[13]

Not only are the number of studies very limited, but the number of tested taxa is also too few to be used in the context of setting an EQS. The reliability and interpretation of the available ecotoxicity data is furthermore impeded as a result of factors such as particle impurities, suspension preparation methods, release of free metal ions, and particle aggregation.[13,17,18]

Besides these issues, mainly related to the lack of relevant data, it is also questionable whether the principles for deriving EQSs for chemicals can be directly transferred to nanoparticles. The setting of EQS is based on a chemical safety assessment similar to the one required under REACH and, as noted above, the European Commission's SCENIHR have pointed out that amendments have to be made to the guidelines for chemical safety assessment.[11,19]

Another manner in which nanomaterials could meet the criteria to be included in a WFD list of priority substances is if there is "evidence from monitoring of widespread environmental contamination".[12] However, when it comes to nanomaterials, monitoring in natural waters represents some profound challenges.[20,21] While applicable methods for in situ monitoring remain to be developed and refined,[22] it is also challenging to set up a reliable monitoring program for nanoparticles since a number of issues still remain to be resolved, e.g., choice of suitable sampling materials, preconcentration/fractionation methods, and analytical methods to characterize and quantify collected particles.[21] Despite significant progress in recent years, reliable methods are not yet available to determine nanoparticle identity, concentrations, and characteristics in complex environmental matrices, such as water, soil, sediment, sewage sludge, and biological specimens.

Pharmaceutical Regulation

Liposomes, polymer–protein conjugates, polymeric substances, or suspensions are examples of well-described and understood medicinal products containing nanoparticles and have been given marketing authorizations within the EU under the existing regulatory framework.[23–26]

As in the case of REACH, nanomedicine and nanomaterials are not specifically mentioned in the EU legislation on medicinal products and devices, tissue engineering, and other advanced therapies. Although the scope of the various EU regulations and directives that constitutes this framework covers nanomedicine, they have been accused of being too general, non-specific, and fraught with difficulties in case of complex drugs.[27,28] Given this, it does seem that it is generally believed that the regulatory framework for medicine covers medical products based on nanotechnology, and that the extensive pre-market safety assessment of medicine in general is sufficient to ensure that the benefits outweigh any identified risks or the adverse side effects.[29,30]

Concerns have, however, been raised that the risk assessment, safety, and quality requirements for medicine may not be designed to address nanomedicine and medical devices based on nanotechnology, as these have to be fulfilled by conformity to established quality systems and published product standards. This might be especially true for novel applications such as nanostructure scaffolds for tissue replacement, nanostructures enabling transport across biological barriers, remote control of nanoprobes, integrated implantable sensory nanoelectronic systems, and chemical structures for drug delivery and targeting of disease.[31]

Currently, the mechanism of action is key to decide whether a product should be regulated as a medicinal product or as a medical device. This could be problematic when it comes to many novel applications of nanomedicinal products as they are likely to span regulatory boundaries between medicinal products and medical devices.[29,31] This is due to the notion that they may exhibit a complex mechanism of action combining mechanical, chemical, pharmacological, and immunological properties, and combining diagnostic and therapeutic functions.

For new marketing authorization applications of pharmaceuticals, an environmental risk assessment has to be provided, which involves a rough calculation of the predicted environmental concentration (PEC) for surface water. Actions have to be initiated if the PEC is predicted to surpass 0.01 ppb.[32] However, this threshold cannot be interpreted as a safe concentration, and it is not based on a scientific evaluation.[32] It could furthermore be problematic when it comes to nanomedicine, as concentration in terms of mass per volume might not be the relevant metric to characterize the environmental hazard of nanomaterials.[33–35]

Nanofood Regulation

Food and food packaging are regulated by a number of directives and regulations in the EU, such as the EU Food Law Regulation and the EU Novel Foods Regulation.[36] As an overarching principle, all food are required to be safe and this overarching principle of safety applies to all foods and food packaging that contain nanomaterials. This has, however, been criticized for being too loose.[37]

During the recent discussion related to the update of regulation regarding food additives, the European Parliament's Committee on Environment, Public Health, and Food Safety stated that it wanted separate limit values for nanotechnologies and that the permitted limits for an additive in nanoparticle form should not be the same as when it is in traditional form.[38] This demand, however, never made into the actual regulation and the final adopted regulation on food additives is limited to requiring that food additives that have been produced via nanotechnology or consist of/or include materials fulfill a number of criteria before it can be include on the list of approved food, food additives, food enzymes, and food flavorings. Nanotechnology and nanomaterials are not defined in the regulation, but these criteria include what use does not pose a safety concern to the health of the consumer at the level of use proposed on the basis of available scientific evidence. Furthermore, there has to be a reasonable technological need that cannot be achieved by other economically and technologically practicable means, and using the food additives should entail consumer advantages and benefits.[39]

Another important piece of legislation in regard to food regulation in the EU is the Novel Foods Regulation. This regulation requires mandatory premarket approval of all new ingredients and products. In 2008, the European Commission adopted a proposal to revise the Novel Foods Regulation with the purpose of improving the access of new and innovative foods to the EU market.[40] The definition of novel foods was broadened to include those modified by new production processes, such as nanotechnology and nanoscience, which might have an impact on the food itself. This proposal is currently being discussed in the European Parliament and is going through what is known as a "third reading," and has to be adopted after a co-decision wherein both the Council of the European Union and the Parliament has to agree on the final text of the regulation. If agreement cannot be reached, it goes to conciliation.

There are a number of areas on which the European Parliament and the Council of the European Union disagree in regard to nanomaterials. The requirement of having mandatory labeling is also controversial and so is the issue of whether to have premarket safety testing of nanotechnology and nanomaterials in food and packaging.[41]

In the first line of revisions suggested to the Novel Foods Regulation, both the Council and the Parliament mention the lack of adequate information and lack of test methods for assessing the risks of nanomaterials.[41] Once the European Commission receives an application for authorization of a novel food, the European Food Safety Authority (EFSA) is responsible for the evaluation of whether a novel food and its use as an ingredient presents a danger to or misleads consumers. By regulation, the EFSA is required to provide assessment on the composition, nutritional value, metabolism, intended use, and the level of microbiological and chemical contaminants. Studies on the toxicology, allergenicity, and details of the manufacturing process may also be considered. No distinction is, however, made in regulation in regard to particle size, and hence nanoparticles will not require new safety assessments if the substance has already been approved in bulk form.

Risk Assessment of Nanomaterials

Three different kinds of limitations have been identified in various independent analysis of the applicability of existing regulatory frameworks when it comes to nanomaterials.

The first category of limitations are related to the limitations of definitions of what qualifies as a "substance," "novel food," etc., when it comes to nanomaterials. For instance, does the definition of a chemical substance cover both the bulk from as well as the nanoform of the substance, and does any given application of nanotechnology to manufacture a given food fall under the definition of a novel food? This issue is currently being discussed in a multistakeholder expert working group; however, this has failed to reach a consensus.[42]

In the second category fall requirements triggered by thresholds values not tailored to the nanoscale, but based on bulk material. For instance, for pharmaceuticals, the environmental concentration of medical products has to be estimated before marketing, and if it is below 0.01 ppb and "no other environmental concerns are apparent," no further actions are to be taken for the medical product in terms of environmental risk assessment.[32] Such a predefined action limit could potentially be problematic since the new properties of nanobased products are expected to also affect their environmental profiles, and this problem has yet to be addressed.[35]

The third category of limitations are related to lack of metrological tools, (eco)toxicological data, and environmental exposure limits as required by, e.g., REACH, the pharmaceuticals regulation, and the recast of the Novel Foods Regulation. The availability of (eco)toxicological data and chemical risk assessments is necessary to support existing legislation.

In regard to REACH, companies are urged to use already existing guidelines when performing chemical risk assessments, despite the fact that both the European Commission[10] and its SCENIHR,[11] as well as others,[9,10] have pointed out that current test guidelines supporting REACH are based on conventional methodologies for assessing chemical risks and may not be appropriate for the assessment of risks associated with nanomaterials.

Chemical risk assessment consists of four elements i.e., hazard identification, dose–response assessment, exposure assessment, and risk characterization. In Europe, legislation for controlling the production, use, and release of chemical substances is based on chemical safety assessment or risk assessment, as described in detail in the "Guidance on Information Requirements and Chemical Safety Assessment".[43] The guidance totals a staggering number of pages and is issued by the ECHA to help companies carry out chemical safety assessments. It includes extensive technical details for conducting hazard identification, dose (concentration)–response (effect) assessment, exposure assessment, and risk characterization in relation to human health and the environment.[43] Each of these four elements holds a number of limitations that are not easily overcome despite the fact that a lot of effort is being put into investigating the applicability of each of these four elements.

Hazard Identification of Nanomaterials

Toxicity and ecotoxicity have been reported on for multiple nanoparticles (metal and metal oxide nanoparticles, carbonaceous nanomaterials, and quantum dots) in scientific studies; however, many of these need further confirmation. Univocal hazard identification is currently impossible as it is hard to systematically link reported nanoparticle properties to the observed effects.

For instance, in regard to multiwalled CNTs (MWCNTs), Poland et al.[44] compared the toxicity of four kinds of MWCNTs of various diameters, lengths, shape, and chemical composition by exposing the mesothelial lining of the body cavity of three mice with 50 mg MWCNT for 24 hr or 7 days. This method was used as a surrogate for the mesothelial lining of the chest cavity. It was found that long MWCNTs "produced length-dependent inflammation, FBGCs, and granulomas that were qualitatively and quantitatively similar to the foreign body inflammatory response caused by long asbestos." Only the long MWCNTs caused significant increase in polymorphonuclear leukocytes or protein exudation. The short MWCNTs failed to cause any significant inflammation at 1 day or giant cell formation at 7 days. Poland et al.[44] also found that the water-soluble components of MWCNT did not produce significant inflammatory effects 24 hr after injection, which rules out that residue metals were the cause of the observed effects, as others previously had speculated on the basis on in vitro studies.[45,46] The findings by Poland et al.[44] have since then been supported by Ma-Hock et al.[47] and Pauluhn et al.[48] in 90-day inhalation toxicity studies.

Less work has been done in regard to exploring the ecotoxicological aspects of nanomaterials, but a number of significant studies have been published.

In 2004, Oberdorster[49] published the first ecotoxicological study and reported observed significant increase in lipid peroxidation of the brain of juvenile largemouth bass after exposure to uncoated fullerenes (99.5%) in concentrations of 0.5 and 1 ppm after exposure for 48 hr. C60 was dissolved in tetrahydrofuran (THF), which have since then led to some discussion about whether C60 or the THF was responsible for the effects observed.[50,51] The use of THF is no longer recommended.[18]

In regard to CNTs, Templeton et al.[52] compared "as prepared" single-walled CNTs (SWCNTs) with electro- phorectically purified SWCNTs and the fluorescent fraction of nanocarbon by-products. They observed an average cumulative life cycle mortality of 13 ± 4%, while mean life cycle mortalities of 12 ± 3%, 19 ± 2%, 21 ± 3%, and 36 ± 11% were observed for 0.58, 0.97, 1.6, and 10 mg/L. Exposure to 10 mg/L showed: 1) significantly increased mortalities for the naupliar stage and cumulative life cycle; 2) a dramatically reduced development success to 51% for the nauplius to copepodite window, 89% for the copepoddite to adult window, and 34% overall for the nauplius to adult period; and 3) a significantly depressed fertilization rate averaging only 64 ± 13%.

A number of studies have furthermore highlighted the need to investigate the potential interactions with existing environmental contaminants or what has become known as the "Trojan horse effect." For instance, Baun et al.[53] found that the toxicity of phenanthrene was increased toward algae and crustaceans following sorption to C60 aggregates. In contrast, Baun et al.[53] found that the toxic effect of pentachlorophenol decreased when C60 was added. After studying the ecotoxicity of cadmium to algae in the presence of 2 mg/L TiO_2 nanoparticles of three different sizes, Hartmann et al.[17] found that the presence of TiO_2 in algal tests reduced the toxicity of cadmium. This is thought to be due to decreased bioavailability of cadmium resulting from sorption/complexation of Cd^{2+} ions to the TiO_2 surface. However, the observed growth inhibition was, however, greater for the 30 nm TiO_2 nanoparticles than could be explained by the concentration of dissolved Cd(II) species alone, which indicates a possible carrier effect, or combined toxic effect of TiO_2 nanoparticles and cadmium.

Dose–Response Relationship in Regard to Nanomaterials

In regard to the second element of chemical risk assessment, it is fundamental that a dose–response relationship can be established so that no-effect concentrations or no effect levels need to be predicted or derived. It is unclear whether a no-effect threshold can be actually be established and what the best hazard descriptor(s) of nanoparticles is, and what the most relevant dose metrics and the what the most sensitive endpoints are. Several studies have reported observing a dose–response relationship. This goes for, especially, in vitro studies on, among others, C60, SWCNTs and MWCNTs, and various forms of nanometals. Normally, dose refers to "dose by mass"; however, based on the experiences gained in biological tests of nanoparticles, it has been suggested that biological activity of nanoparticles might not be mass dependent, but dependent on physical and chemical properties not routinely considered in toxicity studies.[54] For instance, Oberdorster and col-leagues[55,56] and Stoeger and colleagues[57,58] found that the surface area of the nanoparticles is a better descriptor of the toxicity of low-soluble, low-toxicity particles, whereas Wittmaack[59,60] found that the particle number worked best as dose metrics. Warheit et al.[61,62] found that toxicity was related to the number of functional groups in the surface of nanoparticles.

Exposure Assessment

Completing a full exposure assessment requires extensive knowledge about, among others, manufacturing conditions, level of production, industrial applications and uses, consumer products and behavior, and environmental fate and distribution. Such detailed information is not available, and thus far no full exposure assessment has been published for any one or more nanomaterials. This may partly be due to difficulties in monitoring nanomaterial exposure in the workplace and the environment, and partly due to the fact that the biological and environmental pathways of nanomaterials are still largely unexplored.[63] Some efforts have been made to assess occupational, consumer, and environmental exposure, however, both to assess the level of exposure and to assess the applicability of current exposure assessment methods and guidelines.

These are, however, hampered by the paucity of knowledge, lack of access to information, difficulties in monitoring nanomaterial exposure in the workplace and the environment, and by the fact that the biological and environmental pathways of nanomaterials are still largely unexplored. Hence, they should be seen as "proof of principle" rather than actual assessment of the exposure.[64–67]

Risk Characterization

All the information from the first three elements of the risk assessment come together in the fourth and final element of chemical risk assessment, namely risk characterization.[63] In the risk characterization process, exposure levels are compared with quantitative or qualitative hazard information, then suitable predicted no-effect concentrations or derived no-effect levels are determined in order to decide if risks are adequately controlled.[43]

Often, risk characterization boils down to the estimation of a risk quotient. For the environment, this is, for instance, defined as the PEC/predicted no effect concentration (PNEC). If the risk quotient is <1, no further testing or risk reduction measures are needed according to the European Chemical Agency.[43] If it is >1, further testing can be initiated to lower the PEC/PNEC ratio. If that is not possible, risk reduction could be implemented.

A number of studies reported having completed—or attempted to complete—risk assessments of various nanomaterials such as CeO_2, TiO_2, C60, and CNTs.[18,67–69] For instance, in regard to the use of CeO2-based diesel fuel additive in the United Kingdom, Park et al.[67] assessed the risk of CeO_2 causing pulmonary inflammation. First, they estimated an internal dose of $3.8 \times 10^{-7}\,cm^2/cm^2$ by converting the retained dose into surface area units and then dividing by the area of the proximal alveolar region of the lung. Then, they compared this value to the highest noobserved-effect level found in a number of in vitro toxicity studies. This value was $26.75\,cm^2/cm^2$. Assuming that in vitro exposure data can be accurately projected to the in vivo situation, Park et al.[67] concluded that "it is highly unlikely that exposure to cerium oxide at the environmental levels (from both monitored and modeled experimental data) would elicit pulmonary inflammation."

Mueller and Nowack[69] reported having completed the first quantitative risk assessment of nanoparticles in the environment. In a first attempt to derive PEC values, Mueller and Nowack used the threshold concentrations of 20 and 40 mg/L reported in the literature for nano-Ag on *Bacillus subtilis* and *Escherichia coli,* and considered it to be equivalent to a no-observed-effect concentration. For nano-TiO_2 and CNT, the lowest value found in the literature was <1 mg/L for algae, daphnia, and fish.[69] Applying the assessment factor of 1000, the PNEC in water was found to be 0.04, <0.001, and <0.0001 mg/L for nano- Ag, nano-TiO_2, and CNT, respectively. Combining these PNEC values with the predicted exposure, Mueller and Nowack[69] calculated the environmental concentrations in Switzerland for nano-Ag, nano-TiO_2, and CNTs stemming from textiles, cosmetics, coatings, plastics, sports gear, electronics, etc. Assuming worse-case exposure levels, Mueller and Nowack[69] found that the risk quotient for nano-Ag and CNT is less than one-thousandth, and they state that their modeling suggests that currently little or no risk is to be expected from nano-Ag and CNT to organisms in water and air. Nano-TiO_2, on the other hand, might pose a risk to organism in water—according to Mueller and Nowack[69]—with risk quotients ranging from >0.7 to >16. The PNEC for soil could not be determined due to lack of information.

Despite the preliminary risk characterizations by Park et al.,[67] Mueller and Nowack,[69] Shinohara et al.,[68] and Stone et al.,[18] it is important to realize that risk characterization critically involves reflection of the data behind each step and determining what the overall risk will be.[63] As elaborated on previously, each of the three first steps of risk assessment holds a number of challenges, and since risk characterization is the fourth and final step where all the information is to come together, the sum or maybe even the power all of these limitations are conveyed to calculating risk quotients for nanomaterials under REACH.[9]

Revisions of the Technical Guidance of Risk Assessment

The European Commission has commissioned an expert/multistakeholder investigation of whether nanospecific amendments are needed to the current technical guidelines on chemical safety assessment. This has to develop, among others, specific advice on

1. How REACH information requirements on intrinsic properties of nanomaterials can be fulfilled
2. The appropriateness of the relevant test methods for nanomaterials
3. The possible specific testing strategies, if relevant
4. Information needed for safety evaluation and risk management of nanomaterials (especially, information beyond the current information requirements under REACH)
5. How to do exposure assessment for nanomaterials, hazard, and risk characterization for nanomaterials[3,4]

The latter will involve threshold/non-threshold considerations, analysis of existing evidence related to setting limit values for nanomaterials, identification of critical items for dose description (mass, number concentration, surface area, particle size(s) etc.), whether and how no-effect-levels for health and the environment could be established, and finally development of recommendations on the feasibility of whether categorization of nanomaterials (e.g., different types of CNTs) in the hazard assessment is compatible with the exposure assessment parameters/metrics in order to prepare a meaningful risk characterization.[3,4]

In regard to novel food, EFSA published a scientific opinion in 2008 on the potential risks arising from the use of nanotechnology in food, concluding that nanotechnology aspects shall be considered when risk assessment guidance documents in the food and feed area are reviewed, and, among others, recommend that risk assessment of nanomaterials in the food and feed areas should consider the specific properties of nanomaterials in addition to those common to the equivalent non-nanoforms.[70] Recently, EFSA closed for public comments on a draft guidance on risk assessment concerning potential risks arising from applications of nanoscience and nanotechnologies to food and feed. This guidance holds practical advice on how to complete risk assessments of nanomaterials used in food and food products.[71]

In the light of the limitations of chemical risk assessment, a number of alternative or complementary tools and methods, such the precautionary matrix[72] and multicriteria decision analysis,[73] have been proposed recently. Many of them hold great promises, but they need further evaluation and validation.[74]

Conclusion

In this entry, we presented a number of major pieces of legislation such as REACH, the WFD, and the Novel Foods Regulation, and discussed their relevance and limitations in regard to nanomaterials. Only a limited number of EU regulations, directives, etc., actually mention nanotechnology and/nanomaterials. In general, there seem to be three overall challenges when it comes to current regulation of nanomaterials: 1) limitations in regard to terminology and definitions of key terms such as a "substance," "novel food," etc.; 2) safety assessment requirements triggered by thresholds values not tailored to the nanoscale, but based on bulk material and; 3) limitations related to lack of metrological tools, (eco) toxicological data, and environmental exposure limits as required by, e.g., REACH, WFD, the pharmaceuticals regulation, and the recast of the Novel Foods Regulation. Chemical risk assessment provides a fundamental element in support of existing legislation. Risk assessment is normally said to consist of four elements, i.e., hazard identification, dose–response assessment, exposure assessment, and risk characterization. Each of these four elements holds a number of limitations that are not easily overcome, although a lot of effort is being put into investigating the applicability of each of them. However, political decisions to revise substance definition and the current thresholds that trigger safety evaluation are still needed as these are not tailored to the nanoscale, but based on bulk material.

Industrial Waste: Soil Pollution and Remediation

W. Friesl-Hanl,
M.H. Gerzabek,
W.W. Wenzel, and
W.E.H. Blum

Introduction

Anthropogenic activities such as mining and smelting, combustion of waste and fossil fuels, as well as the use of organic and inorganic chemicals and radionuclides in agriculture and industry entail risks for the overall environment and human beings. The awareness of these risks due to industrial wastes emerged through numerous cases of severe environmental impacts many years after their disposal. Notorious examples include hazardous waste disposal in the Love Canal, New York, United States[1]; Lekkerkerk near Rotterdam, Netherlands[2]; the collapsed tailing dams containing acidic pyrite sludge in Donana, Spain[3]; cyanide- and metal-rich liquid waste disposals near Baia Mare, Romania[4]; and many other accidents.[5] A report describing the world's worst-polluted industrial sites was updated in 2016 with the focus on the top polluting industries identified as (1) used lead–acid battery recycling, (2) mining and ore processing, (3) lead smelting, (4) tanneries, (5) artisanal small-scale gold mining, (6) industrial dumpsites, (7) industrial estates, (8) chemical manufacturing, (9) product manufacturing, and (10) dye industry. These industries put over 32 million people at risk and account for 7 million to 17 million Disability-Adjusted Life Years (DALYs) in low- and middle-income countries.[6] Heavily polluted sites are distributed across all continents, and a former report highlighted only the tip of an iceberg, listing sites such as Dzerzinsk (chemical weapons, Russia), Linfen (coal industry, China), Ranipet (tanning industry, India), Kabwe (mining and smelting of Pb, Zambia), Haina (recycling of Pb, Dominican Republic), and La Oroya (polymetallic smelter, Peru).[7] While full remediation of these sites is economically and technically impossible, low-cost in situ technologies for managing and monitoring aiming at risk reduction are becoming increasingly available. More importantly, we need to learn our lessons and avoid similar pollution in the future.

Besides these negative effects of industrial waste, their reuse potential for soil amelioration, remediation, and recultivation also should be considered. Future perspectives and visions for handling industrial waste must be discussed in terms of the potential environmental risks and how to minimize them. The proclaimed Sustainable Development Goals (SDGs) by the United Nations (UN) should be a guidance for these next steps.[8]

Industrial Waste Overview

Generally, industrial activities generate three categories of waste: (1) gaseous emissions, (2) wastewater, and (3) solid waste. Gaseous pollutants or particulates are generated by combusting fossil fuels and wastes; they are found both close to the emitter and far away, especially in forest ecosystems, due to their filter capacity.[9] Dispersion and long-term transport of heavy metals, radionuclides, and persistent organic pollutants occur.[10] Acidification and eutrophication are due to the transboundary distribution of nutrients often involved in combustion processes (e.g., S, N compounds). Wastewater derives from domestic and industrial establishments; combined, they are known as municipal wastewater. Surface water and groundwater are the most threatened sinks of pollutants, besides irrigated areas. Upon removal of water, wastewater turns to sludge and later to solid waste. Generally, solid waste generation starts with mining and petroleum production and with the subsequent processing of these raw materials to goods for consumption. Emerging waste includes mineral ores, tailings, slags, and oil-contaminated soils and residues that stem from the processing of these materials.

Industrial activities generate mostly mixed wastes, yielding transient waste types. Pollutants can be released in gaseous, particulate, aqueous, or solid form, depending on the industrial processes involved. They emanate from point[11] or diffuse[12] sources. Generally, pollution tends to be highest close to emitters and declines with increasing distance. However, elevated concentrations of persistent organic chemicals have been found in environments far from pollution sources, such as in the Arctic, in distant mountain regions, and in remote forest soils.[13]

Soil quality is prone to degradation through physical, chemical, and biological processes, resulting in soil erosion, reduced productivity, and soil and groundwater contamination. Detrimental effects of industrial waste on soil comprise the following: (1) siltation and compaction through application of fine-grained and salt-rich materials; (2) any type of pollution, acidification, or landfilling; and (3) loss of macro- and microfaunal diversity by intoxication. Heavy metals (Pb, Hg, Cd, Cr), metalloids (As, Sb), and organic compounds (e.g., dioxins and other persistent organic pollutants) are the most relevant soil pollutants. Since 1950, more than 140,000 new chemicals and pesticides have been synthesized whereof 5,000 are produced in large quantities, dispersed in the environment, and responsible for human exposure.[14] Waste generation has dramatically increased from chemical manufacturing, wastewater treatment, agriculture, mining and smelting, food processing, energy production, pulp and paper production, and other industries. The subsequent waste–environmental interactions have potential consequences on soil and water qualities. Estimates show that up to 75% of the materials used in industrial processes do not end up in final products.[15]

Prevention of industrial waste production, enhanced by optimization of processes reducing the amount of generated waste and the concentration of pollutants in waste streams, has a higher priority than end-of-pipe technologies such as soil remediation. However, emerging technologies to filter and retain pollutants in solid industrial waste materials require close monitoring as this may limit the re-use of such materials, for example, in soil remediation, due to increased pollutant concentrations. For instance, novel clean coal technologies lead to changed coal combustion residues (CCR) composition as volatile elements (e.g., Hg and Se) are more efficiently retained while due to concurrent changes in pH the solubility (Hg, Cd, Cu) and volatilization (Hg, NH_3) of certain pollutants are likely enhanced.[16]

Potential Use of Industrial Waste

Soil Amelioration

In the case of metals, humankind has imbalanced biogeochemical cycles through the use of metals. Considerable amounts are lost in technical processes into the above-mentioned waste categories. Electronic waste is one of the most rapidly growing problems.[17] E-waste volume estimation for 2013 is given in Table 1. Instead of exporting this waste[18] from "developed" into "developing" countries and thereby contaminating soil and water due to the lack of legal regulations there, the strategy should be to promote recycling and reuse of metals. Besides heavy metal-contaminated arable land, nutrient-deficient areas are widespread over the world. Here, the reuse of Cu, Mn, Mo, Fe, and Zn from electronic waste as nutrients could contribute toward more sustainable systems.

Gravel sludge, a fine-grained by-product of the gravel industry—applied on sandy soils poor in nutrients—can improve soil physical properties and crop production.

On the other hand, the use of industrial waste materials as soil amendments has been estimated to contaminate thousands of hectares of productive agricultural land in countries throughout the world. This is a particular problem in the Asia Pacific region, where land-based disposal of untreated wastes is still being practiced due to the lack of regulatory guidelines.[19] If crops are cultivated on contaminated soils, they may become less competitive on the world market, provided efficient quality control is implemented. Figure 1 gives a schematic overview of waste reuse possibilities.

Soil Remediation

In situ fixation of labile metals in soils by addition of amendments is one option to remediate heavy metal-contaminated soils. The aim is to reduce the risk of contamination by balancing ecological and economical needs. Several industrial wastes or by-products have been screened for their ability to immobilize heavy metals. Red mud is produced by the alumina industry around the world in countries like Jamaica, Australia, the United States, and Germany[20] (Table 1). Results of greenhouse, outdoor, and field experiments indicate immobilization of many heavy metals in soil after red

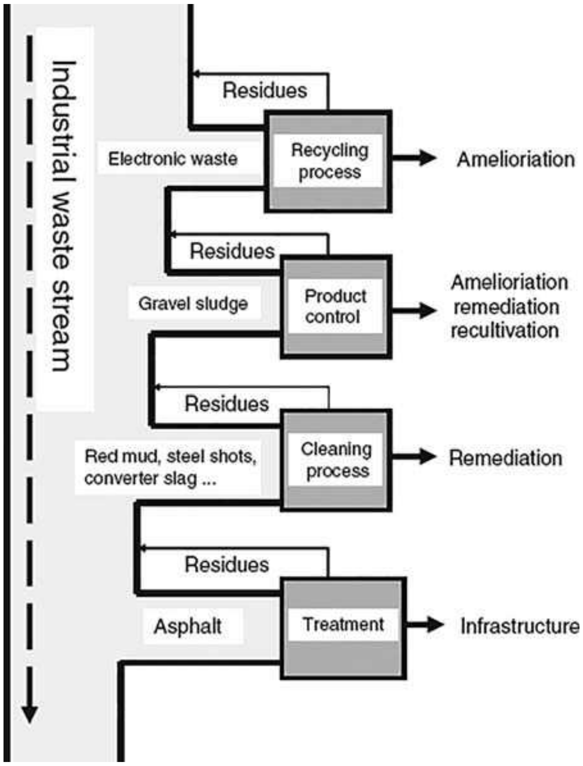

FIGURE 1 A schematic overview of waste reuse possibilities.

TABLE 1 Industrial Waste Quantities

Industry	Industrial Waste	Produced Amount (Mg/a)
Electronic industry	Electronic waste	20–50 Mio, worldwide[16]
Alumina industry	Red mud	120 Mio, worldwide[20]
Pulp and paper industry	Paper mill sludge	16 Mio, US[24], CA[25]
Iron	Slags (25%–30% of crude iron)	300–360 Mio,[a] worldwide[29]
Steel industry	Slags (10%–15% of crude steel)	190–290 Mio,[b] worldwide[29]
Energy production	CCP	40 Mio, EU15, (2016)[30]
	CCP	110 Mio, US (2017)[31]

[a] Calculated from produced amount of iron.

[b] Calculated from produced amount of steel. CCP, coal combustion products (including fly ash, flue-gas desulfurization gypsum, bottom ash); US, United States; CA, Canada.

mud addition.[21–23] Similar results were obtained for steel shots, a waste product of the metal shaping industry; converter and basic slag from the steel and iron industry; and "Iron Rich," generated by TiO_2 production.[26] Fly ash, a coal combustion residue, and beringite, a modified aluminosilicate that originates from the fluidized bed burning of coal refuse from a former coal mine in Beringen (Belgium), also have potential for metal immobilization.[27] A further example could be the reuse of the tailings of the world's largest siderite mining site (Erzberg, Austria).[28] The tailings consist of high amounts of fine-textured iron and carbonates, and it has been demonstrated in pot and field experiments that they hold promise for in situ inactivation of heavy metals in polluted soils and associated improvement of crop yield and quality if applied to arable land.[32] The composition of these amendments varies considerably, and the immobilizing effect is mostly due to Al-, Fe-, Mn-oxides, phosphates, silicates, and alkaline materials.

An emerging amendment for soil remediation/amelioration could be biochar. These materials derive from different sources. If organic residues/waste by-products will be pyrolyzed and applied on soils, different functions could be improved. Besides the storage of carbon in soil,[33] also soil physical (e.g., water holding capacity[34]) or chemical (e.g., immobilization of contaminants) properties can be improved.[35]

Application rates of these mentioned amendments up to 5% (w/w) are practicable and result in establishing a vegetation cover on bare land, reduction of visual symptoms of metal phytotoxicity, and a significant reduction of the metal accumulation in aboveground biomass. An example of a field application is given in Friesl-Hanl et al. (2017).[23]

Advantages of these easily available materials, including contaminant inactivation and often low costs,[36] are opposed by some disadvantages or failures that may occur due to indigenous contamination.[37] Monitoring of the sustainability of the applied measures is necessary and should be mandatory.[24] The recommendation is to adjust the amendment and application rate on a case-by-case basis. In certain cases, removal of contaminants may be required.

Conclusions

Pollution by industrial waste is widespread throughout the world, adversely affecting soil and environment qualities. Management of these wastes is necessary to achieve a more sustainable system. After exhausting the two approaches of preventing waste generation and recycling suitable materials, the use of wastes, by-products, or mixtures of different materials for amelioration, remediation, or recultivation is one option to regulate material fluxes. Besides considering the advantages of using waste materials, we also have to take into account the disadvantages and assess them on a case-by-case basis.

Pest Management: Crop Diversity

Maria R. Finckh and
Jan Henrik Schmidt

Introduction

Improvement in crop management using modern machinery equipment, fertilizers, and pesticides and progress in plant breeding within a few selected crops has led in recent decades to highly specialized agricultural practices on farms. Out of more than 300,000 plant species existing, about 7,000 crops are known to be cultivated for human or animal diet; however, 60% of the word's energy source is based on only three crops, namely wheat, maize, and rice [1]. As a consequence, a general impoverishment of plant diversity and a high degree of genetic erosion in several important crops for human nutrition is documented since the end of World War II [2].

Simplification of the ecosystem by using one-sided crop rotations, monoculture, and crop plants of uniform genotype and the elimination of weeds with herbicides results in a strong selection for adapted pests, pathogens, and weeds leading to frequent resistance breakdown and severe weed infestations [3–5] and, importantly, a general loss of biodiversity [6].

Increasing the diversity of selection pressures acting on pests and weeds can reduce their ability to develop resistances to pesticides. Diverse crop ecosystems with adapted crops in sequential cropping including cover crops and living mulches, crop populations, and species mixtures are generally less damaged by pests, pathogens, and weeds compared to monocultures [2]. Interestingly, weeds are less abundant but weed species diversity is often higher within such diverse crop rotations. Hence, outbreaks of weed, pest, and disease epidemics and the probability of losses are reduced [4,7,8].

In this chapter, diversity by planting sequence (crop rotation), crop-border diversity, and crop-weed diversity are discussed.

Influence of Crop Rotation on Diseases, Insect Pests, and Weeds

The positive effects of a diverse crop rotation on yield and agricultural stability have been well known since ancient times. Awareness has built that much of the rotation effects lie in the plants themselves as they release considerable amounts of organic compounds into the soil in order to influence the microbiome, the solubility of nutrients and to interact with other plants. Most pathogens and pests are weak competitors outside their hosts and barely survive. If soil life is abundant, then it will outcompete and often directly live on the resting stages of pests and pathogens and weeds [9].

Crop rotation is most effective in the case of specialized pathogens and pests that are dependent on a host crop or have a narrow host range. For example, many soil-borne pathogens or insects survive on root or plant residues and require the cultivation of a susceptible crop for continuous survival. The length of host crop interval for insect or disease control will depend on how quickly the insect pest or pathogen can be destroyed by starvation and/or by other antagonistic effects [10,11].

With respect to weeds, important criteria for their control are variation in planting time and timing as well as techniques of seed bed preparation [12,13]. To prevent weeds from germinating simultaneously with the cash crop or at least from seed shed, the whole cropping system needs to be considered [14]. Main effects are caused by the sowing time of crops (winter or spring crops), sequence and placement of crops in the crop rotation, competitive ability of different crops against weeds, and direct weed control (herbicides and/or mechanical control) [15]. Allelopathic effects, that is, the exudation of specific compounds from the roots of certain crops may reduce germination of different weeds [15,16]. For perennial weeds, methods that deplete the weed storage organs through competition, for example, due to living mulches and perennial forage crops, and/or frequent mowing can be useful to reduce number and biomass of weeds [17–19]. These methods combined with fragmentation of weed rhizomes that can reduce the viability of storage organs have proven a high efficacy in Quackgrass (*Elymus repens*) control in Sweden [20]. In monoculture and pure grain rotations, weed infestation can reach a high level and weeds are more difficult to control compared to a rotation in alternation with dicotyledonous plants, for example, field beans, potatoes, or canola [21,22]. Especially the degree of infestation of problem weeds, for example, *Apera spica venti*, *Viola tricolor arvensis*, and *Matricaria* spp., increases considerably [23,24].

When developing a crop rotation, certain criteria should thus be considered: adequate change in tillage practices and timing, maintenance of high levels of organic matter in the soil, inclusion of crops which do not stimulate subsequent growth of the pathogen or crops that have direct negative effects on pests and pathogens (e.g., producing toxins) [11]. For example, oats and brassicas, such as various mustards, are known to exude substances that are directly suppressive to many pathogens, pests, and weeds and therefore justifying their recent popularity in rotations [25–27]. However, they are also hosts to some broad-range pathogens such as *Fusarium avenaceum*. Such broad host range pathogens need to be managed through the enhancement of soil suppressiveness [28,29]. To achieve this, soil protection from damaging compaction through heavy machinery, radiation, drought, and heavy rainfall by high aboveground living and dead biomass, such as occurring in minimum tillage systems, is mandatory [28,30]. In addition, this will foster the microbial activity in the topsoil layers and result, in the long term, in sustainable production systems.

Influence of Decoy and Trap Crops on Pests

Decoy crops are non-host crops that are sown to stimulate the activation of dormant propagules of the pathogen in the absence of the host. In this way, the soil-borne pathogens waste their inoculum potential. For example, *Lolium* spec., *Papaver rhoeas*, and *Reseda odorata* can act as decoy crops for the pathogen *Plasmodiophora brassicae* in Brassica [31]. In the case of trap crops, the crop is host to the pathogen often nematodes. The trap crop attracts nematodes to infect, but the crop is harvested or destroyed before the nematode can complete its life cycle. A famous, still effective method had been developed by Julius Kühn in the 1840s in Germany when certain crucifers are sown and plowed before the beet cyst nematode (*Heterodera schachtii*) can fully develop its life cycle [26]. Recent breeding efforts resulted in *H. schachtii*-resistant oilseed radish varieties that are used as winter cover crops prior to growing sugar beets. Root exudates of resistant varieties induce hatching of young nematode larvae from eggs and cysts with subsequent penetration of the radish roots. However, due to the resistance mechanism, *H. schachtii* juveniles are not capable of building large feeding sites within the radish roots, which prevents the forming of new cysts [32].

Influence of Weed and Border Diversity on Pests and Diseases

Weeds not only compete with crops; they may also be intermediate hosts for diseases and parasites while at the same time offering food and refuge to beneficial insects within the agricultural ecosystem. Within monocropped fields, weeds are important sources of biodiversity and may be useful to improve the stability of the agricultural ecosystem. They play an important ecological role by supporting a complex of beneficial arthropods that aid in suppressing pest populations and thus the pest damage [33–36]. Strip management with weeds or flowering crops is by now standard in many sustainable perennial cropping systems such as orchards (e.g., [37–39]). Weed strips or living mulches, such as grasses or clover species, sown between winter cereals increase ground beetle densities and the number of species considerably by providing these beneficial arthropods with better food supplies and more suitable overwintering sites, from which they can colonize cereals in spring [40].

The abundance and diversity of entomophagous insects within a field are closely related to the character of the surrounding vegetation but also to the field size [6,41]. There are many examples that indicate that crops cultivated near hedgerows, grassy margins, or uncultivated fields with flowering weeds sustain less damage by insect pests than crops cultivated in the absence of such flowering vegetation [33–36]. Nevertheless, it is important to consider the complete life cycle and feeding habit of pathogens and insect pests. Certain weeds and structure elements will serve as alternate hosts to crop pathogens. Carrot flies (*Psila rosae*) need hedges nearby to protect themselves from heat and many aphids overwinter in woody plants. There, adequate distances to fields or the inclusion of specific border strips as trap crops need to be considered [7]. In most cases, field margins, consisting of hedges, sown grasses, and flower strips, for example, provide more beneficial effects through natural enemies regulating pest populations than detrimental effects through pest habitat provision [42].

Future Concerns

Diversity provides an essential key to reduce the risk of losing crop yield to pest damage. Of immediate concern are the effects of climate vagaries and change that will lead to the permanent change and invasions of new pests to new areas [43]. Many pesticides may disappear from the market in the near future due to their detrimental effects. Thus, massive insecticide use in combination with increasing field sizes and simplified cropping sequences were made responsible for the drastic insect decline in the past decades [44], while glyphosate and other herbicides are antibiotics and suspected of being responsible for the development of multi-resistance with direct implications on human health [45–48] including in bee decline [46]. The realization of greater crop diversity by crop rotation and trap crops and surrounding vegetation to stabilize overall crop yields will be of even greater importance in the face of climate change and the need to reduce pesticide use. The most effective way to increase general biodiversity is to simply reduce overall field sizes, though [6]. The implementation of concepts based on crop diversity will preserve long-term stability and productivity of agricultural land and minimize environmental problems caused by intensive agriculture, for example, biodiversity loss, soil erosion, groundwater and air pollution with nutrients and pesticides.

Pest Management: Intercropping

Maria R. Finckh

Introduction

Until the past few hundred years, agricultural systems were based on large numbers of different crops, crop varieties, and landraces that were heterogeneous in their genetic make-up [1]. In addition, farming systems included both animals and plants further increasing diversity. As a result of increasing specialization, mechanization, and modern plant breeding, diversity on the farming system level and crop level has been drastically reduced worldwide at an ever-accelerating speed especially over the past 100 years. Fewer and fewer varieties that are genetically homogeneous are being grown in ever-larger fields [2]. The large-scale monoculture agricultural practices relying on pesticide and mineral fertilizer inputs have also led to a general decline in soil organic carbon and with this in soil microbial diversity and activity [3,4] with consequent effects on soil fertility and health [5].

Monoculture is usually understood to be the continuous use of a single crop species over a large area. However, with respect to plant pathogens and pests, it is important to differentiate between monoculture at the level of *species*, *variety*, or *resistance genes* (see Table 1) [1,6]. For example, within a species, there may be many different genotypes with different resistances to a specific pest or pathogen and great variation with respect to competitiveness with weeds and other crops. Depending on the breeding system, within a variety, diversity for resistance or morphological traits can be non-existent or high. Especially clonally reproduced or strictly inbreeding species may contain no diversity within a given

TABLE 1 Possibilities for Intercropping at Three Levels of Uniformity on Which Monocultures Are Commonly Practiced [1]

Level of Uniformity	Intercropping Possibilities
Species: Different individuals may differ in genetic make-up (resistance, morphology, etc.)	Arrangements among and within species, varieties, and resistances using intercropping
Variety: Usually genetically uniform, the same gene(s) in the same genetic background	Arrangements among and within varieties and resistances—includes variety mixtures, multilines, and populations
Resistance gene: The same gene may exist in different genetic backgrounds	Arrangements among resistances—multilines and populations

variety. Resistance gene monocultures can arise if different varieties all possess the same resistance (or susceptibility) gene(s). For example, in the late 1960s, virtually all hybrid maize cultivars in the southeastern United States possessed the cytoplasmically inherited Texas male sterility (*Tms*). Unfortunately, *Tms* is closely linked to susceptibility to certain strains of the pathogen *Cochliobolus carbonum* (syn. *Helminthosporium maydis*). The monoculture for susceptibility (while different varieties had been planted) led to selection for these strains and in 1970 the pathogen caused more than $1 billion (= 10^9) losses [7]. Currently, Europe is experiencing the decline of the European ash (*Fraxinus excelsior*) due to the invasion of a novel pathogen (*Hymenoscyphus fraxineus*) for which there is almost no resistance present, that is, a monoculture of susceptibility [8].

Intercropping [9] can be practiced at the species, variety, and gene level (Table 1) with effects on pathogens [1,6,10], insect pests [11,12], and weeds [13–15] (Table 2). One of the most important considerations for the successful design of intercropping systems for pest control is the achievement of *functional diversity*, that is, diversity that limits pathogen and pest expansion and that is designed to make use of knowledge about host–pest/pathogen interactions to direct host and pathogen evolution [1,10]. Moreover, functional diversity is also a matter of complementary use of resource niches, for example, deep versus shallow rooting, legume versus non-legume crops. A famous example, not only in terms of functional diversity but also of human diet, is the successful intercropping of the “Three sisters”, namely maize, bean, and winter squash, in Central and North America since 3500 B.C. [16].

Protection Mechanisms Acting in Intercropped Systems

Pathogens, insect pests, and weeds differ fundamentally in their biology and their effects on crops, and different protection mechanisms act with respect to these organisms (Table 2).

Pathogens are mostly dispersed through wind, water splash, soil, and animals (vectors). In intercropped systems, the most important mechanisms for disease control are mechanical distance and barrier effects and changes in microclimatic conditions due to differences in plant architecture. In addition, resistance reactions induced by avirulent pathogen strains may prevent or delay infection by virulent strains. A large percentage of the reduction of airborne diseases such as the powdery mildews and rusts in cereal cultivar mixtures has been shown to be due to induced resistance [17,18]. The protection mechanisms are universal with respect to airborne, splashborne, and some soilborne, diseases and they may be enhanced by pathogen diversity that, in turn, is enhanced by plant diversity [19]. Mixtures of plants varying in reaction to a range of diseases will lead to a multitude of additional interactions and the overall response in such populations will tend to correlate with the disease levels of the components that are most resistant to these diseases. In addition, less affected plants may compensate for yield losses due to reduced competition from diseased neighbors [1].

In contrast to pathogens for which passive or vectored dispersal is the norm, insects often search actively for their hosts. Thus, behavioral, visual, and olfactory cues play an important role. While environmental factors and landing on a non-host is likely the most important mortality factor for pathogens, natural enemies are at least as important for insect population dynamics [11,12]. Host dilution may affect an insect’s ability to see and/or smell its hosts. Predators and parasitoids are dependent on the constant presence of prey and alternative food sources, such as pollen and nectar, in the absence of the hosts and for effective control of insect pests, the presence of sufficient numbers of natural enemies is critical. The importance of natural enemies was often only recognized after insecticide applications induced pest resurgence due to the destruction of natural enemy populations. Intercrops and weeds therefore can play an important role in regulating insect pests. Plant–insect communication also plays a role. For example, plants may signal their neighbors about insect attacks leading to the production of antinutritive compounds or attractants for natural enemies [20,21].

Weeds usually are early successional plants adapted to colonize open, nutrient-rich spaces. Intercrops, especially cover and mulch crops, directly compete with weeds for these spaces and also for light. As many weeds are adapted to certain crops and cropping patterns, changing these patterns (e.g., rotations)

TABLE 2 Mechanisms Affecting Pathogens, Insect Pests, and Weeds in Intercropped Systems and Selected Additional Interactions of Importance [1,13,19,29]

Mechanisms Reducing Disease
Increased distance between susceptible plants
Barrier effects of intercrop
Variation in plant architecture may lead to less humid microclimate
Induced resistance
Selection for the most resistant and/or competitive genotypes
Interactions among pathogen strains on host plants
Increased microbial diversity and activity above and below ground
Mechanisms Reducing Insect Pests
Enhancement of natural enemies
Reduction of host density (reduced resource concentration)
Reduction of plant apparency (visual or olfactory cues reduced)
Alteration of host quality (with respect to the insect pest) through plant–plant and plant–microbe interactions
Increased microbial diversity and activity above and below ground
Mechanisms Reducing Weeds
Reduction of bare soil and layering of crops (increased competition for light, water, and nutrients)
Variation in tillage needs and operations of intercrops may disturb weeds
Other Beneficial Interactions
Yield enhancement through niche differentiation of hosts
Compensation for yield losses by less affected hosts
Better soil cover with intercrop (soil and water conservation, microclimatic effects)
Possible Unwanted Interactions
Weeds may serve as alternate hosts for pathogens and insects
Interactions among virus vectors and weeds
Greater difficulty to specifically reduce weeds with herbicides or mechanically
Overall denser intercropped stands may produce a more humid microclimate that may enhance certain problems

and management operations (e.g., sowing time) connected with different kinds of crops within the same field impede the adaptation and dominance of (problem) weeds. Also, filling the spaces that usually would be taken up by weeds with useful or more neutral plants will reduce weed habitat and help out-competing them [13,14,22]. An important consideration is that plants may be weeds only during certain phases of crop development. At other stages, the presence of the same "weeds" may be beneficial because they may provide food and habitat for beneficial insects and erosion control.

Besides the many positive effects of intercrops, it is important to keep in mind that weeds may serve as alternative hosts for insect pests and pathogens and that insects often are disease vectors, especially for viruses that may reside symptomless in certain weeds [1].

In order to understand the many interactions in intercropped systems, it is indispensable not only to consider plants, insects, and pathogens in the system but also the whole microbiome that interacts with them [23]. Plants not only take up nutrients from the soil, but they also actively release organic carbon-based chemicals such as organic acids and sugars into the soil. Roughly speaking about 30%–50% of the carbon that plants assimilate through photosynthesis is released into the soil [24]. These compounds provide the energy (carbon) and organic acids necessary for the microorganisms in order to function as well as for supporting the weathering of soil minerals making them available as plant nutrients. In addition, most plants live in symbiosis with root infecting mycorrhizal fungi that usually are very specific and genetically diverse [25]. The diversity of root exudates and in turn the diversity of the soil microbiome is greatly enhanced by plant diversity including intraspecific diversity (e.g., [26]), and by this, many of the interactive processes between crops, weeds, insects, and pathogens are influenced. For example, high microbial diversity and activity in the soil usually supports resistance induction and direct disease suppression [19,27]. Also, suppression of the production of certain secondary metabolites by plants can be triggered by certain rhizosphere bacteria. In turn, this may reduce their attractiveness to certain insects. In the case of cucumbers, this is helpful in suppressing the spotted and striped cucumber beetles (*Diabrotica undecimpunctata* and *Acalymma vittata*, respectively) that act as vectors (transmitting agents) of bacterial wilt of cucumber due to *Erwinia tracheiphila* [28].

Intercropping in Practice

Variety mixtures and multilines are used mainly to control diseases. For example, they are used in cereals on a commercial scale in the United States, Denmark, Finland, Poland, and Switzerland to control rusts, mildews, and certain soilborne diseases (e.g., *Cephalosporium* stripe). When barley cultivar mixtures were used on more than 360,000 ha in the former German Democratic Republic, powdery mildew of barley and consequently fungicide input was reduced by 80% within 5 years [1]. Wheat cultivar mixtures and multilines are grown on several hundred thousand hectares in the United States in the Pacific Northwest and in Kansas to protect against diseases and abiotic stresses. In Colombia, coffee multilines are grown on more than 700,000 ha to control coffee rust [1].

Attention has also been called to possible beneficial effects of greater intravarietal diversity in the oat-frit fly (*Oscinella frit* L.) system. The flies can attack the host plants only at a particular growth stage and a higher degree of variability within an oat crop could allow for escape from attack and subsequent compensation.

Cereal species mixtures for feed production have been reported as important practice in Poland and have been shown consistently to restrict diseases. In Switzerland, the “maize-ley” system (i.e., maize planted without tillage into established leys), which is being promoted to reduce soil losses and nutrient leaching, has been shown to reduce smut disease and attacks by European stem borer and aphids [30].

The deliberate planting or maintenance of flowering weeds and grass in established vineyards and orchards in Switzerland and Germany greatly increases natural enemies while reducing soil erosion. This practice is becoming increasingly popular world-wide if water is not the limiting factor in the system.

The required reduction in insect populations for effective reduction of insect-transmitted diseases may be beyond that which can be achieved by diversity alone. However, simultaneous reduction of insect vectors, for example, by enhancing natural enemies and plant resistance and diversity and disease inoculum, for example, by dilution of the susceptible hosts through intercropping with resistant varieties or non-host species can be effective [31,32]; in addition, interactions with the soil microbiome making hosts less attractive to their insect pests as described above [28] may play a role.

Future Concerns

There are many reasons why intercropping is not practiced more widely. First, modern crops are bred to be grown in monoculture and may not necessarily be well adapted to intercropping. Efforts of breeders to produce breeding lines adapted to intercropping need to be strengthened. Breeding for intra-and inter-specific diversity has recently gained momentum [10,33]. EU legislation has been put into place to support these activities at least for the organic sector [34], and there is a need to expand this into the agricultural sector as a whole. Second, while intercropping clearly provides a means for reducing pesticide needs, there is a lack of adapted machinery allowing for efficient management of intercropped cultures. Third, successful intercropping strategies have to be carefully designed as preventive measures that include the whole growing system and rotational cycle [23], while monoculture cropping is very simple due to the availability of (very) cheap fertilizer and pesticides that can be applied once a problem occurs. However, pesticides are more and more criticized for their unintended side-effects causing insect decline [35] and affecting human and environmental health [36,37] and alternative approaches based on applied agroecology are needed [38]. Fourth, a concern often raised is the quality of products raised as intercrops such as varietal mixtures of cereals. In some countries, there is resistance in the food processing industry to such products. However, such problems could be overcome if breeders, producers, and processors work together. For example, in the 1980s, in the German Democratic Republic, first-quality malting barley was produced in large-scale mixtures in collaboration with breeders, growers, and processors [39]. Also, some of the highest-quality coffee in the world from Colombia is produced from multilines demonstrating that quality produce is not dependent on genetic uniformity. For the use of products grown from species mixtures, technological advances (e.g., color- or shape-based optical and/or mechanical separation devices during harvest or processing) need to be implemented.

Precision Agriculture: Water and Nutrient Management

Robert J. Lascano,
Timothy S. Goebel,
and J.D. Booker

Introduction

Management of agronomic inputs, such as water and fertilizers, to cropping systems requires information on when and how much of each input to apply. The correct management decision is essential to maintain the productivity of the cropping system, and a management strategy is to use crop production functions that describe (mathematically) maximum economic yield (profit) as a function of agronomic inputs. Essentially, the strategy is to apply the least amount of input to produce the maximum economic crop yield in the farming operation. In conventional cropping systems, inputs are generally applied uniformly across a field regardless of their need, and the amount applied is normally based on average responses of these inputs to crop yield across the field. Since the 1970s, increased costs of crop production and emphasis on production efficiency revolutionized production agriculture. Environmental concerns, including quality and safety of harvested products and impact of the cropping procedures on the ecosystem, are also considered in the decision-making process. Developments in spatial statistics and computer hardware (i.e., increased microprocessor speed and decreased cost), and increased availability of soil, elevation, and weather data have contributed to improved concepts and procedures to address spatial and temporal variability in cropping systems.

Precision agriculture (PA) and precision farming are generic terms that describe the way production management inputs (e.g., water, nutrients, harvest aids, and herbicides) are managed in response to cropping system variability. In contrast to a uniform blanket application of an input across the field, each input is applied according to specific needs across the field. PA is an integrated crop management system that attempts to match the kind and amount of inputs with the actual crop needs for small areas within a farm field. Perhaps a better descriptor for this type of farming is site-specific management, which manages an agricultural crop at a spatial scale smaller than the entire field by dividing it into management zones, defined by topography, soil type, and level of a particular nutrient, such as nitrogen and phosphorus.

Driving forces that have contributed to producers implementing and adopting PA procedures are advances in computer hardware and software, electronics, and equipment technology (sensors); decreased profit margins due to increased costs of production; and environmental awareness. For example, advances in crop growth simulation models, variable-rate application equipment, adoption of soil sampling for nutrients across the field and as a function of soil depth, and integration of crop yield monitors with global positioning satellite systems have contributed to the use of PA concepts to manage crops. The cost of agronomic inputs continues to increase, for example, petroleum-based inputs such as fertilizer, diesel, insecticides, and herbicides. Awareness of environmental concerns related to nutrient contamination of groundwater and surface water and the quality and safety of food and fiber are factors that impact how crops are produced and delivered to the consumer. Operating a farm requires management strategies that consider both economic and environmental consequences, and PA provides the concepts that can be used to achieve this goal.

In recent years, the development of sensors to measure soil properties[1,2] and of using remote sensing techniques[3,4] has increased the availability of georeferenced digital data used in PA. These large databases are generically referred to as "Big Data", and examples of their application to PA are given by Sonka[5] and by Fulton and Port.[6] Further, the availability of real-time weather information via networks known as Mesonets[7] and the use of software applications that are accessed via smart phones[2,8,9] has both modernized and revolutionized crop production and gives producers information to manage their farming operation more efficiently. Examples of these applications for nutrient and water management are given by Hedley,[10] Abit et al.[11] and by Neupane and Gao.[12] In PA, the rate of adoption and use of this technology will continue to increase. The factors that contribute to this implementation are the decreased cost of computer hardware, increased availability of input data, and development of computer software providing tools to manage the farming enterprise more efficiently. Also, tailoring production inputs to site-specific locations contributes to improve the sustainability of the food supply.[13]

This chapter gives a general overview of PA with emphasis on crop water and nutrient use, and crop yield using the state-space analysis to describe, for example, how cotton lint yield varies at a landscape scale. This entry is divided into five parts. First, we give a general overview of PA. Second, we describe the relation between crop yield and water use. Third, as examples, we show measurements of cotton water use along two 700 m transects on a 60-ha field and the use of a large-scale model to calculate the temporal and spatial variability of soil water content in a 70-ha field. Fourth, we use geostatistical tools to quantify cotton lint yield as a function of nitrogen, topography, and soil water. Fifth, we describe how the future of PA will leverage knowledge from PA research, such as that presented here, to further support the development and use of large-scale cropping system models.

Precision Agriculture

PA, also known as site-specific management,[13,14] refers to the practice of applying agronomic inputs across a farm, mainly fertilizers and other chemicals, at variable rates based on soil nutrients or chemical tests, soil textural changes, weed pressures, and/or yield maps for each field in the farm.[13–15] In large fields (e.g., >40 ha), crop yield and thus crop water and nutrient use are notoriously variable.[12,14,16] The sources of this variation are related to soil physical and chemical properties, pests, microclimate, genetic and phenological responses of the crop and their interactions.[16] The technology for crop yield mapping is more advanced than current methodologies for determining and understanding the causes of yield variability. Prevailing and traditional management practices treat fields uniformly as one unit. However, reports[15–18] show that to understand underlying soil processes that explain crop yield variability, research must be done at the landscape level and using appropriate statistical tools for large-scale studies.[18]

Crop Yield and Water Use

There is a linear relation between crop yield and water use when the only limiting factor is water[19]; however, root water uptake is synergistically related to nutrient uptake, and the two processes cannot be separated. Precision farming has the potential to improve water and nutrient use efficiency on large fields provided there is quantitative understanding of what factors affect crop water and nutrient use and how they vary across the field.[16,20,21] It is known that crop water and nutrient use are a function of many biotic and abiotic variables, including managed inputs, and harvestable yield is a manifestation of how these variables and inputs interact and are integrated during the growing season. However, it is difficult to determine a hierarchy on the contribution of each input and variable to the measured crop yield using classical statistics.[22–25] Often, variables that affect water and nutrient supply to the plant contribute to crop yield at a high level assuming an adequate plant stand and weed control. The cause-and-effect relation between a single state variable and crop yield is site specific and is difficult to establish without considerable sampling of the soil and/or crop. The establishment of response functions, that is, crop water and nutrient use as a function of variable x_i, gives only a partial answer to explain crop water use, nutrient use, and yield based on inputs. The general idea of PA is to optimize input application to the measured crop yield at each sampling location using the law of the optimum formulated by Liebscher, which states that a production factor that is in minimum supply contributes more to production, the closer other production factors are to their optimum.[26] This is a simple premise; however, the decisions for variable-rate application of any agronomic input must consider temporal and spatial variability of the soil's properties affecting crop growth, water and nutrient use, and yield. Soil factors that affect water storage, such as depth of the root-restricting layer and soil textural differences, must be considered in any precision farming operations that attempt to improve crop water use and yield related to agronomic inputs. Similarly, to improve the use of any micro- and macronutrient by the crop, the overall cycle of the nutrient must be considered, including its availability in the soil and demand by the crop. Examples of managing nitrogen fertilization and irrigation at a site-specific and farm scale for cotton production is given by Bronson et al.,[17] Li et al.,[18] and Booker et al.[27]

Precision farming must incorporate the inherent spatial and temporal variability of soil physical, chemical, and biological factors within a field for input management. Accurate representation of spatial and temporal variability in a field requires taking and analyzing many samples. Sampling is normally done on a grid with a scale that can vary from one to several hundred meters.[22,23] Once properties are measured, geostatistical tools (e.g., semivariogram, kriging, cokriging), and other spatial statistical tools (e.g., autocorrelation, cross-correlation, state-space analysis), can be used to establish statistical relations in space and to minimize the number of soil samples to characterize and map fields.[22,23,25] The number of samples required *a priori* to determine spatial and temporal variability is perhaps the single largest deterrent in the application of precision farming practices to manage and improve crop water and nutrient use. Collection of field data to characterize the spatial variability must remain a priority for any study that attempts to understand how to maximize crop yield across the landscape. The trend of using data generated from pedotransfer functions[28] rather than field measured data is of concern and results thus obtained are preliminary at best and should be verified using measured field data. Further, input data generated from pedotransfer functions and used to assess the spatial variability of soil properties can be used as a guide to establish a sampling scheme to measure the properties of interest. Input data generated from pedotransfer functions are not a substitute to field measured data.

There is not much information published on combined crop water and nutrient use across large fields at the landscape level and in the context of precision farming.[17,29–31] An exception is the study by Li et al.[18] where cotton water and total nitrogen uses were measured along a 700-m transect to illustrate the landscape pattern of cotton water and total nitrogen uses and to determine the underlying soil processes governing cotton lint yield variability. In this study, state-space analysis[18,22,25] was used to formulate management decisions that may improve crop water and nitrogen use and lint yield using precision farming practices. An additional study regarding variable-rate nitrogen at different locations within a

48-ha field is given by Bronson et al.,[17] and in a 14-ha field, by Booker et al.[27] A global-scale assessment showing that global yield crop variability is a function of fertilizer use, irrigation, and climate is given by Mueller et al.[32] and a review of integrated nutrient management to sustain crop productivity while minimizing the environmental impact is given by Wu and Ma.[33]

Landscape Crop Water Use

The concept of crop water and nitrogen use in a 60-ha field study is given by Li et al.[18] and Li and Lascano.[34] In 1999, a field experiment was conducted near Lamesa, Texas, on a research farm of Texas A&M University on the southern edge of the High Plains of Texas. The soil was classified as an Amarillo sandy loam. The field was 60 ha with slopes ranging between 0.3% and 6.3%.[18] To evaluate the effect of soil water, nitrate-nitrogen (NO_3-N), and topography on cotton lint yield across the landscape, two irrigation levels were used. The irrigation treatments consisted of water applications at a 50% and 75% grass reference evapotranspiration (ET_o) with a center-pivot low-energy precision application irrigation system.[35] At each irrigation level, one transect was established following the circular pattern of the center pivot. The two transects were instrumented with 50 neutron access tubes, each 15 m apart, and soil volumetric water content (θ_v) was measured periodically throughout the growing season. At each point, θ_v was measured in 0.3 m depth increments to 2.0 m depth using a neutron probe calibrated for this soil. In addition, at each transect point soil texture, soil and plant NO_3-N, leaf area index, cotton lint yield, slope, plant density, and other parameters were measured.[18,34]

A comprehensive study to evaluate site-specific management of cotton production systems at a landscape scale was done by Booker et al.[36,37] using the Precision Agricultural Landscape Modeling System (PALMS),[38] which was integrated with the cotton simulation model GOSSYM.[39] The combined model, PALMSCot, was applied to simulate a cotton crop irrigated with a 400-m center pivot system and covering a ¼-section of land (~65 ha). The PALMSCot model is grid-based (10-m resolution) and defines up to 26 soil depth layers and for each "cell" the water, energy, nutrient, and carbon balance is calculated on a ¼-h time interval for the length of the growing season. This model provides a detailed calculation of the water and nitrogen use for each cell across the field. For example, for an irrigated field with a 400-m-long center pivot sprinkler system, PALMSCot calculates the cotton lint yield, evapotranspiration, and nitrogen use for each of the 5,026 cells defined by the 10 × 10 m grid system (length and width) and the assigned soil depth.

Statistical Calculations

It has been shown that the use of classical statistics, such as regression analysis and analysis of variance, is designed to describe the strength of the covariance structure between variables and fails to completely explain the cause and effect between, for example, crop yield and measured soil variables in precision farming experiments.[18,22,23,25,31] These techniques, in general, account for spatial and temporal variability through blocking and do not describe the spatial and temporal structure. Instead, there are other more appropriate statistical tools for relating the variability of soil and plant parameters measured in space and time. For example, the structure of the spatial (or less often, temporal) variance between measurements may be derived from the sample semivariogram, which is the average variance between neighboring measurements separated by the same distance. Spatial or temporal structure between variables is often determined using autocorrelation and cross-correlation functions. Although these techniques can be used to evaluate the temporal variability structure, they are most often used in PA to analyze spatial variables. Autocorrelation measures the linear correlation of a variable in space along a transect. Cross-correlation is the comparison of two variables measured along a transect and is used to describe the spatial correlation between two landscape variables, that is, where one variable, the tail variable, lags behind the head variable by some distance. The spatial association between several variables can be described using state-space analysis, which is a multivariate autoregressive technique.[18,22]

Spatial Analysis of Crop Water Use

To illustrate the variability of crop water use or crop evapotranspiration (ET_c), values measured along the 50% irrigation transect were selected.[18] In Figure 1, the relation between the scaled ET_c and elevation, both as a function of distance along the transect, is shown. The ET_c data are scaled to the maximum value of 426 mm of water, which was measured 210 m from the south end of the transect. These results show, as expected and, that in general higher ET_c was measured at lower elevations and that ET_c tended to decrease at the higher elevations. Higher elevations are eroded and the depth of the root zone is shallower holding less water. In contrast, lower elevations tend to have more clay and thus hold more water.

Calculated values of soil volumetric water content for the surface 0.05 m for a center pivot irrigated cotton field in Floydada, Texas, are shown in Figure 2.[36,37] The four circles shown in Figure 2 illustrate the corresponding wetted soil area (blue) by the center pivot, with values of 45% soil water content over a 6-day period, starting on the 10 July and ending on the 16 July. This is an example of the spatial resolution, 20 × 20 m, and temporal variability that can be used to analyze crop water use across the landscape that can be obtained with a model such as PALMSCot.

Spatial cross-correlation between cotton lint yield and soil water, cotton lint yield and site elevation, and soil water and site elevation are shown in Figure 3. For a 95% confidence interval, the cotton lint yield was positively cross-correlated with soil θ_v across a lag distance of ±30 m. Cotton lint yield and θ_v were negatively cross-correlated with elevation at a lag distance of ±30 m. These results show the effect of topography on the θ_v and of crop water use measured along the transect. Similar results are given in other reports.[17,30,31,40] In this example, the cross-correlation between θ_v and elevation shows the spatial structure of measured variables and, further, that more water was stored in lower elevations, resulting in higher ET_c.

FIGURE 2 Calculated values of soil volumetric water content for the surface 0.05 m obtained with the PALMSCot model using 20 × 20 m grid cells for the period from 10 to 16 July 2011. This is a center pivot irrigated cotton production field located in Floydada, Texas. The soils at the site are classified as a Pullman clay loam with 0%–1% slope and an Olton clay loam with a 1%–3% slope. The blue zones correspond to irrigation water applied by the center pivot sprinkler system.
Source: Booker et al.[37]

Linear regression analysis between θ_v and cotton lint yield and relative site elevation is shown in Figure 4, and the state-space analysis for the relation between cotton lint yield and three measured parameters is shown in Figure 5. Results in Figure 4 show the shortcomings of using an inappropriate statistical tool to understand underlying processes explained with the state-space analysis. This analysis (Figure 5) quantified how cotton lint yields varied as a function of distance and showed that by using θ_v, soil NO_3-N and elevation the variation in cotton lint yield can be explained with a high level of confidence. While studies like those of Li et al.,[18] Bronson et al.,[17] and Booker et al.[27] are empirical in design, the relationships that are evaluated provide important validation and field testing of the more mechanistic mass and energy balance accounting provided by models such as PALMS.[38] These studies also provide foundational information for developing PA management strategies at the crop production scale.

Benefits of PA to improve crop water and nutrient use may be obtained by an economic analysis of maximizing crop yield as a function of application of nitrogen fertilizer and irrigation water as given by the state-space equation.[18,34] In the example given, the decision can be made to apply more

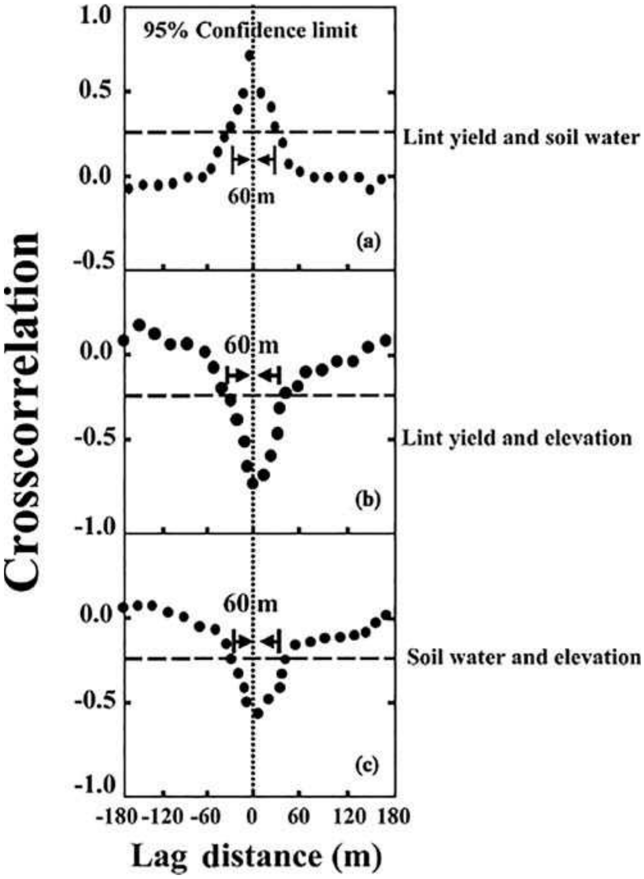

FIGURE 3 Cross-correlation as a function of lag distance. (a) Lint yield and soil water, (b) lint yield and elevation, and (c) soil water and elevation. Shown is the 95% confidence for the cross-correlation distance.

nitrogen fertilizer to the lower areas of the field that also hold more water and increase crop water use and nitrogen and lint yield. With the introduction of variable rate planters, it is possible to discriminate site locations and plant more "drought"-tolerant varieties or change the seeding rate in areas that are prone to have less soil water. This implies the delineation of management zones[14,15] within a field that are defined based on potential crop water use and their interaction with other input variables to maximize economic yield across the field. This type of precision farming is slowly being adopted, and wide use remains within the realm of possibilities that this type of farming has to offer. The introduction and use of computer models of cropping systems will likely expedite and facilitate the adoption of PA management techniques.[38]

$$Y_{(50\%ET)i} = -0.201\ Y_{i-1} + 1.107\ W_{i-1} + 0.332\ N_{i-1} D49.54\ E_{i-1} + \varepsilon_i$$

A final consideration is the cost/benefit of PA practices and its impact on agriculture. Currently, hardware for variable-rate application of agronomic inputs is relatively expensive and in many cases unavailable; however, with increased adoption and use of these practices, the cost will be reduced. For example, tractor guidance systems[41,42] were quickly adopted by producers, and high demand reduced its cost. Further, environmental and material cost concerns for a given area will probably place limits on the amount of certain nutrients, for example, nitrogen fertilizer, used for crop production. This will force producers to apply nitrogen and other nutrients across the field according to site-specific needs and position along the landscape. These practices will be beneficial from both an environmental and an economical point of view.[10,11,20,33]

Future of PA

Considerable PA-related research, similar to that presented above, has been conducted over the past decade, studying empirical relationships and attempting to better understand the underlying processes controlling crop yield variability. Much of this research has focused on grid soil and crop sampling,[43] surface characterization (e.g., apparent electrical conductivity),[44] and ground- or aerial-based remote sensing.[3,4,45,46] Such research has described numerous useful process relationships but has been somewhat less successful in providing broad-based tools to support production-scale management. The lack of development of decision-support systems to implement precision decisions is the major impediment to the adoption of PA.[47]

Recent advances in the availability of soil data provided by the U.S. Department of Agriculture, elevation data provided by the U.S. Geological Survey, and weather data from weather Mesonets (networks) provide the necessary input to model the water, energy, nutrient, and carbon balance of large-scale agricultural fields. An example of such a model is the Precision Agricultural-Landscape Modeling System (PALMS) given by Molling et al.[38] The integration of PALMS with crop growth models[36,37] provides a framework whereby site-specific management of crops is an achievable goal.

The concept of using simulation models to manage crops was introduced in the 1970s. Many of the theoretical algorithms related to model crop photosynthesis and transpiration were formulated by C.T. de Wit and coworkers at Wageningen University, Netherlands.[48] An example of such model is the simulation of field water use and crop yield given by Feddes et al.[49] An example of a crop-specific model, that is, cotton, known as GOSSYM/COMAX was developed by McKinion et al.[39] This model was used by crop consultants in the Texas High Plains to provide services on irrigation scheduling and application of nitrogen fertilizer, growth regulators, and chemicals to terminate the crop.[50] The biggest drawback ofthe application of these models was that the required inputs, soil and weather, were both difficult and expensive to obtain. Furthermore, these models provided only an average estimate of crop yield for the entire field regardless of size. The models could be run separately for different parts of a field, but this increased the demand on limited computer and input resources and even then did not represent the interaction between various parts of the field. In retrospect, we now recognize that these models were ahead of their time. Given the current availability of soil and weather data that is required by these models, along with the increased computer speed and reduced cost, a resurgence in the application of simulation models to manage crops and cropping systems is anticipated.

In coming years, a likely scenario to emerge to manage cropping systems will be based on the combination of three factors. First, is the realization from site-specific management that shows that crop yield varies temporally and spatially and that increases in crop yield are possible by targeting different amounts of an input, for example, irrigation water and fertilizer, to specific parts of the field. Second, crop management, from planting to harvesting, is complex, and simulation models can be used as a decision aid. Use of crop simulation models, developed in the 1970s–1980s, is facilitated due to the increased availability of required soil, elevation, and weather input data to execute the models and reduced cost of computer hardware. The third factor is an increased awareness of producers on production efficiency and environmental concerns. For example, in many agricultural areas, the amount of nitrogen fertilizer that can be applied is restricted and linked to the residual nitrogen in the soil and its potential effect on contamination of surface water and groundwater.[11,13,14,33,51] Advances in management information systems, development of computer software, and communication via the Internet provide us with the tools to manage a crop in real time.[1,6,36,52] We are currently working toward the development of a PA model that includes all of the above factors.[52,53]

The integration of a landscape-scale model such as PALMS[38] with a cotton growth model[39] using site-specific management of water and nitrogen[17,18] can give us the tools to manage, for example, a 50-ha irrigated cotton field. The model provides three key features important to real-time production-scale management: (1) it represents the variability in space and time within the entire field and accounts for hydrologic interactions between areas within the field; (2) it provides water, energy, nutrient, and carbon balance information without reliance on field-installed hardware that must be avoided during management operations; and (3) it can provide predictive information that can support various what-if scenario evaluations (something that physical field measurements do not provide). For example, this field can be divided into 5,000 (100 m^2) or 20,000 (25 m^2) cells, and the model will calculate a cotton lint yield value for each cell, using weather data collected at or near the field and previously collected soil and elevation data, both of which are stable and once developed can be used for many growing seasons. Further, the estimate of cotton lint yield is based on interactions of soil–plant–weather parameters, and the model itself can be used to explore what combination of inputs (e.g., water and nitrogen) would give the highest economic yield while minimizing leaching of nitrogen below the root zone. This is a current topic of research of our cropping system research unit.[52,53]

The input and output terms of the water balance of a cropping system are usually well quantified except for information on the input variable rain, that is, frequency and rate of rainfall events across the landscape.[53] Rainfall events are normally measured at a single point in space and seldom is the rate of individual rain events measured and/or recorded. Determining, the amount of water from a rain event that is stored in the soil, that is, effective rain, and runs off is key to correctly model the water balance across the landscape. For example, in the semiarid Texas High Plains, about 86% of annual rain events are <13 mm[54] and a large portion of this rain is lost as evaporation from the soil before it can be used by the crop as transpiration.[55] To correctly calculate the water balance across the landscape we need to determine the amount for any rain event that is stored in the soil and is used by the crop as transpiration.[55,56] Rainfall is variable in space and an appropriate cluster of rain gauges is needed across the landscape to measure effective rain and correctly determine the water balance across the landscape.

Conclusion

PA is a generic term that describes the way that agronomic inputs to a farming operation are managed and each input is applied according to specific needs across the field. An outcome of PA is the recognition that crop yields vary temporally and spatially. Crop management, from planting to harvest, is complex and requires management strategies that consider economic and environmental consequences. Recently, nutrient contamination and quality and safety of food delivered to consumers are also factors that have received consideration. A summary of general concepts learned from PA experiments follows.

First, agronomic experimental work needs to be done at the scale of application. For example, results from small research plots are normally not transferable to large fields.[22,25,40] The underlying principle is to take advantage of the inherent spatial variability of soil properties across the landscape. In PA experiments, the spatial variability of a given property is used as the source of variation instead of imposing treatments (e.g., levels of nitrogen fertilizer) to obtain variation. Second, the use of classical statistics fails to explain the cause and effect between variables. Spatial structure between variables can be quantified using specialized statistical tools such as autocorrelation, cross-correlation, and state-space analysis.[22,25] Third, given the complexity of current cropping systems, crop models[39,48] introduced in the 1980s are being combined with geographic information data of soils and elevation, real-time weather, and management information systems to provide a framework to manage crops. These models can provide three key features important to real-time production-scale management: (1) representation of variability in space and time within the entire field and hydrologic interactions between areas within the field; (2) water, energy, nutrient, and carbon balance information without reliance on field-installed hardware that must be avoided during management operations; and (3) predictive information to support various what-if scenario evaluations. As a result, we now have the capability of tracking different layers of data (soil, plant, and weather) and, for example, a 50-ha field may be divided into 5,000 cells, each cell 10 m wide, 10 m long, and 2.0 m deep.[36,37,52,53] The water, energy, carbon, and nitrogen balance (input equal to output) of each cell is calculated, and the change of any one variable on crop yield can be evaluated. This is a powerful management tool that will assist producers on how to maximize economic crop yield while minimizing nutrient losses to surface or groundwater.[52,53] Adoption of PA practices will continue to rise given the increased constraints of production, advances in technology, and demand for safe food and fiber of high quality.[13,33,46,47]

Green Processes and Projects: Systems Analysis

Abhishek Tiwary

Introduction

Given the level of inadvertent impacts generated from human breakthroughs in science and technology post industrial revolution, be it from the combustion engines based on coal/fossil fuel or the use of plastic in modern day commodities, it is imperative to develop a systems perspective on the sustainability of a process or project. This chapter introduces a holistic approach to environmental appraisal for minimizing the impacts from transboundary interactions between the material flows of a system, thereby ensuring efficient management of any potential environmental impacts. This approach combines application of "dynamic science-based" geo-spatial analysis with "static inventory-based" life cycle assessment (LCA) to understand the full-scale of impacts generated from a proposed process or project at the systems level, thereby ascertaining their true "greening" potential. Hereafter a "process" implies a set of activities targeting a specific output (e.g., 1 MW electricity, 1 ton of a material), whereas a "project" implies a combination of cross-cutting processes to achieve a specific objective (e.g., constructing a new building, greening of transport network). Two case studies are presented, one each for a green process and a green project, to enable the readers to get a grasp of the usefulness of this tool in global environmental management, more so in the context of supply chain spread diffusively over numerous geographical regions.

Systems Approach in Environmental Management

In the context of fool-proofing human existence from untoward climate change feedbacks, management of both built-up and natural environments has gained center stage in recent years. It is widely agreed now that effective environmental management involves striking a fine balance between the technological innovations underpinning its viability (essential for economic growth) and the constraints to long-term sustainability (Figure 1). This chapter deals with how a systems approach can be applied to achieve this goal.

Traditionally, systems approach has its roots in industrial (or laboratory) processes that simply comprise a series of related activities aimed at optimizing production (and hence the profit). However, in the face of climate change, much of the environmental research conducted over the last decade has changed our notion of the scale of management problem we face. Take, for instance, the case of cheap biofuel provisioning in the first decade of the 21st century—the demand for palm oil in the Western world has caused massive deforestation in Indonesia and Amazonia. Having a wider scope to environmental management, beyond what can be considered as local activities within a country's borders, has given way to the systems approach in environmental management. Although simple in principle and rigorously tested in processing industries, its adaptation to the wider environmental problems comes with extreme operational challenges. The latter is mainly highlighted in terms of data availability, essential to the success of this vision. Despite this, it is considered as an efficient framework to facilitate a more holistic management of material, energy, and pollution across a range of related activities, usually spread over large geographical areas.

The main advantage of using a systems approach is to figure out the hotspots of environmental concerns (greenhouse gas emissions, ecotoxicity, air pollution, etc.) within a system. For this purpose, the scope of environmental management has now crossed local boundaries to a systems scale, encompassing the whole range of supply-chain spreading over several countries to ensure global sustainability. These associated activities form what is known as a "life cycle" in terms of environmental appraisal. It facilitates mapping of the "stocks" and "flows" of emissions (also called environmental burdens) through different stages. The concept has been used to develop the LCA and Material Flow Analysis (MFA) methods. Both these techniques have proven to be useful diagnostic tools. Detailed texts describing the LCA/MFA methods exist in the literature. Interested readers can find some useful sources listed in different parts of this chapter; in particular, *The Hitch Hiker's Guide to LCA*[1] serves as a good starting point to develop fundamental understanding of these concepts.

The main objective of applying LCA/MFA is to assess the critical environmental burdens and impacts contributing to the adverse effects on human and ecological health. These critical pollutants can then

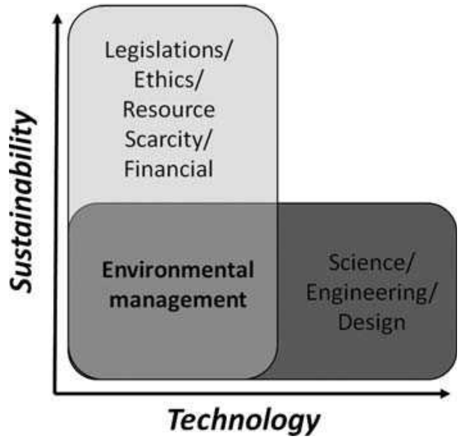

FIGURE 1 Constraints to environmental management at a systems scale.

be dealt with, and their impacts mitigated, through implementation of effective control measures. This ensures a solution to an environmental problem at the local scale while considering its footprints at the global scale, literally over the whole life cycle. As a consequence, this approach offers a robust framework for implementing holistic sustainability.

Best Practice Guidelines in Systems Analysis

Standard Protocols

In essence, the International Organization for Standardization ISO 14044[2] specifies four mandatory steps for quality assurance in LCA, namely—goal and scope definition, inventory analysis, impact assessment, and interpretation. To ensure that the environment as a whole is protected, the process chain forming the system can be scoped in two ways. The first comprises pre-chains involved in excavation of the resources and their transportation to the industrial site, the end-of-pipe emissions from the plants, and the disposal of the wastes at the end of the cycle. This approach in life cycle thinking is usually referred to as “cradle-to-gate” since it follows an activity from the extraction of raw materials (i.e., cradle) to the delivery of the product or service (i.e., the exit gate). The other, in addition to accounting for all the above, also includes one-off construction and demolition of the infrastructures or end-of-life processing and disposal of the equipment/commodities used. Appropriately so, it is then called a “cradle-to-grave” system.

As a standard practice, the resources utilized and the emissions added to the environment in all these activities are usually modeled on a unit basis, typically annual turnover for the industrial products and annual usage for the services. This is termed as the “functional unit” of analysis in LCA. Typical functional unit for an assessment can be “activities over 1 year,” representative of the quantitative metric of the output of products or services that the system is expected to deliver. Likewise, the typical timescale for an assessment could range from hours to 100 years. The latter is specifically relevant for assessing long-term environmental impacts such as global warming potential and acidification.

The spatial context of setting up a life cycle model is also essential in order to establish its system boundaries. Typical spatial scales range from local (e.g., urban) to wider environment (e.g., remote excavation site, mines) and possibly representing a global scale. This aspect of the analysis is useful for consistency checks, comparing different LCA results, and ensuring they have been conducted on comparable system boundaries. Given that life cycle approach facilitates assessment of a full spectrum of process chains involved in a process for all the activities, it is recommended to group the burdens and impacts obtained from an analysis into two distinct categories: (1) arising in the direct environment from the main activity/ies under investigation (commonly known as “foreground”) and (2) arising from a whole series of linked pre- and post-chain activities in the wider global environment (known as “background”). This is clearly shown in Figure 2, which shows a series of activities associated with the production of electricity from biofuel through a schematic representing a power generation system. In this figure, the main activity (i.e., the cogeneration plant) is shown as the foreground (shaded region), whereas the peripheral activities, associated primarily with the sourcing of the raw materials, shipment, and final disposal are shown in the background. On the one hand, this approach enables clear accounting of the environmental impacts and, on the other, it offers insight into the hotspots at each stage of process chain, facilitating effective management of the problem through visualizing the entire system at the same time. This is considered superior to resource- and cost-intensive piecemeal solutions encountered in traditional management approaches, specifically so in the context of achieving global sustainability.

The environmental impacts from LCA are usually calculated from mass balances of the input/output flows on the basis of the problem-oriented (midpoint) approach. It is a baseline method that provides a list of impact assessment categories grouped into obligatory impacts, used in most LCAs. A baseline indicator is considered suitable for simplified studies since it utilizes the principle of best available practice when several methods for obligatory impact categories are available.

Uncertainty Assessment

To decide on the future courses of action based purely on results of LCA analysis, one needs to account for the uncertainty in these results—this enables reaching better decisions. The information on uncertainty in LCA is usually contained in the assessment of probability of realistic representativeness of the results. This is expressed in terms of the confidence bounds on LCA results, which illustrate the region within which the true values have an estimated likelihood of falling.

This section covers only the fundamentals of uncertainty inherent in LCA. Readers will be guided to use dedicated literature to pursue a more in-depth uncertainty assessment exercise.

A number of approaches have been suggested in the literature for the integrated consideration of both technical and valuation uncertainties involved in LCA. The former is associated with the uncertainties in data collection, while the latter is inherent to the impact assessment method used. The reason we need to care about uncertainty in LCA is because the statements or assertions we tend to make about the world on the basis of direct LCA outputs may be wrong. These errors have been mainly associated with either uncertainty or variability in the outputs. Whereas variability is considered to be inherent in the real world, uncertainty is mainly associated with inaccurate measurements, lack of data, and/or model assumptions.[4] The following can be considered as a rigorous (although not an exhaustive) list of categories of uncertainties identified in the literature:

- *Parameter uncertainty*: This is due to the uncertainty within the large number of parameters used in LCA models. It leads to uncertainty in the final output from the LCA exercise. Empirical inaccuracy, non-representativeness (incomplete or outdated measurements), and lack of data are common sources of parameter uncertainty.
- *Epistemological uncertainty*: The use of the information in databases for life cycle inventory (LCI) introduces epistemological uncertainty since the system where the data is to be used to model a process may differ from the system where the data was generated.[5]
- *Model uncertainty*: In situations where an LCA model suffers from uncertainty in the underlying model assumptions and the basic model calculations (departure from the default linear

programming), the results of a parameter uncertainty analysis can be misleading and hence provide no useful information.

- *Spatial variability*: Application of spatially averaged data to model specific processes in certain parts of the world leads to these discrepancies.
- *Temporal variability*: These are mainly attributed to time-dependent variations in emissions and other technical process characteristics.

Handling Uncertainty in Systems Analysis

It has been suggested that not all the methods of statistical analyses of uncertainty can be applied to LCA, primarily because the underlying LCA data are not based on random samples, that is, we are not strictly dealing with random variables that follow some known frequency distribution. However, one can apply subjective probability distributions to quantify the uncertainties involved. The established procedure to achieve this consists of the following five steps: selection of essential parameters, determination of probability distributions, Monte Carlo simulation, significance analysis, and interpretation of the results.[4,6]

Recent approaches have tried to integrate consideration of both technical and valuation uncertainties during decision making on the basis of the results provided by LCA. These are to be used in conjunction with established decision support tools based on multiple criteria decision analysis since it has been demonstrated that the structure of LCA has parallels with a decision analysis approach to decision making.[7] Key elements of this approach include "distinguish ability analysis" to determine whether the uncertainty in the performance information is likely to make it impossible to distinguish between the activities under consideration, and the use of a multivariate statistical analysis approach, such as principal component analysis. The latter enables rapid analysis of large numbers of parallel sets of results, thereby allowing for the identification of choices (options) that lead to similar and/or opposite evaluation of activities.

Application of Subjective Probability Distributions Approach

This method of uncertainty analysis in LCA has inherent attributes since they are an alternative to simple point estimates, which allow for the use of a range within which we expect the true value to lie rather than using a single number to estimate the results of some real-world quantity (e.g., tons of sheet of steel required to make 1 ton of an output product). In this manner, by developing subjective probability distribution, the methods of uncertainty analysis can be used in LCA to account for the uncertainty in the results. This further enables accounting for the reliability of the decisions reached on the basis of the LCA outcomes, and if the reliability of the conclusions is not sufficient for our decision-making needs, then uncertainty analysis helps identify which data uncertainties are most significant, that is, influential in the process chain. Furthermore, applying the inverse method, this step can help the decision maker determine the levels of reduction in data uncertainty required to reach a specific level of confidence in the results. For example, to attain "90% confidence" in the results, one would need to assure that using the subjective probability distribution approach if the LCA analysis of a process is repeated several times, each time using new and equally probable randomly selected values for the uncertain input quantities, the conclusions would be correct 90% of the time.

Uncertainty Analysis versus Data Quality Characterization

The LCA is very dependent on data of good quality. In most cases, LCA practitioners rely on generic databases provided by different sources. The commonly available databases to date are the European Union's (EU) European Reference Life Cycle Data System (ELCD), Swiss National LCI Database (ecoinvent), the U.S. LCI Database created by the National Renewable Energy Laboratory and its partners, the Canadian Raw Materials Database (CRMD), the Swedish National LCA Database (SPINE@ CPM), the Danish Food Database, and the Korean National LCI Database (KNCPC). Apart from these, currently Australia and Japan also have ongoing initiatives to generate national LCA databases.

Owing to a limited number of sources providing information while generating the LCI data, quite often the uncertainty related to the amount of a specific input or output cannot be derived from the available information. For such circumstances Frischknecht et al.[8] have developed a simplified standard procedure to quantify the uncertainty. This simplified approach includes a qualitative assessment of data quality indicators on the basis of a pedigree matrix from published literature. Basic uncertainty factors are used for the kind of input and output considered. For example, it is assumed that CO_2 emissions generally show a much lower uncertainty as compared with CO emissions since the former is usually calculated from fuel input, whereas the latter depends on numerous parameters such as boiler characteristics, engine maintenance, and load factors. Table 1 provides a list of proposed uncertainty factors in a pedigree matrix, which have been based on expert judgments.

TABLE 1 Examples of Basic Uncertainty Factors (Dimensionless) Applied for Technosphere Inputs and Outputs and for Elementary Flows

Case Study I—System Analysis of Biofuel-Based Electricity Generation Process

This example demonstrates the application of a systems approach in assessing the merits of biofuels as a green process. The LCA generates a profile of all the steps involved in the process chain—both onsite and upstream—to provide quantitative information on potential impacts of an industrial activity (i.e., a system). Usually, this is done in terms of the released emissions (i.e., burdens), using a linear model. It takes into account the emission factors of all the known pollutants, inventoried during controlled analysis following standard monitoring protocols. These are then scaled by the volume of the industrial activity to provide their actual burdens. Also, in the case that LCA data are available for multiple similar installations, their respective operational performances can be benchmarked and links between operational efficiency and environmental impacts can be established.[9] A number of LCA studies available in the literature compare the environmental impacts of energy production (heat and/or electricity) from co-firing different biofuels in an existing coal-fired power plant, showing their overall greenhouse gas benefits. These cover the use of agricultural residues such as straw and residual wood, short rotation coppiced (SRC) wood,[10] and perennial rhizomatous grasses.[11,12] A more recent study quantifies the airborne emissions from different biomass-based electricity production systems using different technologies, feedstocks, and scales in order to establish the extent to which offsite emissions may contribute to overall environmental impact.[13]

In LCA, the emission factors are adjusted according to the pollution abatement technologies used in the industry to compensate for the release of acidic gases, although they do not reflect the fate of the emissions once they are out of the stack. Thus, this approach remains capable of providing realistic emission scenarios as long as the fate of the released emissions is not altered significantly by the dispersion and chemical transformation in the surrounding media (air, water, or soil). Whereas it allows successful prediction of greenhouse gas emissions in a fairly straightforward manner (assuming minimal phase alterations), the modeling of the gas–particle interactions leading to quantification of total particulate matter (PM) loading is far from complete. For example, the PM emissions calculated in the LCA from a biofuel combustion plant represent mainly the dust emissions from fly ash.[14] Any additional aerosols generated from gas-phase interactions of the resulting emissions, either during biofuel cultivation or combustion, would not be adequately quantified within this approach.

This case study utilizes the power of LCA as a diagnostic tool to track the pollutants and carbon emissions over the whole life cycle and mainly focuses on feasible management options for mitigating secondary aerosol generation potential from photochemical neutralization of the acidic emissions with ammonia using the following precursor chemistry[15]:

$$NH_{3(g)} + HCl_{(g)} \leftrightarrow NH^{+}_{4(aq)} + Cl^{-}_{(aq)}$$

A cradle-to-gate system is applied to all the energy systems modeled in this study, accounting for all the relevant flows involved in the extraction of resources (renewable/non-renewable) and cultivation of biofuels leading up to production of the required amount of energy outputs. As shown in Figure 2, the system comprises a series of foreground and background activities. The foreground activities are considered as the focal point of the system. Shown in the central part as shaded region in the figure, it involves storage and preprocessing of the fuel and its combustion to produce electricity. The background activities primarily include the cultivation and harvesting of the biofuel, production of required chemicals, and their transport to the power plant. The other end of the process chain accounts for the disposal of wastes generated. The atmospheric emissions from all these stages have been accounted for in the models.

Electricity production from different renewable biofuel sources has been modeled using scenario analysis. Representative biofuel options currently feasible have been considered. The analysis in this study is based on the functional unit defined as "1 terajoule (TJ) electricity produced from biomass and delivered to the grid." It is achieved by using available LCI data for a 50-MW electricity steam turbine/back pressure cogeneration plant firing solid biomass.[16] It is important to note that, in this study, the modeled system has not been credited for the cogenerated heat in the process. The following five different electricity production scenarios, representative of the technology for 2010 (base scenarios), have been considered, each using different types of biofuels:

- *Scenario A*: Perennial rhizomatous grass (*Miscanthus giganteas*).
- *Scenario B*: SRC chips.
- *Scenario C*: Residual/waste wood.
- *Scenario D*: SRC chips–grass blend (by energy); SRC chips (80%) and perennial rhizomatous grass (20%).
- *Scenario E*: Waste wood–grass blend (by energy); waste wood (80%) and perennial rhizomatous grass (20%).

In scenarios D and E, a fuel mix of perennial grass and wood in 1:4 ratio (by energy) has been considered. This is meant to improve the combustion quality and minimize excessive atmospheric emissions. In all the base scenarios, the biofuels have been assumed to be sourced locally (50 km distance to the combustion plant) and transported from their origin to the energy production site using 40-ton payload trucks. This is mainly aimed to investigate potential local air quality degradation from interactions of emissions from the power plant and the cultivation sites.

The atmospheric burdens for almost all the base scenarios (A–E) are dominated by pollutant emissions from the power plant (Figure 3). Overall, there is no clear winner among the scenarios. For example, scenarios C and E (waste wood) are best for CO_2, NH_3, non-methylated volatile organic carbons (NMVOCs), and CH_4, and scenario B (SRC chips) has the lowest HCl emissions. Scenario A (miscanthus) is best for N_2O and PM; however, it is worst for HCl and SO_2. For both miscanthus and SRC wood (scenarios A, B, and D), only biomass cultivation is considered to be the main source of NH_3 release to the local environment. However, it can be noted that a considerable amount of CO_2 is emitted during biomass production, transport, storage, and drying processes for these scenarios, which are mainly associated with the use of fossil-based energy sources in these stages. It has been reported that the forest logging operations involved in harvesting SRC wood contribute to significant atmospheric emissions

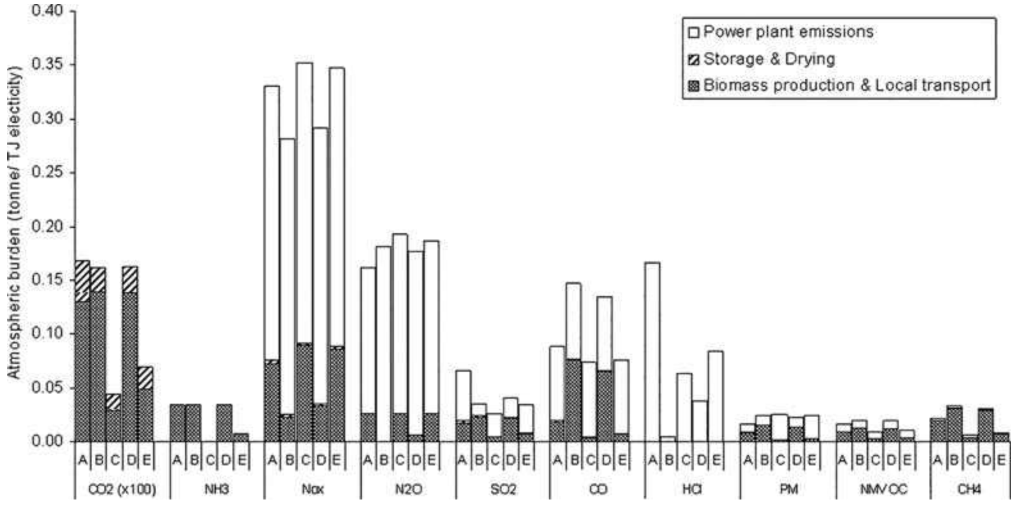

FIGURE 3 Environmental burdens of atmospheric emissions for base scenarios A–E.
Source: Tiwary and Colls.[3]

of CO_2, CO, NMVOCs, and PM due to fuel, chainsaw, and hydraulic oil consumption by heavy-duty diesel engine vehicles (Athanassiadis, 2000). This is reflected for the base scenarios B and D whose emissions of these pollutants from the "biomass production and local transport" stage are much higher compared with the rest of the scenarios. In case of waste wood, no mechanical chipping was assumed to be involved and hence the corresponding emissions from scenarios C and E have been relatively much lower. However, the power plant loadings of NO_x, SO_2, HCl, and PM in these two scenarios are found to be much higher than in scenarios B and D. This could be due to their incomplete combustion, which has been reported in earlier studies to result in highly variable emissions.[17,18]

Emissions of CO and NO_x per terajoule electricity output from power plant alone show comparable values for all the base scenarios but on a life cycle basis, that is, including the biofuel sourcing and storage stages, waste wood (scenarios C and E) seems to have up to 25% higher NO_x burdens, whereas SRC wood (scenarios B and D) seems to have up to 100% higher CO burdens. The corresponding emissions of SO_2 and HCl from miscanthus plant (scenario A) are higher by as much as 120% and 350%, respectively, compared with the rest of the scenarios. Therefore, scenario A poses the maximum likelihood of secondary aerosol generation potential through interactions of the acidic gas emissions from the power plant with the ammonia released from nearby harvest fields. On the other hand, SRC wood combustion plant (scenario B) has much lower HCl emissions (<5 kg T/J electricity) and, therefore, despite having considerable contributions to NH_3 release from the harvesting stage, its secondary aerosol generation potential is over 35-fold lower. Results indicate that co-firing waste wood sourced locally (scenarios C and E) would have the least secondary aerosol generation potential from photochemical neutralization, despite having higher HCl loadings than SRC wood, as it shows negligible NH_3 emissions over its fuel life cycle. Nevertheless, this is balanced by higher direct PM releases and life cycle NO_x releases from waste wood combustion. Although in this study heavy metals have not been included in the analysis owing to limited information, separate studies have reported wood combustion to be enhancing emissions of heavy metals.[19,20] The latter highlights additional air quality problems associated with large-scale implementation of wood-burning installations in the future.

The LCA model offers the flexibility to assess reduction in aerosol formation from different mitigation options, both for material (and cost) and energy, which is an invaluable screening exercise in order to come up with a viable and cost-effective management solution. For example, in this case study, the following three mitigation measures have been assessed.

Biomass Gasification and Direct Firing

Gasification technology is considered to provide efficient and clean power generation from biomass.[21] In this study, gasification of three different types of biomass (miscanthus, SRC, and waste wood) through air injection into the fuel in a circulating fluidized bed has been considered. The synthesis gas generated is compressed and injected into the combustion chamber of a cogeneration plant to produce steam that subsequently drives a turbine. As in the base scenarios, the system has not been credited for the cogenerated heat in the process for consistency.

Relative changes in the environmental burdens from application of biomass integrated gasification/combined cycle technology have been estimated with reference to the power plant emissions from the base scenarios (Figure 4). Results suggest significant reductions (up to 100% in some cases) in the emissions of acidic gases in the direct vicinity of the power plant. This is mainly due to much lower release of HCl and SO_2 from the plant for all scenarios considered. Likewise, PM emission in the foreground is also reduced as a consequence of gasification. In addition, N_2O emission is also lowered in all cases, whereas little change is observed in NO_x emission, except for a prominent decrease in the case of residual waste wood combustion (scenario C). However, while achieving the significant reduction in acidic gas burdens, this approach apparently increases end-of-pipe emissions of CH_4 and CO. Both these pollutants are produced during gasification of the biofuel, and their atmospheric emissions are associated with unintended (fugitive) release from the gasifier plant.[22] The main consideration for no obvious relative change (%) in

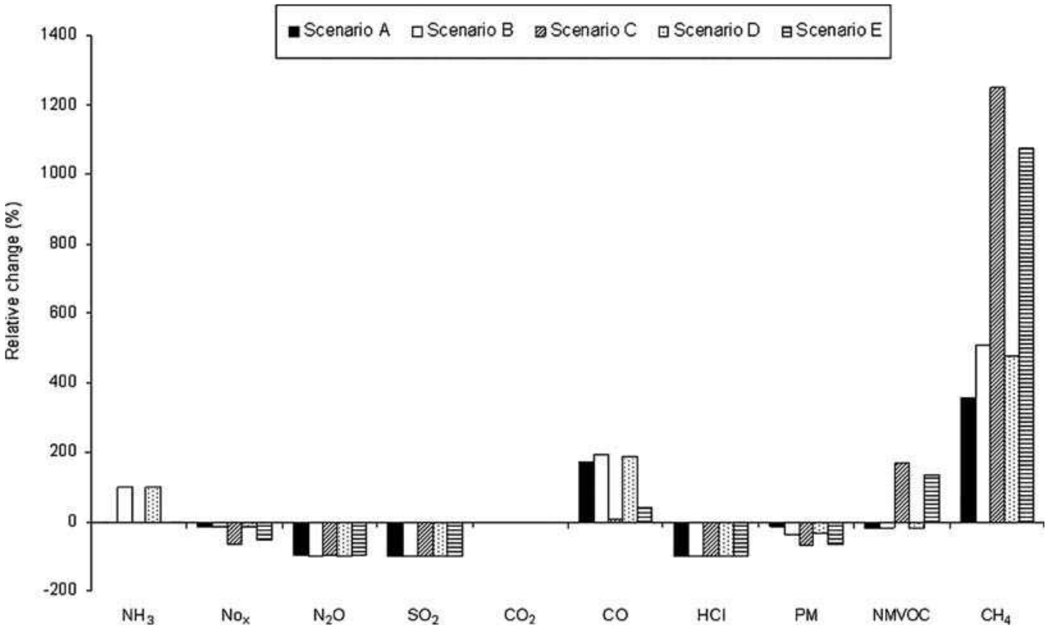

FIGURE 4 Relative change in environmental burdens by application of gasification option to base scenarios A–E.
Source: Tiwary and Colls.[3]

CO_2 emission in gasification options relative to base case is due to offsetting of the emissions enhancement from processing of additional feedstock with the increased efficiency in combustion of the gasified fuel. The increase in CH_4 emissions for scenarios A, B, and D ranges between 200% and 500%; however, for scenarios C and E, it appears to be exceptionally high (up to 1,250%). The latter two scenarios also show increased emissions of NMVOCs. As both CH_4 and NMVOCs contribute to global warming, the two scenarios (C and E) do not seem to present sustainable alternatives. Excessive release of methane could be potentially minimized by optimizing the gasification temperature and circulating the fugitive methane into the combustion process.[22] It is also noticed that power production from SRC wood biomass from this approach leads to production of NH_3, which makes scenarios B and D unviable too. Therefore, although gasification for scenario A enhances its CO emissions (up to 200% increase) relative to the corresponding base scenario, it presents the best option for reducing secondary aerosol generation potential.

Delaying the Harvest of Perennial Energy Crop

Delaying the harvest of miscanthus from late autumn (current common practice) to early spring has been reported to foster prolonged soil–vegetation interactions by allowing the stems to dry during the winter months. In effect, it allows for leaching of a substantial portion of the ash, chlorine, and potassium contents from the biomass through roots,[12] thereby reducing the adverse environmental impacts later during combustion. Delaying the harvest also allows for extended recycling of nutrients by their rhizome systems, which enables them to have low demand for nutrient inputs, especially for nitrogen. This lowers their fertilization needs. However, it has been reported that this delaying approach inadvertently leads to substantial yield losses (of up to 35%) and reduction in calorific value of the biofuel. The latter entails additional emissions from extra biomass combustion for the same energy throughput.

This study used the data provided by recent studies on reduction in dry matter yield, water content, and concentrations of specific toxic components, including ash, nitrogen, chlorine, and sulfur, as a consequence of delaying the harvest.[12] It mainly focused on assessing the influence of delaying the harvest of the biomass and its linked effects on storage and drying, whereas additional effects of topography and soil properties for differences in site locations could not be quantified at this stage. The ideal late harvest is recommended at a water content of 20% or less, as this minimizes the cost of harvesting and drying while keeping a high biomass quality of the crop. For the purpose of estimating the environmental burdens from drying of harvested biomass during storage, we have used literature data (Table 2).

Although the emission per unit biomass consumption is reduced in this manner, the resulting biofuel has deteriorated in calorific value. The requirement of additional biomass supply to compensate the lost calorific value of the fuel leads to considerable increase in the life cycle environmental burdens for NH_3, N_2O, and CO and slight increments for SO_2, PM, NMVOCs, and CH_4 (Figure 5). Delaying the harvest leads to reduction in the water content of the biomass. Interestingly, this allows for mitigating CO_2 emissions at two stages of the fuel life cycle: (1) reduced demands for fossil fuel in the storage and drying process and (2) increased energy conversion efficiency from enhanced combustion in the power plant. However, despite offering some reduction in emissions of CO_2, NO_x, and HCl, this technique does not seem to provide a definitive and reliable option to mitigate the secondary aerosol generation potential from chemical interactions of the precursor gases.

TABLE 2 Model Parameters for Technical Drying of Energy Crop in Storage

Harvest Type	Energy Use in Drying	Water Content
Autumn harvest (>40 wt.%)[a]	68 kWh heating oil + 9.7 kWh electricity per ton of water removal	15 wt.%[b]
Early winter harvest (20–40 wt.%)[a]	144 kWh electricity per ton of water removal	15 wt.%[b]
Late winter/early spring harvest (<20 wt.%)[a]	No drying is carried out	<20 wt.%[b]

Source: Tiwary and Colls.[3]

Increasing the Separation of Biomass Plant from Harvest Site (Importing the Biofuel)

As preliminary results from base scenarios (as shown in Figure 3) suggest, ammonia emissions from harvesting miscanthus and SRC wood are high. Assuming that the harvest sites in the new locations would be remotely rural with low acidic releases to the ambient air, a third possible mitigation option of reducing the impact of ammonia by displacing the cultivation sites has been considered. This option may also become necessary in the case of an eventual shift to larger production and use of biomass, as the EU is going to need large areas of agricultural land for its production.[23] In the United Kingdom alone, an estimated 125,000 ha of energy cropping would be required by 2010 to meet the government's target for electricity generation from biomass (DEFRA, 2001). In such situations, importing biomass from other European countries that offer favorable climatic conditions, mainly higher solar radiation and soil water contents, has been recommended as a more sustainable option.[24]

As considering all probable transportation means to move biofuels from one country to another gives rise to numerous possible scenarios,[25] some practical assumptions, based on the geographical location of the electricity generation site (here assumed to be in South England), have been made. Each option includes transport from production sites to a central gathering point, followed by a combination of international transport and local transport to a storage location near the generation plant. It is noteworthy that this assessment does not account for the additional emissions from the storage requirements of the biofuel crops, either in the country of their origin or during their long-haul transport.

As shown in Figure 6, the corresponding transport-related emissions for all the pollutants considered from this transport chain are much higher, which makes it less favorable from environmental perspectives. To a larger extent, this is solely dependent on the assumption used in this study to source miscanthus from land-locked Czech Republic and transport it overland across the stretch of European mainland on a freight train to the nearest ferry port. Had the biofuel been sourced from a coastal country and shipped directly to a port, the emission regimes would be very different. Therefore, one message that comes out of this study is that additional emissions from transporting the biofuel are very much site dependent, and this can be optimized.

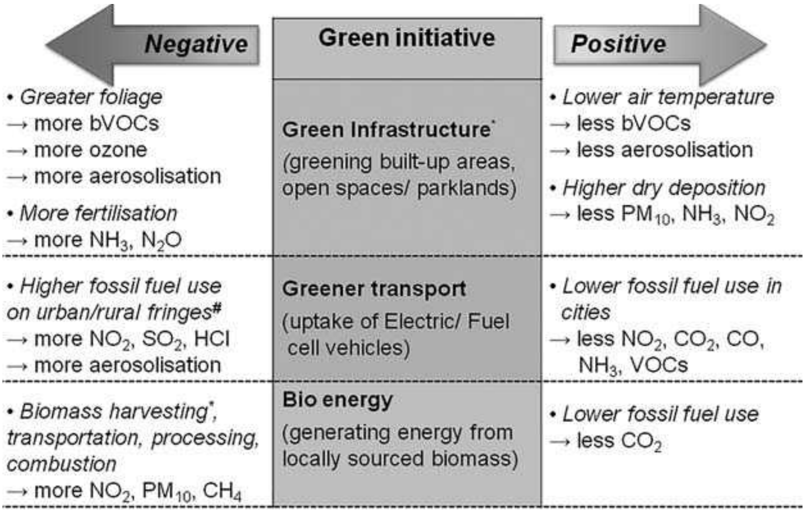
Case Study II—System Analysis of a Project Integrating Green Initiatives

This section demonstrates the application of a systems approach in assessing the environmental impacts of low-carbon urban planning as a green project. Interactions between a suite of cross-sectoral green initiatives have been considered for two scenarios—status quo and aggressive, including decarbonizing of road transport, decentralizing energy production through biomass plants, and increasing the urban green vegetation cover. The study utilized real and projected information for the North East region of the United Kingdom to assess air quality implications on a systems scale. Using a geo-spatial analysis framework, it captures both the direct and the second-order environmental impacts arising from the interplay between different anthropogenic and biogenic components of green initiatives to ensure sustainable development through amelioration of local (and regional) air quality while minimizing climate change impacts. The assessment is mainly confined to pollutants that are currently of particular concern, including both primary and secondary PM (considered here as the combined pool of PM_{10}, $PM_{2.5}$, i.e., particles with aerodynamic diameters <10 and <2.5 μm, respectively), ozone (O_3) and nitrogen dioxide (NO_2).

Cross-Sectoral Assessment Framework for a Green Project

A systems scale assessment framework, encompassing plausible combinations of emerging green initiatives that will be implemented over the next 10–20 years (around 2020/2030 horizons) is presented in Figure 7. It draws together the evidence-base from available literature on cross-disciplinary climate change and urban sustainability research, applying a cross-sectoral approach to three broad categories of green initiatives, including (a) use of vegetation, (b) low-emission personal transport, and (c) renewable energy from biomass. Each initiative (shown in boldface text) is characterized by a set of positive and negative environmental impacts (shown in italicized text) with their resulting air quality implications. These depend on the activities involved and their influence on either formation or removal of air pollutants. This was considered as an essential first step toward scoping the systems framework of landscape interactions between biogenic emissions (primarily biogenic volatile organics, bVOCs) and the anthropogenic emissions from fossil fuel combustion (mainly from transport and energy sources) in



Negative	**Green initiative**	**Positive**
• *Greater foliage* → more bVOCs → more ozone → more aerosolisation • *More fertilisation* → more NH_3, N_2O	**Green Infrastructure*** (greening built-up areas, open spaces/ parklands)	• *Lower air temperature* → less bVOCs → less aerosolisation • *Higher dry deposition* → less PM_{10}, NH_3, NO_2
• *Higher fossil fuel use on urban/rural fringes*$^{\#}$ → more NO_2, SO_2, HCl → more aerosolisation	**Greener transport** (uptake of Electric/ Fuel cell vehicles)	• *Lower fossil fuel use in cities* → less NO_2, CO_2, CO, NH_3, VOCs
• *Biomass harvesting***, transportation, processing, combustion* → more NO_2, PM_{10}, CH_4	**Bio energy** (generating energy from locally sourced biomass)	• *Lower fossil fuel use* → less CO_2

FIGURE 7 Theoretical framework illustrating the positive and negative implications for air quality from emerging green initiatives (2020/2030 horizons).
Source: Tiwary et al.[26]

future Green Cities. This step incorporates both the positive and the negative effects arising from such interactions, in order to assess the overall sustainability implications of the green initiatives.

Uptake of greener transportation technologies, through a combination of low-emitting internal combustion and electric/fuel-cell traction, is projected to reduce primary emissions of CO, NO_x and PM from vehicle use. However, such initiatives can be considered green only to the extent that the source of energy supply is renewable. Fuel cell-powered vehicles may still be associated with pollutant emissions in peri-urban regions if the hydrogen is generated by fossil fuel sources, which would contribute to additional aerosols from atmospheric reactions of SO_2, NO_x, NH_3 and VOCs, originating from the refineries. Incorporating biomass into the future energy mix is meant to keep the decarbonized energy generation affordable but at the cost of air quality. Systems-level assessments of different fuel mixes have found increased N_2O, NH_3 and primary PM from the harvest phase and enhanced NO_x, CH_4 and secondary aerosol (SA) formation potentials from the combustion phase.

The effect of land cover modification on ambient temperature is another key driver to energy demand (for cooling/heating) and corresponding pollutant emissions (both in terms of primary components from associated activities as well as the photochemical precursors, i.e., chemicals that lead to tropospheric ozone production). While climate change effects are projected to contribute to aggravation of the urban heat island effects (and an overall increase in ambient temperature), lower air temperatures (resulting from vegetation cover modifications and retrofitting initiatives to enhance evapotranspiration and albedo-effects) have shown reduction in cooling electricity demand. The implications appear to be varied at global levels depending on the green initiatives pursued and more deterministic scenario modeling would be required to inform the outcomes.

Conclusion

This chapter introduced some basic concepts of system analysis of “greener” processes and projects, specifically in the context of holistic environmental management. It explained the implementation of transboundary material flows and life cycle thinking in terms of ensuring global sustainability, by avoiding unacceptable implications for interventions in wider process chains—both in the supply streams and in the waste streams.

It is noted that uncertainty within systems analysis can be neither neglected nor simply addressed. This is mainly because the information about uncertainty in science-driven data cannot be fully captured within the inventoried databases. This chapter also provides an overview of different sources of uncertainly and the available methods to resolve them. A significant share of this uncertainty arises in practice, based on the relationship between the data and the intended reality being modeled. Software and algorithms should be applied rigorously by researchers on a breadth of real-world case studies in order to closely identify which parameters are the major sources of uncertainty in LCA results.

Two example case studies illustrate the role of LCA and geo-spatial approaches in assessing the greenhouse gases and air quality emissions across system boundaries, respectively, for a process and a project. It shows the merit of this approach in revealing the hotspots contributing to potential environmental impacts while devising green solutions viable at systems scale. Some discussion is presented to develop possible mitigation for transboundary environmental management of the problem, including all associated activities in the process chain. Overall, this chapter provides insight into the role of systems approach in efficient environmental management, through assessment of the “true green credentials” of a process or a project in terms of its greenhouse gas emissions, ecotoxicity, air pollution, etc. within the system.

Green Products: Production

Puangrat Kajitvichyanukul,
Jirapat Ananpattarachai,
and Apichon Watcharenwong

Introduction

Since 1990, there has been a wide concern for environmental product development and how to achieve green products. Products affect the environment in several ways. Once a product has been designed and generated from the manufacturing process, its environmental attributes are largely fixed along its life cycle. Environmental requirements have been made by several attempts to ultimately obtain environmentally friendly products. For example, design processes are aimed to minimize raw material and energy consumption, waste generation, health and safety risk, and ecological degradation. Several terminologies of product design integrating environmental concerns were introduced in the late 1990s. These terms include design for the environment,[1–3] life cycle analysis,[2] green chemistry,[4–6] pollution prevention,[7–10] environmentally conscious manufacturing,[11,12] and sustainable development.[13] The aggregation of these terms is called "industrial ecology."[14] In 1996, the Office of Pollution Prevention and Toxics of the U.S. Environmental Protection Agency (EPA) set up two programs, Design for the Environment (DfE) and green chemistry, under the industrial ecology scope. The DfE has been defined as follows: "Design for environment is the systematic process by which firms design products and processes in an environmentally conscious way."[15] The broad definition of green chemistry has been also provided as follows: "Green chemistry is the design of chemical products and processes that reduce or eliminate the use and generation of hazardous substances and seek to reduce and prevent pollution at source."[16] Since 1995, green chemistry has played an important role in green product development, especially chemical products. Nowadays, green chemistry has become an important tool in achieving sustainable development. The implementation of green chemistry—the design of chemical products and processes that reduce or eliminate the use and generation of hazardous substances—has become essential for increasing the standard of human living without having a negative impact on the environment. In addition, green chemistry provides solutions to critical global challenges such as climate change, sustainable agriculture, energy, toxics in the environment, and depletion of natural resources.

In this entry, the concepts in green chemistry for producing green products, especially involving the chemical industrial process, are reviewed. It is noted that chemical products are largely created using energy-intensive processes and non-renewable, petroleum-based resources as feedstocks.[17] Many of these industrial processes use hazardous materials or generate wastes that are harmful to human health and the environment. Thus, introducing green chemistry concepts through these chemical products is a particularly good example of developments in this field that may inspire future sustainable development.

Principles of Green Chemistry

The principles of green chemistry have been refined from a diverse set of practices and emerging research. The EPA defines green chemistry as the use of chemistry for pollution prevention at the molecular level.[18] The mission of green chemistry is to promote innovative chemical technologies that reduce or eliminate the use or generation of hazardous substances in the design, manufacture, and use of chemical products.[19] They address alternative starting and target materials; alternative reagents, solvents, and catalysts; and improved processes and process control in producing chemical products. Green chemistry consists of chemicals and chemical processes designed to reduce or eliminate negative environmental impacts.

The principles of green chemistry were originally published by Pual Anastas and John Warner in *Green Chemistry: Theory and Practice* (Oxford University Press: New York, 1998). The 12 principles of green chemistry provide a road map to implement green chemistry. Following Anatas and Warner,[20] the principles are as follows:

1. *Prevention.* It is better to prevent waste than to treat or clean up waste after it has been created.
2. *Atom economy.* Synthetic methods should be designed to maximize the incorporation of all materials used in the process into the final product.
3. *Less hazardous chemical syntheses.* Wherever practicable, synthetic methods should be designed to use and generate substances that possess little or no toxicity to human health and the environment.
4. *Designing safer chemicals.* Chemical products should be designed to effect their desired function while minimizing their toxicity.
5. *Safer solvents and auxiliaries.* The use of auxiliary substances (e.g., solvents, separation agents) should be made unnecessary wherever possible and innocuous when used.
6. *Design for energy efficiency.* Energy requirements of chemical processes should be recognized for their environmental and economic impacts and should be minimized. If possible, synthetic methods should be conducted at ambient temperature and pressure.
7. *Use of renewable feedstocks.* A raw material or feedstock should be renewable rather than depleting whenever technically and economically practicable.
8. *Reduce derivatives.* Unnecessary derivatization (use of blocking groups, protection/deprotection, temporary modification of physical/chemical processes) should be minimized or avoided if possible because such steps require additional reagents and can generate waste.
9. *Catalysis.* Catalytic reagents (as selective as possible) are superior to stoichiometric reagents.
10. *Design for degradation.* Chemical products should be designed so that at the end of their function, they break down into innocuous degradation products and do not persist in the environment.
11. *Real-time analysis for pollution prevention.* Analytical methodologies need to be further developed to allow for real-time, in-process monitoring and control before the formation of hazardous substances.
12. *Inherently safer chemistry for accident prevention.* Substances and the form of a substance used in a chemical process should be chosen to minimize the potential for chemical accidents, including releases, explosions, and fires.

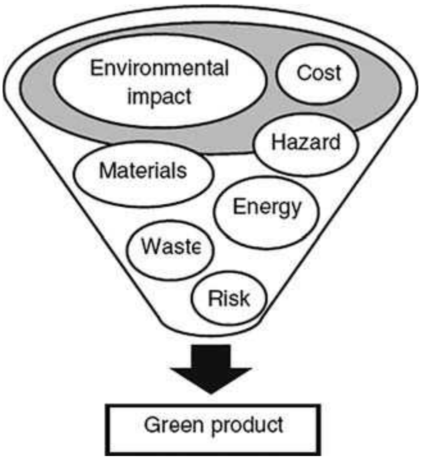

FIGURE 1 Objectives of green chemistry.

Green chemistry addresses hazards, whether physical (flammability, explosivity), toxicological (carcinogenicity, endocrine disruption), or global (ozone depletion, climate change) as an inherent property of a molecule.[21] Green chemistry also addresses all aspects of chemical designing manufacturing.[22,23] The four general objectives derived from the green chemical philosophy are as follows:[24]

- Reduction of use and generation of polluting chemicals in the chemical process
- Reduction of use of dangerous chemicals in the chemical process
- Reduction of the harmful effects of final products.
- Reduction of the use of exhaustible feedstock materials and of scarce resources

The objectives of green chemistry are shown in Figure 1. These concepts lead the movement on the front lines of research, education, and incentive and research programs of the EPA, National Science Foundation, U.S. Department of Energy, U.S. Department of Agriculture, and international organizations worldwide.

Approaching Sustainability through Principles

During the latter half of the 20th century, an exponentially increasing number of environmental regulations were enacted in developed countries. In the United States, the Clean Air Act of 1970, the Clean Water Act of 1972, the Resource Conservation and Recovery Act of 1976, and their amendments, have set the fundamental regulations covering air, water, and hazardous waste pollutants, respectively. In 2001, the EPA promulgated pharmaceutical maximum achievable control technology standards that regulate 187 hazardous air pollutants, including solvents commonly used in the pharmaceutical industry. In Europe, the European Union has a set of common rules for permitting and controlling industrial installations in the Integrated Pollution Prevention and Control (IPPC) Directive of 1996.[25,26] The IPPC Directive is about minimizing pollution from industrial sources throughout the European Union. In 2007, REACH, the new Regulation on Registration, Evaluation, Authorization, and Restriction of Chemicals, was launched and considered a tool for green chemistry. This regulation improves the former legislative framework on chemicals of the European Union.[27] One of the main aims of REACH is to improve the protection of human health and the environment from the risks that can be posed by chemicals. The major concern of REACH is chemical safety and in that it is one of the green chemistry metrics.[28]

As environmental regulation has become more stringent owing to climate concern, industries have to look for innovative ways to obtain purer final products using a reduced amount of raw materials and energy and generating a smaller amount of waste. Concepts of green chemistry have become a solution for the industrial requirement. Many "green" terminologies have emerged and been defined for use in environmental product development. Green engineering has been defined as follows: "Green engineering is the design, commercialization and use of processes that are feasible and economic, reduce the generation of pollution at the source, and minimize the risk to human health and the environment."[16] Green technology is also widely used as it involves using science to create technologies that conserve natural resources and lessen the human impact on the environment.

Green chemistry, green engineering, and green technology have been focused on and proposed by several scientists and researchers worldwide to respond to the need of industry. Collaboration among industries, academic institutes, and government agencies were initiated to push green chemistry to the manufacturing process. In 2003, the collaboration of industry, the EPA, and the U.S. Department of Commerce's Manufacturing Extension Partnership, called the Green Suppliers Network, was officially launched in the automotive industry, and is currently in the aerospace, pharmaceutical and health-care, and office furniture industries. The established outcomes of this program are the effective processes and products with higher profits while minimizing environmental impact. In 2005, the Committee on Grand Challenges for Sustainability in the Chemical Industry arranged a workshop on identifying research needs to enable the industry to develop products and processes for achieving the goal of sustainability. In addition, the pharmaceutical industry and the American Chemical Society Green Chemistry Institute collaborated to encourage innovation while catalyzing the integration of green chemistry and green engineering in the pharmaceutical industry. To support the collaboration in green chemistry, the Green Chemistry Research and Development Act of 2005[29] was proposed and passed by the House Science Committee in April 2005. This bill promotes green chemistry by authorizing a coordinated green chemistry research and development program.

The emergence of these collaborations is the driving force behind the development of green business. It is reported that green chemistry is drawing many investors from different companies to invest in producing green product lines. For example, Wilmar International, a Singaporean company, plans to launch production of derivatives of glycerol through a green chemistry process. Mitsubishi Chemical and Thai Company PTT plc are jointly conducting a study focused on the production of biosuccinic acid and biopolybutylene succinate. Moreover, the Japanese trading house Mitsui & Co. and Toyota Tsusho are also involved in green chemistry investments in the Asian regions.[30]

Nowadays, concepts of green chemistry have widely spread to the manufacturing process with the understaning that it is a superior, innovative chemistry that is cost-effective and has minimal impact on the environment. The applications of the concepts through the manufacturing process are shown in Figure 2. The types of products and processes adopting green chemistry principles include medicine, food, and energy production; packaging materials; household and commercial cleaning products; electronics and automotive chemicals; and a wide range of consumer goods.[31]

Advances in Green Chemistry to Produce Green Products

Catalysts

Catalysts play a significant role in green chemistry by decreasing energy requirements, increasing selectivity, and permitting the use of less hazardous reaction conditions. The first example in applying green chemistry to the catalytic process is the synthesis of maleic anhydride.[32–34] Originally, the benzene process was used; however, it was substituted by the butane process for the following reasons:

- The loss of two carbon atoms (starting from benzene) is avoided.
- Using butane, the by-products are carbon oxides and a small amount of acetic acid. With benzene, several byproducts are formed.
- The toxicity aspects related to the use of benzene are avoided, reducing costs related to safety systems and benzene handling.

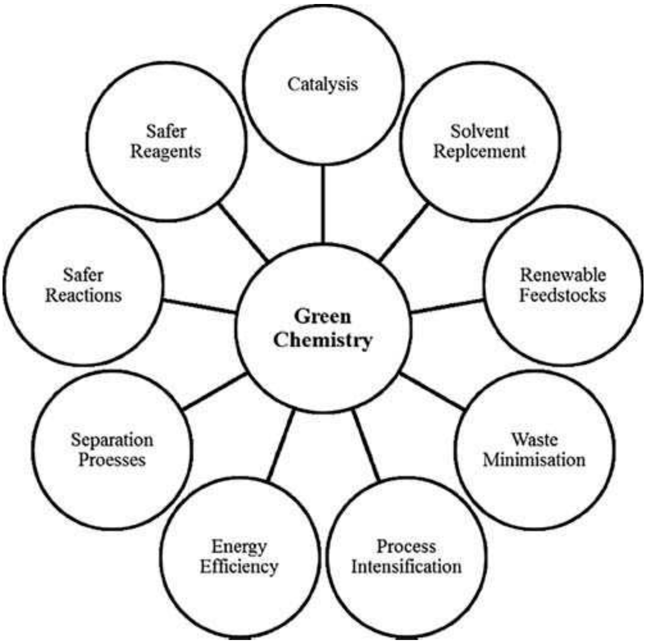

FIGURE 2 Applications of concepts through the manufacturing process.

The benefits of using the butane process following the green chemistry concept are as follows: 1) use of non-toxic reactants; 2) improved atom economy; 3) a complex multistep transformation (the reaction is a 14 e^- oxidation, with abstraction of 8 H atoms from the butane molecule and insertion of 3 O atoms) is realized in one single step, without using solvents; and 4) waste formation is minimized.

Synthesizing adipic acid directly from cyclohexene using an aqueous 30% hydrogen peroxide solution, a catalytic amount of Na_2WO_4, and a phase-transfer catalyst is another green chemistry application.[35] Previously, adipic acid was derived from the reduction of benzene to cyclohexene under high temperature and pressure resulting in nitrous oxide, a greenhouse gas and ozone-depleting substance, as an undesirable product. Using the new process, adipic acid is produced with a high yield without the use of organic solvents and without the generation of nitrous oxide.[36] Using the concept of on-site production is another alternative way in green chemistry that is already used in some new production processes to avoid the storage of toxic or dangerous chemicals. The on-site production of HCN in the manufacturing process of toluene diisocyanate has already been implemented. This was made possible by the combined development of new catalysts and new reactor engineering solutions that allow an economic production even in a small size plant.[34]

Nowadays, biocatalysts, both isolated-enzyme and whole-cell systems, are increasingly being used to assist in synthetic routes to complex molecules. The biggest role for biocatalysis is found in the pharmaceutical sector.[37–39] Biocatalysis is one of the greenest technologies for the synthesis of chiral molecules due to exquisite regioselectivity and stereoselectivity in water under mild conditions. Recently, Tao and Xu[40] reviewed the development of novel biocatalytic pharmaceutical processes to replace chemical routes with poorer process efficiency and higher manufacturing costs. It is emphasized that to empower the green chemistry feature of biocatalysis, it is essential to integrate enzymatic transformations strategically into chemical transformations at the retrosynthetic level. Enzymatic catalysis can provide a new dimension for route redesign to meet both the process and green chemistry metrics. It is underscored that recent advances in large-scale DNA sequencing and enzyme-directed evolution rendered biocatalysis a much more practical technology to provide green chemistry solutions for the industrial production of chemicals.

Nanomaterials

In the search for environmentally friendly materials, recently green chemistry has shown its role in nanomaterials, especially in the preparation and synthesizing steps. A solvent is considered an important chemical that is widely used in synthesizing nanomaterials. It is an important parameter that determines the green nature of the nanoparticle catalysis, regarding the fact that the solvent accounts for 50% of the greenhouse gas emissions during post-treatment and 60% of the energy used in pharmaceutical processes.[41] Recently, there have been several attempts to use other chemicals to substitute these harmful reducing agents and solvents to obtain engineered nanoparticles. For solvent substitution, ionic liquids are very promising replacements for the traditional volatile organic solvents owing to their high mobility, low melting points, negligible vapor pressure, thermal stability, low toxicity, large electrochemical window, non-flammability, and ability to dissolve a variety of chemicals.[42–45] Ionic liquids are versatile solvents that retain their liquid states over a wide range of conditions, but have a minimal vapor pressure. They also possess interesting properties that are a combination of the characteristics of water and organic solvents. The use of ionic liquids as stabilizers for nanoparticles was first demonstrated by Dupont et al. in 2002.[46] Ionic liquids can be functionalized and attached with weak coordination groups to further enhance the stability as well as catalytic activity in the synthesis reaction. Zhao et al.[47] used nitrile- functionalized ionic liquids to protect Pd nanoparticles with an average diameter of 5 nm. The resulting Pd nanoparticles were excellent recyclable catalysts, and an optimum balance between stability and reactivity can be achieved. Ionic liquids widely used in nanomaterial synthesis are BMI(BF_4), BMI(NTf_2), BMI(PF_6), and C_2OHMIM(BF_4). Nowadays, various nanostructured materials, such as iridium,[46] palladium,[47,48] gold,[49] tellurium,[50] TiO_2,[51,52] ZnO,[53–56] and CoPt[57] have been synthesized in ionic liquids.

One of the concerns in the process of preparation of nanomaterials is the choice of the reducing agent. zIt is reported in the literature that in the preparation of super-paramagnetic nanoparticles, the reductants used to date include hydrazine,[58] sodium borohydride,[59] carbon monoxide,[60] and dimethylformamide.[61] All of these are highly reactive chemicals and pose potential environmental and biological risks.[62] As appeared in recent literature reviews, many interesting methods are currently being applied to the green preparation of nanoparticles, called biosynthesis of nanoparticles by glucose,[62] starch,[63–65] plant leaf broth,[66] edible mushroom extract,[67] apiin,[68] and by latex of *Jatropha curcas*.[69] These biological extracts are used as reducing agents in the green synthesis of nanoparticles, especially in metal nanoparticle synthesis. Raveendran et al.[70] reported a completely "green" synthesis of Ag nanoparticles with sizes of 1–8 nm using starch as a capping agent and α-D-glucose as a reducing agent. Mallikarjuna and Varma[71] described a simple method for the shape-controlled synthesis of nanostructures (with size 2–15 nm) of noble metals such as Au, Ag, Pd, and Pt by microwave-assisted spontaneous reduction of noble metal salts using α-D-glucose, sucrose, and maltose in aqueous solution. Fructose, glucose, and sucrose were used as reducing and capping agents for the preparation of Au, Ag, Pd, Pt, and Au–Ag nanoparticles by heating to dryness for 2 h the solutions in a hot water bath.[72] The effect of two different sugars on the sizes and surface morphology for Ag nanoparticle synthesis was also reported by Filippo et al.[73] Furthermore, Nersisyan et al.[74] developed an effective way of preparing a nanosized (10–50 nm) colloidal dispersion of Ag using glucose as a reducing agent. Lu et al.[62] also reported a facile and green method to synthesize superparamagnetic Fe_3O_4 nanoparticles with α-D-glucose as the reductant, which is a mild, renewable, inexpensive, and non-toxic reducing agent, and without any additional stabilizer and dispersant.

Solvents

Solvents play an important role in chemical synthesis. Considering green chemistry requirements, water is an extremely attractive solvent choice. It is inexpensive and readily available, non-toxic, non-carcinogenic, and nonflammable. In addition, water is probably the least expensive among all available solvents.[75]

Besides water, supercritical fluids (SCFs) draw attention from chemists for their several commercial applications. These SCFs are gases that are compressed until their density approaches that of liquids. Compression can occur only above the "critical temperature" of the fluid, since at lower temperatures the fluid liquefies upon compression. Therefore, an SCF is a gas that displays some of the properties of a liquid. The advantages of using SCFs are related to the absence of toxic residues, the relatively low temperature needed for the extraction process, and their higher solvent power.[34] The SCFs are characterized by high diffusivity, low viscosity, and intermediate density. Among the SCFs, supercritical CO_2 (SC-CO_2) is the most widely used solvent in many applications. It is non-toxic, noncarcinogenic, and non-flammable. Oakes et al.[76] investigated the catalysis of the Diels–Alder reaction between *n*-butyl acrylate and cyclopentadiene in SC-CO_2. Scandium tris (trifluoromethanesulfonate) was selected as the Lewis acid catalyst. By varying the pressure of the solvent, a significant improvement over selectivity is achieved in conventional solvent. It was reported that rate enhancement was observed under SC-CO_2 conditions.

High boiling alcohols, including glycerol and polyethylene glycol, are also considered as "green solvents." They have recently attracted much attention as reaction media.[77,78] These high boiling alcohols are of low toxicity and volatility, and are biodegradable, non-expensive, and easily functionalized. These properties represent important environmentally benign characteristics. Glycerol is a natural product widely used as a cosmetic and food additive. Polyethylene glycol is also non-toxic and is widely used in the pharmaceutical,[79] semiconductor,[80] and food industries.[81]

Application of Green Chemistry in the Manufacturing Process

There are several ways to apply green chemistry to the manufacturing process for industries. The concepts can be applied through waste minimization, waste or material recycling, solvent selection, atom utilization, intensive processing, and clean synthesis. According to the Presidential Green Chemistry Challenge from the EPA, three basic methods are currently used in industrial processes:

1. Applications of greener synthetic pathways—Many green pathways for a new chemical product are widely used. It involves using a novel, green pathway to redesign the synthesis of an existing chemical product. The synthetic pathways include
   - Use greener feedstocks that are innocuous or renewable (e.g., biomass, natural oils)
   - Use novel reagents or catalysts, including biocatalysts and microorganisms
   - Apply natural processes, such as fermentation or biomimetic synthesis
   - Use atom-economical systems
   - Use convergent syntheses

An example of applying the synthetic pathway in the manufacturing process is from Dow and BASF, winners of the 2010 Greener Synthetic Pathways Award (EPA). Both companies have jointly developed a new route to make propylene oxide with hydrogen peroxide that eliminates most of the waste and greatly reduces water and energy use.

2. Use of greener reaction conditions—This application is mainly about improving conditions other than the overall design or redesign of a synthesis, including greener analytical methods. The greener reaction conditions include the following:
   - Substitute hazardous solvents with solvents that have a reduced impact on human health and the environment
   - Use solventless reaction conditions and solid-state reactions
   - Use novel processing methods
   - Eliminate energy- or material-intensive separation and purification steps
   - Improve energy efficiency, including reactions running closer to ambient conditions

A successful example of applying green reaction conditions is from Merck and Codexis. Both companies have developed a second-generation green synthesis of sitagliptin, the active ingredient in Januvia™, a treatment for type 2 diabetes. This collaboration has led to an enzymatic process that reduces waste, improves yield and safety, and eliminates the need for a metal catalyst. This work also received the 2010 Greener Reaction Conditions Award from the EPA.

3. Design of greener chemicals—Applications include the design of chemical products that are less hazardous than the products or technologies they replace. These chemical products are:
    - Less toxic than current products
    - Inherently safer with regard to accident potential
    - Recyclable or biodegradable after use
    - Safe for the atmosphere (e.g., do not deplete ozone or form smog)

An example of the design of green chemicals is spinosad. It is an environmentally safe pesticide but is not stable in water and therefore cannot be used to control mosquito larvae. Clarke, the winner of the 2010 Designing Greener Chemicals Award from the EPA, has developed a way to encapsulate spinosad in a plaster matrix, allowing it to be released slowly in water and provide effective control of mosquito larvae. This pesticide, Natular™, replaces organophosphates and other traditional, toxic pesticides and is approved for use in certified organic farming.

Conclusion

The concepts of green chemistry for producing green products and examples of green chemistry implementation in industrial processes have been discussed in this entry. It is known that many industrial processes use hazardous materials or generate wastes that are harmful to human health and the environment. Implementation of green chemistry to the design of chemical products and processes that reduce or eliminate the use and generation of hazardous substances has become essential to increase the standard of human living without the adverse effect on the environment. Using the green production system in the industry can gain the benefit of enabling chemical production that is more profitable, less wasteful, less damaging to the environment, and more socially acceptable. In this entry, the applications of green chemistry through green product production have been reviewed. The process of green products in industrial manufacturing can be applied through several green concepts, including waste minimization, waste or material recycling, solvent selection, atom utilization, intensive processing, and clean synthesis. The challenge for the industrial research and development sector is to develop products, processes, and services to improve the quality of life, the environment, and the industry competitiveness with the sustainable aspect toward the future. Recently, green chemistry has been implemented in several industrial products, including medicines, food, energy, packaging materials, household and commercial cleaning products, electronic and automotive chemicals, and a wide range of consumer goods. Biocatalysts, nanoparticles, and green solvents are the next challenge in green synthesis to produce high-quality merchandise to serve the need of consumers. Beyond green chemistry, green engineering and green technology have been focused on and proposed by several scientists and researchers worldwide. They are in the process of reinforcing steps to create cleaner production in industrial processes in the near future.
