The Revised Wind Erosion Equation (RWEQ) was later developed[75] to estimate erosion during a high wind event based upon assessments of soil moisture, aggregate size, crust cover, surface roughness, and crop residue characteristics. Although empirical, RWEQ was developed using field data and intended to predict real-time soil loss from a field of a known length while WEQ was developed using wind tunnel data and intended to estimate annual soil loss.

Wind Erosion Prediction System

Recent advances in computational power and in the understanding of the physical processes governing wind erosion have resulted in the advent of process-based wind erosion models. The WEPS was developed by USDA scientists to provide more accurate results across climatic zones and land management systems. The WEPS simulates, on a daily time scale, the fundamental processes involved in soil redistribution by wind.[68] The WEPS represents the computer implementation and integrations of several science-based submodels. The weather submodel uses historical statistical information of several weather parameters and stochastic techniques to develop likelihood-based weather scenarios for individual growing seasons. These weather scenarios drive processes in other submodels. The hydrology submodel uses inputs from the weather and other submodels to compute water content of various soil layers and at the soil surface. The management submodel simulates the primary anthropogenic actions that affect a field's susceptibility to wind erosion. These actions include cultural practices such as tillage, planting, harvesting, and irrigation. The soil submodel simulates soil temporal properties that affect the erodibility of the soil. This submodel uses information from the weather, hydrology, and management submodels. The crop submodel is a crop growth model that produces roots, leaves, stems, and reproductive tissues on a daily basis. This submodel is integral to the development of the canopy and stems that modify wind speeds near the surface and flat biomass that protect the surface. The decomposition submodel simulates the microbial breakdown of the biomass created by the crop submodel. Finally, the erosion submodel uses parameters provided by other submodels to simulate the entrainment and transport of soil particles.

The WEPS user interface allows the operator to define the size and orientation of the field, the location of the field, the cropping system including tillage and crop rotation, and the soil series. The location of the field defines the weather station database that is accessed by the weather submodel. The soil series specifies parameters for the soil and hydrology submodels; these paremters are obtained from the USDA-NRCS Soil Survey Geographic (SSURGO) database.

Initial tests in using the WEPS indicated good performance. Reasonable agreement between measured and simulated wind erosion ($R^2=0.71$) was found in the GCTE/SEN exercise.[69] Even better agreement between measured and simulated wind erosion ($R^2>0.9$) was found in Germany.[70] Sensitivity analyses have found WEPS to be sensitive to soil surface conditions including surface wetness, dry aggregate stability, oriented roughness, and residue management.[71] Some of the WEPS simulation inaccuracies noted in the GCTE/SEN exercise have been attributed to errors in soil parameter values or time-dependent changes in soil erodibility.[69] In a very detailed sensitivity analysis,[72] investigators found that the WEPS was most sensitive to changes in biomass flat cover, near-surface soil water content, ridge height, and other parameters including crust cover and random roughness.

Control Strategies

Land management plays a key role in controlling wind erosion. Establishing native perennial species in deserts, rangelands, and shrublands will provide some stability against disease and drought. Likewise, eliminating annual weeds from these ecosystems will offer some protection against the spread of wildfire and thus denuding the land. Limiting grazing on rangelands will ensure adequate vegetative cover to protect the soil surface while limiting recreational pursuits along coast and deserts will protect the sparse vegetation and surface crusts in these landscapes. Regulating water levels of interior seas or lakes may reduce the exposure of beaches to wind, but more stringent efforts such as applying chemical stabilizers may be needed to reduce dust emissions from beaches where desiccation is a natural process.[73]

Land management practices are available in most agricultural regions that will protect the soil resource within a cropping system. No tillage or conservation tillage provides greater protection to the soil surface against the forces of wind as compared with conventional tillage because conservation tillage enhances crop residue cover and minimizes degradation of aggregates or crusts (Figure 13). Ridge tillage, with ridges oriented perpendicular to prevailing winds, provides some protection to the soil surface by enhancing roughness. Intensifying crop rotations or the use of cover crops can also minimize the time when soils are exposed to wind, but may be impractical without irrigation in arid regions. Other practices such as amending the soil with straw, manure, or synthetic binders can be effective but costly. Wind strips or barriers or strip cropping is effective in reducing wind velocities at the soil surface but is only practical in regions with unidirectional winds. Perennial plants are frequently used in wind strips across agricultural fields; their effectiveness in reducing erosion will depend on plant height, spacing, leafiness, and rigidity.

Adoption of practices by land managers to control wind erosion is influenced by an awareness of the practice, availability of resources to apply the practice, effectiveness of the practice, and economics of adopting the practice. In arid and semiarid regions, failure to adopt practices is generally governed by

FIGURE 13 Conservation tillage used to control wind erosion in irrigated corn in southern Washington. Corn was sown into a cover crop that was established the previous autumn (conservation tillage) or using conventional tillage practices. The transition between conservation and conventional tillage is noted by change in color of soil surface along the vertical in the center of the image.

economics (low profit margin). For example, the cost of establishing a wind erosion control practice in an agricultural field cannot be compensated by an increase in crop yield. As such, assistance is typically needed by federal or state governments to offset costs of adopting control practices. Government programs have been effective in promoting the use of conservation practices to reduce soil erosion to tolerable levels in some regions of the world, but these programs are costly. Nonprofit organizations such as the Northern Agricultural Catchments Council of Australia have provided incentives to land managers to adopt conservation practices to control wind erosion. These organizations, however, typically rely on both public and private funding to support adoption of practices. Private industry has also provided incentives to land managers to adopt erosion control practices. For example, Shepherd's Grain contracts crops grown by farmers using sustainable practices for manufacturing food products in the Pacific Northwest, USA. These industries are generally localized and fill a small niche in the market. Therefore, public support is needed to ensure the sustainability of our air, soil, and water across broad regions such that today's land management practices do not jeopardize the air, soil, and water resources to meet the needs of future generations. This support could be in the form of national policies that encourage research and development of simple and cheap wind erosion control technologies.

Conclusion

Wind erosion continues to threaten air, soil, and water resources across the world. Loss of fertile topsoil by wind has contributed to the demise of civilizations.[74] Fine particles emitted from soils by high winds are transported great distances in the atmosphere and have contributed to pollution of our air and water resources. To ensure the sustainability of the soil resource to meet the needs of future generations, cheap and readily available management practices that will protect the soil surface from the forces of the wind are needed. This is a particular challenge in the arid and semiarid regions of the world, but one that can be met through continued education, development, and research. Tools for monitoring and predicting wind erosion have rapidly expanded over the past three decades; these tools will be invaluable in monitoring the effectiveness of new control practices across vast landscapes. Development of technologies to control wind erosion are costly, but must be shared by today's generation to ensure the well-being of future generations.

Erosion Control: Tillage and Residue Methods

Richard Cruse, Jerry Neppel, John Kost, and Krisztina Eleki

Tillage and Soil Erosion Processes

The processes of soil detachment, transport, and deposition occur during erosion. Soil surface conditions created by tillage greatly influence these processes and therefore soil erosion losses. Tillage practices that increase (or at least do not decrease) soil structural stability, leave plant residues on the soil surface, slow surface-water flow velocity, and/ or promote high infiltration rates favor soil conservation.

Surface residue cover greatly influences soil erosion. When 30% of the surface is covered, soil erosion losses are reduced by approximately 50% compared with a bare, tilled soil (Figure 1). Conservation tillage is considered to be any tillage system that has at least 30% of the soil surface covered by plant residues after planting[1] (Figure 1).

Tillage Effect on Soil Properties Critical to Erosion

Residues intercept raindrops and minimize soil detachment. This reduces soil available for transport and also limits surface seal development. This improves infiltration, which in turn reduces the amount of water runoff and transport potential. Residues also slow surface flow velocity, by acting like little dams on the surface. This causes soil deposition to occur on the upslope side of the residue pieces where water flow slows.[2]

Surface roughness and structural stability play dual roles. A rough surface stores water in the surface depressions between the clods or aggregates during heavy rainfall. This slows runoff and limits transport. The large pores of a rough surface also require more soil detachment to create a surface seal than a smooth surface, minimizing transport. Similarly, contour tillage, tillage occurring across the slope, reduces runoff by in-creasing surface water storage and slowing water runoff velocity.

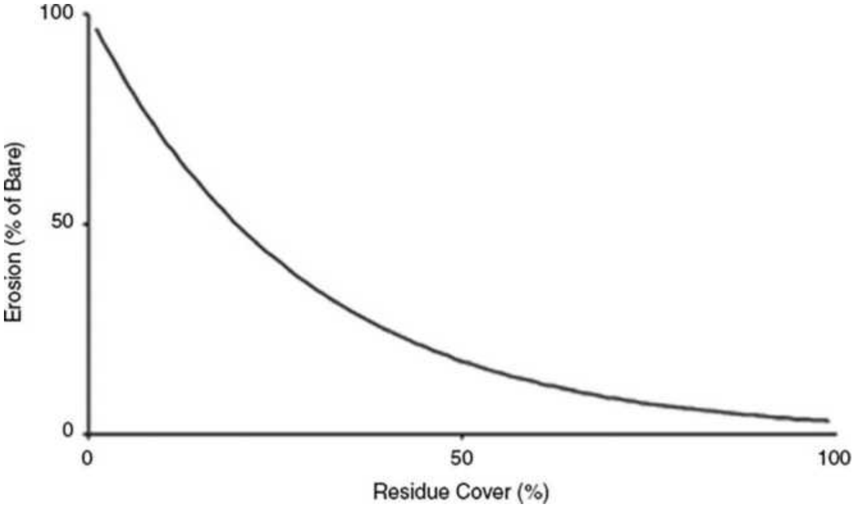

FIGURE 1 Effect of surface residue cover on soil erosion by water, expressed as the percent of erosion observed for bare soil. **Source:** Adapted from Renard et al.[2]

Open pores from the subsurface to the soil surface are critical for high infiltration rates and therefore low transport potential. Tillage practices that promote stable structure and result in surface residues to intercept raindrop impact promote stable open pores. Most tillage practices, however, weaken structure and therefore promote soil detachment from raindrop impact. Tillage also disrupts earthworm activity. Earthworms can play a major role in producing large open pores on the soil surface and very high infiltration rates with selected management systems. Four basic tillage/management systems will be discussed. Many variations of each system exist. Also, other systems using the principles described in this entry have been developed and can be located in other literatures.[3]

No-Till

No-till results in minor soil disturbance only during planting, leaving the greatest possible amount of surface residue after planting (Figure 2).

Compared to cleanly tilled systems, no-till can reduce erosion by as much as 95%.[4] The accumulation of residue from season to season reduces erosion by protecting the soil surface from impacting raindrops, as well as improving structural stability, pore size, and pore stability. Earthworm activity is promoted by no-till. Where large earthworm populations exist and the population is active on or near the surface, runoff can be very low or non-existent, even for large rainfall events.

No-till is best adapted for semiarid regions, sloping soils, and/or soils with good internal drainage. Low soil temperatures can be a problem in cooler climates, especially in early spring if soil is wet. One variation of no-till creates a residue- free band over the planted row with the planter. This helps the row zone warm and dry faster than if the soil is residue covered. In hotter climates, the reduced soil temperature caused by residue can be advantageous. In the absence of tillage, weed control is typically done through herbicide application. However, a combination of herbicide and cultivation for weed control can also be practiced.

Residue-covered surfaces also reduce soil water evaporation. No-till practices may conserve sufficient water under semiarid conditions (or on droughty soils) to significantly increase crop yield relative to that for other tillage methods (Figure 3).

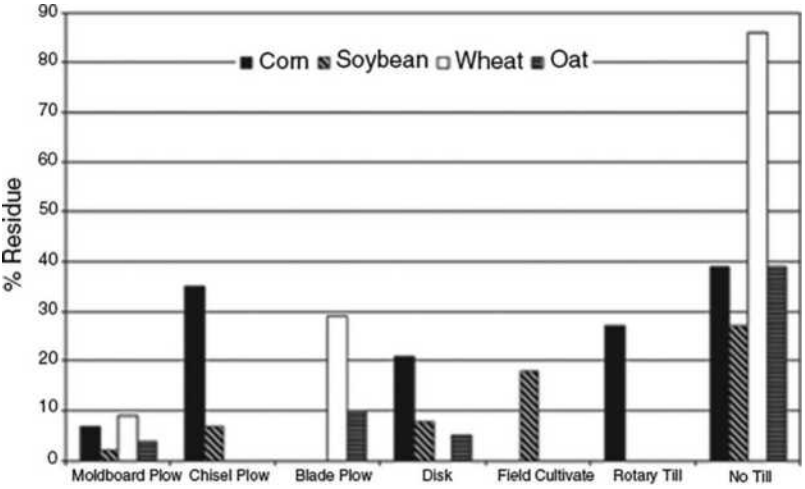

FIGURE 2 Percent residue by tillage method.

FIGURE 3 No-till corn following wheat.

Ridge Tillage

With ridge tillage the soil surface "is left undisturbed from harvest to planting" except for strips up to one-third of the row-width. Planting is completed on the ridge and usually involves removal of the ridge top. Planting is completed with sweeps, disk openers, coulters, or row cleaners. Residue is left on the surface between ridges. Weed control is accomplished with crop protection products (frequently banded) and/or cultivation. Ridges are rebuilt during row cultivation.[1]

Ridge tillage historically is practiced on wetter, poorly drained soils in northern climatic row cropping regions.[5] However, it is also a viable option in semiarid, rain-fed row cropping regions where soil moisture conservation is a necessity.

FIGURE 4 Harvested corn on ridge-till soil.[6]

Selected aspects of ridge tillage systems protect the soil from soil erosion. Crop residues remain on the soil surface from harvest until planting of the succeeding crop. Only a portion of the soil surface is disturbed at planting. This leaves a high percentage of crop residues on the soil surface and maintains the large pores for rapid water infiltration. Crop residues from the row (ridge) are placed in the interrow (valley) area. This "extra" residue decreases detachment and slows water runoff, enhancing infiltration in the interrow area. Ridge tillage promotes controlled traffic, the practice of maintaining a fixed traffic pattern in the field, such that only certain interrow areas experience wheel-caused compaction. Controlled wheel traffic limits soil compaction to preselected interrows. The non-traffic areas maintain large pores and stable structure, enhancing infiltration. Ridge tillage is much more effective at conserving soil if ridging and planting are done on the contour than if up and down hill management is used.

Ridge till also offers opportunities to reduce weed control costs through banding of herbicides and row cultivation for weed management (Figure 4). Nutrient losses may be reduced by injection and/or subsurface application of fertilizers.[7] Also, ridged soil warms quicker in the spring than no-till soil, permitting earlier planting in many situations.[8]

Mulch Tillage

Mulch tillage is a full width conservation tillage system involving one or more soil loosening operations prior to planting. Mulch tillage maintains a substantial amount of plant residue cover before and after crop establishment. Tillage tools such as chisel plows, field cultivators, disks, or blades are typically used for primary tillage. Secondary tillage is minimized to conserve surface residue.[9]

Mulch can be from any crop material. It is normally retained on the surface during harvest of the previous crop. The amount of mulch left on the surface depends on the sequence of the tillage, tool(s) used, and the mulch material of the previous crop. In general, the higher the crop yield, the more surface residue will exist.[10]

Surface mulch reduces the evaporation of soil water, increasing soil water content, relative to that occurring with a bare surface. Consequently soil warming can be slower in the spring, which can slow plant emergence and early development. The higher soil water content can also favorably affect crop yield under dry conditions. Mulch tillage increases soil organic matter content compared to more intensive tillage systems (Figure 5). Weed control can be done mechanically, with herbicides, or with a combination of the two.

FIGURE 5 Mulch tillage procedure.

Strip Tillage

Strip tillage involves tilling only in the crop row zone. The interrow area is untilled with surface residue left undisturbed. Tillage may be done in fall or spring. However, fall tillage is more commonly done. Typically a row cleaner, coulter, shank, and covering disks till each row area. This combination of components is equally spaced to match planter rowspacing so that the succeeding crop is planted in the tilled zones.[11] This system offers the combined advantages of no-till in the interrow zone and conventional tillage in the planted zone. The tilled zone is normally warmer and drier than if no tillage were performed.

Weed control can be through herbicide application, cultivation, or a combination of these methods. Fertilizer can be applied during the tillage operation at the base of the tilled depth and/or during the cropping season. Strip tillage is used only for row crop production. Strip tillage on the contour is much more effective at conserving soil than planting up and down hill.

Summary

Tillage systems that leave residues on the surface, promote stable soil structure, and/or result in open pores to the soil surface favor water infiltration and soil conservation. Surface residue management is closely related to stable soil structure development and open surface pores. No-till, ridge tillage, mulch tillage, and strip tillage exemplify management systems that use these principles for favorable crop production and reduced soil erosion rates.

Pest Management: Modeling

Andrew Paul
Gutierrez

Introduction

Pest management is a key component of sustainable agriculture and may be defined as applied population ecology focusing on human managed populations of plants and/or domesticated animals and their pests and natural enemies in environments modified by weather and agro-technical inputs. The complexity of managing pests in an agroecosystem requires the development of models that enable separation of losses due to pests from yield variation due to weather and agronomic practice.[1] Such models provide the bases for evaluating the dual objectives in modern agriculture of *minimizing* inputs that cause adverse environmental, human, and animal health effects and *maximizing* net profits. In modern societies, these goals may result in conflicts between public and private interests, but this is usually not the case in subsistence ones[2] where the goal is often yield stability.

Some components of crop pest management research are illustrated in Figure 1a, but the same approach applies to medical and veterinary pest management. The methods fall under the ambit of agro-ecosystem analysis.[3] The analysis must be tri-trophic in scope because natural processes such as biological control, when correctly managed, may replace disruptive pesticide inputs that may induce resurgence of target pests, outbreaks of secondary pests, pesticide resistance, and pollution. Misuse of other agronomic inputs (e.g., fertilizers, water) may also exacerbate pest levels and must be considered in the pest management system. Several modeling approaches have been used in pest management, and they may be broadly classed as empirical, statistical, operations research, analytical, and simulation.[1–6] To be truly sustainable, the system must be ecologically, economically, and socially sustainable (Figure 1b).

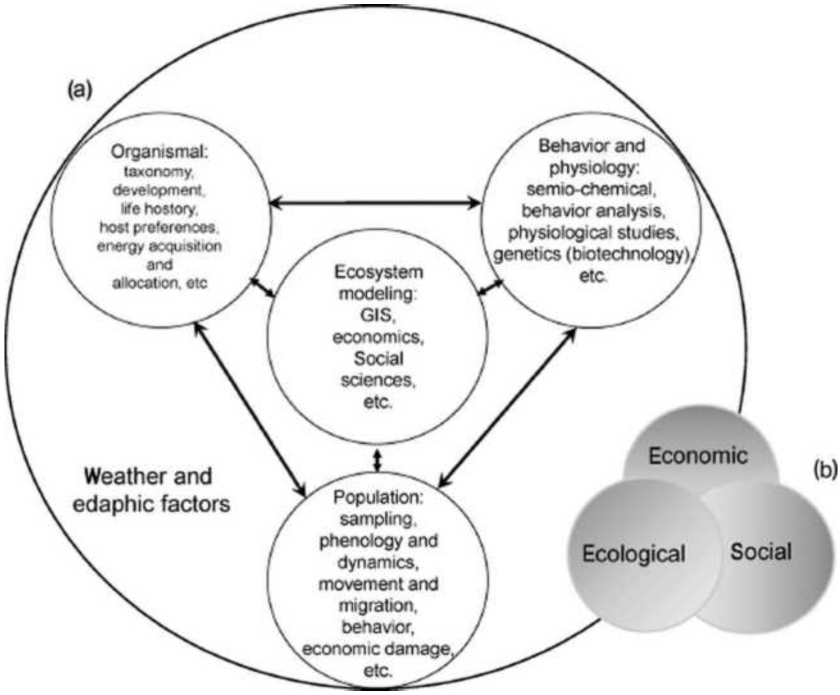

FIGURE 1 Components of pest management research using (a) systems analysis as a unifying tool and (b) components of sustainability.

Modeling Approaches

Empirical models based on trial and error have a long history and accumulated common wisdom. Traditional societies worldwide developed pest management strategies based on common wisdom that reduced pest damage and led to sustainable crop production. These systems may fail when modern agro-technical inputs are introduced and may require the accumulation of new experience to resolve management problem.

Population sampling and agronomic trials have been used to develop statistical models to assess the costs and benefits of pest levels and timing agronomic inputs (e.g., economic threshold studies). These models tend to be static and hence are time and place specific. They may not be able to be used to evaluate factors beyond the range of the data used to develop the model. Such models have, however, yielded useful pest management decision rules.

Attempts have been made to use operations research methods from engineering and economics to determine optimal pest management strategies. Such methods require sufficient knowledge of the system to formulate robust optimization models. Often this information is lacking, and/or the biology may be too complicated, requiring large reductions in the dimensions of the model. These simplifications often obviate their general utility except for general strategic analysis.

Pest management is *applied population ecology* and hence lends itself to demographic modeling methods. Mathematical models of the population dynamics may be simple descriptors of the system having analytical solutions or they may include considerable biological detail requiring numerical simulation. Analytical models may give strategic insights about the system, while richer simulation models may yield tactical recommendations for specific abiotic and biotic conditions. Modeling for tactical decision making requires a detailed understanding of the biology of the interacting species as modified by weather, edaphic, and agronomic factors. Biologically rich mathematical models are usually implemented as computer simulations.

There are many approaches to simulation modeling, but increasingly, mechanistic, physiologically based models of the energy dynamics of cropping systems are being developed because the important role of the plant as the integrator of all factors is being increasingly recognized. Energy is the currency of biology that when multiplied by price leads directly to economic models.

Simulation Models of Crop Systems

Crops are age-structured populations of plants each with *time-varying mass-age-structured* subunit populations of fruits, leaves, stems, and roots. The number in each age-mass class may vary overtime in response to factors that affect birth–death rates of whole plants and/or their subunits as well as those of higher trophic level populations. The crop may be viewed as a canopy of average plants with populations of pests and natural enemies within, or as individual plants each with its own set of pest and natural enemy subpopulations with migration between plants or fields (i.e., a meta-population). Modeling of individuals in pest and natural enemy populations (individual-based models) is not recommended in pest management because the decision rules for individual behavior are rarely known and the computations may be extensive. Simpler approaches that capture the *meta* details of physiologically based approaches may also be used.[7]

A basic premise of the physiological approach is that all organisms, including the economic one, face the same processes of resource (energy) acquisition and allocation.[1,8] Physiological models often assume energy allocation priority first to respiration (maintenance costs in economics), then reproduction (profit) and if assimilate (revenues) remains, then allocation to growth and reserves (infrastructure and savings). The shapes of the acquisition functions are concave (photosynthesis,

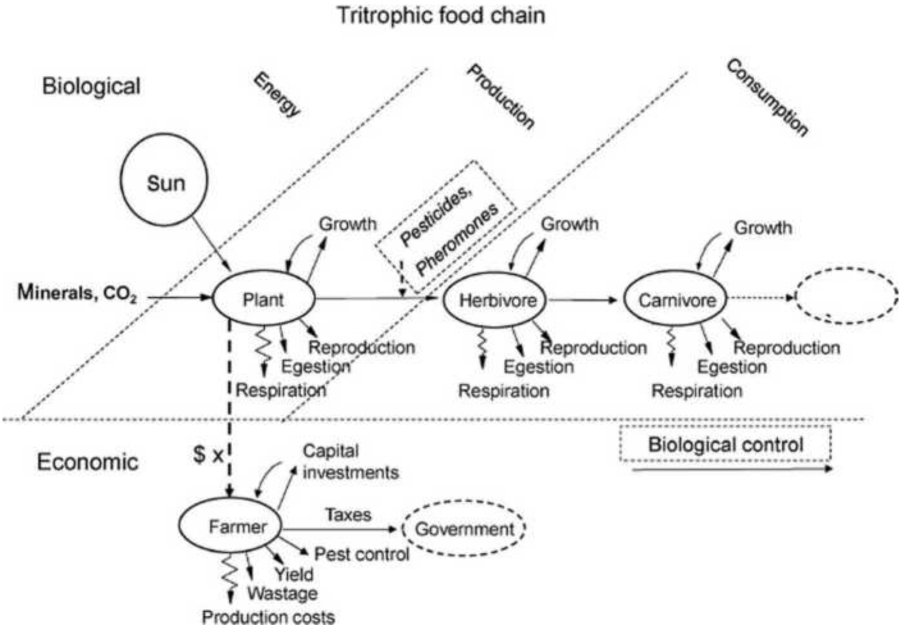

FIGURE 2 Analogies between trophic levels including the economic one.
Source: Courtesy of John Wiley and Sons, New York.

predations, etc.), and those for the maintenance costs are positive exponential (the Q_{10} rule) with the concave net of the two functions being the amount of resources available for allocation. These analogies[3] allow the use of the same model to describe the dynamics of all species (including the economic one) at the per-capita, population and regional levels (Figure 2). Each organism is assumed to try to satisfy a genetic (economic) demand for resources, but the process involves imperfect search, and the supply of a resource obtained is always less than (or equal to) the demand, and shortfall cause reductions in growth, reproduction, and survival rates from the maximum. In the model, all vital rates are controlled by one or more limiting supply/demand ratio with only the units and interpretation of the flow rates differing among species.

How biotic and abiotic factors affect plant growth and development is central to developing plant system models. These factors may affect either the supply (production) or the demand (sinks, e.g., fruits) side of the supply/demand ratio. Occasionally, both sides may be affected, and in other cases, the pests may attack the standing crop. The supply/demand paradigm simplifies model development, allowing assessment of yield loss and in some cases yield compensation in the face of pest damage. Such models facilitate evaluation of the costs and benefits of pest management options basic to the development of dynamic economic thresholds. Incorporating the biology of these factors in the model enables the development of highly realistic models.

Supply-Side Pests

Supply-side pests reduce the photosynthetic rate in various ways. Important supply-side pests are defoliators, sapsuckers, spider mites, nematodes, and diseases. Defoliation depletes leaves and may cause wound healing losses, but the effects on yield depend on the age of leaves attacked, the loss rate, and compensation due to increased light penetration to still intact leaves. In contrast, spider mites kill leaf cells, reducing photosynthesis in damaged leaves that are not shed, and reducing light penetration to lower leaves. Stem borers and vascular plant diseases may slow the photosynthetic rate by reducing the translocation of water and nutrients, and some may kill whole plants. Pests such as thrips and armyworms may damage the apical meristem, inducing developmental delays and reducing yield.

Plant Demand-Side Pests

Pests may attack fruit (e.g., net sinks), causing premature abscission, thereby altering present and future demands for photosynthate. High abscission rates may cause rank growth as the photosynthate is allocated to vegetative growth. Many plant species have reproductive capacity that allow varying degrees of compensation. Some plants may be determinant as all fruit are produced at roughly the same time (e.g., apple) and others are indeterminate (e.g., cotton), producing fruit until the maximum load is reached or the plant is limited by other factors. Of crucial importance in compensation is the time and energy lost in abscised fruits. Little time and energy may be lost when new buds and small fruit are abscised, and in indeterminate species such as cotton, replacement buds may be produced at rates sufficient for complete compensation. In determinate species such as apple, the time for compensation may be very short and compensation may be impossible if the attack rate is too high. In both growth types, attacks on older fruits may involve considerable losses in time and energy that often precludes compensation.

The ratio of the cumulative buds initiated to the cumulative numbers abscised may provide the basis for determining whether and how much compensation is possible. Such data yield a concave function that estimates the *compensation point* and may provide a rule of thumb for estimating the economic threshold. For example, losses of 30% of fruit bud in many cotton varieties do not affect yield.

Other Kinds of Plant Pests

Some pests affect both sides of the supply/demand ratio. For example, pests attacking the apical meristem of a plant or branch kill primordial tissues that introduce time delays and alter future fruit and vegetative dynamics. Other pests may attack the standing crop of fruit without causing fruit to shed and without appreciable reductions in sink demands, making plant compensation in such cases unlikely. Furthermore, damage in such cases accrues over time.

Modeling the Impact of Biotechnology

Increasingly, crop plants are being genetically modified to protect them from insect pests and to make them tolerant to herbicides designed to kill weed competitors, and these developments have added an important genetic level to modeling pest management. One of the most common genetic modifications is the insertions of genes from the bacterium *Bacillus thuringiensis* into transgenic crops for the production of Bt toxin. This innovation is thought to be environmentally friendly, and numerous recent economic studies concluded high benefits and good prospects for the technology (mainly in cotton and maize) in the United States, Australia, Argentina, China, South Africa, and other parts of Africa and Asia.[9] In many of these benefit studies, econometric methods were applied to cross-sectional data from farm surveys or experimental data, and while these methods can provide a good assessment of the static productivity of pest control agents (and other inputs), they are less suitable for capturing the interaction between control decisions and dynamic ecosystem reactions. The complexity introduced by biotechnology is exemplified by the cotton system: There are more than a dozen herbivore pests in cotton [e.g., pink bollworm, tobacco budworm, cotton bollworm, rough bollworm, fall armyworm, beet army-worm, cabbage looper, soybean looper, plant bugs (*Lygus* spp.), whitefly, cotton bollweevil, spider mites, and others], and each of them is affected differently by Bt toxin(s). In addition, their natural enemies may also be affected but at levels considerably less than by pesticides.[10] This complexity was examined using modeling that suggested the potential for secondary outbreaks of pests (i.e., plant bugs) induced by the use of Bt cotton.[10] Increases in secondary pests in Bt cotton have occurred in the Southeastern United States, India, and China, [11] with concomitant increased use of insecticides.[12] The pyramiding of new technologies (more Bt and other toxins) adds more complexity to the analysis. Modeling studies in transgenic crops are also made difficult by intellectual property rights that limit field scientific investigation.

The use of herbicide-resistant crop has increased herbicide use, led to the development of herbicide-resistant weeds, and increased environmental pollution and nontarget effects (e.g., amphibious species).[13] Rather than simplifying the pest management system, biotechnology has greatly increased the complexity in the long run.

Regional Pest Management

Modeling, geographic information system (GIS), and marginal analysis may be used to assess the regional distribution and abundance of pest and their biological control agents due to weather and over the long run of climate. Figure 3a illustrates how the same model at the individual, tri-trophic, field, area, or regional level applies. Weather data [daily maximum and minimum temperatures (°C), solar radiation (kcal $cm^{-2}day^{-1}$), rainfall (mm), daily runs of wind (km day^{-1}), and relative humidity] for each location on a grid (or numerous locations) are used to run the model over given time periods (days, months, years). Appropriate summary variables from the model may be mapped using GIS technology (Figure 3b) and used to show the aggregate regional effects of weather on biological system dynamics.[14] The GIS simulation data may also be analyzed using various statistical methods

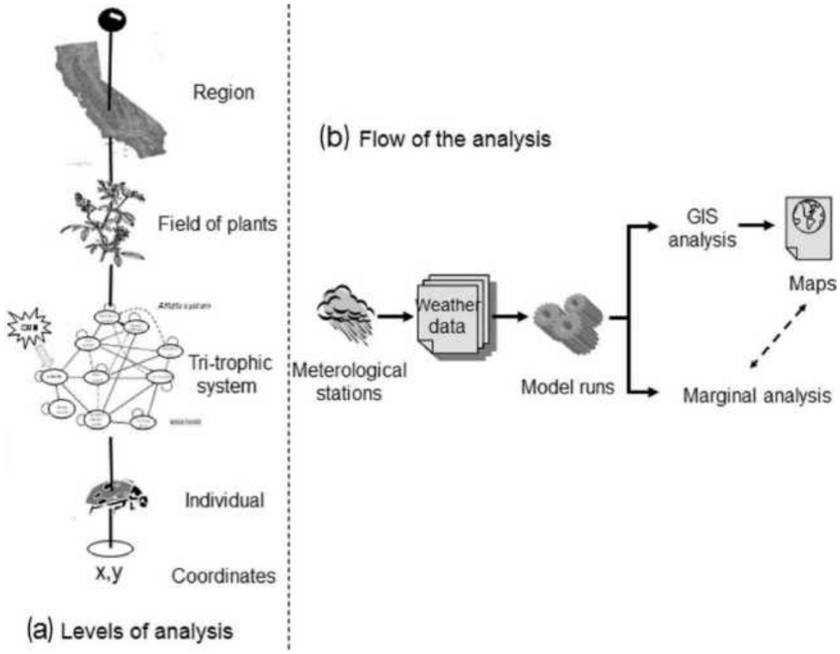

FIGURE 3 (a) Application of the same dynamics model (see Figure 2) at the individual, population, field, or larger geographic area, and (b) the use of the simulation model in regional GIS and marginal analysis.

(e.g., linear multivariate regression), keeping only independent variables and interactions with slopes significantly different from zero (t values, $p < 0.05$) in the statistical model. As in econometrics, marginal analysis may be used to estimate the average magnitude and direction of large effects ($\partial y / \partial x_i$).

Conclusions

Interactions among pests and higher trophic levels (top–down effects) are complicated, time varying, and best integrated via the plant's physiology and dynamics as modified by abiotic factors (bottom–up effects). Tri-trophic models based on the same supply/demand paradigm enable assembling and understanding the top-down biological relationships.[15,16] These models provide the bases for developing ecologically sound pest management strategies that may be implemented as part of a total farm expert system or regionally using GIS technology to develop region-wide pest management strategies. All of these methods fall under the ambit of agro-ecosystems analysis.

Soil Quality: Indicators

Graham P. Sparling

Criteria for Selecting Soil Quality Indicators

Many soil properties and characteristics have been proposed as indicators of soil quality.[1,2] In order to be considered as a valuable indicator, a soil property must meet certain criteria: 1) it needs to get our attention, and 2) it needs to tell us something useful about the condition of the soil. Desirable attributes include being quantitative and responsive within the specified time scale; interpretable; cost effective; scientifically justifiable; socially acceptable; internationally recognized; and preferably a part of historical monitoring procedures.[1–4]

There is some overlap between the categories of soil quality and land quality, of which soil quality is a subset.[2,5] Indicators for land quality generally describe the inherent and intrinsic characteristics of the soil, usually on a landscape scale. Inherent characteristics, such as soil mineralogy and texture, soil depth, and stoniness, are used to assess land capability or suitability for use, and generally are not greatly affected by land management. Other inherent characteristics, such as slope and aspect, overlap with soil quality indicators because they influence the more rapidly changing and dynamic soil properties that are responsive to land management. The variety of proposed indicators reflects the many ways in which soil quality has been defined[5] and the many components of a soil's chemical, physical, and biological attributes that contribute to its overall character. Of its many definitions, quality can be most briefly described as "fitness for use."[1,5] Within a soil context, a quality rating depends on how well the soil characteristics match the suitability for a particular use. Soil characteristics are not fixed—what is good soil quality for one land use may be deemed poor soil quality for another use. Thus, quality ratings are not absolute, but are instead values based on interpretation depending on the intended use of the soil.[6] The soil itself does not change, only our perception of it in relation to human needs.

A Minimum Data Set

Because it is not feasible to measure all soil quality characteristics, indicators need to be selected to address the issues of greatest concern. There are three major categories of soil quality concerns: soil erosion and redistribution; chemical and biological contamination; and soil degradation and depletion. The examples of these categories given in Table 1 are of concern because they adversely influence the role of the soil in ecosystem functioning and services.[5] Their degree of importance varies in different parts of the world.

TABLE 1 Major Aspects of Soil Quality Requiring Indicators

Soil Quality Aspect	Examples
Erosion and deposition	Soil redistribution by wind and water, mass movement, slips and slumps, and tillage displacement
Contamination/pollution	Presence of potentially toxic chemicals Pathogenic organisms
Degradation/depletion	Depletion of soil organic matter Loss of fertility Soil acidification Salinization Structural degradation

Time and Spatial Aspects

Selected indicators must be appropriate to the scale being considered, within both spatial and time dimensions. We tend to classify these items based on human perceptions, and soil processes that geologists consider rapid may be considered slow or relatively static to soil biologists. Examples of time and spatial scales and some relevant soil quality characteristics are shown in Table 2. Human-induced changes to soil, including soil redistribution through erosion and deposition, organic matter depletion, and chemical and radioactive contamination, can take hundreds of years to remediate.

TABLE 2 Spatial and Time Scales of Soil Properties Important for Soil Quality

Spatial Scale	Time Scale	Soil Properties Showing Change	Soil Quality Aspects
		Rapidly changing, highly dynamic characteristics:	
1–100 mm	Minutes and hours	Moisture content and temperature	Moisture and warmth for plant growth and biological activity
100 mm-1 m	Hours and days	Infiltration and drainage Biological activity	Compaction due to treading or wheeled traffic, risk of run-off during rainfall, waterlogging in poorly draining soils, poor root environment Decomposition of fresh organic matter
		Intermediate characteristics:	
1 m–100m	Days and months	Available nutrients and mineralization Soil structure	Nutrient depletion and supply, nutrient imbalances for plant growth Soil damage from compaction; influence on root environment, aeration, moisture retention, and drainage
100 m–1 km	1–5 years	Organic matter content Salinity Acidification Erosion and redistribution	Turnover of moderately decomposable organic matter, nutrient supply Saline water in root zone, toxic stress Soil chemical process leading to acidification in root zone, nutrient imbalances, toxicity Loss of topsoil, soil deposition
		Slowly changing characteristics:	
1km–10km	5–25 years	Soil loss and formation Humus formation or loss Salinity Acidification Weathering	Loss of topsoil and decrease in soil depth, soil deposition Changes in soil structure and nutrient storage due to loss of organic matter Salinity in the root zone, toxic stress, rising water tables Increasing acidity due to leaching and cation/anion imbalance, toxic stress Nutrient release and soil formation from rapidly weathering minerals
10 km–100 km	25–100 years	Stable organic matter	Humus provides exchange sites to retain ions in soil and contributes to soil aggregate formation
>100 km	>100 years	Soil formation Mineralogy	Nutrient release and soil formation from slowly weathering minerals Proportions of sand, silt, and clay, exchange characteristics of the clays

Interpretation

An interpretative framework is needed to make sense of the numeric values obtained for the various soil characteristics. We need to know what constitutes a high or low value, and what target value is desirable for each particular soil and land use. An interpretive framework should also indicate whether there might be off-site consequences for the wider ecosystem. For example, soluble fertilizer contents in soil may benefit crop production (good quality), but not matching the fertilizer to plant needs may result in an excess, increasing the risk of contaminating receiving waters (poor quality). In general, interpretative frameworks are better defined for contaminants than for other soil quality measures, because the presence of a contaminant can be related to an increased risk to plant and animal health. A critical value can be defined based on toxicity. Such dose–response curves are not available for most indicators used for soil loss, deposition, or soil depletion, and in many cases the response curve is an ill-defined continuum rather than a critical point.[2] Much work still needs to be done to define justifiable targets for soil properties, and even the broad categories of "more is better," "less is better," or "optimum range" have been the subject of ongoing discussion.[7] The units of expression can also influence interpretation—expression on a volume or area basis is generally preferred, particularly for comparisons between soils and land uses with differing bulk densities.[8]

Trends

In the absence of defined critical values for soil quality indicators, the importance of the trend over time has been emphasized.[9] Trends away from a target range are interpreted as a decline in soil quality; trends toward the target are interpreted as improved soil quality. However, it can also be argued that short-term trends away from a target value could still be regarded as sustainable, provided the trend can be reversed within an acceptable time frame. Within the present context, recovery or restoration within a human generation of 20–25 years could be regarded as preserving intergenerational equity.[10] Such exploitation-recovery cycles were much used during the shifting agriculture phase of human development. Soils differ in their resistance to change, and the rates at which they re-cover[11,12] affects their soil quality rating. Generally, soils that are resistant to change, or do change but show a rapid rate of recovery, are regarded as having better quality.[11]

Combining indicators

Because multiple data sets are difficult to comprehend, it has been proposed that indicator sets be combined into a single index.[1,2] These single indices are usually additive or multiplicative combinations of the individual indicators, and a weighting factor is used to adjust for the relative importance of each factor.[13] While a single number is easier to remember and communicate, its use has the disadvantage of possibly masking information. When too many indicators are combined, poor-quality soil aspects may be masked by those of modest or good quality. Reporting on any soil environmental quality should reflect the limiting quality rather than the average value. For example, excellent chemical fertility is of little use if the physical structure of the soil is badly degraded. This poor physical structure would therefore dominate the soil characteristics.

Conclusions

Indicators must attract attention and inform. They need to be sufficiently sensitive for their intended task and to respond in a timely manner. Critical values can be set so that a particular indicator value will trigger a management response. The critical values will differ, depending on the soil and land use, and management options. The ability of soils to recover, and their susceptibility to change under use, will define which indicators are useful and where their critical limits may be set. Multiple indicators can be combined into a single index, using weighting factors to adjust for the relative importance of each indicator. When combining indicators, care is needed not to mask poor indicator scores, and a safer option is to identify which soil characteristics are limiting factors.

Acid Sulfate Soils: Management

Michael D. Melville
and Ian White

Introduction

Acid sulfate soils (ASSs) is the name given to all those soils or unconsolidated sediments that contain reduced sulfur minerals and compounds that have been, or have the potential to be, oxidized and thereby produced acidity.[1–5] They occur globally and are an important problem requiring careful management. In our earlier publication on these soils,[6] we stressed the general coastal location of these soils, which contain a range of materials due to the sulfate in seawater that provides a large reservoir of dissolved sulfur that can be reduced biochemically in the presence of organics to form various monosulfides, and eventually the disulfide, pyrite (FeS_2). However, it is now clear that we should also recognize materials and problems from sulfidic hard rocks, generally freshwater bodies, and landscapes in inland areas. This need has been admirably illustrated by Fitzpatrick and Shand,[7,8] working on a wide range of sites and issues in Australia, but the principles and examples that they illustrate have global application.

The biochemical processes in ASSs are analogous to those of acid mine drainage (AMD)/acid rock drainage (ARD), and the rain-induced drainage from some mine sites with these materials also have analogues in the hydrology of acid sulfate soil (ASSs). Nevertheless, there are important differences between problems and management with AMD/ARD and other ASS landscapes, mostly because of their respective scales, material, and mineral characteristics, but particularly in their respective economics that affect the viable management options.

There are three fundamental questions underlying the use of ASS landscapes. Firstly, how best to use the existing environment productively while minimizing any sulfide mineral oxidation. Secondly, how to effectively neutralize any existing or newly created acidity formed during a particular land use. Thirdly, how to eliminate or minimize downstream environmental impacts from ASS drainage waters, which may include deoxygenation of soil or surface waters and the release of metals and nutrients. Therefore, best management of ASS must address these questions.

Existing and Emerging Problems

Much of the early research on ASS, as illustrated in the contents of the early series (from 1973 until 1992) of international symposia organized by ILRI (International Institute for Land Reclamation and Improvement) from Wageningen, the Netherlands, was directed towards improving their agronomic usefulness. However, the 2002 international ASS conference in Australia emphasized the range of environmental problems with ASS and their best management, and the most recent (2008) conference in Guangzhou, China, continued that theme and was combined with research and management for ARD.

While ASSs were recognized in Europe more than 250 years ago,[1] appreciation of their existence and importance in terms of environmental impacts in Australia was limited.[9] The most important ecological impact that changed this appreciation was the 1987 acidity discharge event on the Tweed River in northeastern New South Wales. Twenty-three kilometers of the Tweed River were completely clarified and sterilized of fish, crustaceans, and most benthic organisms after the flooding caused acidic drainage discharges from ASSs of the river floodplain. It was the astute observations of a local entomologist, published in an amateur fisherman's magazine,[10] which identified the true cause of this devastating event that took up to 18 months to heal.[6]

While Australia was slow to become involved in ASS research and management, the Tweed River fish kill initiated broad interest and involvement of stakeholders, researchers, industry groups, regulators, and politicians. The pathway of change with these groups on the issue of ASS in Australia has not always been straightforward without conflict; neither has it been simple.[9] However, a generally very positive outcome has been achieved and Australia now probably provides much of the impetus and methods for global adoption of best management practices with respect to ASS. Each State and the National Commonwealth of Australia have adopted policies and practices for ASS best management. Much of the materials necessary for the dissemination of information on ASS are freely available on the web.[7,23–25] The Queensland Government publications are updated from time to time. A quarterly newsletter, *ASSAY,* which has now been in publication for about 13 years, is available for free electronic subscription.[11]

As we pointed out in White,[9] many coastal floodplains around the world are composed of Holocene-age (<10,000 years BP) sediments that contain iron sulfide minerals,[2] mostly as pyrite, but in some regions, monosulfides are important.[12] It is estimated that the global extent of such ASS is between 10^7 and 10^8 ha, with large deposits in Southeast Asia, the Far East, Africa, and North and South America.[13] The total extent of ASS now mapped in Australia[14] is about 2.2×10^6 ha, of which about 0.6×10^6 ha is coastal and 1.6×10^6 ha is inland.[12] When exposed to air by natural or human-induced drainage, sulfides in these materials oxidize to sulfuric acid that may leach iron, aluminum, and other metals into sediment pore waters. Drainage of these pore waters has significant detrimental ecological impacts,[2,10,15,16] corrosion of engineering infrastructure,[17,18] blooms of cyanobacteria,[19–21] and emission of toxic and greenhouse gases.[22,23] The existence and problems of non-coastal ASS, and the need for considering hard rock sulfidic materials, increase the scope of management strategies.[8,25]

There are many global issues that relate to ASS and that are likely to emerge in the future, but there are two that seem to us are particularly problematic. Firstly, with global warming is the possible oxidation of sulfidic material in organic-rich landscapes presently preserved or protected by permafrost in high latitudes of the Northern Hemisphere (e.g., around James and Hudson Bays in Canada). Drainage of oxidation products and emission of greenhouse and sulfurous gases are likely. Secondly, perhaps also to some extent due to global warming but from population growth and political decisions for development, the increasing upstream abstraction of water resources from major rivers so that delivery of freshwater to coastal deltas or estuaries decreases markedly and wetlands underlain by sulfidic materials or sediments drain and oxidize and/or experience subsidence and increased saline intrusion (e.g., the Mekong Delta of Vietnam, and with the Brahmaputra and Ganges Rivers into Bangladesh). Any sea level rise associated with global warming increases this tidal inundation risk.

In southeastern Australia, the severe drought from 2005 to about 2009 markedly reduced the delivery of discharge to the outflow lakes area of the Murray-Darling Basin (MDB). This caused oxidation of the sulfidic materials and sediments that had accumulated during the various water management regimes that were initiated in the lakes and supply rivers following European settlement (Fitzpatrick and Shand,[8] pp. 38–43). Many different management regimes have been proposed and begun to be implemented to overcome these problems. However, it seems clear that licensing of water abstraction, predominantly for agricultural irrigation in the midcatchment during the multidecadal "flood-dominated rainfall regime" after 1946,[27] exceeded the capacity of the river system to supply water to the outflow lakes and maintain their health when a "drought-dominated rainfall regime"[27] possibly began.

In western Finland, the rapid isostatic uplift (<12 mm/yr) from retreat of the last northern European glacial sheet is exposing sulfidic sediments to natural oxidation, but this is being exacerbated by artificial drainage systems to enable agricultural land uses.[28] Drainage from these ASS landscapes is markedly polluting streams and waters of the Gulf of Bothnia, and it is estimated that the heavy metal pollution from this source is equal to that from all Finnish secondary industry.

It is clear that management of landscapes in which ASSs occur must make due cognizance of the landscape's ability to accommodate human impacts and probable variability in climatic or geomorphic conditions.

In recent years, the distinction between the characteristics, processes, problems, and management options of ASS and ARD have almost disappeared. Soil scientists such as Fitzpatrick and his colleagues are researching on what might previously have been considered ARD issues [e.g., see Fitzpatrick and Shand[8] (pp. 31–37) and Skwarnecki and Fitzpatrick[29]], and management techniques used commonly in AMD sites, such as capping to prevent sulfide oxidation and constructed wetlands for acidity dis-charge neutralization,[30] have been used successfully for ASS management.

Management Approaches

We have previously described[9] how early major problems from ASS on East Coast Australia created significant conflict between fishermen, sugarcane farmers, and environmentalists, and how this was resolved through a cooperative learning and coastal stewardship approach. This began the process that has underlain Australia's becoming a global leader in the understanding and management of ASS.

In complex environmental situations and problems, such as are likely to occur with ASS, significant knowledge gaps are likely to exist as to what is the problem and how best to manage it. Nevertheless, action is thought necessary. Adaptive management is sometimes proposed[9] on the basis that any mistakes due to incorrect information can be corrected provided there is rigorous monitoring. However, adaptive management assumes linear processes where any mistakes can easily be reversed. Unfortunately, with many situations of environmental management, including with ASS, processes are not linear (and are probably generally hysteretic) and environments are susceptible to dramatic collapse. Therefore, environmental degradation is not easily reversed.[31,32]

Many of the problems arising with ASS are the outcome of environmental change from natural processes, anthropogenic activities, or some combination of these. Within the population affected by such environmental changes, management of problems arising is best achieved if the reasons for the change are understood. Appropriate, reliable information, communicated in a relevant way, can provide an important catalyst for changed attitudes. The challenge is to collect and communicate such complex information in a manner that is trusted and accepted by all. Therefore, the first step is to describe the nature and cause of the problem and indicate some likely consequences, but without causing further and new concerns. The next step needs to identify and bring together all stakeholders in a participatory way so that consensus and compromise agreement can be reached.[33] This may require the input of some external, trusted facilitators. Strangely, because many see these personnel as rather "ivory towerish," universities can fulfill this role. Unfortunately, government employees are often unable to take this role because they have a regulatory role in environmental management.[25] In Australia, the problems of managing coastal resources have come from the many top-down, conflicting visions and disparate goals of successive governments and individuals. These goals, past policies, and legislation have concerned issues such as environmental protection and/or rehabilitation, economic development, and regional employment and growth. Politics is an ever-present factor.

Environmental stewardship has been proposed as one way by which conflicts might be reduced so that ownership and pride in the environment and its heritage are encouraged. In Australia, the indigenous original owners of the land have a culture of custodial stewardship and knowledge that can be used for best management practices, but the early European settlers were unable or unwilling to accept this. Now, theirs is a voice that must be heard in environmental management, including that with ASS. Stewardship involves voluntary compliance, strong commitment, and a willing participation in the sustainable use of resources through wise practices. There are probably well-founded concerns that without strong underpinning regulations, voluntary compliance agreements do not have effective mechanisms to address persistent breaches of agreements.

The best management of ASS involves a range of activities that address the issues of minimizing the export of acidity, metals, and nutrients into downstream environments. This involves two issues: 1) the creation of new acidity by sulfide mineral oxidation and 2) the management of existing acidity in the landscape. The latter has been frequently ignored. Across the range of land uses of northern NSW, the existing acidity in the sulfuric layer averages approximately 50 tons of sulfuric acid per hectare.[34] Potential acidity represented in the sulfidic minerals of the deeper subsoil is many times this amount. Nevertheless, the annual discharge of acidity is <0.5 tons/ha.[35] The degree to which soil acidification has been caused by artificial drainage is uncertain but natural processes are also involved.[36] It is clear, however, that artificial drainage networks, which decrease by orders of magnitude the time of inundation of floodplain backswamps from their natural conditions, provide the conduit by which acidity is transferred rapidly to the estuary and potentially causes downstream impacts.[37] Decreasing the density of drains has a major impact on the export of acidity. Laser grading provides a technique for removing surface waters and decreasing drainage density and allows more land to be planted to crops.[37]

The actual impact caused by rain-induced acidic discharges depends upon the magnitude of the discharge relative to the dilution by upland flows and neutralization capacity of receiving waters. Land users on coastal ASS floodplains must appreciate that other parts of the estuarine ecosystem depend on the dissolved alkalinity of the receiving water, consumed during acidity neutralization. Floodplain land uses should be undertaken so as to avoid creating any new acidification and minimizing the export of any acidity.

Overall, best management of ASS involves four possible approaches: 1) education and assessment; 2) avoidance; 3) oxidation prevention; and 4) acidity containment and neutralization. These approaches for ASS management have been included to a varying extent by cases described in Jiggins[31] and Harris[32] and detailed in Queensland's ASS Management Guidelines.[24] The latter work also provides insight to the risks associated with the various management approaches. ASS management is not necessarily straightforward and amenable to a prescriptive set of firm rules. Each project must align with the particular existing and proposed environmental situations.

Education and Assessment

Best management of ASSs requires knowledge of their distribution; the depth of the sulfidic material from the soil surface; the acidity stored in sulfuric material; the hydrological behavior of the soil profiles, landscape, and drainage system; the climatic regime; and the magnitude, tidal characteristics, and water quality of the receiving waters.[37] All of these are infrequently considered.

Australian soil scientists were generally slow in appreciating both the presence and the environmental problems from ASSs, and in raising the awareness of the public, land managers, and policy makers. The first national symposium on ASSs was only in 1993.[8] Nevertheless, in the past 20 years, a major shift has occurred, and now all States and Territories, and the Commonwealth of Australia, have included

ASS management in their environmental policies. Australia is one of the few countries with a national strategy on ASSs. The shift in New South Wales (NSW) has been greatly helped by publication of "Acid Sulphate Soil Risk Maps"[38] for the entire NSW coastline (scale 1:25,000). These maps are being used as the basis for landuse planning instruments ("Local Environment Plans," or LEPs) of local government authorities. These LEPs require submission of a Development Application for any activity that disturbs more than 1 ton of ASS.

The sugar industry, a major user of ASSs in NSW, has been granted State-wide exemption from these requirements for normal farming and drain cleaning activities because each of the 700 cane growers has signed a contract to comply with an approved code of best management practice for ASSs. Less than 20 years ago, the sugar industry was in a state of denial about the existence and problems of ASSs in their cane lands. The industry's new sense of land stewardship with ASSs is exemplary and indications are that economic rewards from up to 30% increase in yields are occurring. Education and capacity building of the cane growers has been helped through an ASS survey demonstration and assessment on each grower's land. Compliance to the agreement is independently audited each year, and to date, there have been very few inadvertent noncompliances found and these were quickly rectified.

The existence and characteristics of ASS across Australia are now provided in the Atlas of Australian Acid Sulfate Soils[14] that is accessible online through the Australian Soil Resource Information System (ASRIS: http://www.aris.gov.au). The management of complex data sets, such as arise in studies of ASS landscapes, can be managed using a system such as that described in Baker.[39] The methods for sampling, laboratory analysis, and assessment of ASS are provided by the ever-evolving Queensland Acid Sulfate Soils Manual.[24] Many organizations across Australia now provide training courses specifically for various aspects about ASS, and these are used for training groups such as stakeholders and regulators (e.g., see various issues of *ASSAT*).[11]

Avoidance

A primary preventative consideration with ASSs should be an avoidance strategy. Such strategies include the decision not to drain ASS wetlands with sulfidic material and to divert or relocate a proposed land use to an alternative site. If use of the site is unavoidable, then treatment so as to prevent sulfide mineral oxidation and export of any existing acidity is necessary.

This seems a relatively easy and sensible first step and one that we advocated as the first principle in an acid sulfate best management consultancy report to the NSW Roads Traffic Authority (RTA), prior to their undertaking major construction of the 1000 km divided highway between Sydney and Brisbane.[40] However, the RTA ASS Guidelines document did not include "avoidance" but most other parts of our report were included verbatim. Nevertheless, we believe that RTA has considered avoidance in assessing the final route of this construction but otherwise has ensured that appropriate treatment has been included in their ASS management plans for the various highway sections that encounter ASS. In assessing the need for avoidance or otherwise, land-use planners will consider relative land values and political advice as well as any engineering issues. This is a complex assessment process.

Oxidation Prevention

This might involve separation of the sulfidic material and its capping with material that is impermeable to oxygen and rainfall infiltration. The use of other sulfidic clays as capping materials must be avoided.[4] Decisions to not drain coastal wetlands are intended not only to avoid the creation of new acidity from sulfide mineral oxidation but also to address the issue of retaining existing acidity.[36] Management techniques such as raising water table elevations are seen as a means of protecting sulfide minerals from oxidation, but this should also consider the hydrological effects with possible increase of existing acidity and the social and economic impact of any subsequently necessary changed land use.

Acidity Containment and Neutralization

Neutralization of ASS acidity by the alkalinity of seawater is the ultimate natural process in the geochemical sulfur cycle. The use of this approach with human-induced acidification and increased acidity discharge needs to be approached with great caution. In eastern Australia, where existing acidity concentrations can exceed 50 tons/ha,[34] application of sufficient crushed limestone or other neutralizing material is impracticable for agriculture. Far better options are land-use practices that minimize acidity export and the strategic application of crushed limestone to drains through which the acidity is exported. These practices can be incorporated into normal activities at the individual paddock scale of intensive agriculture such as with sugarcane. In the NSW sugarcane industry, the adoption of laser grading on estuary floodplains has allowed the marked reduction in the number of field drains that are the main source of acidity export.[36] This has also improved the productivity of the cane land. Low-value land uses, such as with grazing, will be precluded from these new developments, and a more communal approach with some external funding may be necessary. The use of emerging technologies from AMD experience may be useful.[30,41]

Conclusion

The understanding of the need and techniques for best management of ASSs has shifted markedly in the past 20 years. This has been particularly noticeable in Australia and the Baltic coasts and now in inland problems arising in Australia as well. The boundaries between what were previously considered "acid sulfate soil" and "acid rock drainage" or "acid mine drainage" issues have almost disappeared as researchers from both discipline areas have worked together in understanding the chemical and hydrological processes that are associated with their common sulfidic mineral oxidation, and acidity and dissolved metal drainage processes. The issue of ASSs and their problems has involved not only scientific and engineering researchers but also the stakeholders managing land uses and the general public. Across Australia, at least, ASSs and their best management have become incorporated into government policy, regulation, and practice with all three levels of government. It is hoped that adoption by all stakeholders and land managers of a culture of environmental stewardship will greatly reduce the problems arising from ASSs.

Agricultural Water Quantity Management

X. S. Qin and Y. Xu

Introduction

During the past decades, integrated water resource management has been widely recognized as a major challenge to many countries around the world.[1,2] With the rapid economic development and population growth, the water consumption rates have kept rising, leading to serious water shortage problems; meanwhile, the problems are further compounded by a drastic decrease in water quality, resulting from contamination by industrial wastes, domestic sewage water, and agricultural fertilizers and pesticides.[3] Hence, the degradation of water quality is closely linked to the reduction of available water resources. Among various economic activities, the agricultural system has received intensive concerns from government and public, due to the fact that it not only provides necessities for human living but also poses a threat to ambient environmental quality.[4] In a typical agricultural system, the crops' growth requires the nutrients provided by fertilizer and manure. As a consequence, a significant amount of nitrogen and phosphorus may be released from the applied fertilizer and manure, leading to the increase of nutrient levels and deterioration of water quality in the receiving water bodies. In addition, the irrigation activities would consume a huge amount of water, which could exacerbate water shortage problems under disadvantageous conditions.[5] Therefore, an integrated water management strategy becomes important for agricultural development.

Previously, many measures have been proposed and implemented to save water resources or protect water quality for agricultural activities, including promulgation of environmental regulations, reduced application of fertilizers or manures, adoption of soil/water conservation practices, cultivation of low-water-consumption crops, and improvement of farming practices. However, the water shortage and contamination problems have not been significantly ameliorated.[6,7,8,4] One of the major reasons is that management of agricultural water systems is a rather complex issue, involving many interacting components (e.g., type of crops, tillable land areas, and livestock numbers) or influencing factors (e.g., available water resources, environmental loading capacities, and cost implications); single control measures can hardly solve the problem as they are trying to tackle the problem from an unilateral viewpoint instead of a holistic one. On the one hand, the interactive relationships among various system components would lead to difficulties in decision making. For example, the application of the manures and fertilizers provide necessary nutrients to the crops, which are the main source of system benefits; meanwhile, it is related to the applied cost and release of pollutants. On the other hand, an agricultural system involves many social, economic, and environmental factors. For example, a variety of agricultural activities (e.g., crop cultivation and livestock breeding) require enormous infrastructural investment and resources (i.e., land and water); meanwhile, they also pose influences on the socioeconomic activities, which are the main receivers of agricultural products; the socioeconomic activities could also affect agricultural activities through adopting various policies and strategies, such as prescribed pollution-control standards and fertilizer-application practices. Another challenging issue is the existence of uncertainties, which are associated with many system components in an agricultural water management system, such as the economic benefit of crop cultivation, the applied cost of fertilizer and manure, allowable pollutant discharge amounts, and the environmental capacities of receiving water bodies. These uncertainties could be derived from the random nature of the system, errors in measurement, or subjective human judgment, and would directly affect the generation of rational decision schemes.

Over the past decades, many optimization approaches were advanced for handling the above complexities and helping managers for better decision making. Traditionally, to quantify available water resources and identify the relationships among crop yield, crop quality, and irrigation water requirement, the local water authorities should conduct a thorough survey to obtain full meteorological and hydrological information, such as rainfall, surface water inflow and outflow, land areas, crop type and yield, and irrigation frequencies and quotas. Afterward, simulation models could be used to describe the interrelationships among various components within the agricultural system.[9–13] To generate cost-efficient water management strategies, optimization models could be applied.[14–17] Generally, the main objective is to maximize the economic benefit through crop cultivation and livestock breeding; meanwhile, the constraints, such as available water resources and allowable pollutant discharges, should be satisfied.

However, many of the earlier versions of optimization models did not take uncertainty into consideration, leading to oversimplified or inaccurate solutions. In recent years, a large number of inexact optimization techniques were proposed for dealing with uncertainties in agricultural water management fields.[8,4,18,5] A majority of these methods focused on stochastic mathematical programming (SMP), fuzzy mathematical programming (FMP), and interval linear programming (ILP). The selection of uncertainty-analysis techniques depends on the data availability and uncertainty characteristics associated with the system components. Stochastic mathematical programming is used mainly to tackle uncertainties expressed as random variables with probabilistic distribution functions (PDFs). Fuzzy mathematical programming uses fuzzy sets to handle uncertain data showing features of vagueness. The fuzzy membership functions are estimated empirically and can be obtained through human subjective judgments. Interval linear programming can express uncertainties as interval numbers and is effective in situations when little parameter information is available. Conclusively, a variety of optimization models were proposed in the agricultural water management field. In this entry, we aim to systematically introduce a number of the related methodologies, with a focus on demonstration of their applicability through a simplified agricultural water management case. The obtained results will effectively reflect the advantages of various uncertain optimization algorithms. Some implications of the findings and the potential research directions in this field will also be discussed.

General Inexact Optimization Models

In order to realize an integrated agricultural water quantity and quality management, the simulation models should be used to identify the interactive relationships among various system components. The model should be calibrated and verified based on the collection and analysis of long-term historical data. Then, depending on data availability and uncertain features of system components, specific optimization models can be formulated for generating cost- effective management schemes for decision makers. The alternatives of different simulation models or equations can be seen in the work of Zhang et al.,[19] Doorenbos and Kassam[9], Wang[20] Sang,[21] and Lin and Liang.[22] In this entry, the general forms of a number of inexact optimization models will be introduced.

Stochastic Mathematical Programming

Stochastic mathematical programming is used mainly to tackle uncertainties expressed as random variables with PDFs. A series of solutions under different probability levels can be obtained. However, the applicability of SMP is restricted by its rigorous data requirement to specify parameter probability distributions and intensive computational burden.[23] A general SMP model can be written as follows:

$$\text{Minimize} f = \sum_{j=1}^{J} c_j(s) x_j \tag{1a}$$

Subjected to

$$\sum_{j=1}^{J} a_{ij}(s) x_j \le b_i(s)\ \forall i, s \tag{1b}$$

$$\sum_{j=1}^{J} d_{rj} x_j \le e_{r,}\ \ \forall r \tag{1c}$$

$$x_j \ge 0, \forall j \tag{1d}$$

$$c_j(s), a_{ij}(s), d_{rj} \ne 0, \forall i,\ r,\ j,\ s \tag{1e}$$

where x_j are decision variables; $c_j(s)$, $a_{ij}(s)$, and $b_i(s)$ are sets with random elements defined on a probability space s, s ϵ S;[24] and d_{rj} and e_r are fixed coefficients for deterministic constraints. The main step of solving Eq. 1 is to transform the random variables into deterministic ones based on different algorithms. Currently, SMP handles random variables in different ways, such as stochastic chance-constrained programming (SCCP),[8,24–26] two- stage stochastic programming (TSP),[27,28] multistage stochastic programming,[29,30] and stochastic robust opti- mization.[31,26,28,32] The detailed solution procedures can be found in the related references.

Fuzzy Mathematical Programming

Fuzzy mathematical programming is derived through incorporating the fuzzy set theory into the conventional mathematical programming framework. Fuzzy mathematical programming uses fuzzy sets to handle uncertain data, which are characterized by vagueness or imprecision. The fuzzy membership functions are estimated empirically and can be obtained based on subjective judgments. A general FMP can be written as follows:

$$\text{Minimize}\,\tilde{f} = \sum_{j=1}^{J} \tilde{c}_j x_j \tag{2a}$$

Subject to

$$\sum_{j=1}^{J} \tilde{a}_{ij} x_j \le \tilde{b}_i \ \ \forall i \tag{2b}$$

$$\sum_{j=1}^{J} d_{rj} x_j \le e_{r,} \ \ \forall r \tag{2c}$$

$$x_j \ge 0, \forall j \tag{2d}$$

$$\tilde{c}_j, \tilde{a}_{ij}, d_{rj} \ne 0, \forall i,\ r,\ j \tag{2e}$$

where $\tilde{\boldsymbol{f}}$ is the objective function presented in a fuzzy form; *xj* are decision variables; $\tilde{c}_{j,}$ $\tilde{a}_{ij,}$ and $\tilde{\boldsymbol{b}}_i$ are assumed to be different types of fuzzy sets (e.g., triangular, trapezoidal, and exponential forms) with fuzzy membership functions being denoted as $\mu(\tilde{c}_j)$, $\mu(\tilde{a}_{ij})$, and $\mu(\tilde{\boldsymbol{b}}_i)$, respectively; and d_{rj} and e_i are fixed coefficients. To solve Eq. 2, the fuzzy sets are also required to be transformed into deterministic variables. Currently, FMP could be sorted into the following categories based on different modeling structures and solution algorithms: fuzzy flexible programming,[33,34] fuzzy possibilistic programming,[34] fuzzy robust programming (FRP),[23,4] and fuzzy chance-constrained programming (FCCP).[35,3] The detailed solution procedures can be referred to in the related references.

Interval Linear Programming

Interval linear programming is capable of handling the interval-type uncertainties in optimization problems, with all or part of the model parameters being expressed as interval numbers. The model could be solved by the interactive two-step algorithm proposed by Huang et al.[36] A general ILP model can be formulated as follows:

$$\text{Minimize}\,f^{\pm} = \sum_{j=1}^{n} c_j^{\pm} x_j^{\pm} \tag{3a}$$

Subject to

$$\sum_{j=1}^{n} a_{ij}^{\pm} x_j^{\pm} \le b_i^{\pm}\ \forall i \tag{3b}$$

$$x_j^{\pm} \ge 0, \forall j \tag{3c}$$

$$c_j^{\pm}, a_{ij}^{\pm} \ne 0, \forall i,\ j \tag{3d}$$

where $x_j^{\pm}$ are the decision variables presented in interval forms; ± is a boundary symbol for an interval number, representing a spectrum of possible values between the lower and upper bounds; and $a_{ij}^{\pm}$, $b_i^{\pm}$, and $c_j^{\pm}$ are coefficients represented as interval numbers. The term "interval number" is expressed as

$a_{ij}^{\pm} = \left[a_{ij}^{-}, a_{ij}^{\pm}\right]$ where the items a_{ij}^{-}, and a_{ij}^{+} are the lower and upper bounds of a_{ij}^{+} espectively. The objective value and decision variables are obtained as $f_{\text{opt}}^{\pm} = \left[f_{\text{opt}}^{-}, f_{\text{opt}}^{+}\right]$ and $x_{j,\,\text{opt}}^{\pm} = \left[x_{j,\,\text{opt}}^{-}, x_{j,\,\text{opt}}^{+}\right]$, respectively. Previously, many applications of ILP in dealing with environmental management problems were reported.[33,36–39,26,28,32]

Case Study

Overview of the Study Case

To demonstrate the applicability of the introduced inexact optimization methods, a simplified agricultural water quantity and quality management case is adopted.[7,8] The study system is conceptualized as a typical rural area (as shown in Figure 1), consisting of two subareas, where crop cultivation (including wheat, vegetable, and potato) and livestock breeding (including swine and poultry) are the two major economic activities. The water consumption is mainly required by crop irrigation; the pollutants generated from manure/fertilizer applications are discharged into the receiving water bodies. Each subarea has a canal to supply water. The decision makers are responsible for designing optimal farming patterns within a multiperiod horizon, in light of the economic return from the agricultural products, the local land/water resource conditions, pollutant discharge standards, and environmental loading capacities of the receiving water bodies. Figure 2 shows the management framework of the system. For uncertain or deterministic parameters that will be used in different methodologies, they are drawn from literature.[4,5,7,8] In order to better demonstrate methodologies, some parameters are directly assumed based on literature, and the scale of the problem (e.g., the type of agricultural activities and the number of subareas) is considerably simplified.

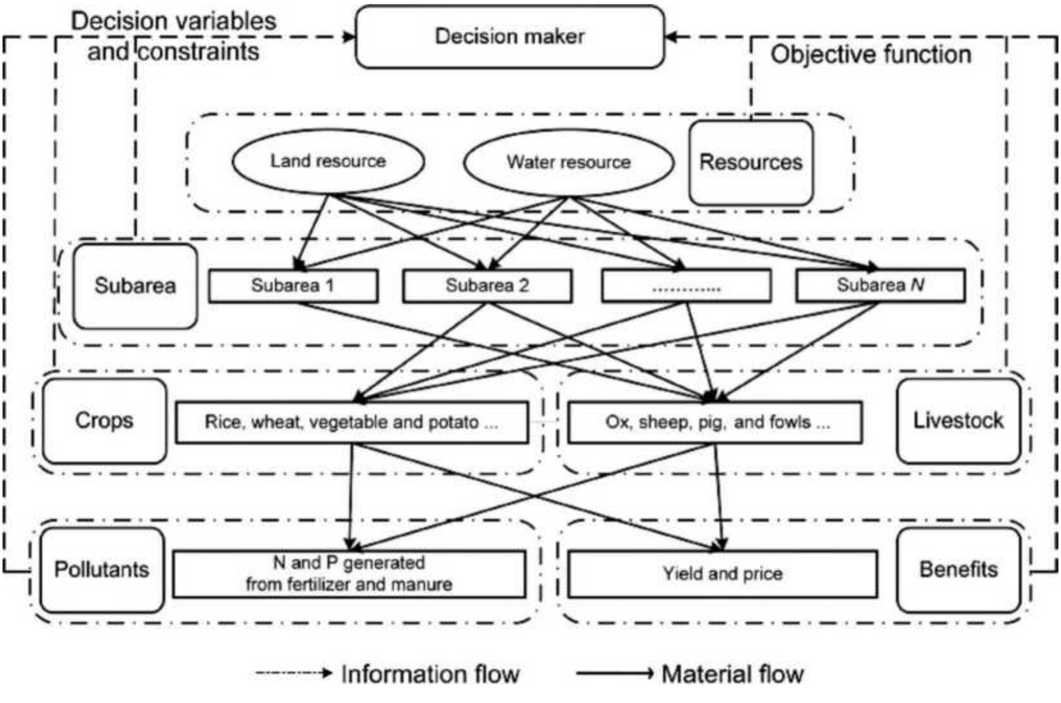

FIGURE 1 Overall structure of the studied system.

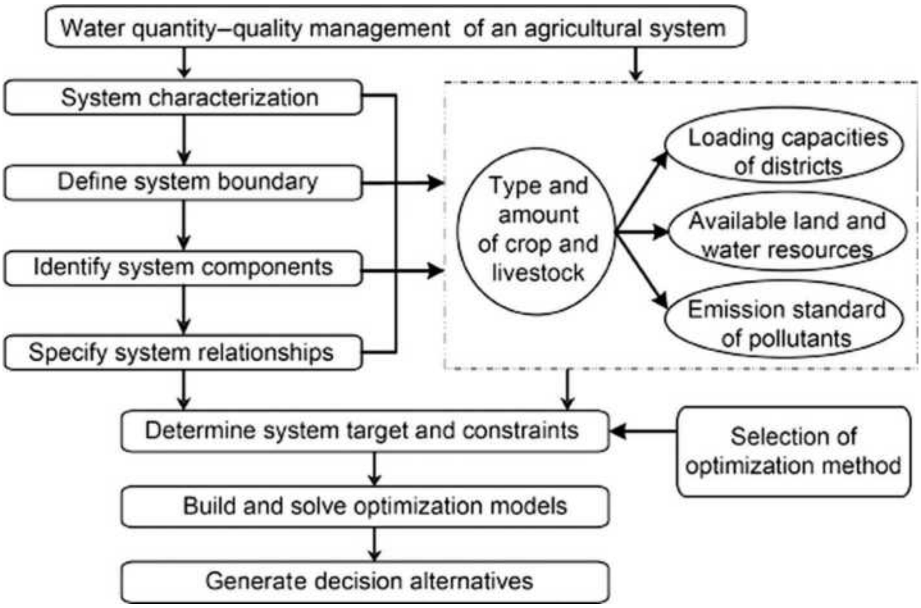

FIGURE 2 Procedures of agricultural water quantity and quality management.

General Model Formulation

A general model for agricultural water quantity–quality management can be formulated as follows:[4,5,7,8]

$$\text{Maximize} f = \sum_{t=1}^{T}\sum_{i=1}^{I}\delta_i Y_i S_{it} + \sum_{j=1}^{J}\eta_j Z_j - \sum_{t=1}^{T}\sum_{i=1}^{I} G_i S_{it}$$

$$-G_M \sum_{i=1}^{I} M_i - G_F \sum_{i=1}^{I} F_i - \sum_{t=1}^{T}\sum_{i=1}^{I} v_{it} W_{it} S_{it} \tag{4a}$$

Subject to

1. Manure mass balance:

$$\sum_{i=1}^{I}\boldsymbol{M}_i - \sum_{j=1}^{J}\boldsymbol{B}_j\boldsymbol{Z}_j = 0 \tag{4b}$$

2. Crop nutrient balances:

$$(1-p_1)\, g_i \boldsymbol{M}_{i+}(1-\boldsymbol{p}_2)\boldsymbol{F}_i - \sum_{t=1}^{\boldsymbol{T}}\boldsymbol{q}_i\boldsymbol{S}_{it} \ge 0, \quad \forall \boldsymbol{i} \tag{4c}$$

3. Energy and digestive protein requirements:

$$\sum_{\boldsymbol{t}=1}^{T}\sum_{\boldsymbol{i}=1}^{I}\boldsymbol{Y}_i\boldsymbol{\beta}_i\boldsymbol{S}_{it} - \sum_{j=1}^{J}\boldsymbol{E}_j\boldsymbol{Z}_j \ge 0 \tag{4d}$$

$$\sum_{t=1}^{T}\sum_{i=1}^{I} Y_i \gamma_i S_{it} - \sum_{j=1}^{J} D_j Z_j \ge 0 \tag{4e}$$

4. Pollutants losses:

$$\sum_{i=1}^{I}\left(M_i g + F_i - q_i \sum_{t=1}^{T} S_{it} \right) \le a \sum_{t=1}^{T} K_t \tag{4f}$$

$$\sum_{i=1}^{I} S_{it} \le K_t \quad \forall t \tag{4g}$$

$$\sum_{t=1}^{T}\sum_{i=1}^{I} L_i S_{it} \le b \sum_{t=1}^{T} K_t \tag{4h}$$

$$\sum_{t=1}^{T}\sum_{i=1}^{I} h_1 L_i S_{it} \le c_1 \sum_{t=1}^{T} K_t \tag{4i}$$

$$\sum_{t=1}^{T}\sum_{i=1}^{I} h_2 L_i S_{it} \le c_2 \sum_{t=1}^{T} K_t \tag{4j}$$

$$\sum_{t=1}^{T}\sum_{i=1}^{I} \left(R_{1i} N_{1i} + R_{2i} N_{2i} \right) S_{it} \le u_1 \sum_{t=1}^{T} K_t \tag{4k}$$

$$\sum_{t=1}^{T}\sum_{i=1}^{I} \left(R_{1i} P_{1i} + R_{2i} P_{2i} \right) S_{it} \le u_2 \sum_{t=1}^{T} K_t \tag{4l}$$

5. Water quantity constraints:

$$\sum_{i=1}^{I} W_{it} S_{it} \le Q_t, \quad \forall t \tag{4m}$$

6. Nonnegativity constraints:

$$S_{it}, M_i, F_i, T_j \ge 0, \ \forall i, j, t \tag{4n}$$

where f=net system income (\$); t, i, and j(t=1, 2,..., T; i=1, 2,..., I;j=1, 2,..., J) are indexes of subarea crops, and livestock, respectively; T, I and J are numbers of subarea, crops, and, livestock, respectively; Y_i=unit yield of crop i (kg/ha); S_{it}=area of crop i in subarea t (ha); Z_j=number of livestock j in the study area; M_i=amount of manure applied to crop i (t); F_i=amount of fertilizer nitrogen applied to crop i (kg);

W_{it} = flow rate of irrigation water required by crop *i* in subarea *t* [(m^3/s)/ha]; *Bj* = unit amount of manure generated by livestock *j* that needs to be disposed (t/unit); p_1 = nitrogen volatilization/denitrification rate of manure (%); *g* = nitrogen concentration of manure (kg/t); p_2 = nitrogen volatilization/denitrification rate of fertilizer (%); q_i = unit nitrogen requirement of crop *i* (kg/ha); β_i = net energy potential of crop *i* (Mcal/kg); *Ej* = unit net energy requirement of livestock *j* (Mcal/unit); γ_i = digestible protein content of crop *i* (%); D_j = unit digestible protein requirement of livestock *j* (kg/unit); K_t = tillable area in subarea *t* (ha); *a* = maximum allowable total nitrogen loss rate (kg/ha); h_1 = nitrogen content of soil (%); h_2 = phosphorus content of soil (%); N_{1i} = dissolved nitrogen concentration in wet season runoff from land planted to crop *i* (mg/l); N_{2i} = dissolved nitrogen concentration in dry season runoff from land planted to crop *i* (mg/l); R_{1i} = wet season runoff from land planted to crop *i* (mm); *R2i* = dry season runoff from land planted to crop *i* (mm); u_1 = maximum allowable loss rate of dissolved nitrogen by runoff (kg/ha); u_2 = maximum allowable loss rate of dissolved phosphorus by runoff (kg/ha); p_{1i} = dissolved phosphorus concentration in wet season runoff from land planted to crop *i* (mg/l); p_2i = dissolved phosphorus concentration in dry season runoff from land planted to crop *i* (mg/l); Q_t = maximum canal flow within subarea *t* (m^3/s); δ_i = unit price of crop *i* ($/kg); *ηj* = unit average return from livestock *j* ($/unit); G_i = unit farming cost for crop *i* ($/ha); G_M = unit cost of manure collection and disposal (dollars/t); G_H = unit cost of fertilizer application ($/kg); v_{it} = unit cost to deliver water to S_{it} {$/(m^3/s)}; L_i = soil loss rate from land planted to crop *i* (kg/ha); *b* = maximum allowable soil loss rate (kg/ha); c_1 = maximum allowable solid-phase nitrogen loss rate (kg/ha); and c_2 = maximum allowable solid-phase phosphorus loss rate (kg/ha).

As discussed in the "Introduction" section, a variety of uncertainties are associated with the agricultural water management system. The optimization model can effectively reflect the relationships between the agricultural and social–economic system and among various system components. The uncertainties can be expressed as random variables, fuzzy sets, or discrete intervals based on the uncertain features of parameters and data availability. In the next section, three inexact optimization models will be used to tackle problem.

Interval Parameter Water Quality Management Model

Huang[7] presented an interval parameter water quality management model (IPWM) for agricultural water quantity and quality planning. The model allowed uncertain information of parameters, expressed as interval numbers, to be effectively communicated into the optimization process and the obtained solutions. Compared with SMP and FMP, the generation of interval numbers has the least data requirement. In a typical agricultural system, many hard-to- get data could be assumed as interval numbers. Table 1 shows part of the interval parameters for the study case. The interval constraints of an IPWM model for the pollutant losses part could be written as follows:

$$\text{Maximize}\, f^{\pm} = \sum_{t=1}^{r}\sum_{i=1}^{m} \delta_i^{\pm} Y_i^{\pm} S_{it}^{\pm} + \sum_{j=1}^{n} \eta_j^{\pm} Z_j^{\pm} - \sum_{t=1}^{r}\sum_{i=1}^{m} G_i^{\pm} S_{it}^{\pm}$$

$$-G_M^{\pm}\sum_{i=1}^{m} M_i^{\pm} - G_F^{\pm}\sum_{i=1}^{m} F_i^{\pm} - G_F^{\pm}\sum_{t=1}^{r}\sum_{i=1}^{m} v_{it}^{\pm} W_{it}^{\pm} S_{it}^{\pm} \tag{5a}$$

Subject to

$$\sum_{i=1}^{m} M_i^{\pm} - \sum_{j=1}^{n} B_j^{\pm} Z_j^{\pm} = 0 \tag{5b}$$

TABLE 1 Part of the Model Parameters Presented as Discrete Intervals

Model Parameters	Values
Nitrogen content of manure (kg/t)	[10, 13]
Unit cost of manure collection/disposal ($/t)	[4, 5]
Unit cost of fertilizer application ($/kg)	[0.7, 0.9]
Nitrogen content of soil (%)	[0.0020, 0.0025]
Phosphorus content of soil (%)	[0.0009, 0.0011]
Nitrogen volatilization/denitrification rate of manure (%)	[0.3, 0.35]
Phosphorus volatilization/denitrification rate of manure (%)	[0.10, 0.12]
Maximum allowable dissolved nitrogen loss rate by runoff (kg/ha)	[2.2, 2.3]
Maximum allowable dissolved phosphorus loss rate by runoff (kg/ha)	[0.20, 0.22]
Maximum allowable nitrogen losses (kg/ha)	[38, 40]
Maximum allowable soil loss (kg/ha)	[3650, 5600]
Maximum allowable soil-phase nitrogen loss rate (kg/ha)	[10, 11]

Source: Adapted from Huang.[7]

$$\left(1-P_1^{\pm}\right)g_i^{\pm}M_i^{\pm}+\left(1-P_2^{\pm}\right)F_1^{\pm}-\sum_{t=1}^{T}q_i^{\pm}S_{it}^{\pm}\geq 0,\ \forall i \tag{5c}$$

$$\sum_{t=1}^{T}\sum_{i=1}^{I}L_i^{\pm}S_{it}^{\pm}\leq b^{\pm}\sum_{t=1}^{T}K_t \tag{5d}$$

$$\sum_{t=1}^{T}\sum_{i=1}^{I}h_1^{\pm}L_i^{\pm}S_{it}^{\pm}\leq c_1^{\pm}\sum_{t=1}^{T}K_t \tag{5e}$$

$$\sum_{t=1}^{T}\sum_{i=1}^{I}h_2^{\pm}L_i^{\pm}S_{it}^{\pm}\leq c_2^{\pm}\sum_{t=1}^{T}K_t \tag{5f}$$

$$\sum_{t=1}^{T}\sum_{i=1}^{I}\left(R_{1i}^{\pm}N_{1i}^{\pm}+R_{2i}^{\pm}N_{2i}^{\pm}\right)S_{it}^{\pm}\leq u_1^{\pm}\sum_{t=1}^{T}K_t \tag{5g}$$

$$\sum_{t=1}^{T}\sum_{i=1}^{I}\left(R_{1i}^{\pm}P_{1i}^{\pm}+R_{2i}^{\pm}P_{2i}^{\pm}\right)S_{it}^{\pm}\leq u_2^{\pm}\sum_{t=1}^{T}K_t \tag{5h}$$

$$\sum_{i=1}^{I}W_{it}^{\pm}S_{it}^{\pm}\leq Q_t^{\pm},\ \forall t \tag{5i}$$

As proposed by Huang et al.[36,38], the solution for Eq. 5 can be obtained through an interactive two-step method. A submodel corresponding to f^+ (when the objective function is to be maximized) is first formulated and solved, and then the relevant submodel corresponding to f can be formulated based on the solution of the first submodel. Finally, the objective value and decision variables as discrete intervals can be obtained as $f_{\text{opt}}^{\pm} = \left[f_{\text{opt}}^{-}, f_{\text{opt}}^{+} \right]$ and $x_{j,\,\text{opt}}^{\pm} = \left[x_{j,\,\text{opt}}^{-}, x_{j,\,\text{opt}}^{+} \right]$ The interactive method does not lead to complicated intermediate models and thus has low computational requirements.

Table 2 shows the solutions from IPWM for the study case. Some results are represented as interval numbers. For example, the objective function value (i.e., net income) would range from \$121.38 × 10^3 to \$310.99 × 10^3. The upper bound of the objective function represents an optimal decision alternative with the highest net income. Correspondingly, the obtained decision variables of cropping area and livestock amount would reach their upper bounds, and the manure and fertilizer would achieve their lower- bound values. For example, the cropping area of the vegetables in subarea 1 is 39.60 km^2; the number of swine is 324 units; the applied manure and fertilizer amounts of the vegetables are 606.12 × 10^6 t and 4004.15 kg, respectively. These upper-bound solutions are obtained under an advantageous condition. For example, the discharge standards of pollutants are relatively loose, and the loading capacities of the receiving water bodies and the available water amounts are relatively larger. This also means that higher system benefits correspond with higher levels of pollutant discharge and/or more serious water shortage problems. Conversely, the lower-bound solution of net income is under conservative consideration, where the conditions are stricter (e.g., the allowable pollutant amounts and provided water amounts are lower). In such a case, the water quality could be maintained at a higher level, and the water shortage crisis could be alleviated somewhat. Based on the obtained interval solutions, a variety of decision alternatives can be generated through adjusting continuously within their solution intervals. In fact, decision variables presented as discrete intervals are rather flexible for decision makers, since they are capable of assisting decision makers in making the decision based on their preferences (e.g., economic development or environmental protection).

Although the ILP method has many advantages, it also has limits. Firstly, the representation of uncertainties by discrete intervals is relatively simple, where much useful information is neglected. Secondly, although ILP has been proven as an effective approach in dealing with uncertainties, it may lead to the difficulties when the model's right- hand-side coefficients are highly uncertain. Therefore, further investigations are needed to improve the applicability of ILP. In fact, many other types of uncertainty methods, such as SCCP, TSP, and FRP, have potential to be further integrated into an ILP framework for mitigating the drawbacks of ILP and reflecting more complex conditions.

TABLE 2 Interval Solutions of IPWM Model

Model Solutions	Values
Cropping area of wheat in subarea 1 (km2)	0
Cropping area of wheat in subarea 2 (km2)	0
Cropping area of vegetable in subarea 1 (km2)	[22.38, 39.60]
Cropping area of vegetable in subarea 2 (km2)	[10.96, 19.23]
Cropping area of potato in subarea 1 (km2)	0
Cropping area of potato in subarea 2 (km2)	0
Applied manure amounts of wheat (106 t)	[0, 8.19]
Applied manure amounts of vegetable (106 t)	606.12
Applied manure amounts of potato (106 t)	0
Applied fertilizer amounts of wheat (kg)	0
Applied fertilizer amounts of vegetable (kg)	4004.15
Applied fertilizer amounts of potato (kg)	0
Swine amounts (unit)	[311, 324]
Poultry amounts (unit)	[379,557]
Net income (103 \$)	[121.38, 310.99]

Inexact Stochastic Water Management Model

Stochastic chance-constrained programming is one of the SMP methods that can tackle uncertain parameters presented as PDFs. Its main advantage is that it does not require that all of the constraints be strictly satisfied. Instead, they can be satisfied in a proportion of cases with given probabilities.[40] However, SCCP is restricted by data availability to generate stochastic distributions.[37,38] Interval linear programming is widely applicable for addressing all uncertain parameters; however, it does not allow any violation of system constraints and might be infeasible when the right-hand-side parameters in constraints are highly uncertain. The two methods have varied strengths and weaknesses, with a potential for compensating each other when they are combined.

Huang[8] proposed an interval-stochastic chance- constrained programming (ISCCP) model for agricultural water quantity and quality management. The ISCCP model is an integration of ILP and SCCP but improves upon both. It allows the right-hand-side parameters in the constraints to be expressed as PDFs and the coefficients in the objective function and the left-hand-side parameters in the constraints to be described as interval numbers. For the introduced study case, the available water resource amount, the maximum allowable soil loss, the maximum allowable soil-phase nitrogen loss, and the maximum allowable soil-phase phosphorus loss are assumed as random variables (expressed as PDFs). Table 3 lists the random parameters used in the ISCCP model. Other uncertain parameters are tackled as discrete intervals, similar to those in the IPWM model.

Thus, the interval-stochastic part of an ISCCP model can be written as follows:

$$\text{Maximize} f^{\pm} = \sum_{t=1}^{r}\sum_{i=1}^{m}\delta_i^{\pm}Y_i^{\pm}S_{it}^{\pm} + \sum_{j=1}^{n}\eta_j^{\pm}Z_j^{\pm} - \sum_{t=1}^{r}\sum_{i=1}^{m}G_i^{\pm}S_{it}^{\pm}$$

$$G_M^{\pm}\sum_{i=1}^{m}M_i^{\pm} - G_F^{\pm}\sum_{i=1}^{m}F_i^{\pm} - \sum_{m}^{r}\sum_{i=1}^{m}V_{it}^{\pm}W_{it}^{\pm}S_{it}^{\pm} \tag{6a}$$

Subject to

$$\sum_{i=1}^{m}M_i^{\pm} - \sum_{j=1}^{n}B_j^{\pm}Z_j^{\pm} = 0 \tag{6b}$$

$$\sum_{t=1}^{T}\sum_{i=1}^{I}L_i^{\pm}S_{it}^{\pm} \le b(s)\sum_{t=1}^{T}K_t \tag{6c}$$

TABLE 3 Random Parameters in ISCCP Model

Model Parameters	Values
Supplied water amounts of canal 1 (m3/ha-s)	(3.6, 0.12)
Supplied water amounts of canal 2 (m3/ha-s)	(0.9, 0.04)
Maximum allowable soil loss (kg/ha)	(4600, 150)
Maximum allowable soil-phase nitrogen loss (kg/ha)	(10.5, 0.5)
Maximum allowable soil-phase phosphorus (kg/ha)	(4.5, 0.2)

Note: (*a1, a2*) represents a random variable where a1and a2 are mean and standard deviation, respectively.

$$\sum_{t=1}^{T}\sum_{i=1}^{I} h_1^{\pm} L_i^{\pm} S_{it}^{\pm} \le c_1(s)\sum_{t=1}^{T} K_t \tag{6d}$$

$$\sum_{t=1}^{T}\sum_{i=1}^{I} h_2^{\pm} L_i^{\pm} S_{it}^{\pm} \le c_2(s)\sum_{t=1}^{T} K_t \tag{6e}$$

$$\sum_{i=1}^{I} W_{it}^{\pm} S_{it}^{\pm} \le Q_t(S),\ \forall t \tag{6f}$$

In the solution process of Eq. 6, the constraints in Eq. 6c–f are required to be satisfied with at least a probability of *1–ph* According to Charnes et al.,[24] these constraints can be written as[24]

$$\boldsymbol{P}_r\left[\sum_{t=1}^{\boldsymbol{T}}\sum_{i=1}^{\boldsymbol{I}} \boldsymbol{L}_i^{\pm} \boldsymbol{S}_{it}^{\pm} \le \boldsymbol{b}(\boldsymbol{s})\sum_{t=1}^{\boldsymbol{T}} \boldsymbol{K}_t\right] \ge 1-\boldsymbol{p}_{h},\ \forall \boldsymbol{t}, \boldsymbol{h} \tag{7a}$$

$$\boldsymbol{P}_r\left[\sum_{t=1}^{\boldsymbol{T}}\sum_{i=1}^{\boldsymbol{I}} \boldsymbol{h}_1^{\pm} \boldsymbol{L}_i^{\pm} \boldsymbol{S}_{it}^{\pm} \le \boldsymbol{c}_1(\boldsymbol{s})\sum_{t=1}^{\boldsymbol{T}} \boldsymbol{K}_t\right] \ge 1-\boldsymbol{p}_{h},\ \forall \boldsymbol{t}, \boldsymbol{h} \tag{7b}$$

$$\boldsymbol{P}_r\left[\sum_{t=1}^{\boldsymbol{T}}\sum_{i=1}^{\boldsymbol{I}} \boldsymbol{h}_2^{\pm} \boldsymbol{L}_i^{\pm} \boldsymbol{S}_{it}^{\pm} \le \boldsymbol{c}_2(\boldsymbol{s})\sum_{t=1}^{\boldsymbol{T}} \boldsymbol{K}_t\right] \ge 1-\boldsymbol{p}_{h},\ \forall \boldsymbol{t}, \boldsymbol{h} \tag{7c}$$

$$\boldsymbol{p}_r\left[\sum_{i=1}^{I} W_{it}^{\pm} \boldsymbol{S}_{it}^{\pm} \le \boldsymbol{Q}_t(\boldsymbol{S})\right] \ge 1-\boldsymbol{p}_{h},\ \forall \boldsymbol{t}, \boldsymbol{h} \tag{7d}$$

where $\boldsymbol{p}_h$ means the allowable probability of violation given by the decision makers. In this entry, the values of $\boldsymbol{p}_h$ are considered to be 0.01 and 0.05, respectively. Referring to Charnes et al.,[24] the constraints in Eq. 7a–7d can be transformed to their equivalent forms as follows:

$$\sum_{t=1}^{T}\sum_{i=1}^{I} L_i^{\pm} S_{it}^{\pm} \le b(s)^{Ph}\sum_{t=1}^{T} K_t \tag{8a}$$

$$\sum_{t=1}^{T}\sum_{i=1}^{I} h_1^{\pm} L_i^{\pm} S_{it}^{\pm} \le c_1(s)^{Ph}\sum_{t=1}^{T} K_t \tag{8b}$$

$$\sum_{t=1}^{T}\sum_{i=1}^{I} h_2^{\pm} L_i^{\pm} S_{it}^{\pm} \le c_2(s)^{Ph}\sum_{t=1}^{T} K_t \tag{8c}$$

$$\sum_{i=1}^{I} W_{it}^{\pm} S_{it}^{\pm} \le Q_t(S)^{Ph},\ \forall t, h \tag{8d}$$

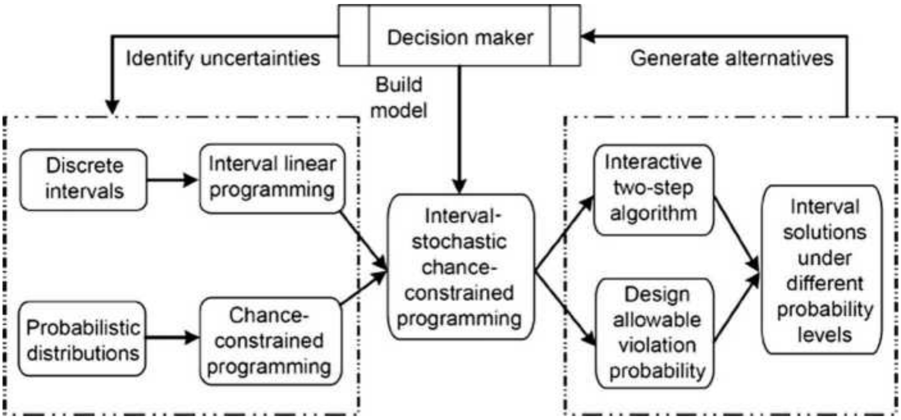

FIGURE 3 The framework for applying the ISCCP model.

where $a(s)^{ph} = Fh^{-1}[a(s)]$, given the cumulative distribution function of $a(s)$ and the probability of violating constraint h (i.e., p_h). Finally, Eq. 8 can be transformed into pure ILP models under various constraint-violation levels and then solved by an interactive two-step method.[36] Figure 3 shows the solution procedures of an ISCCP model.

Table 4 lists the solutions from the ISCCP model under probability levels of 0.01 and 0.05. Since ISCCP is an integration of ILP and SCCP, the obtained solutions reflect characteristics of both methods. Firstly, due to the existence of ILP, a majority of solutions present as interval numbers, which are feasible and stable in the given decision space; thus, the decision schemes can be generated in the ranges of their solution intervals. For example, at a significance level of $p_h = 0.01$, the total system benefits are [124.38, 256.03] $\times 10^3$. The upper bounds of objective function are preferable under advantageous conditions; conversely, the lower bounds of objective function value are more desirable under conservative conditions. The local managers can make decisions based on their preferences.

The solutions of ISCCP also possess features of SCCP where the trade-off between cost and risk can be evaluated (reflected by adjusting *ph*). For example, when *ph* increases from 0.01 to 0.05, the total system benefit would increase from [124.38, 256.03] to [127.40, 262.25] $\times 10^3$. This is due to the fact that, as *ph* increases, the allowable degree of violating constraints would increase (e.g., looser pollutant discharge standards and environmental loading capacities). This indicates that a higher system benefit could lead to a higher system risk. Conversely, if the planner aims toward a lower system benefit, a more reliable management alternative would be generated. The p_h values can be used to help analyze the trade-off between system economy and failure risk and offer local water managers a spectrum of alternatives for decision making.

ISCCP also shows some limitations. Firstly, the conversion from a stochastic constraint into an "equivalent" deterministic one applies only in conditions when the right-hand-side items are stochastic. The interval treatment for the left-hand-side uncertainties is a compromised approach, which may lead to the loss of valuable information if additional distribution information of the interval parameters is available.

Inexact Double-Sided Fuzzy Chance-Constrained Programming

The fuzzy approach is another alternative to deal with uncertainties. Referring to Xu and Qin,[5] an inexact double-sided fuzzy chance-constrained programming (IDFCCP) model was used to solve the agricultural water quantity and quality management problem. The IDFCCP model is formulated through

TABLE 4 Solutions of ISCCP Model at Probability Levels of 0.01 and 0.05

Model Solutions	Probability (pi)	Values
Cropping area of wheat in subarea 1 (km2)	0.01	0
	0.05	0
Cropping area of wheat in subarea 2 (km2)	0.01	0
	0.05	0
Cropping area of vegetable in subarea 1 (km2)	0.01	[23.22, 32.87
	0.05	[23.78, 33.66]
Cropping area of vegetable in subarea 2 (km2)	0.01	[11.10, 15.58]
	0.05	[11.37, 15.96]
Cropping area of potato in subarea 1 (km2)	0.01	0
	0.05	0
Cropping area of potato in subarea 2 (km2)	0.01	0
	0.05	0
Applied manure amounts of wheat (106 t)	0.01	0
	0.05	0
Applied manure amounts of vegetable (106 t)	0.01	499.11
	0.05	511.24
Applied manure amounts of potato (106 t)	0.01	0
	0.05	0
Applied fertilizer amounts of wheat (kg)	0.01	0
	0.05	0
Applied fertilizer amounts of vegetable (kg)	0.01	3297.27
	0.05	3377.35
Applied fertilizer amounts of potato (kg)	0.01	0
	0.05	0

	0.05	470
Net income (103 $)	0.01	[124.38, 256.03
	0.05	[127.40, 262.25]

Notes: [a,b] represents an interval number, where a and b are the lower and upper bounds, respectively.

incorporating ILP into a double-sided fuzzy chance-constrained programming (DFCCP) framework and could be used to deal with uncertainties expressed as fuzzy sets and interval parameters. Recently, FCCP has been presented as a novel FMP method through incorporating predefined confidence levels of fuzzy constraint satisfaction into optimization models. Similar to SCCP models, FCCP requires that the fuzzy chance constraints be transformed to deterministic equivalents at predetermined confidence levels. Fuzzy chance-constrained programming is sorted into single-sided FCCP and DFCCP. In many real-world problems, it is more common that both sides of model constraints be associated with uncertainties. Interval linear programming is capable of handling the uncertainties associated with other parameters in the optimization model if they do not have either fuzzy or stochastic distribution information.

For the introduced study case, the environmental loading capacities (such as allowable soil loss and pollutant discharge amounts) are subject to human judgment and described by fuzzy sets. Table 5 lists

TABLE 5 Fuzzy Parameters in IDFCCP Model

Model Parameters	Values
Supplied water amounts of canal 1 (m3/ha-s)	(0.8, 0.88, 1)
Supplied water amounts of canal 2 (m3/ha-s)	(3.2, 3.5, 4.0)
Maximum allowable soil loss (kg/ha)	(3650, 4600, 5600)
Maximum allowable soil-phase nitrogen loss (kg/ha)	(10, 10.4, 11)
Maximum allowable soil-phase phosphorus (kg/ha)	(4.3, 4.5, 4.7)

Notes: (*a, b, c*) represents a triangular fuzzy set, where *a* and *c* are the minimum and maximum possible values, and b is the most likely value

the related fuzzy parameters. Other uncertain parameters are treated as discrete intervals. The specific constraints related to the IDFCCP model can be formulated as follows:[5]

$$Pos\left\{\tilde{L}_i,\ \tilde{b}\,\middle|\,\sum_{t=1}^{r}\sum_{i=1}^{m}\tilde{L}_i S_{it}^{\pm} \le \tilde{b}\sum_{t=1}^{r}K_t\right\} \ge \alpha \tag{9a}$$

Subject to

$$Pos\left\{\tilde{L}_i,\ \tilde{b}\,\middle|\,\sum_{t=1}^{r}\sum_{i=1}^{m}\tilde{L}_i S_{it}^{\pm} \le \tilde{b}\sum_{t=1}^{r}K_t\right\} \ge \alpha \tag{9b}$$

$$Pos\left\{\tilde{L}_i,\ \tilde{c}_1\,\middle|\,\sum_{t=1}^{r}\sum_{i=1}^{m}h_1^{\pm}\tilde{L}_i S_{it}^{\pm} \le \tilde{c}_1\sum_{t=1}^{r}K_t\right\} \ge \alpha \tag{9c}$$

$$Pos\left\{\tilde{L}_i,\ \tilde{c}_2\,\middle|\,\sum_{t=1}^{r}\sum_{i=1}^{m}h_2^{\pm}\tilde{L}_i S_{it}^{\pm} \le \tilde{c}_2\sum_{t=1}^{r}K_t\right\} \ge \alpha \tag{9d}$$

$$Pos\left\{\tilde{Q}_t\,\middle|\,\sum_{i=1}^{m}W_{it}^{\pm} S_{it}^{\pm} \le \tilde{Q}_t\right\} \ge \alpha,\ \forall t \tag{9e}$$

where *Pos*{·}denotespossibility of events in {·}; and α is a predetermined confidence level, where the values of α are 0.3, 0.6, and 0.9, respectively. According to predetermined confidence levels, a fuzzy chance constraint can be converted to two crisp equivalents as follows:[41]

1. Confidence levels under the minimum reliability.

$$\sum_{t=1}^{r}\sum_{i=1}^{m}L_i^{L}(\alpha)\,S_{it} \le b^{R}(\alpha)\sum_{t=1}^{r}K_t \tag{10a}$$

$$\sum_{t=1}^{r}\sum_{i=1}^{m}h_1^{\pm}L_i^{L}(\alpha)\,s_{it}^{\pm} \le c_1^{R}(\alpha)\sum_{t=1}^{r}K_t \tag{10b}$$

$$\sum_{t=1}^{r}\sum_{i=1}^{m} h_2^{\pm} L_i^L(\alpha) s_{it}^{\pm} \le c_2^R(\alpha) \sum_{t=1}^{r} K_t \tag{10c}$$

$$\sum_{i=1}^{I} W_{it}^{\pm} S_{it}^{\pm} \le Q_t^R(\alpha), \ \forall t \tag{10d}$$

2. Confidence levels under the maximum reliability.

$$\sum_{t=1}^{r}\sum_{i=1}^{m} L_i^R(1-\alpha) S_{it}^{\pm} \le b^L(1-\alpha) \sum_{t=1}^{r} K_t \tag{11a}$$

$$\sum_{t=1}^{r}\sum_{i=1}^{m} h_1^{\pm} L_i^R(1-\alpha) S_{it}^{\pm} \le c_1^L(1-\alpha) \sum_{t=1}^{r} K_t \tag{11b}$$

$$\sum_{t=1}^{r}\sum_{i=1}^{m} h_2^{\pm} L_i^R(1-\alpha) S_{it}^{\pm} \le c_2^L(1-\alpha) \sum_{t=1}^{r} K_t \tag{11c}$$

$$\sum_{i=1}^{I} W_{it}^{\pm} S_{it}^{\pm} \le Q_t^L(1-\alpha), \ \forall t \tag{11d}$$

The solutions at different confidence levels for IDFCCP can be then obtained through the two-step method.[36] Finally, two groups of objective value and decision variables (presented as interval numbers) corresponding to two scenarios of reliabilities can be obtained. Tables 6–8 list the solutions from IDFCCP at confidence levels of 0.3, 0.6, and 0.9 with two reliabilities. It can be found that the objective function value and part of the decision variables would present as discrete intervals. The solutions also have considerable variations under different combinations of α-cut levels and reliability scenarios. Generally, the system income would decrease as α-cut level increases; meanwhile, the system income under the minimum reliability would be lower than that under the maximum one. For example, at confidence levels of 0.3, 0.6, and 0.9 under the minimum reliability, the system incomes are [145.53, 299.48], [139.94, 287.98], and [134.36, 276.47] ($\times 10^3$), respectively. Under the maximum reliability, the system incomes are [129.01, 265.48], [125.53, 258.33], and [122.06, 251.17] ($\times 10^3$), respectively. This is due to the fact that, when α-cut level increases, the confidence levels of constraint satisfaction would increase, and the constraints of pollutant discharge standards, loading capacities, and available water resources would become stricter. This indicates that a high economic benefit could lead to a high system failure risk. Conversely, a conservative decision alternative is more desirable for mitigating water quality and quantity crisis. A trade-off between system benefit and reliability of satisfying model constraints needs to be analyzed in order to gain an in-depth insight into the characteristics of the management system.

One of the limitations associated with IDFCCP is that the determination of the confidence levels is rather arbitrary. There are currently no effective tools or guidelines to help choose proper confidence levels for satisfying constraints. Secondly, IDFCCP generates many sets of solutions under different confidence levels and reliability scenarios, which may complicate the decision-making process. Multicriteria decision analysis tools may be a potential tool to mitigate such a problem.

	Maximum	[129.01, 265.48]

Further Discussions

The methodologies introduced in this study were based on integration of SMP, FMP, and ILP techniques. The major reason is that different types of uncertainty-analysis tools have varied strengths and weaknesses, in terms of the sensitivity to data quality, accuracy of information interpretation, and requirement of computational efforts. Integration of different algorithms could better deal with dual or multiple uncertainties. In agricultural water management, many types of uncertainties may exist. For example, the available water amount is affected by hydrological and meteorological conditions and may show random features; it can normally be expressed as a stochastic variable; the parameters related to allowable pollutant discharge amounts and environmental loading capacities are subject to human judgments and could be expressed by fuzzy membership functions; parameters related to the benefit and the crop yield may fluctuate in a range where their distribution information may be difficult to obtain due to a lack of sufficient historical data, and therefore, they are more suitable to be described by discrete intervals. Depending on the quality of data, how to choose proper uncertainty-analysis methods becomes a critical challenge for decision makers.

	Maximum	[125.53, 258.33]

The study case used in this entry is only for demonstration purpose, and it is therefore highly simplified. The water quantity and quality levels are conceptualized into simple mass-balance expressions (i.e., the left-hand sides of model constraints). In real-world cases, the related processes are not necessity linear, and rigid simulation models are required to quantify the related relationships. For example, the prediction of nonpoint sources of pollution on a watershed scale requires a sophisticated hydrological model. Thus, a coupling of simulation and optimization models is desired to tackle more complicated problems. However, how to effectively realize such integration is a challenging topic and deserves further investigations.[42] Another issue is about the acquisition of data. Many of the parameters used in this study were obtained through subjective assumption or referred to in the literature. In actual applications, the data quality significantly determines the results of models and thus influences the decision-making processes. Although uncertainty-analysis tools are available, they cannot be considered as alternatives to good-quality data. Efforts are still needed to acquire as much accurate information as possible in order to ensure more reliable modeling results and robust management strategies.

Conclusion

This entry gave a general introduction of how to conceptualize and formulate inexact optimization models for supporting integrated agricultural water quantity and quality management under uncertainty. A number of inexact optimization approaches based on stochastic, fuzzy, and interval programming models were introduced. Each of them is capable of handling a certain type of uncertain information, which is dependent on the uncertain features of the system components. A typical agricultural water management problem was used to demonstrate the applicability of different methods. The study results effectively showed the characteristics of various optimization approaches. Limitations associated with different modeling algorithms were also discussed.

Erosion by Water: Vegetative Control

Seth M. Dabney and
Silvio J. Gumiere

Introduction

Vegetation controls erosion by dissipating the erosive forces of rainfall and runoff (erosivity) and by reducing the susceptibility of soil to erosion (erodibility). Vegetation alters the partitioning of rainfall between infiltration, surface storage, and surface runoff. Erosivity is reduced because rainfall kinetic energy is absorbed, runoff volume is reduced due to increased infiltration, and runoff velocity is slowed through increased surface detention and reduced development of areas of concentrated flow. Vegetation also reduces soil erodibility by increasing soil aggregation, binding aggregates together with roots, and lowering soil matric potential. Vegetation may cover the entire soil surface, as with crops, cover crops, or forests, or it may be limited to specific critical areas, as with various types of conservation buffers. This entry reviews the mechanisms and processes by which vegetation reduces soil erosion by water and decreases yield of sediment and associated pollutants from agricultural fields. Emphasis is placed on vegetative buffers. Crop residue effects are considered in another entry.

General Mechanisms

Slower Runoff

Theoretically, if runoff occurs uniformly over a plane, its depth increases in a predictable manner as slope length increases. In practice, the development of concentrated-flow areas of high velocity limits the depth of sheet flows. By slowing runoff, vegetation can reduce or delay the development of rills and associated concentrated-flow erosion. Vegetation may increase runoff depth 10-fold compared with an equivalent discharge over a smooth surface or fivefold deeper than rainfall-impacted flow over a natural bare soil surface.[1] By increasing water depth fivefold, average velocity, V, is reduced fivefold. Since erosivity of runoff is proportional to V^2 and its sediment transport capacity is proportional to V^5,[2] vegetation reduces concentrated-flow erosion and increases deposition of previously eroded sediment. Sediment trapping is most efficient where the flow is shallow and uniform and the filter is not submerged.[3–5]

The retardation of surface runoff is a critical aspect of the functioning of conservation buffers. Figure 1 illustrates the situation where sediment-laden runoff encounters a vegetated buffer. Because of the additional hydraulic resistance of stems and leaves, flow depth within the buffer, D_2, is greater than in the influence area upslope of the buffer, D_0. The depth at the upslope edge of the buffer, D_1, however, is greater even than that within the buffer (D_2) because of the following: 1) enhanced vegetation growth at the buffer margin; 2) compression of stems into a denser barrier; and 3) loading of the buffer edge with trapped residues and thatch. In many studies, more than half of the sediment trapped by vegetated buffers is deposited in the ponded area upslope of the buffer. Where the ponded area is deep and slow flowing, transport capacity is negligible, and the water surface approaches horizontal. In these circumstances, [6] the fraction of particles with fall velocity V_{si} that will be trapped (T_{i}) is given by

$$T_i = 1 - \exp\left[-V_{\mathrm{si}}\ L/q\right] \tag{1}$$

where q is the specific discharge and L is the length of the pond (Figure 1). When the ponded area retains significant transport capacity, trapping efficiency is reduced, and a transport capacity or sediment re-entrainment term must be added.[7] To accurately capture the sediment trapping capability of narrow strips of vegetation, models must consider backwater effects and realistic flow rates.[8] We will consider achievable sediment trapping efficiencies in a later section.

Increased Infiltration of Water into Soil

Vegetation increases infiltration by reducing the development of surface seals that limit infiltration rates, increasing soil water storage capacity through evapotranspiration, and developing soil macroporosity through root growth and enhanced activities of mesofauna such as earthworms and ants. By covering the soil and absorbing the kinetic energy of raindrops, vegetation can prevent the detachment and rearrangement of soil particles that result in the creation of soil surface seals.[9] Although water use varies with species and climate, vegetation transpires approximately 0.3 m^3 of water for each kilogram of aboveground dry matter produced.[10] This transpiration leaves more capacity in the soil for infiltration of subsequent rains and thus reduces runoff and erosion.[11] Vegetation increases soil macroporosity directly through root growth[12] and indirectly by improving the habitat and activity of mesofauna[13] so that the benefits from vegetation on infiltration increase over time.[14] By slowing runoff due to hydraulic roughness, vegetation increases the depth of ponded water and the area of soil that is submerged, thus increasing opportunities for macropore flow infiltration.

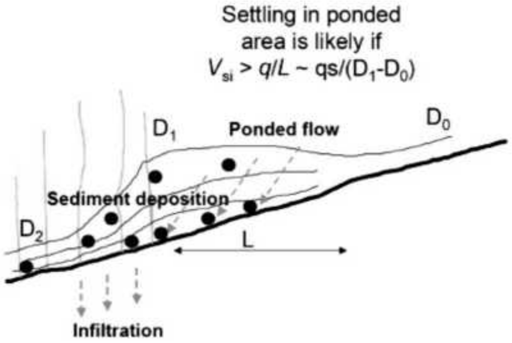

FIGURE 1 Schematic illustration of how vegetative buffers slow runoff, increasing flow depth and trapping sediment.

Reduced Soil Erodibility

Soil erodibility refers to the ease with which soil particles (primary or aggregates) can be detached and transported by the shear forces associated with raindrop splash or flowing water. Soil with increased organic matter content has greater aggregate stability[15] and, hence, greater resistance to detachment and transport. Vegetation may influence soil erodibility due to the additions of soil organic matter from vegetation from litter and roots.[16,17] The effects of vegetation on reducing erodibility include consolidation of soil with time after tillage and binding together of soil particles by roots and by microorganisms, particularly fungi, that use plant biomass and exudates as a food source.[18–20] Although seedling corn roots were not found to significantly reduce interrill erosion,[21] mechanical reinforcement increases soil shear strength and reduces rill, gully, and stream-bank erosion.[22,23]

Vegetative Buffers

Buffer Types

Conservation buffers designed to reduce soil erosion and/ or sediment delivery are usually areas of perennial vegetation placed at critical points in a landscape. These buffers may be located along stream banks or along the edges of fields or may be placed within fields. To distinguish among these buffer types, the nomenclature of the United States Department of Agriculture–Natural Resources Conservation Service (NRCS) is adopted.

The 10 types of conservation buffers that help to prevent soil erosion are summarized in Table 1.[24] The first seven of these buffers are intended to reduce water erosion and sediment delivery in runoff, and the last three help control wind erosion. The first three water erosion control practices are located at the edges of fields, while the other four are usually placed within agricultural fields. Six of the water erosion control buffer types are illustrated in Figure 2.[25] In addition to controlling erosion and/or reducing sediment delivery, many of these buffers can also serve additional purposes, such as improving water quality, sequestering carbon, and providing wildlife habitat (Table 1). Current national standards for these practices are given in the NRCS *National Handbook of Conservation Practices*.[26] Descriptive information about each practice can be found in the CORE4 training materials.[27] Local specification criteria can be found in the local NRCS *Field Office Technical Guide*.

FIGURE 3 Vegetative barriers of vetiver grass *(Vetiveria zizanioides)* planted in rows on contour lines to hold the soil in St. Vincent, British West Indies, during the 1950s.
Source: Vélez.[29]

The three edge-of-field water erosion control buffers are riparian forest buffer (RFB), filter strip (FS), and field border (FB). An RFB is a forested area adjacent to a water body and is frequently combined with grass buffers. An FB is a grassed field margin. Because it may be used for parking and turning equipment, an FB is also usually wider than the minimum indicated in Table 1. In contrast to an FB, traffic is usually excluded from an FS, and vegetation and slope requirements are far more stringent (Table 1). Generally, edge-of-field buffers are designed primarily to trap sediment and infiltrate water, not to control erosion. The RFB is an exception in that it can control concentrated-flow erosion, but this function refers to reducing the velocity of out-of-bank flood flows, thereby minimizing floodplain scour and promoting deposition, and not to reducing erosion from locally generated concentrated runoff. To properly function, these edge-of-field buffers require that runoff pass through them as diffuse sheet flow.

The next four buffer types in Table 1 function within fields and are designed to control in-field erosion. Three of these buffers, alley cropping, contour buffer strip, and vegetative barrier (VB), control sheet-and-rill erosion by interrupting hillslopes with strips of permanent vegetation aligned close to the contour. The widths of these buffers are often varied so that the edges of each cropped zone stay parallel and within strip gradient specifications (Table 1, Figure 2). Alley cropping involves growing crops and forages between strips of trees. Vegetative barriers are usually narrow strips of large stiff-stemmed grasses (Figure 3). Contour buffer strips are somewhat wider strips with less stringent vegetation and contour alignment requirements (Table 1).

Only two buffer practices, grassed waterway and VB, may be specifically designed to control in-field concentrated-flow erosion. Grassed waterways are oriented up and down the slope and are planted with vegetation that is intended to be submerged while functioning. In contrast, VBs designed to control concentrated-flow erosion are planted perpendicular to the flow direction and are intended to remain unsubmerged while retarding runoff.

Buffer Hydraulic Resistance

For fluid flowing over vegetated areas, the total drag force can be divided into two components: 1) the drag force due to the stems and leaves; and 2) the drag force generated by the bed boundary roughness. The drag force due to vegetation may be described by Chow:[28]

$$F_D = \frac{1}{2} C_D \rho A V^2 \tag{2}$$

where C_D is the drag coefficient of vegetation, V is the free stream velocity moving past the stems, A is the cross-sectional momentum-absorbing area of vegetation projected in a plane normal to the flow, and p is the water density.

The hydraulic resistance of vegetation frequently is parameterized with Manning's equation:

$$V = \frac{1}{n} R^{2/3} S^{1/2} \tag{3}$$

where R is the hydraulic radius (flow area divided by wetted perimeter), S is the land slope gradient, and n is a hydraulic resistance parameter (Manning's roughness coefficient). For steady uniform flow where total shear stress is equal to $\rho g R S$, the Manning coefficient for vegetation can be expressed as:

$$n = \left(\frac{1}{2g} R^{1/3} C_D \left(\frac{A}{bl} \right) \right)^{1/2} \tag{4}$$

where g is the gravity acceleration, and b and l are the width and length of the area containing projected vegetal area A, so that the dimensionless term (A/bl) is the vegetal projected area density.

Fig. 4 illustrates how Manning's n varies with the product V and R for three kinds of buffer vegetation. For broad uniform flows, the hydraulic radius reduces to the flow depth, H, and VR is approximately equal to the specific discharge. Also, since the viscosity of water is generally constant, the VR product is also directly related to the flow Reynolds number. At very low flow rates, surface drag caused by soil surface roughness or drag on surface residues may dominate total flow resistance and buffers may have little effect on erosion beyond their ability to reduce detachment. At somewhat higher flow rates, where depths have become several multiples of the diameter of the vegetal elements, the dominant component of hydraulic resistance is drag on emergent stems. When the stems are uniform with height, such as with the simulated filter strips made of brush bristles (Fig. 4) in a flume with a smooth floor,[30] average velocity remains constant with increasing flow and n increases in proportion to the 2/3 power of discharge, as predicted from equation (3).[31,32]

Once vegetation becomes submerged, Manning's n decreases with increasing discharge. At very high flows, all of the vegetation is deeply submerged, the main factor determining hydraulic resistance is the

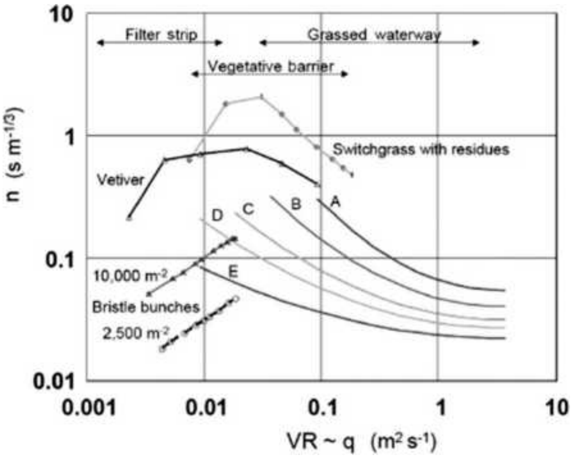

FIGURE 4 Hydraulic roughness of vegetated areas first increases with increasing flow as more vegetation interacts with the flow, then decreases with increasing flow as flow approaches the height of the vegetation and submerges it. Data for A through E from brush bristle data from Jin et al.[30] and Temple et al.[33]; switchgrass (*Panicum virgatum*) data from Dabney[37]; and data on vetiver from Dabney (unpublished).

length of the stems that are dragging in the flow, [33] and momentum transfer is dominated by shear-layer vortices.[34] The vegetal retardance curve labeled “A” in Figure 4 represents 0.9 to 1.0 m tall vegetation while “E” reflects vegetation that had been burned or mowed at about 4 cm height. In designing a GW, the erodibility of the underlying soil and the growth characteristics of the vegetal cover determine a maximum permissible velocity or the allowable hydraulic stress on the soil, and the channel is designed with dimensions great enough that, with expected vegetation, the permissible velocity or stress will not be exceeded at the design discharge.

Vegetative barriers have application at specific discharges that span the range between those of FS and GW (Figure 4) and can thus be used to complement other buffer types by spreading out concentrated runoff. At low flows, the hydraulic resistance of VB increases more rapidly than the 2/3 power of discharge because stems and leaves become less clumped together, increasing projected area with increasing height in the lower canopy.[35] At greater discharges, flow depth increases to the point where stems begin to thin out or bend. Then average velocity increases, the flow resistance, expressed as Manning’s n, reaches a peak value. As with grain roughness,[36] this peak occurs slightly before complete inundation. Beyond this point, hydraulic resistance begins to decline, even while flow depth may continue to increase with increasing discharge.[37] The stiff grasses used to form VB remain erect and emergent at greater flows than other vegetation types in Figure 4 because the large-diameter stems are stiffer and on the order of 2 m tall. The enhanced growth and residue loading noted to occur at the edge of all buffers are also important factors that give VB greater hydraulic resistance than retardance class “A” vegetation. Riparian forest buffer vegetation, of course, remains erect at even greater flows than does VB vegetation, but usually offers less hydraulic resistance at low flows.

Riparian buffers affect flow resistance in streams as well as on floodplains, and they can greatly increase the stability of stream banks through a combination of root reinforcement and hydrologic effects.[38] Riparian buffers generally reduce flow conveyance through drag and by supplying large wood debris to the channel.[39] Reach-scale roughness coefficients of narrow channels may be increased as much as three-or fourfold when grassy banks are replaced by dense woody growth, but effects tend to be much less pronounced for wider channels.[28] The flow resistance induced by a riparian buffer depends on vegetation density, whether the vegetation is rigid or flexible, and whether it is submerged or emergent. Models have been developed to simulate riparian vegetation effects on flow, sediment transport,[40–42] and channel morphology.[43]

Sediment Trapping Efficiency

Native or planted vegetation can remove sediments and other pollutants from surface runoff by filtration, deposition, infiltration, adsorption, absorption, decomposition, and volatilization.[44] However, vegetal effects on flow retardation and sediment transport greatly depend on specific flow rates (Figure 4). Research conducted using rainfall simulators and small plots usually collects buffer performance data over only a narrow range of very low flow rates (below the scale of Figure 4) that cannot represent probable performance under real-world conditions. Unfortunately, such studies are common. For example, a recent extensive review[44] included only two specific flow rates equal to or greater than $0.001\,m^2s^{-1}$. Under those conditions, buffers comprised of either tilled cropland or grass usually trap more than 50% of incoming sediment.[45,46]

At realistic flow rates, the benefits of very narrow, continuous buffers will be underestimated if backwater effects are ignored. Physically based sediment transport models that employ a kinematic wave approximation and ignore[47] or oversimplify[48] sediment deposition in backwater areas can greatly underestimate sediment trapping by narrow buffers[49] where the backwater length may be as large or larger than the buffer width. More physically realistic representations or approximations would recognize the influences of deposited sediment on increasing the water elevation at the buffer and reducing the flow’s sediment transport capacity. Deposited sediment initially flattens local slope, causing a progressive extension of the upslope sediment depositional area[6,8] until the flow over a steepened deposition area has sufficient capacity to transport the sediment load into the buffer.[50]

Flow concentration due to topographic nonuniformity can lead to higher specific flow rates through some portions of buffers than others.[51,52] Sediment trapping efficiency will go down with increasing discharge unless depth and backwater length increase more than specific discharge (Eq. 1). The VB behavior at specific flow rates between 0.001 and 0.01 $m^2 s^{-1}$ (Figure 4) suggests that this may occur under a limited set of conditions. The ability of emergent vegetation to maintain an even distribution of flow despite microscale variation in topography or vegetation density may contribute to the finding that the addition of a VB to an FS increased its sediment retention effectiveness, even when flow was concentrated.[53]

Sediment retention effectiveness of grass[54] and woody[55] vegetative buffers improves over a period of years after establishment due to increased density of grass stem density and/or increased infiltration rate in vegetated areas. Significant gaps or channels through buffers can greatly reduce performance of a buffer of any size. Tillage-induced ridges and channels at the edges of vegetated areas may alter the hydraulic flow patterns of surface runoff, which has the potential for altering the effectiveness of buffers in real-world applications.[56] Field studies demonstrate a wide variety of sediment trapping efficiencies that reflect the local impacts of vegetation buffers on hydrological and sedimentological connectivities. Sediment trapping efficiency was about 50% for grass buffers on 45 m long plots with a 12% to 17% slope in Norway,[57] and a 6 m buffer reduced sediment yield from 35 m long, 1.8% slopes by over 95% in northeast Italy.[58] A riparian buffer along the last 300 m of an ephemeral stream draining a 249 ha watershed trapped 18% of the total sediment load in China.[59] Riparian buffers receiving runoff from hillslopes removed 80% to 90% of incoming sediment in North Carolina, United States.[60,61]

The spatial organization of natural and planned vegetative buffers can significantly alter the hydrological and sedimentological connectivity and, hence, the global water and sediment yields.[62–64] In some cases, the location of the vegetation has more effect than a variation in the size of the buffer.

Conclusions

The effectiveness of vegetation to control erosion and reduce sediment delivery is due to its ability to reduce both detachment of soil particles and the transport capacity of sediment-laden flows. The first increment of buffer has a larger impact on sediment transport than any subsequent increment.[25] Erect emergent vegetation helps to spread runoff and maintain the sediment retention functionality of buffers over a wider range of variation in topography and flow rate. Buffers alter sedimentological connectivity both at the local scale between two adjacent fields and in a distributed way at the watershed scale. Optimal buffer placement in a landscape will rarely resemble a uniformly wide green strip along a stream. Rather, optimal arrangement of buffers for multiple resource concerns calls for a variety of buffer types, sizes, and shapes at different landscape locations starting in watershed headwater areas.[24]

Erosion Control: Soil Conservation

Eric T. Craswell

Introduction

Soil formation is a biologically driven process that is so slow, soil may be considered to be a nonrenewable resource. In most areas of the Earth's surface, the loss of soil due to wind or water erosion by natural processes is balanced by the soil formation creating a dynamic equilibrium so that soil depth depends largely on the climax vegetation. The exceptions are landscapes where volcanic activity exposes new parent material or changes the slope, or lack of precipitation, which leaves soil vulnerable to natural water and wind erosion. By far, the most widespread cause of erosion is human-induced land transformation for infrastructure, forestry, grazing, and crop production, which now covers 98 million km^2 of the Earth's land surface. Soil erosion by water can have serious local off-site impacts especially where the construction of roads and buildings occurs on unstable slopes in high rainfall areas. However, the most widespread water erosion of soils occurs in the vast areas of land developed for crop production and exposed by plowing to rainfall and runoff. The expansion of cropped land to more than 15 million km^2 has been driven by population growth, which is projected to continue to reach 9 billion in 2050. On the other hand, suitably stocked rangelands used for grazing, which retain a relatively complete vegetative cover, are generally protected from water erosion. On the 47 million km^2 of grazing lands, and especially in very dry areas, overgrazing causes de-vegetation, making erosion by wind, rather than by water, the major threat. Either cause of erosion results in loss of the surface layer of soil, which generally contains the highest level of nutrients and organic matter, and hence, the residual soil fertility is significantly reduced. Off-site impacts of the water- and wind-borne soil particles on water bodies and coastal zones are exacerbated by the nutrients they contain, which perturbate natural ecosystem functioning and nutrient cycling processes.

This entry reviews current knowledge of the problem of water and wind erosion of soils, focusing on the environmental impacts, then describes some of the technologies developed to conserve soil and minimize off-site impacts and community-based approaches to promote the technologies.

The Scope and Impact of Soil Erosion

Available global estimates[1] indicate that 7.48 million km^2 of land are affected by moderate to serious soil erosion by water and 2.8 million km^2 are affected by wind erosion. The widespread extent of erosion has raised concerns that the future of agriculture and civilization itself may be threatened.[2,3] The estimates[1] indicate that 6.73 million km^2 of the total soil erosion is occurring in Asia and Africa, which have large areas of tropical soils with high rainfall and steep slopes. These lands, which traditionally were cultivated infrequently by shifting cultivators, are being cropped more intensively or destabilized by inappropriate clearing methods used to establish plantation crops. The recent trend to expand biofuel crop production in these areas may accelerate soil erosion and increase the rates of sediment flow.

The movement of eroded soil in watersheds involves both transport and deposition of sediments in water bodies. Recently published global estimates suggest that human activity has increased the flow of sediments in the world's rivers by 2.3 ± 0.6 billion metric tons per annum.[4] However, the construction of dams has reduced the flow of sediment to the coasts by 1.4 ± 0.3 billion metric tons per annum. The estimates indicate that globally in the last 50 years, 100 billion tons of sediment accumulated in reservoirs, resulting in massive economic costs due to reduced storage capacity, damage to power-generating turbines, and reduced water quality for domestic and industrial uses. Such large off-site economic impacts of soil erosion make a strong case for investments to promote soil conservation. The most significant sediment outflows to the coast occur in areas with short, fast-flowing rivers in archipelago countries such as Indonesia and the Philippines. From an environmental protection perspective, an important ultimate destination of sediments whether natural or human induced is the coastal zone, where assets such as pristine coastal reefs can be severely affected by changed water quality and nutrient inputs. This kind of damage is widespread in some tropical coastal areas where negative economic impacts on the tourist and fishing industries can be serious.

Other off-site impacts of soil erosion by water include both positive and negative effects. Historically, sediment deposition in floodplain areas has contributed to the fertility of the soil of deltas that have become major population centers. However, sediment deposition in water bodies such as streams and lakes affects freshwater biodiversity and recreational fisheries and can cause streams to change course, leading to damage to infrastructure such as roads and bridges. On the other hand, poorly implemented construction of roads and bridges, and urban and industrial development in general, can be a major cause of localized soil erosion, the engineering aspects of which are addressed by organizations such as the International Erosion Control Association.[5] Drainage structures and the stabilization of steep banks with vegetation and screens can prevent surface erosion, but construction must also address the risk of landslips caused by subsurface flows.

Viewed at the landscape level, soil erosion on agricultural land may channel runoff, creating gullies that worldwide are responsible for 44% of soil erosion.[6] Thus, measurements of soil erosion on small plots, which dominated much of the soil erosion research in the past, do not capture the full extent and complexity of the problem. Furthermore, as with infrastructure developments, subsurface flow of water on hill slopes and stream banks also contributes significantly to the generation of sediment that impairs stream flow.[7] These considerations, which have only recently become better understood, strengthen the case for a landscape approach not only to research on soil erosion but also to the development and implementation of soil and water conservation practices.

The extent of wind erosion is less well understood than water erosion but is understood to be episodic and largely restricted to dryland areas. In China alone, 1.91 million km^2, equal to 20% of the land area of the country, is estimated to be affected.[8] The extent of the problem is increasing due to intensification of soil cultivation and increased grazing pressure on native pastures. This pattern is repeated in some other dryland and desert areas such as those in West Africa, Australia, and North America (where the infamous "dust bowl" of the 1930s occurred). Some scientists have labeled wind erosion as "dust storm erosion," indicating that the off-site impact on air quality should be emphasized. Although episodic and sometimes uncommon, these air quality impacts affect the health and lives of millions of urban dwellers far from the sites where wind erosion is occurring. The impacts of wind erosion and dryland degradation are considered so important by the international community that the United Nations Convention to Combat Desertification (UNCCD) was created. The UNCCD estimates that 70% of the Earth's drylands are degraded.[9] The extent of this problem is projected to expand in many regions due to climate change.

Productivity Impacts of Soil Erosion

The extent of soil erosion by water depends on the steepness and length of the slope of the land, the rainfall and runoff intensity/erosivity, the erodibility of the soil, and the management of the soil surface and other support practices such as strip cropping, vegetative strips, etc. These factors from the Revised Universal Soil Loss Equation (RUSLE) can be combined in an equation to calculate the average soil loss per annum.[10] By comparing this rate with an estimate of "tolerable" soil loss, soil conservationists can assess needs and plan soil and water conservation measures. Soil loss tolerance (T) is the maximum amount of soil loss in tons per acre per year that can be tolerated and still permit a high level of crop productivity to be sustained economically and indefinitely. The RUSLE has been extensively studied and used in North America where an extensive database provides a sound basis for estimating the empirical parameters for the case of mechanized agriculture. Other simulation models based on an understanding of the physical process of soil erosion provide an alternative to the RUSLE and can be adapted more easily to areas such as tropical steeplands. One example of such a model is the Griffith University Erosion System Template (GUEST),[11] which has been successfully applied to steep- land areas with high rainfall intensities in several Asian countries and Australia. The validated soil erosion model provides a basis for developing new tools for research including decision support tools for the evaluation of sustainable land management.[12]

The on-site impacts of soil erosion on productivity vary considerably and appear to be site specific. A review[13] of extensive experimental data sets showed that relative impacts of past erosion on crop yields measured in North America and Europe were two to three times smaller than those in Africa, Asia, Australia, and Latin America. Apparently, the lower crop yields in the latter regions caused yields to decline proportionally more significantly with the same amount of soil loss. Contributing to this difference may have been factors such as the shallower depth of the soil and the absence of the effects of higher fertilizer applications in North America and Europe that might mask the nutrient loss due to erosion. Further analysis of published data[14] showed that, on an annual global average basis, soil erosion caused a 0.3% loss of yield of six crops (maize, millet, potatoes, sorghum, soybeans, and wheat), resulting in an annual economic loss of $523 million. Such global averages do not take account of significant variations, especially in humid tropical areas where shallow soils, steep slopes, and high rainfall intensities make soil erosion by water a highly significant threat to the sustainability of smallholder farming.

Soil Erosion Control

The problem of soil erosion in steeplands spawned conservation measures that date back centuries and are still practiced in some developing countries. These technologies based on indigenous knowledge utilize the same principles as modern soil conservation measures and include a wide range of methods that comprise terraces, handmade ridges, natural vegetation strips, stone bunds, logs, etc. Some examples are listed in Table 1.

Table 2 shows the wide array of vegetative and mechanical approaches to soil conservation in agricultural landscapes. Some of these technologies are finding especially widespread applicability, depending on the farming system and site characteristics. Protecting the soil surface from raindrop or wind impacts is the first principle of onsite erosion prevention. In modern mechanized agriculture, this increasingly is being achieved through the adoption of no-till practices based on the development of machines that can plant through mulched crop residues and on the availability of herbicides to control weeds. The protection of the soil surface afforded by the mulch reduces the erodibility of the soil while arresting the decline in soil organic matter caused by conventional plowing and reducing the use of

TABLE 1 Some Indigenous Technologies for Soil Conservation and Erosion Control[15,16]

Country	Technology	Description
China	Ditches along hillsides	Grassed contour ditches between rows of fruit trees
Ethiopia	Stone bunds	Stones collected and placed in lines on contours
India	Kana bandi	Windbreaks of dead wood
Kenya	Fanya-juu terraces	Soil thrown uphill to form contour bunds
Laos	Lao Theung systems	Sustainable shifting cultivation on mid-altitude steeplands
Nepal	Terraces	Manually built on steep slopes; terrace risers sliced regularly

TABLE 2 Technologies for Soil Erosion Control in Agricultural Landscapes

Vegetative	Mechanical
Cultivated crop land	Cultivated crop, forest, and grazing land
• Mulching	• Conservation tillage
• Crop management	Contour tillage
Dense planting	Ridging and ridge tying
Multiple cropping/agroforestry (contour strips or rotations)	Minimum till and no till
Cover cropping	• Terracing
Forest land	• Waterways
• Tree planting	• Structures
• Agri-silviculture	
Grazing land	
• Plant grasses	
• Plant shrubs

fossil fuels for tillage. The adoption of no-till practices in the major grain-producing and -exporting countries is gathering pace[18]; in major South American food-producing countries, average adoption ranges from 38% to 67%, whereas adoption in Canada, the United States, and Australia is 26%, 14%, and 18%, respectively. Future expansion in the adoption of no-till practices has enormous potential to reduce on- and off-site impacts of soil erosion in large-scale agricultural production areas.

As shown in Table 2, traditional soil conservation measures in areas with mechanized agriculture were based on a wide array of structures such as contour banks, but recently, this principle has been extended to contour plowing, vegetative strips, and even controlled traffic systems and geospatial technologies such as global positioning systems, remote sensing, and geographic information systems. Utilizing the last-mentioned technologies, precision conservation[19] provides a means to plan conservation on a whole-farm or watershed basis rather than on a singlefield basis. Tools such as erosion hazard maps help land managers to pinpoint hotspots and prioritize conservation measures accordingly. Thus, cultivated fields, vegetation strips, and riparian zones can be managed on a precise site- specific basis to reduce soil erosion and sediment outflows.

As mentioned above, soil conservation presents special and difficult challenges in many developing countries. The steepland areas in the humid tropics are a particular concern because of the high rainfall intensities and steep slopes, which make soil erosion a potent risk. Additionally, the poverty of subsistence farmers and their lack of tenure over the land add to the problems faced by soil conservation agencies. In these areas, agroforestry, based on contour plantings of shrubs, is a promising way to create biological terraces that stabilize the soil and provide level areas in between on which food crops can be planted.[20] The inclusion of fruit trees, or other perennial cash trees and shrubs, in the hedgerows provides a source of extra income and, at the same time, helps to stabilize the hillside.

From a broader whole-farm or watershed perspective, modern approaches to soil and water conservation can be seen to encompass concepts such as the multifunctionality of agricultural land. This concept promoted in Organisation for Economic Co-operation and Development (OECD)[21] countries entails food security, economic and social functions of land, and environmental functions. Although the multifunctionality concept may be (mis)used in some developed countries to justify farm subsidies and hence play a role in trade negotiations,[22] the application of this holistic concept has been used to analyze and illustrate the benefits of integrated farming practices in countries such as Thailand.[23] In developing countries, the various farm enterprises such as cropping, aquaculture, livestock production, forestry, and fruit production have considerable potential for synergies that increase productivity and profitability while protecting soil and enhancing ecosystem services.

Attaining Widespread Soil Erosion Control

In the 20th century, concern about the on- and off-site impacts of soil erosion prompted governments, mainly in developed countries, to establish soil conservation services. The traditional approach to these services in areas of mechanized agriculture was for a government agency to provide trained soil conservationists to advise and help farmers plan contour banks, strip cropping, minimum and zero tillage, and other measures to reduce erosion in their fields. While these efforts have not been successful in many countries, in the United States, despite massive investments in soil conservation since the 1930s, some experts believe that up until recently, the rates of soil erosion have not declined.[24] To replace the old top–down approach to soil conservation extension, many practitioners now advocate community-based approaches.

The usual starting point for the introduction of soil conservation measures is the farm because individual land managers are directly responsible for managing their soil and water resources in the context of the needs of the watershed and community as well as their own needs. The following examples from China and Uganda show that farmer commitment and soil conservation policy implementation can yield success in defined regions within a country. On the Loess Plateau, which had a history of massive erosion during times of war, and even the cultural revolution, the introduction of the farmer responsibility system and the adoption of watershed-based comprehensive soil conservation policies by the Chinese government have significantly reduced erosion and the flows of sediment into the Yellow River.[25] The support of farmers in the Kigezi district, or at least an absence of resistance from them, has proven to be the key to the successful implementation of soil conservation policies introduced in colonial Uganda.[26] Farmers understood that their livelihoods depended on their conservation of the soil.

In developed countries, successful movements such as the landcare program in Australia[27] and conservation districts in the United States[28] are based on a bottom–up approach in which members of rural communities work together to conserve not only the soil and water resources but also, on the basis of a more holistic watershed approach, the biodiversity and landscape integrity. These movements encourage principles of stewardship of natural resources while sustaining the productivity of the farms. The success of the landcare approach—Australia has 6000 landcare and coastcare groups—is built on a bottom–up organization based on networking through boards and committees and leaders who are passionate about conservation. Governments at the local, state, province, or national level provide support through coordination at the broader catchment and regional levels, as well as through developing long-term strategies, identifying knowledge gaps, and supporting research and development. The ultimate scale is the river basin in which the cumulative effects of soil and water management on runoff, nutrient, and sediment flows combine with riparian management impacts to determine the nature and extent of human influences on estuarine and coastal zones. In the case of large river basins, national and international levels of governance may be involved.

While it is difficult to precisely pinpoint the drivers of the shift in thinking towards a broad-scale, community- based approach to soil conservation, one of its important dimensions has been the widespread recognition of the importance of the ecosystem services provided by farmers. The associated increase in emphasis on the need to reduce the off-site negative impacts of soil erosion has culminated in the proposition that farmers be paid Green Water Credits (Green Water Credits is a mechanism for transfer of cash to rural people in return for water management activities that determine the supply of all freshwater at source—these activities are presently unrecognised and unrewarded, see Green Water Credits).[29] This approach, and the promise of benefits from carbon credits, may help accelerate the adoption of soil conservation technologies in developing countries, because while the landcare model has been adopted in parts of some developing countries, e.g., the Philippines, a comprehensive and expensive national-scale approach such as that in Australia and the United States has not been feasible in many parts of the developing world. Ultimately, a broad view of sustainable land management is needed, and this can be achieved at a range of scales provided it entails a community-based approach with farmer participation; these are the keys to success in both developed and developing countries, although the most appropriate frameworks for community, institution, and government involvement vary from place to place. Nevertheless, progress is being made, as indicated by a comprehensive review of 286 "bright spots" in 57 countries.[30] The bright spots were defined as examples of intervention—where poor farmers have increased their productivity and income—having a positive impact on land and water resources. Factors identified as keys to success were investment in appropriate land and water management technologies and human factors such as the aspirations of the leaders and community to improve their circumstances and entrepreneurship. Applying such lessons to facilitate the widespread adoption of soil conservation in every country with an agricultural base presents a major future challenge to land managers, technologists, and policy makers.

Farming: Organic Pest Management

Ján Gallo

Introduction

Organic farming in its essence is defined as a system of efficient production that is expected to create an environmentally beneficial, integrated, human, and economically stable agricultural system. Organic farming changes the philosophy of human consideration of nature from anthropocentric and technocratic arrogance to the gradual return of a holistic view in which humans are a part in the sense of the old trueism: "*We have not received soil, water and landscape from our parents, but we have borrowed them from our children.*" According to this philosophy, nature is the uniform whole with its internal natural value and from this point of view ecological, economic, and social aspects of agricultural production are derived. The organic system of farming is based on a maximally closed flow of energy without any additional outside inputs; therefore, it is a sustainable system that uses local and renewable resources. Control of harmful biotic (diseases, pests, and weeds) and abiotic factors is an integral part of the system.[1,2]

Strategy of Control against Animal Pests

The strategy of controlling harmful animal organisms in the organic farming system is based first of all on natural factors of resistance. It includes mainly internal factors (genetic predisposition of organisms) as well as the external ones that act inside the ecosystem. External ecosystem factors are of an abiotic (pedo-hydrometeo factors) and biological character. The biotic resistance of the environment has been applied prevailingly against animal pests using mainly the factor of natural mortality.[2,3]

Basic strategic objectives for pest regulation can be summarized as follows:

A species that seems to be a potential pest can survive under certain acceptable abundance. This means that the population density of an individual species is regulated and those measures that are directed to species eradication at all costs are not realized. The term "pest" is relative, and for this reason, animals in agricultural crops within organic farming cannot be subdivided to harmful, indifferent, and useful.

The unit of regulation is the ecosystem; and for this reason, there is a need to contribute to maintaining its autoregulation capability in maximum range.

Great emphasis is placed upon knowledge of natural antagonists (parasitoids, predators, and pathogens). Miscellaneous species must be maintained within the landscape.

Measures against pests have to be in accordance with economic aspects.

Organic farming does not represent the simple substitution of synthetic chemical pesticides by biological ones, it is a system of complex measures that promotes the good health of plants and not the total annihilation of pathogens.[2–4]

Regulation of Animal Pests

Animal pests live in all field crops, but within each individual crop they require different conditions for their development. Under our conditions, 69% of field crop pests are staying on arable soil during the year. This linkage to arable soil is manifested in the population dynamics of individual species.

This strategy of control against animal pests requires that the regulation of animal pest occurrences is realized mainly through the utilization of

1. the phenomenon of biotic resistance of the environment and
2. anthropogenic measures

Phenomenon of Biotic (Natural) Resistance of the Environment

Natural mortality (which is caused first of all by the activity of predators, parasitoids, and parasites) is a significant natural regulator (bioregulator) of plant pest populations in agriculture. This regulation is manifested in the long-term maintenance of pest population density below the level of harmfulness. Bioregulators in the organic farming system belong mainly to the group of spiders (Araneida), predacious mites (Acarina), and parasitoidic insects (Insecta) predominantly within the order of Hymenoptera and Diptera. Another group of bioregulators can be found within the group of phytopathogenic microorganisms (for instance fungi, bacteria, and others). Spiders (Araneida) occur in all biotopes on soil surfaces and on the above-ground parts of plants and can effectively reduce the population of harmful insects, mainly aphids (Aphidoidea), in field crops. Predacious mites (Acarina) belong to edaphic fauna and within stands of field crops are effective natural regulators of pests that live in the soil. Predacious polyphagous bugs, (Heteroptera) for example, within the Anthocoridae family feed on the larvae of thrips (Thysanoptera), aphids (Aphidoidea), and mites (Acarina). The golden-eyed fly (Chrysopa perla) is able to destroy 200 to 500 aphids during its larval stage, but it can also feed on Diaspididae, Tetranychidae, and the larvae of flies. Parasitoidic Hymenoptera, predominantly the species that belongs to the families of Ichneumonidae, Braconidae, and Chalcidoidae, in the larval stage feed on the different stages of insect, starting with eggs and finishing with imagos. Imagos of these parasites as well as their larvae frequently injure the body of the host, feed on its body fluid, and finally cause the death of the host. For example, *Apanteles, Angitia,* and *Microgaster* are some of the main regulators of white butterflies (Pieridae). *Tersilochus heterocerus* is an important parasitoid of rape beetle (*Meligethes aeneus*). Beetles of the Carabidae family represent a significant group of predacious insects (for instance, *Calosoma sycophanta, C. inquisitor*) in field crops. They feed on aphids (Aphidoidea), larvae of beetles (Coleoptera), caterpillars of butterflies (Lepidoptera), and larvae of Diptera that they chase on the soil surface. Beetles *(Coleoptera)* within the Staphilinidae family stay on the surface of soil and feed on aphids, eggs, larvae, and cocoons of insects, partially also on fungi (*Aleochara bilineata* significantly regulates *Delia brassicae*). Another very important group of predacious insects in field crops is ladybugs (Coccinellidae), the larvae and imagos of which feed on aphids (Aphidoidea) and help to reduce their numbers (an imago consumes 40 to 60 aphids per day). Syrphidae live in all cultural crops and their larvae feed on aphids and belong to the effective factors through which an occurrence of aphids is regulated in cereals, sugar beet, potatoes, and legumes (a larva consumes about 100 aphids per day).[3,5]

It is necessary to protect the above-mentioned components of natural resistance in the environment and create optimum conditions for their existence. However, in many cases, the overpopulation of pests cannot be regulated only by means of their natural enemies (bioregulators).

Anthropogenic Measures

In the cases when biotic resistance of environment is less effective and there is a danger of substantial reduction in yields or deterioration of bioproduct quality, anthropogenic measures can be applied. Anthropogenic measures fulfill two essential roles:

1. To prevent pests from attacking healthy plants
2. To improve the health of attacked plants

These are mainly indirect (preventive or prophylactic) methods for pest regulation. Direct (repressive or therapeutic) methods can be used only in the most necessary cases, and only those that are in accordance with International Federation of Organic Agriculture Movements (IFOAM) rules. Indirect measures include crop rotation, selection of proper species and cultivars, appropriate soil cultivation, suitable fertilization, green fertilizing, and outside and inside quarantine. Crop rotation seems to be the dominant sustainable procedure on the farm that protects, renews, and supports biodiversity and also plays a key role in soil fertility preservation. By means of the above-mentioned indirect principles, overpopulation of pests can be restricted completely, or at least very substantially. *Zabrus gibus* damages winter wheat five to eight times less when winter wheat follows after sunflowers or maize within crop rotation. If cereal crops are grown several years in the same place, they are frequently damaged by *Scotia segetum*, nematodes (*Heterodera*), and frit fly (*Oscinella frit*). Within organic farming, the portion of cereals in crop rotation would not exceed 50%. Early plowing of stubble can eliminate 70% to 80% of thrips (*Haplothrips tritici*). On the other side, late sowings of peas are more likely to be attacked by pea aphids (*Acyrthosiphon onobrychys*) and weevils (*Apion* spp.). Harvesting maize to the shortest possible stubble (0.08 to 0.10 m) substantially decreases the number of overwintering carterpillars of European corn borer (*Ostrinia nubilalis*). If the harvest is done early enough it enables about 80% of pests to be removed together with plant material. Occurrence of bean weevils (*Acanthoscelides obsoletus*) on bean plants can be effectively reduced if rows of beans are alternated with rows of maize, which by its "odor" causes this pest to become disoriented as it is flying toward bean plants. Fertilization within organic farming is based predominantly on own farm organic fertilizer utilization, however, its application must follow the rules of IFOAM.[3,5]

For the future, solutions are needed for problems related to bioproducts from the raw materials grown within organic farming and that have received a certificate according to the rules of IFOAM. We have to face the fact that growing plants are exposed to biotic and abiotic stresses and in some cases they react by forming "natural pesticides" that can be dangerous for humans (e.g., carcinogenic psoralens in celery, parsley, and parsnip). While the above-mentioned and similar matters have to be solved, the medicinal advantages of bioproducts resulting from organic farming must not be doubted.[1,5]

In addition to the principles of sustainable development, appropriate laws should be created including legislative treatment of organic farming and biofoods production for each respective country (224/1998 Z.z in the Slovak Republic). By means of the law a new historical paradigm will be defined, within which nature will become a globally respected value.

Integrated Nutrient Management

Bal Ram Singh

Introduction

The basic concept underlying integrated nutrient management (INM) is the maintenance or adjustment of soil fertility/productivity and of optimal plant nutrient supply for sustaining the desired level of crop productivity.[1] The objective is to accomplish this through optimization of the benefits from all possible sources of plant nutrients, including locally available ones, in an integrated manner while ensuring environmental quality. This provides a system of crop nutrition in which plant nutrient needs are met through a preplanned integrated use of mineral fertilizers, organic manures/fertilizers (e.g., green manures, recyclable wastes, crop residues, and FYM), and biofertilizers.[1] However, to safeguard the environment from degradation and to maintain clean and safe water, air, and food, the use of chemical fertilizers must be based on sound scientific and ecological lines.[2] The use of nutrient sources and their combination can vary greatly depending on the landuse system and on ecological, social, and economic conditions at the local level.[1]

Nutrient mining (implying more extraction of nutrient than returned back to the soil) in many developing countries and excessive fertilization (more fertilizer application than required for maximum yield) in developed countries are major causes for soil fertility decline and environmental degradation. These situations have created the need for the use of INM practices. In low- and medium-input agriculture such as in Africa and in intensive cropping systems with high cropping intensity of high yielding crops in many Asian countries, nutrient balance is increasingly becoming negative. For example, in Bangladesh, high-yielding crops remove considerable quantities of nutrient leading to annual depletion of nutrients (NPK) to as much as 250 kg ha^{-1} yr^{-1}. Besides the depletion of NPK, S and Zn deficiency areas have been identified in more than 4 and 2 million ha, respectively.[3]

Excessive fertilization is wasteful in terms of fertilizer, and it not only creates antagonistic effects that disturb the nutrient balance and thus leads to reduced crop yield and produce quality but also produces suboptimal economic returns. Although excessive fertilization, for example, with P could lead to significant residual benefits, it blocks the farmer's capital unnecessarily on one hand and can also lead to higher P losses to water resources in erosion-prone areas on the other hand. Excessive fertilization with N often results in poor N use efficiency, greater possibility of lodging and pest and disease attack, and greater N losses leading to negative impacts on the environment.

INM identifies the best combination of various types of plant nutrients in different fields for a balanced plant nutrient and plant yield, while sustaining soil fertility and controlling nutrient losses. Therefore, the cropping system (rather than a single crop) and the farming system (rather than an individual field) are the focus of INM approach for developing the practices for the main agro-ecological region of a country and for the various categories of farms.[1] It is envisaged that locally available materials of plant or animal origin as by-products of agricultural activities be used or, where such materials are not available, in situ production of organics, such as fast-growing leguminous shrubs or green manure crops, blue green algae (BGA), and phosphate-solubilizing bacteria (PSB), be practiced. Experiments conducted at several locations in north India have shown that green manure crops of sesbania (*Sesbania aculeata*) or sunnhemp (*Crotalaria juncea*) along with recommended fertilizers resulted in increased productivity of the system by 8%–20%. Furthermore, large biomass of narrow C:N ratio incorporated into the soil contributed to a sizable amount of plant nutrients, especially N, and improved soil physical properties.[2] In contrast to organic farming, INM involves a needs-based external input approach, taking into account a holistic view of soil fertility.

For a successful INM, we have to have judicious use of mineral fertilizers, maximum use of organic materials, and minimum negative environmental impacts. To achieve this, we need to include several steps, such as 1) availability of on-farm and off-farm resources; 2) yield target based on resource availability; 3) nutrient requirement to achieve desired yield; 4) integration of mineral and organic fertilizers; 5) time and method of fertilizer application; 6) efficient soil and water conservation measures; and 7) sustaining physical, chemical, and biological fertility of soils.[4]

This entry presents the integrated management of plant nutrients coming from mineral fertilizers and biofertilizers to increase crop productivity, nutrient use efficiency, and sequestration of soil carbon and other nutrients in soils and to avoid environmental degradation. Examples are cited from different soil and environmental conditions to illustrate the significance of INM for sustainable use of nutrient resources and soil carbon sequestration and to safeguard the environment for future generations.

Components of INM Systems

The main components of an INM system are shown in Figure 1. The figure shows a judicious integration of mineral and synthetic fertilizers, suitable minerals [e.g., phosphate rock (PR), elemental sulfur], crop residues, green manures, organic manures of plant or animal origin (e.g., compost, farm yard manure, animal slurry) and recyclable organic wastes from industry and households, and microbial inoculants (e.g., biofertilizers). At the farm level, INM aims to optimize the productivity of the nutrient flows through the soil/crop/livestock system during a crop rotation. Furthermore, INM improves the production capacity of a farm through the application of external plant nutrient sources and amendments and the efficient processing and recycling of crop residues and on-farm organic wastes. The nutrient cycling in soil–plant–air–water systems is shown in a schematic diagram (Figure 2).

The INM involves a more rational use of plant nutrients by balanced, efficient, yield-targeted, site- and soil- specific nutrient supply and a combination of mineral and organic fertilizers on a cropping-system or crop-rotation basis. It puts emphasis on monitoring and controlling the unwanted side effects of fertilization and the possible adverse consequences for soil health, crop diseases, and pollution of water and air. The main aim of INM is to obtain high yields and good product quality with

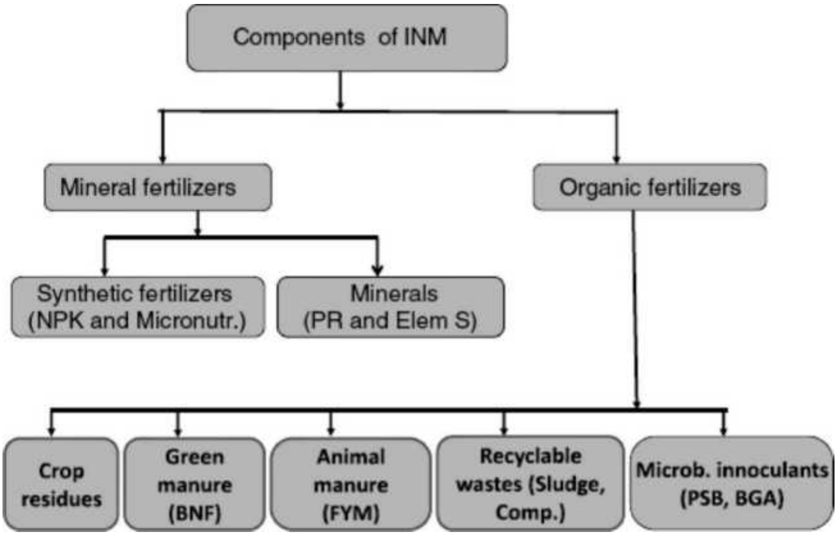

FIGURE 1 Components of integrated nutrient management system.

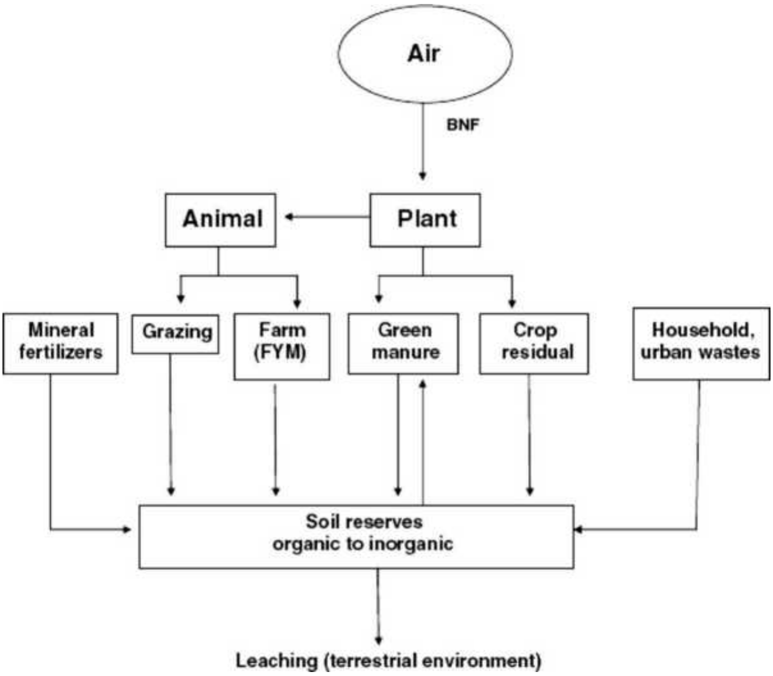

FIGURE 2 Nutrient cycling in soil–plant–air–water systems. BNF, biological N fixation; FYM, farmyard manure.

minimum damage to the environment. It also provides opportunities for saving resources, protecting the environment, and promoting more economical cropping for the farmers. It also promotes changes in land use, crop rotations, and interactions between forestry, livestock, and cropping systems as part of agricultural intensification and diversification.[1] Different components are described briefly below.

Mineral and Synthetic Fertilizers

Fertilizer use in the past has accounted for about 50% of the annual global food harvest and thus has played a very important role in increasing the food supply for the evergrowing population in the world. Improvements in agricultural production in many parts of the world, especially in Asia, have primarily come from intensive use of chemical fertilizers. A good example of the role played by fertilizers in increasing food production by many fold can be seen from India. During the last five decades, grain production in India has gone hand in hand with fertilizer consumption (Figure 3). The grain production increased from 52 million megagrams (M Mg) in 1950/1951 to 231 M Mg in 2007/2008 while the fertilizer (NPK) consumption during the same period increased from 0.07 to 24.7 M Mg.[5] It needs, however, to be emphasized here that along with fertilizer consumption, use of high-yielding varieties, increased irrigation facilities, and enhanced use of pesticides have also played a key role in this spectacular rise in grain production in India. At the same time, the quality of soil, air, and water has deteriorated and the area of natural ecosystems has decreased because of the intensification and extension of agricultural production.[6,7] On the contrary, the increase in food production in Africa and the Cerrito of Brazil is caused by the expansion of the cultivated area.

Worldwide mineral fertilizer nutrient use is expected to increase from 142 M Mg in 2002/2003 to 165 M Mg in 2009/2010, to 175 M Mg in 2015, to 199 M Mg in 2030.[8] However, the demand differs considerably among the regions (Table 1). The largest share of mineral fertilizers will be used by East Asia, followed by South Asia. These two regions together will account for about half of world mineral fertilizer use by 2030. The average application rates of mineral fertilizers in different development regions

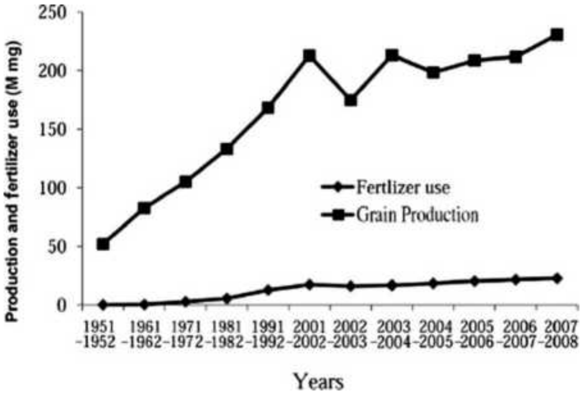

FIGURE 3 Fertilizer use and grain production scenario in India.

TABLE 1 Mineral Fertilizer Use in Developing Regions

Region	Total Nutrients ($N+P_2O_5+K_2O$) 2002/2003 (M Mg)	2009/2010 (M Mg)
Sub-Saharan Africa	2.3	
Near East and North Africa	7.9	
East Asia	50.6	59.5
South Asia	20.9	25.7
Latin America	13.2	18.3
World	141.6	165.0

Source: Food and Agriculture Organization.[8]

of the world have also increased greatly while the rate applied in Sub-Saharan African (SSA) countries have continued to be very low. This has resulted in continuous decrease in per capita food production in Africa in contrast to sustained increase in Asia and Latin America.

Mineral fertilizers normally supply three major nutrients (N, P, and K), but since the last few decades, incorporation of micronutrients in mineral fertilizers has also become very common in many regions of the world because of increasing cases of their deficiencies in food and feed crops and added focus on human and animal health. A brief description of these fertilizers is presented below.

Nitrogen

The nitrogen requirement of 1 Mg of cereal grains is 15–30 kg N,[9] and globally, 85 M Mg of N through fertilizers is used,[8] which makes nearly 60% of all fertilizers used. Even in the future, N will be the most needed nutrient because of increasing food demands. Losses of N can range from 30% to 50% of mineralized N. If not taken by plants, it can be leached to underground layers because it is not retained by soils. Leaching losses coupled with N loss to the atmosphere through denitrification and ammonium volatilization lead to low N use efficiency of fertilizers. The average recovery of N by crops depends on crops and fertilizer used and the soil and management conditions. Nutrient recovery from different fertilizers is shown in Table 2. The table shows that N recovery varied from 20% to 70% depending upon the N source. In a long-term experiment (22 years) in India, it was found that N recovery was 17% in maize and 32% in wheat with application of N alone, but the recovery was almost doubled (33% in maize and 65% in wheat) when P and K along with N were applied.[10] The later treatment also resulted in buildup of organic C in the soil. Singh and Swarup[11] also made similar observations based on the results from several long-term experiments from different parts of India. They also found that continuous use of N alone resulted in the greatest decline in yield at all centers, indicating that other major nutrients and micronutrients were becoming limiting factors, and adequate response to N could not be obtained unless the yield-limiting factors were remedied.

Nitrogen balance is very important in the INM as it is an excellent tool in choosing appropriate nitrogen sources. The N cycle, considering natural to anthropogenic fluxes, is currently under the influence of anthropogenic control in many parts of the world. Nitrogen pool and flux studies should adopt a comprehensive and consistent treatment of the reservoirs and cycling of terrestrial N, so as to improve the treatment of N cycling in models and mass balance studies. This will facilitate better scientific explanation of historical N-related environmental changes and more closely balance N budgets on a range of geographical and temporal scale as the N balance surplus is an important indicator for the evaluation of the sustainability of agriculture.[12]

Although biomonitoring techniques are usually simple and relatively inexpensive on an individual basis, the natural variability of the environment may require large numbers of samples to be taken to meet the required statistical precision. Consequently, biomonitoring should not necessarily be seen as a low-cost approach to compliance assessment. The requirement for a statistically sound method places stringent constraints on the sampling design. Total tissue nitrogen (N) has been measured for many

TABLE 2 Average Utilization Rate of Fertilizer Nutrients by the First Crop

Nutrient and Source	Utilization Rate (% recovery)
Nitrogen, mineral	50–70
Nitrogen slurry	30–50
Nitrogen manure	20–40
Phosphorus, mineral	10–20
Potassium, mineral	50–60
Micronutrient mineral	0.5–5

Source: Roy et al.[1]

years in all types of plant tissue to assess atmospheric nitrogen de- position.[13] This method requires both field sampling and laboratory analyses. On a limited scale, the method has also been used to assess the N need of plants during their growth to work out for overdressing of N fertilizers as well as to determine the N requirements of plants.

Phosphorus

The dynamics of phosphate in soil presents special problems because of the low solubility of most P compounds. Phosphorus added through soluble fertilizers first enters the soil solution, but much of it is converted into adsorbed P within a few hours. Furthermore, organic manure is not able to meet crop requirement and hence P fertilizer is necessary to overcome P depletion. As shown in Table 2, the recovery of P is much lower than that of N, being only 10%–20%, but P, unlike N, gets accumulated into its reserves in soil as it is not lost from the soil except through soil erosion. In the high P-sorbing soils of Cerrado, Brazil, large application of P can replenish P and the residual effects of P can last for 5 to 10 years.[14] These corrective applications, along with subsequent maintenance application and sound agronomic practices, have proved very successful in this region.[14]

Reactive PRs can be used in acid soils and for long- duration crops. Their suitability depends on the reactivity of the rock, its particle size, soil pH, and type of crop. In several African countries, deposits of high to medium reactive (>15 g citrate-soluble P kg^{-1}) PRs have been found, which can be used without any pretreatment. The effectiveness of PRs not only is related to the reactive “available” portion but also depends on the P-mobilization capacity of the soil, which is related to pH, moisture status, and biological activity. [15] On-farm trials in P-deficient soils in western Kenya demonstrate that Minjingu PR was found to be as effective as triple superphosphate (TSP, 20% P) at equal P rates. The benefits are most pronounced with the integration of agroforestry technologies that improve soil fertility. Besides Minjingu PR, Busumbu PR from Uganda (BPR) is potentially another source of P.[16] Sharma et al.[17] calculated the relative agronomic effectiveness (RAE), defined as follows:

$$\text{RAE}\ (\%)\ = \frac{\text{Yield with PR control}}{\text{Yield with DAP control}} \times 100 \tag{1}$$

They[17] found that the RAE of Mussoorie rock phosphate (MRP) + PSB in relation to diammonium phosphate (DAP) as judged by the total productivity was 53%–65% in the first cycle but reached 69%–106% in the third cycle of the cropping system. The P balance (application—crop removal) was generally more positive for MRP + PSB than for DAP, and the highest P balance was recorded with an application of 52.5 kg P ha^{-1} as MRP + PSB, and it resulted in the highest 0.5 M NaHCO3 extractable P content in soil.

Potassium

Potassium (K) dynamics are determined by the rate of K exchange from the clay and organic matter surfaces and the rate of release from soil minerals. Potassium is generally stored on the surface of negatively charged clay minerals. This easily replaceable supply provides the soil solution with additional K when the soil-solution K concentration decreases as a result of crop uptake.[1] Furthermore, most K is retained in straw, and hence, if crop residue is returned to the soil, the bulk of the depleted K can be replenished. However, soils such as oxisols and ultisols are too deficient in reserve K and profitable yields cannot be obtained without K application.

The integrated use of FYM and inorganic fertilizer maintained a high amount of plant-available ammonium acetate extractable K, as compared to GM and inorganic fertilizer alone. It was observed that, under intensive cropping, application of the recommended dose of NPK along with FYM reduced the mining of K from the soil. The regression analysis of the data showed that water-soluble, exchangeable, and non-exchangeable K together accounted for 36%, 74%, and 99% variability in grain yield, crop K uptake, and available K in soil, respectively.[18]

Micronutrients

Widespread deficiencies of micronutrients have been found in many parts of the world, and in the last decades, their importance is increased both for increased crop productivity and for their effects on animal and human health. About 3 billion people in the world are affected with micronutrient malnutrition. Similar to major nutrients, micronutrients are present in several forms and fractions, and their soil concentration is very low. However, most micronutrients are in a dynamic equilibrium with their exchangeable and adsorbed forms, which sustain the soil solution and replenish it continuously as the nutrients are taken up by plants roots. Gupta[19] reported that the majority of Indian soils are deficient in zinc, followed by iron, copper, and manganese. Application of micronutrient fertilizers can mitigate the deficiency of these nutrients and help exploit the potential of crops. INM is another option for meeting the deficiency of micronutrients in various cropping systems.

Biofertilizers

Continuous application of chemical fertilizers alone has been reported to deteriorate soil health, and the application of organic manures alone does not produce required yields due to their low nutrient status. Hence, a judicious combination of mineral fertilizers with organic and biological sources of nutrients is being promoted. Such integrated applications are not only complementary but also synergistic as organic inputs have beneficial effects beyond their nutrient content.[1,20] Since nutrients are slowly released from biofertilizers, their combined use with mineral fertilizers (fast nutrient release) in INM system is capable of synchronizing nutrient supply with nutrient needs throughout crop growth, thereby maximizing nutrient use and minimizing nutrient loss and environmental pollution. Currently, farmers make limited use of this concept, primarily because there are no routine techniques available to rapidly assess the nutrient availability from biofertilizers and then adjust the mineral fertilizer rates accordingly. Among biofertilizers, biologically fixed nitrogen, crop residue, organic manures and composts, and sewage sludge are commonly used, but the use of microbial inoculants, artificially multiplied cultures of certain soil organisms, is also spreading, though on a limited scale because of limited supply to farmers.

Biological Nitrogen Fixation, Leguminous Crop Rotations, and Agroforestry

The major sources of biological nitrogen fixation (BNF) are the *legume–Rhizobium* symbiosis and *Cyanophyta* (BGA) and non-symbiotic N fixers *(Azospirillum* and *Azotobacter)*. However, others such as *Azolla* and Actinorrhizae *(Frankia)* make a small but significant contribution to N cycling in natural ecosystems. Estimates of global terrestrial BNF range from 100 to 290 M Mg of N yr^{-1}. Of this total, 40–48 M Mg is estimated to be biologically fixed in agricultural crops and fields.[1] As compared to this, only 87 M Mg of fertilizer N was supplied through mineral fertilizers in 2000, thus emphasizing the contribution of BNF to global N cycle.[1] Green manures of leguminous crops can add substantial amounts of organic matter and N as well as other nutrients. The bulk of the N input through leguminous green manures comes from BNF. Using rice culture as an example, this can range from 50 to 200 kg N ha^{-1}.[1] Agroforestry that includes legume trees provides another venue for BNF benefits, besides recycling of mineral nutrients brought up from below the root zone of annual crops; organic amendments with PR also enhance P availability.[21]

Most of the biological N fixed is present in organic form, and therefore, it must be mineralized before the following crop can utilize it. It thus has the potential to complement the crop nutrient needs with readily available nutrients such as from mineral and synthetic fertilizers in an INM system. Legume green manuring and incorporation of catch crops could also be used towards that purpose although limitation of land and water for this practice and cheaper N fertilizers restrict its widespread use.

Biosolids, Manures, Composts, and By-products (e.g., Crop Residue, Sewage Sludge)

Manures and composts not only provide N, P, and K as well as other nutrients to crops but also affect both physical and biological properties of soil. Average, well-rotted FYM contains 0.5%–1.0% N, 0.15%–0.20% P_2O_5, and 0.5%–0.6% K_2O. The desired C:N ratio in FYM is 15–20:1. Average content of different organic manure is presented in Table 4. In an integrated crop–animal farming system, nutrient contribution from applied manures and composts becomes significant and synchronizes nutrient supply to crops when complemented by mineral and synthetic fertilizers. For example, Mollah et al.[22] found significantly higher average yield (3 years) of Boro and T Aman rice under INM as compared to chemical fertilizer alone, while the nutrient (NPK) supply was generally lower under INM (Table 3). Similarly, the higher wheat yield (though not statistically significant) was obtained in the treatment with 50% N from FYM compost and 50% from urea as to 100% N supplied with urea.[23] Since N release from manure occurs over a number of seasons (20%–40% in the first season and 10%–20% in subsequent seasons), the cumulative effect of manure application is much greater than that assessed in a single season. Furthermore, since N in compost is more stabilized than in manure, the rate of N release from the former would be slower.

Since P contained in rock phosphate is less available than that in superphosphate, its availability is enhanced when it is added in manure and organic wastes and composted together (phospho-compost) before its application to the field.

In low-input farming systems, return of crop residues provides significant quantities of N, P, K, and Ca; in the aboveground crop biomass, the latter two exceed more than 60% of the total nutrient uptake. The low N concentration of straw presents a special problem for its decomposition where the soil contains insufficient available N. In spite of the low concentrations, as much as 125%–250% kg K_2O can be added to the soil by 10 Mg of cereal straw or 5 Mg of oilseed rape straw. This becomes especially critical in some tropical ultisols, oxisols, and alfisols, with low exchangeable Ca and K in these soils. For example, Sanchez and Benites[24] reported that the retention of rice and cow- pea crop residues returned to an ultisol (94% Ca and 89% K) that was accumulated by the crops. Addition of legume residues of *Sesbania*, *Gliricidia*, and *Leucaena* and supplementation with fertilizers are an important component of INM system, especially in low-input farming systems.

Urbanization has necessitated the need for safe and economic disposal of sewage sludge. Application of sewage sludge to soil ensures the recycling of nutrients and organic matter and benefits plant production. The general composition of sewage sludge is 1.1%–2.3% N, 0.8%–2.1% P_2O_5, and 0.5%–1.7% K_2O. Significant ammonia volatilization could occur from surface application of sludge, especially liquid

TABLE 3 Nutrient Supply and Rice Yields under Different Nutrient Management Systems

	Boro Rice		T Aman Rice	
	NPK		NPK	
Treatment	(kg ha–1)	Mg ha–1	(kg ha–1)	Mg ha–1

TABLE 4 Environmental Problems Associated with Fertilizer Use and Possible Solutions

Problem	Causes	Possible Solutions
Groundwater contamination	Leaching of nitrate (most important), chloride, sulfate, etc.	Balanced use of fertilizers; optimal loading rates of organic fertilizers, increased N efficiency; deep placement of N fertilizer and integrated N and water management
Eutrophication	Nutrient loss from soils with erosion, surface runoff, or groundwater discharge	Reduce runoff, grow cover crops, adopt water harvesting and controlled irrigation, control soil erosion
Methemoglobinemia	Consumption of high-nitrate drinking water and food	Reduce leaching losses of N, improve water quality
Acid rain	Nitric acid formation in the air, ammonia volatilization, and sulfur dioxide emissions	Reduce denitrification, adopt proper N application methods to reduce NH3 volatilization, correct high soil pH, increase CEC by organic additions
Ozone depletion and global warming	Nitrous oxide emission from soil through denitrification	Use of nitrification inhibitors and urease inhibitors, increase N-use efficiency, prevent denitrification
Itai-itai disease	Eating rice and drinking water contaminated with Cd	Soil management such as liming or water control in rice fields, reduction in Cd content of PR and chemical fertilizers
Fluorosis in animals	Ingestion of soil or fertilizer treated with high-fluoride PR	Monitor the F content of PR applied directly to acid soils

Source: Extracted and modified from Pathak et al.[25]

sludge and animal slurries. Since sewage sludge contains relatively more P than N required by crops, the application rates based on P requirements of the crops require supplementary N applications. Thus, it would require the INM approach to balance the N and P needs of the crops.

Nitrogen-Fixing Biofertilizers

1. *Rhizobium* (RHZ), known for its ability to fix atmospheric nitrogen in symbiotic association with plants forming nodules in roots. Inoculation of grain legumes such as pulses is associated with a N gain of 20–40 kg N ha^{-1}.
2. *Azotobacter* (AZT), a free-living and non-symbiotic nitrogen-fixing organism that also produces certain substances good for the growth of plants and antibodies that suppress many root pathogens.
3. *Azospirillum* (AZS), also a nitrogen-fixing microorganism beneficial for non-leguminous plants (e.g., onion, plantation crops). It can fix 20–50 kg N ha^{-1} in association with roots. It also produces hormones such as indole acetic acid (IAA), gibberellic acid (GA), cytokinins, and vitamins.
4. BGA and *Azolla,* photosynthetic nitrogen fixers and free-living organisms found in rice fields. These are used as biofertilizers for wetland rice (paddy) and can provide 25–30 kg N ha^{-1} in one crop season, or up to 50 kg N ha^{-1} yr^{-1}.

Phosphate-Solubilizing Biofertilizers

PSB help in the solubilization of P from PR and other sparingly soluble forms of soil P by secreting organic acids, and in the process decreasing their particle size, reducing it to nearly amorphous forms. In addition to bacteria, the fungus *Penicillium belaji* has been shown to increase P availability from native soil and PR sources in calcareous soils.[1] Although their use is rather limited, in some countries like India, PSB use is becoming popular, ranking next to BNF.

Nutrient-Mobilizing Biofertilizers

The common nutrient mobilizers in the soil are mycorrhi- zae, which form association with plant roots and improve the capability of roots to acquire nutrients. The vesicular-arbuscular mycorrhizae (VAM) have been associated with enhanced accumulation of P, Zn, Cu, and S, primarily through greater soil exploration by the mycorrhizal hyphae, thus leading to higher plant growth.

Adoption of INM at Farm

At the farm level, INM optimizes the productivity of the nutrient flows through the soil/crop/livestock system during a crop rotation by making a balance sheet of every nutrient and especially of the major nutrients N, P, and K. The efficiency of a production system depends on the importance of crop uptake versus the total supply of nutrients. Exploitation of plant nutrient stocks is permissible as long as it does not affect the supply of nutrients and the general status of soil fertility.

Moreover, INM improves the production capacity of a farm through the application of external plant nutrient sources and amendments and the efficient processing and recycling of crop residues and on-farm organic wastes. It empowers farmers by increasing their technical expertise and decision-making capacity.[1] During the adoption of INM, special attention should be given to sources of nutrients that may be mobilized by the farmers themselves (manures, crop residues, soil reserves, BNF, etc.). Minimization of losses and replenishment of nutrients from both internal and external sources are of major interest. Although the effects of organic inputs go beyond the nutritional aspects, by contributing to improving soil physical properties and to a better efficiency of fertilizer use, the recycling of organic materials does not suffice to fully replenish the nutrients that are removed by crop harvests. Therefore, an increased and more efficient use of mineral fertilizers in most developing countries is required in the medium term.[8]

A quantitative knowledge of the depletion of plant nutrients from soils may be helpful in devising nutrient management strategies. Nutrient balance exercises serve as instruments to provide indicators for the sustainability of agricultural systems. Nutrient budget and nutrient balance methodologies using various approaches for different situations have been applied widely in recent years at a variety of levels: plot, farm, regional, national, and continental.[1]

Environmental Concerns of INM

Nutrients added through fertilizers, manures, and composts can have both positive and negative effects on the environment depending on the management practices. In this section, the focus is on negative effects. Nutrients, if not taken by plants, can be immobilized by the soil or lost from the soil system. Depending on the nutrient and soil condition, losses can be by volatilization to atmosphere, through soil and water erosion, and by leaching in the soil profile. Leached N can also be lost to the atmosphere through denitrification. A summary of the environmental problems associated with fertilizer use and general strategies to minimize them is presented in Table 4.[25] In general, the negative effects can be summarized as follows:

1. The constant removal of nutrients by crop products without their sufficient replenishment causes a steady decline in soil fertility. The use of low levels of input places additional stress on soil nutrient supplies, resulting in excessive mining of soil nutrients and in depletion of soil fertility, leading to land degradation.
2. Low crop yields resulting from nutrient depletion force farmers to cultivate land under forests or marginal soils that are subject to erosion or desertification, thus leading to soil degradation.
3. Large areas of soils in the tropics are inherently poor in soil nutrients and in addition suffer from problems of acidity, salinity, alkalinity, and Al toxicity.

Nutrient Losses

Of all the inputs, N applications have had the single largest effect on crop yields but N application also creates a matter of greater environmental concern. Nitrogen, if not taken up by plants, can be lost through soil erosion and surface runoff, leached to groundwater, volatilized as ammonia, and denitrified as nitrous oxide (NO) to the atmosphere. The losses can range from 0 to >100 kg N h^{-1} yr^{-1} and they are more in soils with large rainfall intensities and low storage capacity. INM through organic and inorganic input of N can also minimize the leaching losses by improving soil chemical and physical properties.

Nitrate lost by leaching or transported in surface runoff can result in increased nitrate concentrations in drinking water, eutrophication of surface waters, and increased production of NO. It has been estimated that the groundwater under some 22% of the cultivated land in the European Union (EU) has NO_3^- concentrations exceeding the EU upper limit of 20 mg L^{-1}.[1] Nitrate leaching has another associated negative effect because it causes loss of basic cations (Ca^{2+}, Mg^{2+}, and K^+), leading to increased soil acidity. Ammonia volatilization from soil and vegetation contributes to about 21 M Mg yr^{-1} of N,[23] and 14% of mineral N fertilizer used globally is lost as ammonia.[27] The highest emissions of ammonia are in regions with intensive animal production activity (Europe), widespread use of urea (India), and application of ammonium carbonate fertilizer (China). The dominant source of ammonia emission is animal manure, as about 30% N in urine and dung is lost through this route.

Denitrification losses as gaseous dinitrogen (N2) amount to about 14 M Mg yr^{-1}, and N_2O and NO from nitrification/denitrification contribute about another 8 M Mg yr^{-1}N to the total loss.[26] It is estimated that N_2O contributes 5%–6% to the present greenhouse gas effect.

Most of P is lost through crop removal and surface erosion. The $N:P_2O_5$ ratio in most animal manures is about 1:1, whereas plants remove about 2.4–4.5 times more N than P_2O_5. Such residual organic forms of P can thus be leached. However, inorganic forms of P are bound strongly to clays and oxide surfaces in acid soils and precipitated as relatively insoluble calcium phosphates in alkaline soils. Therefore, leaching and surface runoff of phosphate in solution do not generally contribute to eutrophication.

Neither fixed nor exchangeable K is very mobile in soils containing silicate minerals. However, oxisols and ultisols have limited capacity to maintain adequate K. Leaching losses in tropical soils are reported to vary from 52 to 165 kg K ha^{-1} yr^{-1} and they are especially higher under slush and burn.[28] INM with organic matter input is important in the later soils to increase their cation exchange capacity. The loss of K through leaching and erosion is a waste of resources, but it is not known to constitute any environmental or health hazard.

Soil Carbon Sequestration

INM has been shown to have a beneficial impact on C sequestration in soils. For example, in India, the use of NPK and farmyard manure maintained the SOC at 15 g kg^{-1} for a 25 years period compared with a decline to 8.0 g kg^{-1} with NPK alone and 5.0 g kg^{-1} with no fertilizer use. The data in Table 5 from India show an increase in SOC content by application of NPK and manure in five out of six soils, and increase in two out of six soils by use of chemical fertilizers.[29] There was a drastic decrease in SOC content in all soils, which received neither fertilizer nor manure (Table 5). It was also reported that in both rice–wheat and maize–wheat cropping systems, application of FYM or balanced fertilization with NPK resulted in higher C sequestration.[30] The SOC concentration was higher with FYM than with NPK application in both rice–wheat and maize–wheat systems after a period of 32 years.[27] Smith and Powlson[31] reported that 820 M Mg $years^{-1}$ of manure is produced in Europe but only 54% is applied to arable land and the remainder is applied to non-arable agricultural land. They observed that applying manure to cropland can enhance its SOC pool more than it does on pasture land. Smith and Powlson[31] estimated that if all manure were incorporated into arable land in the EU, there would be a net sequestration of 6.8 Tg C yr^{-1}, which is equivalent to 0.8% of the 1990 CO_2–C emissions for the region.

TABLE 5 Average Content of Nutrients in Organic Manures

Manure	N (%)	P_2O_5 (%)	K_2O (%)
Cattle dung	0.3	0.1	0.15
Sheep/goat dung	0.65	0.5	0.03
Human excreta	1.2–1.5	0.8	0.5
Farmyard	0.5	0.15	0.5
Poultry manure	2.9	2.9	2.4
Urban compost	0.5	0.2	0.5

Toxic Accumulation

Along with atmospheric deposition, phosphate fertilizers (both chemically produced ones and PRs) can be a major source of metal addition, especially Cd, to agricultural soils.[32] PRs are the basic raw materials for the production of phosphate fertilizers and PR can contain hazardous elements including undesired heavy metals (e.g., Cd, Cr, Hg, and Pb) and radioactive elements (e.g., U) that are considered to be toxic to human and animal health.[15] Undesirable heavy metals can also originate from finished fertilizers and organic manures (Table 6). In addition to P fertilizers, sewage sludge and animal manure may also contain high amount of metals (Table 6).[33] Repeated application of such wastes is reported to increase crop uptake of metals.[34] Soils from fertilized fields and especially in Europe and Northern America have shown accumulation of Cd. Cadmium ingested by animals and humans accumulates in the kidneys and can lead to organ dysfunction. Therefore, in many countries, the regulatory limits for food, so-called “maximum permissible concentrations (MPCs),” have been worked out. Some countries have also introduced voluntary or mandated concentrations of Cd in fertilizers. Such limits are under constant review, and efforts are also being made to reduce the Cd content of the chemically produced fertilizers.

Soil Fertility Degradation/Improvement

Widespread fertility degradation occurs under many cropping systems even on soils with good initial soil fertility, because nutrient mining or depletion is a widespread problem in low- and medium-input agriculture. This is a major threat to productive sustainable farming. Negative nutrient balances are quite common in many African and Asian countries. For example, in India, the annual gap between nutrients removed by crops and those added through fertilizers has been in the range of 8–10 M Mg of $N+P_2O_5+K_2O$ for several years.[35] Furthermore, soil organic matter (SOM) losses from the surface soils under continuous cultivation are a common phenomenon in the tropics and subtropics. For example, the SOM content of an oxisol in Zambia decreased at a rate of 1.6 Mg h^{-1} yr^{-1} in a long-term experiment.[36] Similarly, long-term studies in subtropics[9] and temperate regions[37] have shown that the

TABLE 6 Soil C Sequestration through INM for 20 Years in Some Indian Soils

Location	Soil	Cropping System	Initial SOC (g kg–1)	SOC after 20 Years (g kg–1)		
				Control	NPK	NPK+FYM
Bhubaneswar	Inceptisol	Rice–rice	2.7	4.1	5.9	7.6

organic matter of soil can be maintained or raised modestly by proper fertilization and especially by organic manures and crop residue management. On the other hand, even under conditions of low-input cropping and with nutrient-depleted soils, fertility degradation can be reversed in acid soils, through better P supply with phosphate fertilizers with lime application and N input via N fixation by legumes. While soil improvements may result in 50% higher yields at a low-input level, more impressive results can be obtained at a high-input level (Table 7). A good example is that of the formerly degraded and low-yielding, but now highly productive soils of Western Europe with present wheat yields of 8–10 Mg ha^{-1}, while the original cereal yield ranged from 0.5 to 1.5 Mg ha^{-1}.[1]

Conclusions

Persistent decline in soil fertility in many parts of the developing world and overfertilization in many temperate developed countries have created nutrient and fertility imbalances in terms of nutrient depletion and hence low crop productivity on one hand, and the excessive nutrients have resulted in the pollution of soil, water, and air on the other. To overcome such problems, the use of the INM system is considered as the most useful strategy because it supplies adequate nutrient, in synchrony with crop demands within a framework of improved land and soil management practices. Implementation of INM systems not only could increase crop production per unit area of land to meet the demands of an increasing population by using chemical fertilizers in integration with nutrients in organic resources available at the community level, coupled with microbial inoculants (e.g., N_2 fixer, PSB, mycorrhizae), but also improves the environment by utilizing these resources more efficiently and in synchrony with crop demands to avoid their losses. Furthermore, the improved understanding of nutrient availability from these resources and the fate of nutrients in an integrated (soil–plant–water–air) system is required as they impinge on soil's chemical, biological, and physical functions for sustainable production and environmental protection.

Integrated Pest Management

H.F. van Emden

Introduction

There have been many definitions of integrated pest management. The most practical operational definition is probably that by President Jimmy Carter of the United States in his 1979 environmental message: Integrated Pest Management "uses a system approach to reduce pest damage to tolerable levels through a variety of techniques … and, when necessary and appropriate, chemical pesticides." An excellent, more detailed definition is given by Flint and van den Bosch: "Integrated pest management (IPM) is an ecologically based pest control strategy that relies heavily on natural mortality factors such as natural enemies and weather and seeks out control tactics that disrupt these factors as little as possible. IPM uses pesticides, but only after systematic monitoring of pest populations and natural control factors indicates a need. Ideally, an integrated pest management program considers all available pest control actions, including no action, and evaluates the potential interaction among various control tactics, cultural practices, weather, other pests, and the crop to be protected."[1]

IPM as defined above represents, as a result of usage, a rather different concept from Apple and Smith's[2] original 1976 definition (see below) and is so well used that it is often written or spoken as IPM without further explanation. IPM is now the preferred option to replace both prophylactic (= insurance) reliance on insecticides and the concept of replacing insecticides with single-component biological control. Both these latter methods are now universally seen as components of IPM, though biological control alone still has its niche in low value subsistence agriculture and other situations where insecticide cost is prohibitive or where the pest has multiple tolerance to insecticides.

Derivation of Integrated Pest Management

Following on from problems created by the extensive use of pesticides in the 1940s and 1950s, particularly the selection of pest strains resistant to insecticides and damage to biological control, workers at the University of California at Berkeley evolved the concept of "integrated control." This was based on their work combining biological control with reduced and more selective pesticide doses against pesticide-resistant spotted alfalfa aphid (*Therioaphis maculata*), published in a landmark paper in the scientific journal *Hilgardia* in 1959.[3] The more selective pesticide doses improved the survival of natural enemies while still killing a proportion of the aphids. This principle was reflected in the definition of "integrated control" by the Californians as "pest control which combines and integrates biological and chemical control. Chemical control is used as necessary and in a manner which is least disruptive to biological control." This episode is the origin of the "I" in IPM.

Following on from an Australian concept of "managing" pest populations, the Canadian Beirne proposed "Pest Management" at a conference in Raleigh, North Carolina, in 1970.[4] It was an all-embracing expression for the selection of that combination of control measures or that single measure that was "in the best long term interests of mankind." Beirne envisaged that sometimes a single measure, for example, biological control alone, might be a better solution in environmental terms than the use of more than one measure implicit in "integrated control." Whether this represented any substantive change in thinking is debatable, especially as Beirne himself conceded that most often "integrated control" would be the preferred "pest management" solution. Be this as it may, the replacement of the word "control" with "management" was appealing and topical, and it caught on.

In 1976, there appeared a book[2] entitled *Integrated Pest Management* edited by Lawrence Apple of North Carolina State University and Ray Smith of The University of California at Berkeley. Their description of IPM ran as follows: "The concept of pest management has now been broadened to include all classes of pests (pathogens, insects, nematodes, weeds) and in this context is commonly referred to as IPM with the implication of both methodological and disciplinary integration." As pointed out earlier, the "disciplinary integration" implications have never been generally accepted. Today, the next step in the evolution of the terminology is to take IPM in Apple and Smith's sense and to see this as just one aspect of crop production. The term "Integrated Crop Management" now seems to be gathering momentum.

Need for Integrated Pest Management

The intensification of agriculture with the overuse of and overreliance on synthetic pesticides in the 1940s and 1950s caused serious side effects including the resurgence of the target pests, the appearance of new pests, and the development of tolerance to individual pesticides in many pest species. It was therefore clear that pests had been "mismanaged," and the following failures to manage them correctly could be identified:

1. Overdosing with pesticides, leading to the development of tolerance;
2. Loss of biological control as result of pesticide use and a reduction of biodiversity in agroecosytems;
3. The introduction of genetically uniform, high-yielding but pest susceptible new cultivars over large areas of monoculture;
4. Agronomic changes such as abandonment of cultural controls and of mixed cropping.

These translate respectively into the four main building blocks of IPM[5]:

a. *Chemical control:* Decisions to spray are guided by economic thresholds, and selective materials are chosen where available;
b. *Biological control:* Use of pesticides in a selective manner. Natural enemies can also be introduced or recolonized and/or promoted by habitat modification, including the planning of biodiversity into farm management;
c. *Host plant resistance:* The introduction of crop varieties with at least partial plant resistance, based as far as possible on more than a single mechanism;
d. *Cultural control:* Can break the life cycle of a pest or greatly improve conditions for natural enemies, but must be compatible with farm management systems.

Other components of IPM, such as insect growth regulators, the confusion pheromone technique, and sterile male release, are also available in relation to particular targets.

As IPM for a single target implies managing the pest population by more than one method, the following two "golden rules" of IPM are particularly important:

a. *If* a single method gives adequate control on its own, then there is danger of a tolerant pest strain increasing in gene frequency and no opportunity to use a second method in addition. The method therefore needs to be made less efficient (reduced dose of pesticide, partial host plant resistance rather than immunity) for there to be value in introducing another control method to supplement it;
b. Methods are increasingly worth combining to the extent that the control then achieved exceeds the additive effects of the two methods in isolation.

Development of Pest Management Packages

There are three distinct philosophies to the synthesis of pest management packages.[5]

Menu Systems

These provide considerable choice for a farmer to select control methods for combination in relation to the pest spectrum in the area. The results of many scientist-years of research into different methods enable menus to be provided but, as the choice of the farmer may vary, the methods will be highly target-specific and not dependent on interaction with each other. Often several methods may be available against one pest species. Cotton pest management is a good example of a menu system. Menu systems may be transferable to the same crop in another country or continent with little modification.

Computer-Derived Packages

If sufficient data are available, a computer should be able to select the components of a menu that are in the best interests of whatever selection criteria the computer is given. Some sophisticated models driven by crop growth via the weather are already available for orchard systems. Again, however, interactions between control methods are unlikely to be exploited, as they are rarely adequately understood.

Protocols

These are "dish-of-the-day" menus—that is, a complete package on a "take it or leave it" basis. These are characteristic of crop scenarios where there is a paucity of the detailed long-term research needed for a menu system. Protocols may be very simple. For example, quite effective IPM has been introduced in developing agriculture by little more than combining the introduction of economic thresholds with more selective pesticidal materials (e.g., bacterial toxins). Later stages may be the release of mass-produced beneficials (particularly the egg parasitoid *Trichogramma)* and the introduction of partial plant resistance against a key pest following cultivar testing and plant breeding at national research stations.

Protocols may also be derived directly by experimentation, without the need for the extensive background biological and ecological understanding needed for menu systems.

Conclusions

Apart from IPM being seen as one component of a holistic integration of crop production (integrated crop management), the concept is the widely accepted view of what pest control in modern crop production should be. In many countries around the world it has been declared as the national policy; it is also the policy of international agencies such as the Food and Agriculture Organization. It is the approach being used by many crop consultants and the method favored in developed countries by the large supermarkets, which have such an influence on farm management today.

Until relatively recently, the integrated approach to pest control was accepted temporarily by growers at times of a crisis of pest tolerance to insecticides, to be abandoned just as soon as a new and effective pesticide was marketed. However, IPM is now being introduced even where there is not a current crisis; at long last the message seems to have sunk in, that it is a way of preventing pesticide crises in the first place.

Integrated Weed Management

Heinz Müller-Schärer and Alexandra Robin Collins

Introduction

Agrochemical companies promise that transgenic crops will simplify pest management programs through the use of singular chemical tactics. This "silver-bullet" approach has consistently failed and almost certainly will again because of a failure to understand the ecological relationships governing population size and diversity.[1] Furthermore, in many countries, pesticide policies have called for significant use reductions together with the promotion of biodiversity in agro-ecosystems.[2] Initiatives to reduce reliance on herbicides will require a much fuller understanding of how management practices complement one another to maintain weed populations at low equilibrium densities. Biological control approaches require, but also provide, detailed insight into weed–crop interactions and how they are influenced by both the biotic and abiotic environments. They can, thus, be viewed as the basis for integrated production.[3] In most cases, only combinations with other weed management tools will result in acceptable levels of weed control. Various types of integration can be envisaged, of which preventative measures will be most important for developing sustainable agricultural production.

Weed Control, Weed Science, and Integrated Weed Management

Agricultural weed management in farming systems is diverging in two distinct directions. In one set of farming systems, farmers rely primarily on herbicides to suppress weeds. This approach is exemplified by the extensive maize (*Zea mays* L.)/soybean [*Glycine max* (L.) Merr.] system of the midwestern United States, where >110 million kg of herbicide active ingredients are applied annually to >95% of the area planted with those two crops.[4] In a second set of farming systems, herbicides are largely or entirely avoided, and weeds are mainly suppressed using physical and ecological tactics. The existence and risk of development of herbicide resistance make herbicide-dependent cropping systems increasingly vulnerable. Moreover, widespread concern about environmental side effects of herbicides, combined with fear for public health, has resulted in several herbicides being banned in some countries and increasing pressure on farmers to reduce their use.[4]

In contrast to the disciplines of plant pathology and entomology, the "how to control" approach was shaped early on in weed science and, until recently, has dominated the discipline. The fact that weeds have been regarded as a problem that can be controlled with herbicides, rather than managed through cropping system design,[5] has resulted in a time lag in developing integrated weed management systems, as compared to integrated pest and disease management systems.[1] The United Nations Conference on Environment and Development (UNCED), in its Agenda 21, recognized integrated pest management (IPM) as the preferred strategy to achieve sustainable agricultural production.[6] IPM typically involves a reduction in the reliance on chemical pesticides, including herbicides.[7] Furthermore, the Convention on Biological Diversity[8] and prominent researchers in the field make the case that biological control should be given priority as a component of future pest management.[9,10]

Methods Used to Control Crop Weeds Biologically

Three principal methods of biological weed control can be distinguished (Figure 1).[3,11] First, the "inoculative" or "classical" approach aims to control naturalized weeds by the introduction of exotic control organisms from the weed's native range. They are released over only a small area of the total weed infestation and control is achieved gradually. Successful control depends on favorable conditions promoting an increase in the control agent's population, establishment of epiphytotics, and, thus, reduction of the target weed population. Second, the "inundative" or "bioherbicide" method uses periodic releases of an abundant supply of the control agent over the entire weed population to be controlled. Such biological agents generally are manufactured, formulated, standardized, packaged, and registered like chemical herbicides. Compared to the other two approaches, this approach is characterized by higher application costs and a relatively short time period to achieve a potential control success. Though there have been a number of successful biological control programs against crop weeds with some products resulting in commercial registration (Table 1), bioherbicides have still not managed to occupy a sizable share of

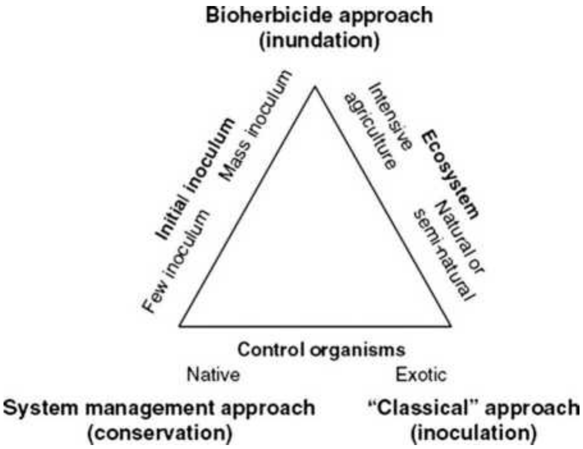

FIGURE 1 Schematic diagram showing the three methods of biological weed control in agro-ecosystems (from Müller- Schärer and Schaffner[11]) with respect to the initial size of the inoculum released, the origin of the control organisms used, and the ecosystem where the biological control program was implemented. See text for details.

TABLE 1 Selected Examples of Applied Integrated Weed Management Involving Biological Control, and Present Product Status

Target Weed	Common Pathogen(s)	Crop/Habitat	Type of Integration[a]	Type of Biological Control Strategy and Status of Product	Reference(s)
Northern jointvetch (.*Aeschynomene virginica*)	Collego™: *Colletotrichum gloeosporioides* f. sp. *aeschynomene*	Rice and soybean fields	Pathogen–pathogen–herbicide [H] (PSA)	Inundative method Reregistered as Lockdown.	[19]
Stranglervine (*Morrenia odorata*)	DeVine®: *Phytophthora palmivora*	Citrus groves	Pathogen–herbicide [H]	Inundative method Status unknown; EPA issued a Reregistration Eligibility Document (RED) in 2006; it appears that no one has come forward to reregister DeVine.	[20,21]
Velvetleaf (*Abutilon theophrasti*)	*Colletotrichum coccodes*	Corn, soybean	Pathogen–herbicide [H;V/P] (PSA)	Classical method Several organisms are being studied for use as biocontrol agents, though none are currently available for release.	[22,23]
Barnyard grass (*Echinochloa crus-galli*)	*Colletotrichum graminicola*	Various crops	Pathogen–herbicide [V/P]	Classical method Several organisms are being studied for use as biocontrol agents, though none are currently available for release.	[24]
Nutsedges (*Cyperus* spp.)	Dr BioSedge: *Puccinia canaliculata*	Various crops	Pathogen–herbicide [V/P] (PSA)	Inundative method Registered, but commercial development abandoned due to uneconomic production system and resistance in some weed biotypes	[25,26]
Spotted knapweed (*Centaurea maculosa*)	*Cyphocleonus achates, Agapeta zoegana, Larinus* spp., *Urophora* spp., etc. (see Julien and Griffiths 1998)	Rangeland	Insect–plant competition [V/E] Insect–herbicide [V/P or PS]	Classical method Several organisms are being studied for use as biocontrol agents, though none are currently available for release.	[27–30]

(*Continued*)

TABLE 1 (*Continued*) Selected Examples of Applied Integrated Weed Management Involving Biological Control, and Present Product Status

Target Weed	Common Pathogen(s)	Crop/Habitat	Type of Integrationa	Type of Biological Control Strategy and Status of Product	Reference(s)
Nodding thistle (*Carduus nutans*)	*Rhinocyllus conicus, Trichosirocalus horridus. Cassida rubiginosa*	Rangeland	Insect–herbicide [V/P] Insect–plant competition [V/E]	Classical method Several organisms are being studied for use as biocontrol agents, though none are currently available for release.	[31]
St. John's wort (*Hypericum perforatum*)	*Chiysolina hyperici, Chrysolina quadrigemina*	Rangeland	Insect–fire [V/E] Insect–plant competition [V/E]	Classical method Several organisms are being studied for use as biocontrol agents, though none are currently available for release.	[32–34]
Water hyacinth (*Eichhomia crassipes*)	*Neochetina eichhorniae, Neochetina bruchi, Sameodes albiguttalis*	Aquatic	Insect–herbicide [V/P] Insect–pathogen–herbicide [PS]	Classical method Currently, there are no registered bioherbicides, but several candidates have been identified.	[35]
Floating fern (*Salvinia molesta*)	*Cyrtobagous salviniae*	Aquatic	Insect–herbicide [V/PS or P] Insect–fertilizer [V/P]	Classical method Currently, there are no registered bioherbicides, but several candidates have been identified.	[36]
Dyer's woad (*Isatis tinctoria*)	Woad Warrior: *Puccinia thlaspeos*	Farms, rangeland, waste areas, and roadsides	Pathogen (rust)–herbicide [V/P]	Inundative method Registered product. Consists of rust spores on finely ground leaf and stem pieces of infected dyers woad.	[37]
Alders, aspen, and other hardwoods	Chontrol™: *Chondrostereum purpureum*	Rights of way and forests	Pathogen (fungus) – herbicide [V/P]	Inundative method Registered in Canada and the United States and commercially available.	[38–39]
Dandelion (*Taraxacum*)	Sanitor: *Sclerotinia minor*	Lawn and turf	Pathogen (fungus)–herbicide [H;V/P]	Inundative method Registered and commercially available in Canada. U.S. registration is pending.	[40–12]

the market.[12] This is mainly due to the fact that the reliability of field efficacy has not reached levels comparable with that of chemical herbicides.[13] According to Charudattan,[14] of the bioherbicide projects underway, only 8% of them were successful, leaving 91.5% of the projects uncertain, untried, or ineffective. Thus, it has become increasingly important to prioritize projects with high pathogen aggressiveness, high speed of disease increase, and high rates of population increase, what Charudattan[9] refers to as "killer traits." Third, and more recently, the "system management approach" of biological weed control had been described.[15,16] It is related to the conservation and augmentative approaches distinguished by some authors. Its aim is to shift the competitive weed–crop relationship in favor of the latter, mainly by stimulating the buildup of a disease epidemic or insect outbreak on the target weed population. The approach excludes the use of exotic organisms (classical approach) and the use of mass amounts of inoculum applied like a herbicide to the whole weed population (bioherbicide approach).

Integrating Biological Control with Other Methods of Weed Management

Weed problems in agro-ecosystems are rarely caused by single weed species. Clearly, biological control, with its inherently narrow species-specific approach, has to be considered as an integrated component of a well-designed pest management strategy, not as a cure by itself. In most cases, combinations of biological agents with other weed management tools will be needed to produce acceptable levels of overall weed control. Such integration can be viewed as a vertical integration of various control tactics against a single weed species, or as a horizontal integration across different weed species in one crop (Table 1).[17] Horizontal integration mainly involves the combination of microbial herbicides with chemical herbicides or mechanical methods to broaden the spectrum of weed species controlled. Furthermore, in situations where particularly high doses of herbicides are needed to control a single weed species while the rest of the weed flora could be controlled by lower amounts, biological control may allow considerable reduction of herbicide inputs and contribute to maintaining species diversity in crops. Three possible types of vertical integration of biological control with other methods of weed management can be distinguished, both in time and space: purpose-specific approaches, ecological integration, and physiological integration (Table 1).[18]

Purpose-Specific Approaches

The type and level of control are chosen according to the context-specific requirements. This often involves different management methods to be applied at different sites. For instance, for a weed that is still spreading, chemical herbicides may well be the method of choice to remove new infestations, while biological control may be relied on to give long-term control of large, established infestations.[43]

Ecological Integration

This term is given to situations where different approaches are used often at the same time on the same infestation. Integration with herbicides[44,45] and with plant (crop) competition[146–481] is most widely envisaged. This type of integration essentially summarizes holistic approaches that encompass all modifications to the environment, which may favor the effectiveness of biological control agents and facilitate the management of a weed population.[49]

Physiological Integration

This type of integration exploits synergistic interactions between changes in the biochemistry of weeds, often produced by sublethal effects of herbicides and the effectiveness of biological control agents.

Herbicides (or other "synergists") are known to increase incidence of infection and to enhance the growth of pathogens,[50–55] but infection by the pathogen may also facilitate the uptake of herbicides, mainly by injuring the cuticle and epidermis of the host. In addition, various studies have shown greatly increased disease severity and agent effects when combined with phytotoxic metabolites produced by the pathogen[56] or with specific formulation and delivery techniques of microbial herbicides.[53,57] Thus, physiological integration is directed toward combined effects with biological control agents on plant individuals.

Ultimately, optimal management, with minimal disruptive interventions, requires a good understanding of the weed's biology and, especially, population dynamics.[58] Biological weed control requires, and provides, a detailed ex ante analysis of the problem situation, especially of the crop environment, revealing interactions between the various components and their underlying interactions. It should, therefore, be the strategy that is basic to integrated production systems. Bridges between different disciplines need to be built to optimize the fit of biological control into existing management systems.[3,18,59]

Conclusions

When weeds are no longer regarded as a problem to be resolved by curative tactics, then prevention becomes the keyword and integrated cropping management becomes the new focus, of which integrated weed management is an important component. Much work remains to be done by scientists spanning a broad range of disciplines in order to be able to integrate soil, crop, and weed management effectively.[4] Further challenges for weed science are the elaboration of effective practices for new crops, new production systems for enlarged farms and fields, and the consequences of climate change. Furthermore, adequate answers need to be found for the increased concern about the conservation of biodiversity and the growing consumer demands on food safety.[60] In parallel, to transfer the scientific knowledge into farming practices, a considerable amount of time must be spent with farmers in order to understand the true practical dimensions of the increasingly complex study systems. In this cropping system design approach, numerous fitness-reducing and mortality events are integrated to manage weed populations, with herbicides being used as a last resort. Prevention involves any aspect of management that favors the crop relative to the weed. This includes the development of competitive crop cultivars, crop rotation, mixed cropping, and allelopathy.[61] Preventative control requires a detailed insight into weed biology and ecology and the ways in which they interact with the crop. Biological control provides a fundamental tool for successful management of weed populations, where weed control no longer considers crop production in a weed-free environment, but instead as a reduction of weed-induced yield losses. By that, it greatly contributes to promoting biodiversity in human-influenced landscapes, a central pillar of modern sustainable agriculture.

Acknowledgments

We greatly thank Karen L. Bailey, Graëme Bourdôt, Raghavan (Charu) Charudattan, Gary Peng, and Maurizio Vurro for sending us information and references for updating Table 1.

Manure Management: Compost and Biosolids

Bahman Eghball
and Kenneth
A. Barbarick

Manure

Manure (animal waste) is generated in beef cattle feedlots, swine operations, dairy barns, poultry houses, and other livestock operations. The number of animals and the number of large production facilities in U.S.A. have significantly increased in the past 10 years.[1] Manure, as well as composts and biosolids, is a renewable resource and an excellent source of macro- (N, P, K, Ca, Mg, and S) and micronutrients (Zn, Cu, Fe, Mn, etc.), that are essential for growing plants. For centuries manure was used throughout the world for improving soil fertility and enhancing crop productivity. However, with the advent of synthetic fertilizers after World War II, manure was considered more a liability than a nutrient resource for crop production.

When animals are grazing on pastures and rangelands, manure is dispersed across a large area and little management is needed because the material is not concentrated and decomposes rapidly. However, when animals are concentrated in small feeding areas, the quantity of manure requiring proper management increases greatly. Significant amounts of manure are generated each year in U.S.A. from the confined feedlots of major livestock species (Table 1). The amount of N, P, and K present in the manure from these species would replace 25%, 25%, and 45% of the purchased N, P, and K fertilizers, respectively, in U.S.A., if utilized at agronomic application rates (Table 1). However, because of the high hauling cost, replacement of fertilizer is presently limited to specific areas in the country where the animal feeding operations are located. Crop producers are also reluctant to use manure because of factors such as hauling and spreading costs, potential introduction of weed seeds, nonavailability of manure where needed, uncertainty about availability of manure nutrients to plants, and problems of odor and application uniformity. The global numbers of major livestock species are given in Table 2.

Even though manure is an excellent source of multiple nutrients and organic matter, it can also contribute to water, air, and land pollution because of the potential for environmental loading with excess phosphorus, nitrate, salts, undesirable microorganisms, pathogens (disease-causing organisms), and greenhouse gases. Manure application in excess of crop needs can cause a significant buildup of P, N, trace elements (As, Cd, Pb, Hg, Mo, Ni, Cu, Fe, Mn, Se, and Zn), and salts in soils. Trace-element limits in soil are given in Table 3. The elevated P and N levels in soil are of environmental concern when these nutrients are carried by runoff to streams and lakes and cause "eutrophication," which is the nutrient

Note: Concentration and quantities are on dry weight basis.

enrichment of water that can promote algal growth and depletion of dissolved oxygen in water. This oxygen is essential for aquatic animals. Pathogens (such as bacteria, viruses, and parasites) in runoff from fields treated with manure can be another source of water pollution. Pathogens and odorous materials can also be carried by wind from the feeding operations to neighboring areas. Excess manure application can contaminate the groundwater with nitrate-N. Nitrate is a water-soluble ion that moves with water into the soil and can reach the groundwater within a few days after application. The U.S. Environmental Protection Agency (USEPA) has set a 10 mg NO_3–N/L standard for drinking water.

Compost

Composting is the aerobic decomposition of organic materials in the thermophilic temperature range of 40–65°C. The composted material should be an odorless, fine textured, low-moisture content material that can be bagged and sold for use in gardens, potting, and nurseries or used as a source of nutrients and organic matter on cropland with little fly-breeding potential. Other advantages of composting include improving the handling characteristics of any organic residue by reducing its volume and weight. Composting also has the potential to kill pathogens and weed seeds. Disadvantages of composting organic residues include loss of N and other nutrients during composting, the time taken for processing, cost of handling equipment, need for available land for composting, odors during composting, marketing, diversion of manure or residue from cropland, and slow release of available nutrients. Similar to manure or biosolids, composts can cause water, air, and land pollution if not used properly.

Temperature, water content, C : N ratio, pH level, aeration rate, and the physical structure of organic materials are important factors influencing the rate and efficiency of the composting process. Ideal values for these factors include a temperature of 54–60°C, C : N ratio of 25 : 1–30 : 1, 50%–60% moisture content, oxygen concentration > 5%, pH of 6.5–8.0, and particle size of 3–13 mm. The requirement set by the U.S. Environmental Protection Agency regulations for composting municipal waste is that the temperature should be maintained at 55°C or above for at least three days so as to destroy the pathogens. A temperature of 63°C within the compost pile is needed to destroy the weed seeds.

Homogeneous manure solids can be composted alone without mixing with bulk materials. Bulking agents are required to provide structural support when manure solids, or other organic residues, are too wet to maintain air space within the composting pile, and to reduce water content and/ or to change the C : N ratio. Dry and fibrous materials, such as saw dust, leaves, and finely chopped straw or peat moss, are good bulking agents for composting wet manure or organic residues. Depending on the ambient temperature, a complete composting process may take two to six months.

There are a number of methods for composting organic materials. These include active windrow (with turning), passive composting piles, passively aerated windrow (supplying air through perforated pipes embedded in the windrow), active aerated windrow (forced air), bins, rectangular agitated beds, silos, rotating drums, containers, anaerobic digestion, and vermicompost (using earthworms). Carcass composting can be done by using all types of animals. Mortality composting can be accomplished in backyard-type bins, indicator composter bins, and in temporary open bins using layers of saw dust or chopped straw and dead animals. Water content is an important factor to be considered when composting dead animals, and should be maintained at about 40–50%.

Biosolids

Treatment of municipal wastewater results in a mostly organic by-product known as “biosolids.” Land application of biosolids for beneficial use has been practiced since the early 20th century in U.S.A. The USEPA announced requirements regarding beneficial use of biosolids with promulgation of the 40 CFR503 regulations in February 1993. The USEPA and the state agencies that control land application of biosolids encourage the judicious recycling of biosolids on crop- or rangeland, as they contain essential plant nutrients and organic matter.

A key aspect of USEPA and Colorado Department of Health (CDH) regulations requires the application of biosolids at an agronomic rate. The CDH[5] defines agronomic rate as "the rate at which biosolids are applied to land such that the amount of nitrogen required by the food crop, feed crop, fiber crop, cover crop or vegetation grown on the land is supplied over a defined growth period, and such that the amount of nitrogen in the biosolids which passes below the root zone of the crop or vegetation grown to groundwater is minimized." The USEPA trace-element limits for land application of biosolids are shown in Table 3. State agencies that control biosolids recycling on land are required to adopt these limits as minimum requirements to protect the environment and public health. Risk assessment of different biological pathways served as the foundation for establishing the trace-element restrictions. For example, the concentrations for Littleton/Englewood biosolids shown in Table 3 indicate that it meets the agronomic-rate limits and can, therefore, be applied at an agronomic rate with minimal restriction. New, aggressive pretreatment programs have significantly reduced trace-element concentration in biosolids since about 1970, and therefore, environmental and public health risks are even more minimal.

The USEPA requires municipal wastewater treatment facilities to reduce pathogens and to reduce the attraction of insects and animals before applying biosolids to land. Most municipal wastewater treatment plants use heat and attack by beneficent micro-organisms through anaerobic (without air) or aerobic (with air) digestion to kill potential pathogens and reduce odors that may reside in wastewater. Municipalities accomplish further reduction of pathogens and stabilization by composting, drying, or other techniques.

The major reason that the USEPA promotes land application of biosolids is that the plant nutrients and organic matter can benefit the soil–plant agroecosystem. For example, Littleton/Englewood biosolids used at two research locations contained up to 5.0% organic–N, 1.3% ammonium–N, 140 mg/kg nitrate–N, 3.7% P, and 0.30% K. Biosolids can also provide plant micronutrients such as Fe and Zn. The organic carbon in biosolids can help to develop and stabilize soil structure with a concomitant increase in precipitation capture and decrease in soil erosion. Efficacious land application of biosolids changes the perspective from disposal of a waste (i.e., a nuisance) to recycling a valuable resource (i.e., a beneficial process).

Conclusions

Organic residuals (wastes)can serve as excellent sources of plant nutrients such as N, P, and micronutrients such as Fe and Zn. Proper management is required, however, to match nutrient amounts supplied by the organic materials with crop needs so as to avoid potential pollution problems.

Manure Management: Dairy

H.H. Van Horn
and D.R. Bray

Introduction

Water use is essential for all dairies. Drinking water is indispensable for cattlelife; some amount of water is necessary for cleaning and sanitation procedures; moderate amounts are important during periods of heat stress for evaporative cooling of cows to improve animal production and health; additional amounts can be used in labor-saving methods to move manure and clean barns by flushing in properly designed facilities; and the recovered wastewater can be recycled to supplement water requirements of forage crops grown to meet roughage requirements of the dairy herd. Extensive water use, however, increases the potential of surface runoff and its penetration into the ground with possible environmental impacts offsite. Heightened environmental concerns and the need for resource conservation, in many cases, have caused implementation of water-use permits. Thus, it is important to determine various essential uses of water, other uses that are important to management, and also consider whether reuse of some water is possible and if it is necessary to do so.

Some of the useful unit conversions are listed as follows:

1 gal of water = 8.346 lb.
1 ft^3 of water = 7.48 gal.
1 acre = 43,560 ft^2.
1 acre in. of water = 27,152 gal

Calibration methods to estimate use: Water flow meters should be installed on major water supply lines. If water meters are not in place to measure gallons pumped, it becomes necessary to estimate the usage. This can be achieved by capturing flow through various water lines for specified times and multiplying by the time the water flows through these lines every day.

Drinking

Table 1 provides estimates of drinking water requirements in gallons per cow per day. Consumption of 25–30 gal of water per day by lactating cows is common, which varies depending on milk yield, dry matter intake (DMI), temperature, and other environmental conditions.[1]

Cow Washing

Presently most dairies, in warm climates, bring cows to be milked into a holding area equipped with floor-level sprinklers, which spray water upward to wash cows. Each cow usually has a holding area of about 15 ft^2 and are typically washed for 3 min. Amount of water used per cow should be calculated for each dairy. An estimate for conservative use is that a holding area for 300 cows is 30 × 150ft^2 (15 ft^2 per cow) and is equipped with sprinklers with 5-ft spacing (say 7 across and 30 rows) having 210 sprinklers. If each sprinkler applies 5 gal min^{-1}, total usage is 1050gal min^{-1} or 3150 gal for 3 min, the average consumption per cow would be 3150/300 = 10.5 gal per cow per wash cycle. If cows are milked three times this would require 31.5 gal per cow per day.

The washing system previously described also helps in cooling of cows while they are crowded together waiting to be milked. However, the cooling effect could be achieved by sprinkling a little amount of water from above, alternatively with fans to give evaporative cooling, if cows were clean enough so that extensive washing was not required and water conservation was necessary.

Washing Milking Equipment and Milking Parlor

Use of water for these purposes is not as directly related to the number of cows as for other uses. For washing milking equipment, a common wash vat volume is 75 gal. If this is filled for rinse, wash, acid rinse, and sanitizing at each of three milkings, this amounts to 900 gal for the herd, e.g., with 300 cows, only 3 gal per cow per day. This is an extremely small component of the total water budget. The amount used to wash out the milking parlor varies largely. If only hoses are used, the amount may be as little as 2 gal per cow per milking or 6 gal per cow per day if cows are milked three times daily. If flush tanks are used, the amount may be more, i.e., nearly 3000gal per milking or 9000 gal day^{-1} for three times, equivalent to 30 gal per cow per day for a 300-cow system.

TABLE 1 Predicted Saily Water Intake of Dairy Cattle as Influenced by Milk Yield, DMI, and Season[a,b]

	Cool Season (e.g., February)		Warm Season (e.g., August)	
Milk Yield (lb)	DMI (lb)	Water Intake (gal)	DMI (lb)	Water Intake (gal)
0	25	11.5	25	16.3
60	45	22.2	44	26.8
100	55	28.6	48	31.9

[a] Drinking water intake predicted from equation of Murphy et al., J. Dairy Sci., 1983, 66, 35: Water intake (lb day^{-1}) = 35.2 × DMI (lb day^{-1}) + 0.90 × milk produced (lb day^{-1}) + 0.11 × *sodium* intake (g day^{-1}) + 2.64 × weekly mean minimum temperature [°C = (°F −32) ×5/9]. For examples above, diet dry matter was assumed to contain 0.35% Na. Predicted water intakes (lb) from formula calculations were divided by 8.346lb water per gal to convert to gallons.

[b] Average minimum monthly temperatures for February (43.5°F) and August (71°F) used with prediction equation were 70 years averages for specified months at Gainesville, FL (Whitty et al., Agronomy Dept, Univ. FL, 1991).

Sprinkling and Cooling

Sprinklers along with fans are used for evaporative cooling to relieve heat stress in dairy cows during hot periods of the year. Their use has shown increased cow comfort (lowered body temperature and respiration rates) and economic increases in milk production and reproductive performance.[2,3] Application rates used by dairymen vary. Florida experiments compared application rates of 51 gal per cow per day, 88 gal per cow per day, and 108 gal per cow per day at 10 psi in one experiment and 13 gal per cow per day, 25 gal per cow per day, and 40 gal per cow per day in another experiment. The application rate, 13 gal per cow per day, is close to the estimated evaporation rate from the cow and surrounding floors. This component should be considered in water use but not in runoff water that must be managed in the manure management system. We estimate 25 gal per cow per day as the minimum practical application rate in order to get adequate coverage of cows to cool them because often they are not in the sprinkled area. Total application days per year vary from 120 days to 240 days. A separate water well, or reserve tank and booster pump, may be needed to supply short-term high demand required by the sprinkler system.

Flushing Manure

Flushing manure can be made a clean and labor-saving process, if facilities include concrete floors with enough slope so that water flow propelled by gravity could be used to move manure. Amounts of water used per cow vary widely depending on size and design of facilities and frequency of flushing. However, usually a flush of about 3000 gal is required to clean an alley width of 10–16 ft. If 4 alleys are common for every 400 cows and alleys are flushed twice daily, this would amount to an average use of 60 gal per cow per day. Many dairies use more flushings per day.

Recycling Dairy Wastewater through Irrigation of Forage Crops

Most often nitrogen is the nutrient on which manure application rates are budgeted. To maximize nutrient uptake, crop growth should be as vigorous as possible. This requires irrigation during most of the year in many dairy regions for the disposal of flushed wastewater. In southern regions, multiple cropping systems are possible, which will recycle effectively nitrogen excretions from 100 cows on a sprayfield or manure application field of about 30 acres.[4]

Tentative estimates of total water needs of the growing crops in warm climates average about 1.75 in. of water per week (0.25 in. per day) from irrigation plus rainfall with a minimum of 0.5 in. per week tolerated even in rainy season on sandy soils.[5,6] Table 2 provides estimates of water requirements for two triple cropping forage systems that are common in southern climates. In sandy soils that hold only about 1.0 in. of water per foot of soil depth, some amount of rainfall cannot be stored. Therefore, even in heavy rainfall seasons, judicious irrigation is often needed during lower rainfall weeks. Limited data are available on the maximum amount of water that could be applied and not reduce yield or quality of forage and not result in pollution of groundwater with nitrates and other minerals. However, the maximum probably is at least 35–45 in. per year above the acre totals in Table 2.

Rainwater from Roofs and Concrete Areas

Rainwater entering wastewater holding areas can be significant. For example in the dairy representing typical minimum water usage with a flush system in southeast United States (Table 3), the net accumulation during the hot season was calculated as follows: assumed wastewater holding area is 1 acre surface area per 100 cows, net rainfall accumulation in holding area is 3 in. more than evaporation per month, concrete areas and/or undiverted roof areas that capture rainfall are 15,000 ft^2 per 100 cows that divert 15,000/43,560 ft^2 per acre of the 3 in. to the wastewater holding facility. Thus, 3 in. + $0.344 \times 3 = 4.03$ acre in. mo^{-1} or essentially 1.0 acre in. per week per 100 cows (approximately 27,000 gal per 100 cows).

TABLE 2 Crop Yield and Water Requirement Estimates for Two Triple Cropping Forage Systems

		Silage Yield				Water Required		
Crop No.	Name	Ton/A 35% DM	Ton/A DM	lb/A DM	lb/lb DM	lb/A Total	gal/A Total	A-in. Total
1	Wheat	10	3.5	7000	500	3,500,000	419,362	15.4
2	Corn	24	8.4	16,800	368	6,182,400	740,762	27.3
3	Corn	14	4.9	9800	368	3,606,400	432,111	15.9
	Total	48	16.8	33,600		13,288,800	1,592,235	58.6
1	Rye	10	3.5	7000	500	3,500,000	419,362	15.4
2	Corn	24	8.4	16,800	368	6,182,400	740,762	27.3
3	F. Sorghum	18	6.3	12,600	271	3,414,600	409,130	15.1
	Total	52	18.2	36,400		13,097,000	1,569,254	57.8

[a] A = acre; No. = number; DM = dry matter.

Developing a Water Budget

A wide range exists in water usage on dairy farms. For most dairy waste management systems designed to utilize flushed manure nutrients through cropping systems grown under irrigation, water amounts are small in relation to irrigation needs for crop production. Costs for construction of storage structures for holding wastewater until used for irrigation warrant consideration. For example, water-use budgets given in Table 3 show that water usage is small in comparison to irrigation needs when there are 30 acre of sprayfield crop production per 100 cows. Conversely, the amounts used in most dairy systems would be large and unmanageable if application through irrigation is not an option or if less acreage for irrigation is available than needed for application of all manure nutrients.

If a dairy does not have acreage available close by to utilize manure nutrients and water through an environmentally accountable sprayfield application system, it would be necessary to export nutrients off the farm, preferably as solid wastes to avoid excessive hauling or pumping costs. If the water and manure nutrients cannot be used through irrigation, a non-flush system should be utilized. However, usually some irrigation is possible, permitting dairymen to use cow washers and limited flushing if they scrape and haul manure from some areas.

Strategies to minimize water usage: Table 3 presents one column indicating a theoretical minimum amount of water use in a dairy. This system implies that cows are clean and cool enough so that sprinkler washers are not required to clean and cool cows while being held for milking. In addition, it is assumed that all of the manure is scraped and hauled to manure disposal fields or transported off the dairy in some other fashion. Intermediate steps that might be taken include the following:

1. Scraping and hauling manure from high use areas such as the feeding barn so that this manure can be managed off the dairy.
2. Using wastewater rather than fresh water to flush manure from feeding areas and freestall barns.
3. Using a housing system that will keep cows clean enough so that cow washers are not required to clean cows before milking. This system, however, may require use of alternating sprinklers and fans to keep crowded cows cool during hot weather conditions.

If flushing is desired in conjunction with scraping and hauling from heavy use areas, perhaps the feeding area could be flushed with recycled water after scraping to clean the area. These procedures would reduce total nutrient loads retained in wastewater and would significantly reduce the size of the sprayfield needed for water and manure nutrient recycling.

TABLE 3 Estimated Water Budgets for Three Example Dairies

	Flush Systems			
Water Use in the Dairy	Typical Need during Hot Season	Common Usage on Some Dairies	Non-Flush Theoretical Minimum	Worksheet for Your Dairy
Drinking (cows)	25	25	25	
Cleaning cows	32	150	0	
Cleaning milking equipment	3	5	3	
Cleaning milking parlor	30	30	6	
Sprinklers for cooling	25	130	12	
Flushing manure	60	80	0	
Total use per cow per day	175	400	46	
Total use per 100 cows per day	17,500	40,000	4600	
Use per 100 cows per week	122,500	280,000	32,200	
Water in milk per 100 cows per week	4500	4500	4500	
Estimated evaporation (at 20% of use)	24,500	56,000	6440	
Average rainfall and watershed drainage into storage facility per 100 cows per week	27,000	27,000	13,000	
Wastewater produced from 100 cows/week	120,500	246,500	38,760	
Acre in. per 100 cows per week	4.44	9.08	1.43	
in. per week if 30 acre in sprayfield	0.15	0.30	0.05	

[a] All values are in gal unless otherwise noted.

Example calculations (column 1): Total use per cow per day = 175 gal; total use per 100 cows per week = 122,500 gal less 4500 in milk and 24,500 gal evaporation = 93,500 gal week^{-1}; net rainfall and watershed drainage to storage per 100 per cows per week = 27,000; acre in. per 100 cows per week = (93,500 + 27,000)/27,152 gal per acre in. = 4.44.; if 30 acre were in sprayfield, 4.44/30 = 0.15 in. week^{-1}.; if crop needed 1.75 acre in. week^{-1} (a common average), a total of 1.75 in. × 30 acre × 27,152 gal per acre in. = 1,425,480 gal is needed of which only 120,500 gal (8.5%) would come from dairy wastewater. The remaining (91.5% of total) would have to come from rainfall or fresh irrigation water.

Manure Management: Phosphorus

Rory O. Maguire,
John T. Brake, and
Peter W. Plumstead

Recent Progress in Nutrient Management Practices

With increasing human population and awareness of environmental problems associated with pollution of rivers and streams with P, the end of the 20th century saw a refocusing of nutrient management strategies from increasing production toward environmental protection, in developed countries.[1] Initially, nutrient management strategies were aimed at avoiding overapplication of nutrients and voluntary best management practices were developed. However, manure still tended to be applied at a rate to supply crops with sufficient N, which typically leads to overapplication of P, as manures have N: P ratios of around 2: 1 to 4: 1 (depending on species) while crop requirements have an N: P ratio of 8: 1. When P is overapplied to soils, it builds up the soil test P (STP) concentration and over a period of many years, this leads to STP rising to levels in excess of crop requirement.[2] Soil test P in excess of crop requirement is undesirable, as studies have shown that when STP rises above agronomically optimum values P losses to rivers and streams increase to the detriment of water quality, [2] and it can also lead to a negative effect on some micronutrients, e.g., Zn.

Nutritional Strategies to Reduce the Manure Phosphorus Concentration

In the past, dietary P levels frequently included a safety margin that allows for any potential variation in both the requirement of the animals and the degree of dietary P utilization, with little attention paid to the resultant manure P concentration. However, recent research in broilers and broiler breeders demonstrates that levels of inorganic P, supplemented to both broiler and broiler breeder diets may be considerably reduced relative to minimum requirements published by the National Research Council without an adverse effect on performance.[3,4]

When considering strategies to increase P digestion and retention, species can be split into two categories according to their ability to digest phytate-P: ruminants (cattle, sheep) can digest phytate-P, while monogastric species (poultry, swine) can digest little. As approximately 66% of the P in corn and soybean is in the form of phytic acid, and these ingredients frequently constitute about 60%–90% of the diet, up to 80% of the total fecal P output may originate directly from corn and soybean meal in poultry diets.[5] The primary strategy to address the low digestibility of phytate-P in monogastric species has been the application of exogenous phytase enzymes to these diets and is done on the basis of replacing 0.1% of available P from supplemental calcium phosphate with a more or less standard amount of enzyme. Alternate strategies other than the use of phytase include the development of low phytate variants of corn and soybean cultivars, because these possess similar, if not greater, potential in reducing manure P excretion. However, the commercial application of these new cultivars has to date been limited as a result of the practical complications arising from the identity preservation of these ingredients from harvest to point of feeding.

Impact of Diet Modification on Nutrient Management

The total P and soluble P concentrations in manures have been shown to be affected by dietary P concentration, P contributing ingredients, and dietary phytase supplementation. Total P is important because applications of manure total P contribute to long-term changes in STP. Once optimum STP for crop production is attained, it is beneficial to balance manure total P applications with crop removal of P. This will maintain crop production without raising STP to levels of environmental concern; although in some soils, P can revert to less available forms so P availability needs to be monitored with soil testing. Applications of soluble P in manure have been correlated to soluble P losses in runoff from manure-amended soils, so minimizing the soluble P concentration in manure is important when P losses to rivers and streams are of concern. Reducing the P concentration in animal feeds (high vs. low nonphytate P diets) and using phytase (phytase vs. no phytase diets) can reduce the total and soluble P concentrations in poultry wastes (Figure 1).[6] It is estimated that using currently available technology, dietary amendment can potentially de-crease the total P concentration in poultry by 40%, swine by 50% and dairy by 30%, while future advances could raise these figures to 60% for both poultry and swine.[7] Research on the impact of dietary amendments on soluble P in manure and P losses in runoff from manure-amended soils is at an early stage; however, trends are starting to appear. Supplying P at an adequate level to satisfy animal requirements is generally achieved through a reduction in the added inorganic dietary calcium phosphate component, and results in a reduction in both total and soluble P in the manures generated. While most studies show that feed additives such as phytase reduce manure total P while having little effect on soluble P, this effect is very dependent on the level of dietary P relative to the requirements of the animals.[6,7] Phytase supplementation to diets containing P in excess of animal requirements, or without an adequate reduction in the P from supplemental calcium phosphate, will result in a potential increase in the water soluble P when expressed on a percentage basis.[5]

Traditionally, manure application rates to cropland have been decided by individual farmers. However, increasing concerns over the impact of the land application of nutrients in excess of crop requirement on water quality in rivers and streams, have led to increasing regulation of land application of manures in many developed countries. These regulations are primarily based on N and P application rates that are often linked to problems identified in localized areas and are based on the current levels of soil N and P, and the annual rate of removal of these nutrients through their incorporation into harvested crops. As forage crops typically have an N : P ratio of 8 : 1 and manure contains N : P ratios of approximately 2 : 1 to 4 : 1, nutrient management regulations based on P application may require up to four times more cropland than previous N-based application guidelines. The limitation of available land in areas proximate to intensive livestock production can cause problems associated with what to do with the manure if it cannot be land applied, as other uses of manure are currently fairly limited and transport costs limit the potential transportation of the wastes over any appreciable distance. If nutrient management regulations are based on P, then reducing the P concentration in manures could greatly alleviate these problems. For example, if one could reduce the total P concentration in a manure by 40%, then application of 40% more manure by weight to meet the same total P application limit would be possible. This may eliminate problems with excess manure P in some areas of intensive animal production, but may not be sufficient for other areas that already have high STP.

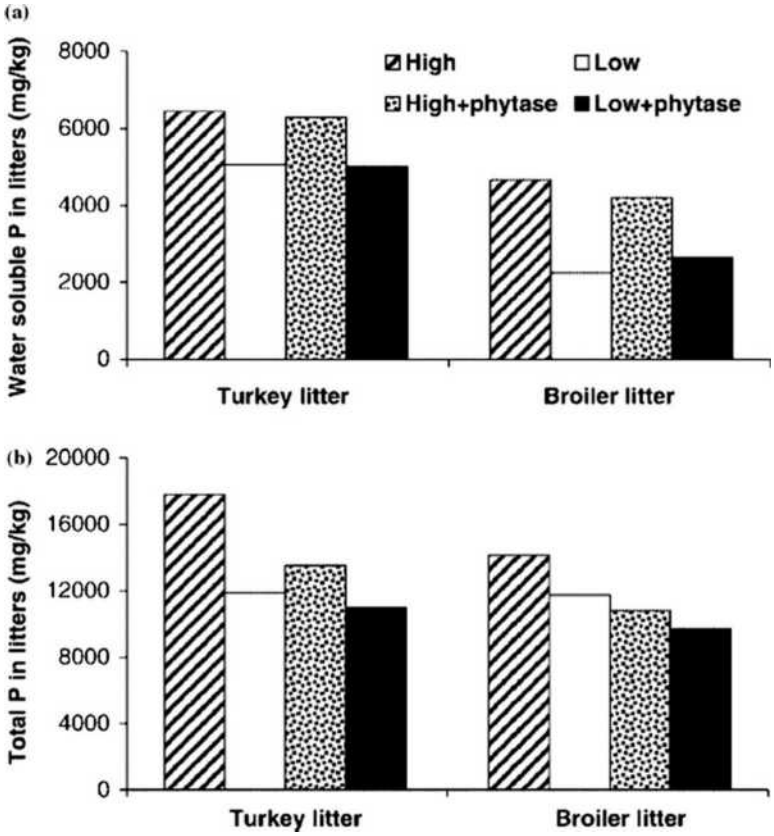

FIGURE 1 Effects of diets high and low in dietary nonphytate P, and the impact of dietary phytase on (a) water soluble P in litters, and (b) total P in litters produced.
Source: Maguire et al.[6]

Conclusions

Dietary amendment to reduce the P concentration in feeds and hence manures generated will help address concerns over the fate of manure nutrients in areas of intensive animal production. If manures have the same N concentrations but reduced P concentrations, then these manures will come closer to meeting crop N needs without oversupply of P. However, dietary amendment alone will not solve the problem of excessive manure P in all areas of animal production. Dietary amendment will, however, certainly help alleviate the current situation where applying animal manures to meet crop N requirements leads to overapplication of P, buildup of STP, and eventually increased losses of P to rivers and streams.

Manure Management: Poultry

Shafiqur Rahman
and Thomas R. Way

Introduction

The U.S. Environment Protection Agency (EPA) includes a number of species, including chicken, turkey, and duck, in their definition of poultry. In the United States, approximately 8.55 billion broilers, 337 million laying hens, and 247 million turkeys were raised in 2009.[1] The total revenue from the poultry industry in 2008 was $35.9 billion, which was up 11% as compared with 2007 ($32.2 billion). Of the combined total revenue, the broiler, layer, and turkey industries contributed 64%, 23%, and 12%, respectively. Modern poultry production occurs primarily in confined facilities, which allows larger intensive production in smaller areas. Owing to intensive poultry production systems, large amount of manure (i.e., feces, urine, undigested feed, spilled water, bedding used in poultry houses, etc.), is produced in a smaller area, which leads to air pollution (including odors and pollutant gas emissions) and water pollution (i.e., eutrophication) problems. It is the producer's responsibility to manage manure in an environmentally safe way. Therefore, poultry manure management is the focus of this entry.

Manure Production and Management System

Table 1 lists the total number of broilers, layers, and turkeys produced and the estimated manure production by bird type. A large quantity of manure or litter is produced daily, which needs to be managed properly to maximize agronomic benefits (i.e., nutrient values) and minimize environmental concerns (i.e., water and air pollution). Poultry manure management is composed of manure collection and handling, storing, and utilization. Manure collection and handling depend on manure properties, and they are influenced by bird type, bird age, diet, bird productivity, and management system.[2] Manure can be handled as a solid (>20 total solids), semisolid (10%–20% total solids), slurry (4%–10% solids), or liquid (<4% solids).[3] Solid manure can be stacked, while liquid manure can be stored in earthen anaerobic lagoons or storage structures (e.g., concrete or steel). For economical reasons, liquid manure is typically stored in anaerobic lagoons.

TABLE 1 Poultry Manure Production, as Excreted

Bird Type	Live Market Weight (kg)[a]	Manure per 1000 Birds/Day (kg)[a]	Total Number of Birds (1000s)[b]	Total Manure Production/Day (tons)
Broiler	2.0	80	8,550,500	684,040
Layer	1.8	118	337,376	39,810
Turkey (tom, light)	10.0	267	249,914	66,727
Total manure production				790,577

[a] From Poultry Waste Management Handbook, NRAES-132.[4]
[b] From National Agricultural Statistics Service.[1]

In broiler and turkey facilities, bedding or litter materials (e.g., sawdust, wood shavings, peanut hulls, rice hulls, sunflower hulls, etc.), are used, and litter is handled as a solid (Figure 1). Litter is sometimes completely removed after each flock or partially cleaned between flocks when litter is wet and packed around feeders and waterers. After partial cleaning, a thin layer of fresh bedding material is added.[2] It is also common that producers decake litter between flocks using a decaking implement to remove the

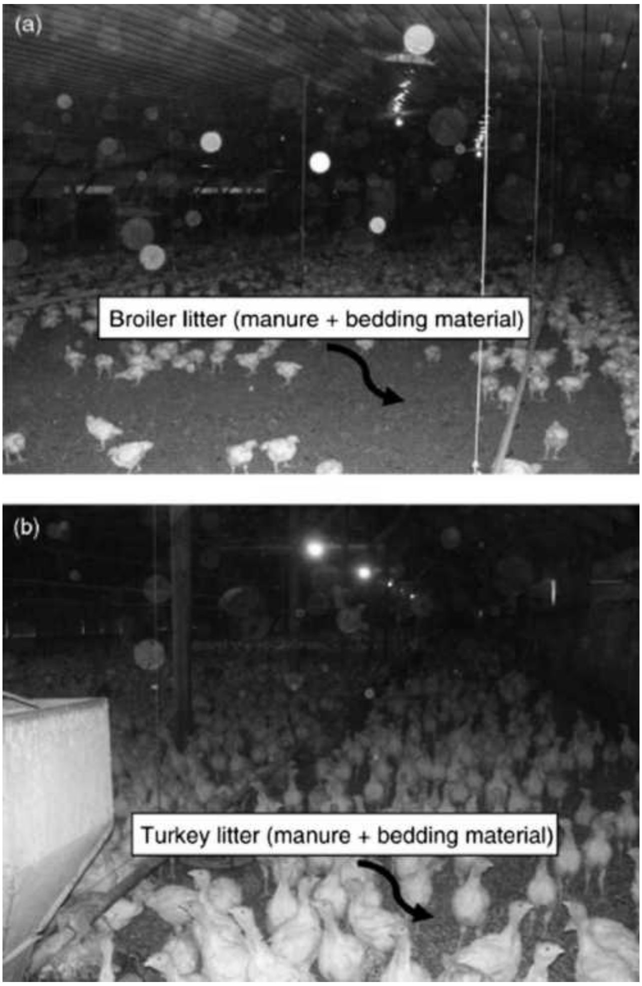

FIGURE 1 Poultry production facility and litter for (a) broiler and (b) turkey.

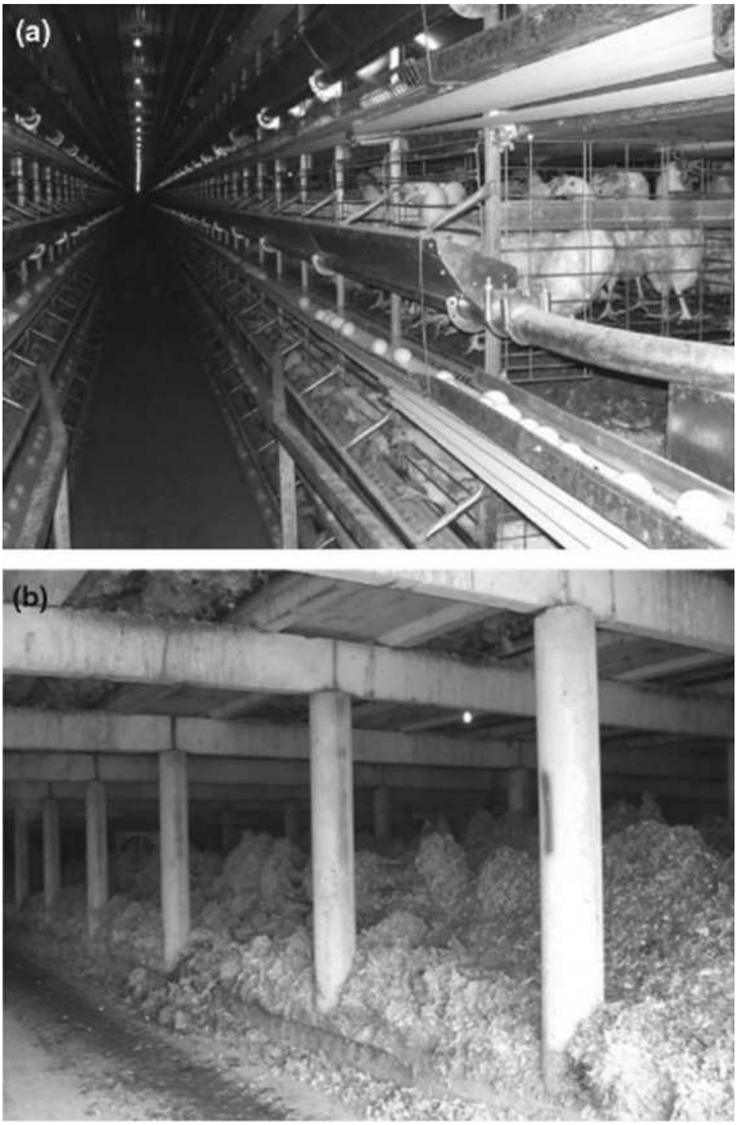

FIGURE 2 (a) High-rise layer house and (b) manure storage pit (stockpiled beneath cages).

larger clumps of litter while leaving the smaller clumps as bedding for the next flock. Depending on the management practices, litter cleanout varies significantly from farm to farm.

High-rise layer facilities (elevated cages) (Figure 2a) produce solid manure, and that manure is stored in the portion of the poultry house beneath the cages, as shown in Figure 2b. Manure is removed once or twice a year depending on individual farm management practices and regulatory requirements.

Some layer facilities with a shallow pit remove manure two or three times per week using a scraper (Figure 3a) and may produce semisolid or liquid manure and store it in an earthen anaerobic lagoon or outdoor storage (Figure 3b). However, manure cleaning or removing frequency may vary depending on the storage capacity, manure storage conditions (dry or wet), and environmental (indoor air quality) conditions.

Manure Storage

Manure or litter can be stored both indoors and outdoors depending on manure type and management practices. Both options have some pros and cons as discussed below.

Indoor Storage

Most of the high-rise layer houses (Figure 2a) stockpile manure directly beneath the birdcages, i.e., deep-pit storage, as shown in Figure 2b. This option minimizes runoff from precipitation, and manure can be stored for a longer time to allow scheduling of land application around crop nutrient requirements.[5] Although this option minimizes water pollution from runoff, it may cause air quality issues with the house, if not managed properly. Typically, high-rise layer houses are cleaned of manure once or twice a year; however, a manure storage pit should be inspected daily for any sign of water leakage. Ammonia (NH_3) and hydrogen sulfide (H_2S) emissions from indoor stockpiled manure may cause poor air quality and may affect bird health and productivity as well as worker health and safety. It is important to maintain recommended ventilation rates and to keep manure as dry as possible to minimize anaerobic conditions in manure stockpiles. Fans are commonly used in the pit to keep the manure pile relatively dry. If any portion of the manure stockpile is wet from water leakage, it is important to promptly remove manure from indoors and correct any water leakage problem. Typically, wet manure will require more frequent removal than dry manure.

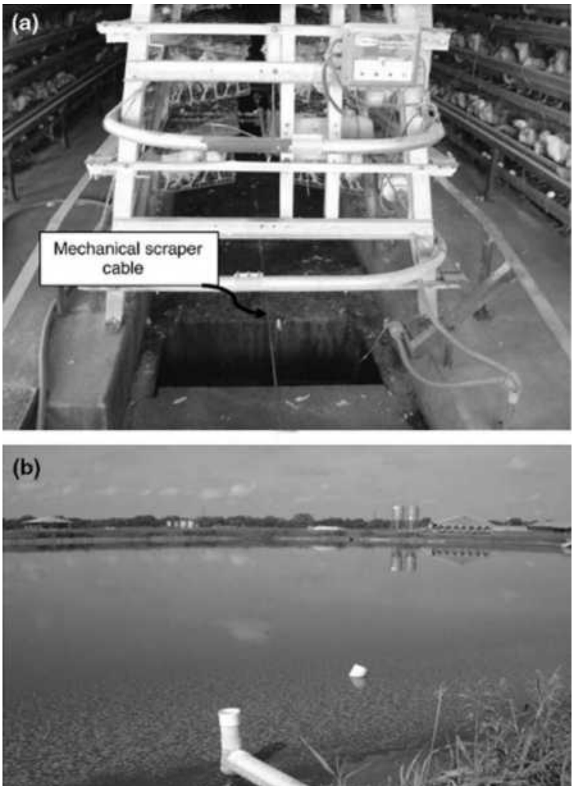

FIGURE 3 (a) Layer house with mechanical scraper and (b) anaerobic earthen lagoon system.

Outdoor Storage

Poultry litter should be removed from the house between flocks. The litter should be stored outside if no land is available for immediate manure application or if there is insufficient indoor storage room for a period of 6 to 9 mo. If solid manure is stored outside, proper management is necessary to minimize runoff and groundwater pollution. Outdoor stockpiles should be at least 30 m from the nearest surface water and should be separated from groundwater by an impervious soil layer having a minimum thickness of 1.2 m. To minimize runoff resulting from rainfall and to reduce nutrient losses, a cover on top of the litter pile is required to limit manure exposure to air. If regulatory guidelines and time permit, and if cropping conditions are appropriate, outside stockpiled manure should be applied to cropland as soon as possible.

Liquid manure or slurry is removed from under caged birds by mechanical scrapers (Figure 3) or mechanical belts or flushed with water and stored in an outdoor anaerobic lagoon or containment pond (Figure 3b). Manure is typically stored in an anaerobic earthen lagoon for a period of 6 to 9 mo and applied to cropland near or during the growing season to optimize use of manure nutrients. However, during manure pumping, it is very important to maintain the minimum design volume or treatment volume of an anaerobic lagoon to provide a dual function of storing and treating the manure.[6] Otherwise, anaerobic lagoons may be a significant source of nuisance odor.

Manure Utilization

Poultry manure contains essential nutrients (e.g., nitrogen, phosphorus, potassium, etc.), and can be applied to land as fertilizer to meet crop nutrient requirements. However, when land application of poultry manure as fertilizer is not an environmentally and economically sound option, manure (especially solid manure) can be composted (Figure 4), and the compost can be used as a fertilizer source for crops, gardens, and nurseries. In that case, nuisance odor can be minimized, and nutrients become bound in organic forms. However, for proper composting, several parameters (carbon-nitrogen ratio, pile moisture content, pile temperature, oxygen concentration, etc.), need to be maintained appropriately. Otherwise, anaerobic conditions may prevail, and the pile may become a source of nuisance odor.

FIGURE 4 Turkey litter composting pile and temperature sensors.

During storage, nutrient losses are a normal phenomenon. A portion of nutrient losses occurs during land application depending on the application method, such as surface vs. subsurface injection. Typically, most solid manure is applied on the surface, often followed by incorporation. Solid manure is commonly applied using truck-mounted spreaders (Figure 5). There are many options for solid manure spreaders, including side delivery and rear delivery (spinner spreader; single or double horizontal beater; vertical beaters). With a single beater, it is difficult to have uniform manure distribution to take full advantages of nutrients in manure, and it is difficult to break litter cake or large clumps. Researchers[6] concluded that distribution of manure across the application swath of a spreader needs to be relatively uniform to take full advantage of the fertilizer value of solid manure. To overcome this issue, double vertical beaters might be a better option (Figure 5b and c).

Traditional surface application of manure may cause nutrient losses, nuisance odor, and nutrient runoff, and reduces nutrient availability. Although incorporation will minimize some of these concerns, delayed incorporation (more than 24 hr) can result in increased nuisance odor, nitrogen nutrient losses through volatilization, and surface runoff.

To overcome problems associated with surface application of solid manure, manure can be subsurface banded. Until recently, subsurface application has been available for only liquid manure or slurry. Research has been conducted in both Canada and the United States to develop implements for subsurface band application of solid manure from poultry and feedlots.[7–9] Applying the manure in a controlled way decreases odor and greenhouse gas emissions while improving air quality and the social acceptance of the practice.[7] The U.S. Department of Agriculture–Agricultural Research Service (USDA-ARS) National Soil Dynamics Laboratory (Auburn, Alabama) has developed a four-row prototype implement for subsurface band application of poultry litter (Figure 6) and has used the implement to apply poultry litter in row crops and pastures.

The implement is equipped with conveyors, one for each trencher. Each conveyor drops the litter into a trencher, where the litter falls by gravity down into the trencher. The band spacing is adjustable from 0.25 to 1.0 m in increments of 25 mm. The implement is capable of applying poultry litter in a side-dressing manner to row crops, and the band spacing is then typically equal to the crop row spacing. Also, the implement is capable of applying litter to pastures, and typical band spacings that have been used for pastures are 250 to 380 mm. One disadvantage of the implement is that litter clumps measuring larger than 25 mm across have to be run through a hammer mill before being loaded into the hopper. Also, the litter moisture content should be <40% (wet basis). The implement is being modified to include on-the-go grinding as part of the machine. Subsurface banding of broiler litter to cotton with this implement has been shown to increase lint yield relative to surface broadcast application of litter.[10]

Subsurface band application of broiler litter to tall fescue and bermudagrass pastures using band spacings of 250 and 380 mm was found to produce forage yields equivalent to those for surface broadcast application of litter.[11] When broiler litter has been subsurface banded in a pasture with the implement, and rainfall has been applied using rainfall simulation, concentrations of phosphorus and nitrogen in runoff water have typically been reduced by 80%–95% relative to those for surface broadcast application of litter.

In contrast, liquid manure can be applied on both the surface and subsurface, and technologies are improving very fast. Injection of liquid manure limits the exposure of manure to the surface water and air, resulting in reduced nutrient losses and nuisance odor. For a liquid manure application system, a liquid storage tank with a flush spreader or injector assembly is used. However, a fully loaded tank may cause soil compaction, especially in wet clay soil. To overcome compaction issues, manure can be injected using a drag-hose system (Figure 7a). One new technology, namely, AerWay SSD® (Holland Equipment Inc., Norwich, Ontario, Canada), can place liquid manure in the active root zone and can substantially reduce any risk of groundwater contamination (Figure 7b).

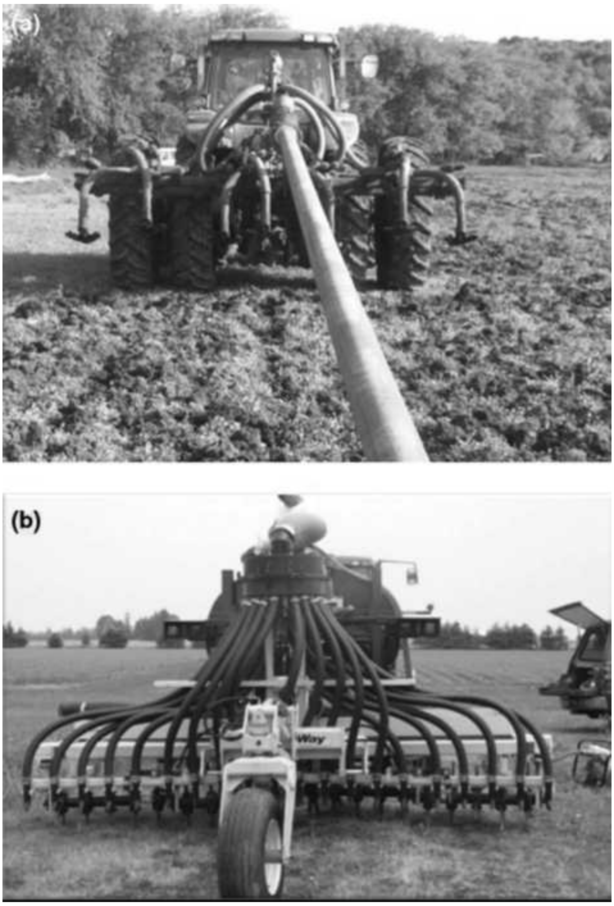

FIGURE 7 Liquid manure injection system: (a) drag-hose system and (b) AerWay SSD system.

Energy Uses

As of April 2010, there are 151 anaerobic digester systems operating at commercial livestock farms in the United States. Of these, only three anaerobic digester systems were using poultry manure. Poultry manure has higher biodegradable organic matter content than other livestock wastes,[12] and a substantial amount of water would be required to dilute poultry litter. They also found that efficiency of organic matter conversion to methane decreased with increasing organic loads to the digesters. As a result, limited anaerobic digester systems are using poultry manure.

Conclusions

Poultry manure management poses challenges at different steps of manure management, including manure collection, storage and handling, and utilization or disposal. Utilization or disposal of manure in an environmentally safe way is one of the biggest challenges. Poultry manure can be handled as either a solid or a liquid. Owing to enriched nutrient content in manure, it may be applied to crops to meet crop nutrient requirements. However, selection of manure application tools and methods is important in minimizing environmental concerns and maximizing agronomic benefits from manure.

Organic Matter: Management

R. Cesar Izaurralde
and Carlos C. Cerri

Introduction

Soil organic matter (SOM) consists of a complex array of living organisms such as bacteria and fungi, plant and animal debris in different stages of decomposition, and *humus*—a rather stable brown to black material showing no resemblance to the organisms from which it originates. Because SOM is or has been part of living tissues, its composition is dominated by carbon (C), hydrogen, oxygen and—in lesser abundance—by nitrogen, phosphorus, sulfur among other elements. Levels of SOM are expressed in terms of soil organic carbon (SOC) concentration (g kg^{-1}) or mass per unit area (g m^{-2}) to a given depth. The level of SOC in virgin soils reflects the action and interaction of the major factors of soil formation: climate, vegetation, topography, parent material, and age. These factors control SOC content by regulating the balance between C gains via photosynthesis and losses via autotrophic and heterotrophic respiration, as well as C losses in soluble and solid form. The SOC content usually ranges between 5 and 100 g kg^{-1} in mineral soils. These concentrations appear modest but at 1500 Pg, the amount of organic C stored globally in soils is second only to that contained in oceans and at least twice that found in either terrestrial vegetation or the atmosphere.

Cultivated soils usually contain less SOC than virgin soils[1] due to the magnification of two biophysical processes: 1) net nutrient mineralization accompanied by release of CO_2 due to microbial respiration and 2) soil erosion. SOC losses of up to 50% have been reported within 30–70 years of land use conversions under temperate conditions.[2–5] SOC losses reported in subtropical and tropical environments often match or even surpass those observed under temperate conditions.[6–8] In subtropical and tropical environments, shifting cultivation systems appear to conserve more SOC than forestlands permanently cleared for cultivation.[9]

Major Processes Leading to Carbon Losses from Soil

Mineralization Processes

Depending on its frequency and kind, tillage changes the soil biophysical environment in ways that affect the net mineralization of nutrients and the release of carbon. These changes can be described in terms of increases or decreases in soil porosity, disruption of soil aggregates, and redistribution in the proportion of soil aggregate size, as well as alteration of energy and water fluxes. All these changes enhance, at least temporarily, the conversion of organic C into CO_2[10] and the net release of nutrients from SOM. Much of the success of past agricultural practices relied heavily on the control of decomposition processes through tillage operations to satisfy plant nutrient demands. All this came at a price, however, for a heavy reliance on soil nutrients to feed crops without proper replenishment led to the worldwide declines of SOM.[11]

Soil Erosion Processes

Agricultural ecosystems normally experience soil losses at rates considerably greater than natural ecosystems because of an incomplete plant or residue cover of the soil during rainy or windy conditions. When surface and environmental conditions are right (i.e., bare soil, sloping land, intense rain, windy weather), the kinetic energy embedded in wind and water is transferred to soil aggregates causing them to be detached and transported away from their original position across fields or downhill. Besides the physical loss of soil particles and on-site impact on soil productivity, the detachment and transport processes also cause aggregate breakdown, thereby exposing labile C to microbial activity. This aggregate breakdown also facilitates the preferential removal of soil materials comprised mainly of humus and clay or silt fractions. Consequently, water- and windborne sediments become enriched in C with respect to the contributing soil. Carbon enrichment ratios ranging from 3 to 360 have been reported.[12,13] The fate of these C-enriched sediments is not well known, for while transport and burial of C in eroded sediments may lead to “sequestration,” [14] it may also result in part of it being emitted back to the atmosphere as CO_2.[15]

Restoring Soil Organic Matter: The Emerging Science of Soil Carbon Sequestration

Role of Long-Term Field Experiments

SOM is an essential attribute of soil quality[16] and has an essential role in soil conservation and sustainable agriculture. Many practices—some involving land use changes—have been shown to increase SOM and thus received considerable attention for their possible role in climate change mitigation.[17–19] Carbon sequestration in managed soils occurs when there is a net removal of atmospheric CO_2 because C inputs (nonharvestable net primary productivity) are greater than C outputs (soil respiration, C costs related to fossil fuels and fertilizers). Soil C sequestration has the additional appeal that all its practices conform to principles of sustainable agriculture (e.g., reduced tillage, erosion control, diversified cropping systems, improved soil fertility). Long-term field experiments have been instrumental to increase our understanding of SOM dynamics.[20,21] The first and longest standing experiment was started at Rothamsted, England, by J. B. Lawes and J. H. Gilbert who in 1843 began documenting the impact of nutrient manipulation on crop yields and soil properties.[22] Other experiments were initiated thereafter in America, Europe, and Oceania with the goal of discovering interactions among climate, soil, and management practices. The knowledge that emerged from these experiments has been instrumental for the development and testing of agroecosystem and SOM models.[23]

Global Importance of Soil C Sequestration

There appears to be a significant opportunity for managed ecosystems to act as C sinks. For example, results from inverse modeling experiments suggest that during 1988–1992, terrestrial ecosystems may have been sequestering atmospheric C at rates of 1–2.2 Pg y^{-1}.[24] Some of the likely causes include the growth of new forest in previously cultivated land[25] and the "CO_2-fertilization effect."[26] Globally, agricultural soils have been estimated to have the capacity to sequester C at rates of 0.6 Pg y^{-1}[11] during several decades. The realization of this potential C sequestration would not be trivial since it would offset roughly about one-tenth of the current emissions from fossil fuels. In the U.S., annual gains in soil C from improved agricultural practices have been estimated at 0.14 Pg yr^{-1}.[25] Whether or not soil C sequestration practices are widely adopted will depend on their value relative to other C capture and sequestration technologies.

Mechanisms of Soil C Sequestration

Recent reviews of experimental results have contributed to organize our understanding of the environmental and management controls of soil C sequestration in grassland[27,28] and agricultural[29,30] ecosystems. The use of C balance, soil fractionation, and isotope techniques have been instrumental to reveal how new C (from crop residues, roots, and organic amendments) enters soil, resides shortly (for a few years) in labile soil fractions, and finally becomes a longtime constituent (for hundreds of years) of recalcitrant organo-mineral complexes.[31] Figure 1 contrasts young (labile) organic matter fractions extracted

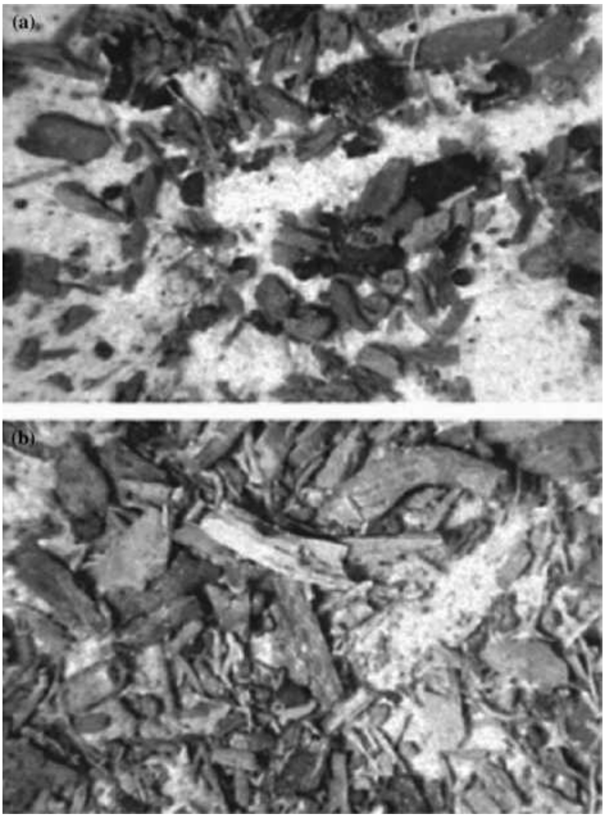

FIGURE 1 Young organic matters (fine roots and other organic debris) extracted from two Cryoboralfs under cereal cropping for 13 years receiving N at annual rates of 0 (a) and 50 kg ha^{-1} (b). The black material is charcoal. **Source:** Solberg et al.[32]

from two cultivated soils with and without N fertilizer.[32] The amounts of labile organic matter—fine roots and other organic debris— present in each soil reflect differences in crop productivity induced by addition of N at annual rates of 50 kg ha^{-1} for 13 years. "Terra Preta" soil—in tropical regions of South America and West Africa—represents a prime example of ancient wisdom applied to develop sustainable agriculture through the improvement of soil fertility and SOM.[33]

The quantity and quality of C entering soil as well as the interaction of this C with the soil biophysical environment are major factors determining the rate and duration of soil C sequestration. The quantity of C added to soil in the form of roots, crop residues, and organic amendments has been shown to play a dominant role in defining the trajectory of SOC over time.[34] Management practices geared toward optimizing nutrient supply and building nutrient reserves (e.g., fertilization, use of legumes in crop rotations) are almost guaranteed to increase soil C stocks. The quality of crop residues and the timing of their incorporation to soil also have an influential role on C decomposition and, thus, on soil C storage.[35] The degree of soil disturbance— through its impact on soil aggregation—constitutes another major factor regulating C decomposition and retention in soil.[36] In this context, no tillage agriculture has come to represent one of the most significant technological innovations of the last 30 years because it allows farmers the possibility of growing crops economically while reducing erosion and improving both quantity and quality of SOM. A few examples of the management impacts on soil C sequestration from around the world are presented in Table 1.

Soil Organic Matter, Energy, and Full C Accounting

Land is the natural habitat of humans. Humans dwell on it and use it as a resource for the production of food, fiber, and other goods. Simply put, land is managed when there is a manipulation of energy and matter flows in order to meet certain economic and social objectives. Farm mechanization and fertilizers are two of the many technical innovations that—though they rely on the utilization of fossil energy—have brought dramatic increases in food production during the last century. Changes in management practices that include soil C sequestration as an objective require careful evaluation of their impact not only on soil C gains but also on C costs from the use of fossil energy (e.g., manufacture of fertilizers)[46,47] and on the net greenhouse gas emissions.[48]

Role of Soil Organic Matter in the 21st Century

SOM has played and will continue to play a central role in sustainable land management. The restoration of SOM at global scales offers a unique opportunity to mitigate global warming. As population levels and affluence increase, demands on land to produce food, fiber, biomass, and other products will remain high. Because land is finite, important decisions will have to be made in order to balance such demands with functional objectives such as the preservation of natural ecosystems. As part of any climate policy, the impact of land use changes and management on SOM storage should be included as a criterion for making these decisions. Depending on their degree of expansion, several evolving agricultural technologies—such as genetically modified crops, conservation tillage, organic farming, and precision farming—may have important implications for soil C sequestration.[19] Their ultimate impact on C sequestration will depend not only on the economic benefit realized by individual producers but also on whether society recognizes the value of soil C storage to mitigate global warming.

Pest Management

E.F. Legner

Pest management is a broad concept that involves considerations of genetics, climate, ecology, natural enemies, and cultural or chemical applications. Therefore, it is difficult to define this category exactly. A high level of sophistication is required to manage events in the environment for the efficient production of food and fiber and the abatement of public health and nuisance pests. A principal objective to the addition of sound environmental management is the reduction of pesticide usage albeit at the irritation of large commercial interests.[1,2]

Although scientific investigations in colleges and universities have led to a high level of production and pest abatement, deployment continues to face obstacles that are largely related to the absence of competent supervisory personnel. As expertise resides largely in the research community, this group is encumbered by an academic system that continues to stress research and teaching and to minimize the deployment aspect. The most successful programs in environmental management regularly require 5 or more years to develop. Investigator survival in the system demands frequent publication but not in the kind of journals that stress implementation. This distracts from the ultimate goal of deployment, which diminishes the amount of time an investigator has to be directly involved in an advisory capacity. Several examples of successful projects that have receded in the absence of this supervision but that could be reactivated with the proper advisory personnel present will explain some of the problems and difficulties involved.

Navel Orangeworm Management in Almond Orchards

The almond industry in California has suffered from the invasion of the navel orangeworm, *Amyelois transitella* (Walker), from Mexico and South America. Two external insect larval parasites, *Goniozus legneri* Gordh and *Goniozus emigratus* (Rohwer), and one internal egg-larval parasite, *Copidosomopsis plethorica* Caltagirone, which are dominant in south Texas, Mexico, Uruguay, and Argentina, were successfully established in irrigated and non-irrigated almond orchards in California.[3–4] Separate k-value analyses indicated significant regulation of their navel orangeworm host during the warm summer season. There is a diapause (hibernation) in the host triggered by several seasonally varying factors and a diapause in the parasites triggered by hormonal changes in the host. Possible latitudinal effects on diapause also are present. The ability of the imported parasites to diapause with their host enables their permanent establishment and ability to reduce host population densities to below economic levels.[5]

Although navel orangeworm infestations have decreased with the establishment of the three parasites,[6] the almond reject levels are not always below the economic threshold of 4%. Such rejects are sometimes due to other causes, such as ant damage and fungus infections. In certain years, the peach tree borer, *Synanthedon exitiosa* (Say), has been involved as its attacks stimulate oviposition by navel orangeworm moths and subsequent damage attributed to the latter.

In some orchards, the growers have sustained a reject level of 2.5% or less through 2008. Storing rejected almond mummies in ventilated sheds through winter allows for a buildup of natural enemies and their subsequent early entry into the fields to reduce orangeworm populations before the latter have an opportunity to increase. Commercial insectaries have harvested *G. legneri* from orchards for introductions elsewhere. *C. plethorica* and *G. legneri,* and to a lesser extent, *G. emigratus*, successfully overwinter in orchards year after year. However, only *Copidosomopsis* can consistently be recovered at all times of the year. The *Goniozus* species are not recovered in significant numbers until early summer. Therefore, pest management in almond orchards may require periodic releases of *G. legneri* to reestablish balances that were disrupted by insecticidal drift or by the absence of overwintering rejected almond refuges through aggressive sanitation practices. Although sanitation in this case may appeal to the grower, it is a costly procedure that also disrupts natural balances at low pest densities.

G. legneri has been reared from codling moth and oriental fruit moth in peaches in addition to navel orangeworm from almonds. A reservoir of residual almonds that remain in the trees after harvest is desirable to maintain a synchrony of these parasites with navel orangeworms in order to achieve the lowest pest densities. In fact, such reservoirs often exceed 1000 residual almonds per tree through the winter months and produce navel orangeworm densities at harvest that are below 1% on soft-shelled varieties. Superimposed upon the system is the diapausing mechanism in both the navel orangeworm and the parasites.[5] All of these forces must be considered for a sound, reliable integrated management. Almond producers have to make reasonable decisions on whether or not to remove residual almonds, a very costly procedure, or to use within-season insecticidal sprays. However, orchard managers rarely understand population stability through the interaction of natural enemies and their prey. Because the management of this pest with parasitic insects depends heavily on the perpetuation of parasites in orchards, it can be accomplished only by an understanding of the dynamics involved. Storing rejected almonds in protective shelters during winter months increases parasite abundance. This allows the parasites to reproduce in large numbers for subsequent spread throughout an orchard in the spring when outdoor temperatures rise. Complete sanitation of an orchard by removal of all rejected almonds is counterproductive to successful management as this also eliminates natural enemies.

Australian Bush Fly Management in Micronesia

Pestiferous flies in the Marshall Islands provide a classic example of the adaptation of invading noxious insects to an area with a salubrious climate. With nearly perfect temperature–humidity conditions for their development, an abundance of carbohydrate and protein-rich food in the form of organic wastes and excreta provided by humans and their animals, and a general absence of effective natural enemies, several species were able to reach maximum numbers.

There are principally four types of pestiferous flies in Kwajalein Atoll of the Marshall Islands, with the African–Australian bush fly, *Musca sorbens* Wiedemann, being by far the most pestiferous species. The common housefly, *Musca domestica* L., of lesser importance, frequents houses and is attracted to food in recreation areas. The remaining two types are the Calliphoridae (*Chrysomya megacephala* [Fab.] and [Wiedemann]) and the Sarcophagidae (*Parasarcophaga misera* [Walker] and *Phytosarcophaga gressitti* Hall and Bohart). These latter species are abundant around refuse disposal sites and wherever rotting meat and decaying fish are available. Most of the fly species differ from the common housefly and the bush fly in being more sluggish and noisy and by their general avoidance of humans. Because residents do not distinguish the different kinds of flies, non-pestiferous types are often blamed as nuisances when in fact they may be considered to fulfill a useful role in the biodegradation of refuse and rotting meat.

An initial assessment of the problem led to the expedient implementation of breeding source reduction to reduce the population of the housefly, *M. domestica* L., and both the Calliphoridae and Sarcophagidae to inconspicuous levels. These involved slight modifications of refuse disposal sites to disfavor fly breeding. These simple measures resulted in an estimated one-third reduction of total population of flies concentrating around beaches and residential areas. Because the housefly especially enters dwellings, the reduction in its numbers was desirable for the general health of the community, and fly annoyances indoors diminished. Thorough surveys of breeding sites and natural enemy complexes revealed that *M. sorbens* population reduction would not be quickly forthcoming, however. A schedule of importation of natural enemies was begun, and other integrated management approaches were investigated, e.g., baiting and breeding habitat reduction.

Bush Fly Origin and Habits

This species is known as the bazaar fly in North Africa, a housefly in India, and the bush fly in Australia.[7] It was first described from Sierra Leone in West Africa in 1830, where it is a notorious nuisance to humans and animals. The flies are attracted to wounds, sores, and skin lesions, searching for any possible food sources such as blood and other exudations. Although not a biting species, its habits of transmitting eye diseases, enteric infections, pathogenic bacteria, and helminth eggs make it a most important and dangerous public health insect.[8–11]

The bush fly has spread through a major portion of the Old World, Africa, and parts of Asia.[12] In Oceania, its distribution is in Australia,[13] New Guinea,[13] Samoa and Guam,[14] and the Marshall Islands.[15] In Hawaii, Joyce[16] first reported it in 1950. Later, Hardy[17] listed it in the *Catalog of Hawaiian Diptera,* and Wilton[18] reported its predilection for dog excrement. The importance of the bush fly increased in the 1960s, when it was incriminated as a potential vector of beta-hemolytic streptococci in an epidemic of acute glomerulonephritis.[8]

On the islands of Kwajalein Atoll, a substantial portion of the main density of *M. sorbens* emanated from dog, pig, and human feces. Inspections of pig droppings in the bush of 10 widely separated islets revealed high numbers of larvae (over 100 per dropping), making this dung, as in Guam,[15] a primary breeding source in the atoll. Pigs that are corralled on soil or concrete slabs concentrate and trample their droppings, making them less suitable breeding sites. In such situations, flies were able to complete their development only along the periphery of corrals. Coconut husks placed under pigs in corrals results in the production of greater numbers of flies by reducing the effectiveness of trampling. Kitchen and other organic wastes were not found to breed *M. sorbens,* although a very low percentage of the adult population could originate there judging from reports elsewhere. Nevertheless, this medium is certainly not responsible for producing a significant percentage of the adult densities observed in the Atoll.

Management Efforts Worldwide

Successful partial reduction of the bush fly population had been achieved only in Hawaii, through a combination of the elimination of breeding sites, principally dog droppings, and the activities of parasitic and predatory insects introduced earlier to combat other fly species, e.g., *M. domestica.*[19] The density of the bush fly population varies in different climatic zones in Hawaii, but the importance of this fly is minimal compared with Kwajalein. At times, hymenopterous parasites have been found to parasitize over 95% of flies sampled in the Waikiki area (H.S. Yu, unpublished data). Other parts of Oceania (e.g., Australia) either were not suitable for maximum effectiveness of known parasitic species or had principle breeding habitats that were not attractive to the natural enemies. Therefore, in Australia, a concerted effort has been made to secure scavenger and predatory insects from southern Africa that are effective in managing fly populations on range cattle and sheep dung, the principal fly-producing source.[20]

Kwajalein Atoll

Integrated fly management had reached a level of partial success by 1974. Initial surveys for natural enemies of *M. sorbens* revealed the presence of four scavenger and predatory insects: the histerid *Carcinops troglodytes* Erichson, the nitidulid *Carpophilus pilosellus* Motschulsky, the tenebrionid *Alphitobius diaperinus* (Panzer), and the dermapteran *Labidura riparia* (Pallas). Dog numbers were significantly reduced, and all privies were reconstructed or improved on one island, Ebeye. Dogs were reduced or tethered on Kwajalein Island and refuse fish, etc., disposed of thoroughly on Illeginni and other islands with American residents. Importations of natural enemies were made throughout the atoll, and the average population density of *M. sorbens* on Ebeye was subsequently reduced from an estimated 8.5 flies attracted to the face per minute to less than 0.5 fly per minute, which was readily appreciated by the inhabitants. The single most important cause appeared to be the partial elimination of breeding sources, with natural enemies playing a secondary role.

For the further reduction of bush fly numbers, the integration of a nondestructive insecticidal reduction measure was desirable. Sugar bait mixtures that have been used for houseflies in years prior to 1972 were wholly ineffective for killing adult *M. sorbens* due to their almost complete lack of attractiveness. However, a variety of decomposing foodstuffs including rotting eggs and rotting fish sauces were very highly attractive. Experiments using a 6-day-old mixture of one part fresh whole eggs to one part water[21] attracted over 50,000 bush flies that were then killed by a 0.5 ppm Dichlorvos additive. The poisoned mixture was poured in quantities of 100 mL each in flat plastic trays with damp sand at 20 sites in the shade and spaced every 10 m along a public beach on Kwajalein. Baits placed above the height of 1 m or against walls in open pavilions were only weakly attractive. After 48 hours, flies were reduced to inconspicuous levels all over Kwajalein Island. This condition endured for at least 3 days, after which newly emerging and immigrating flies managed to slowly increase to annoying levels as the baits ceased to be attractive. However, the former density of flies was never reached even one week after the baiting; these populations were subsequently reduced to even lower levels by applying additional fresh poisoned baits.

Baiting was extended to other islands in the atoll with the result of sustained reductions of bush fly numbers to below general annoyance levels (less than 0.01 attracted per minute on Kwajalein, Roi-Namur, Illeginni, and Meck Islands). A new attractant that augmented the rotting egg mixture consisted of beach sand soaked for one week in the decomposing body fluids of buried sharks. This new attractant was far superior to rotting eggs in both rate and time of attraction, the latter sometimes exceeding 5 days. The baiting method could be used effectively if applied initially twice a week, and only biweekly applications were necessary in the following months.

After January 2000, in the absence of specialist supervision, the baiting procedure in the atoll has not continued with the sophistication initially determined necessary. In the absence of supervision, the number of flies was not adequately reduced. Periodic personnel changes precluded the passing on of accurate information critical to managing the fly densities. Of vital importance is habitat reduction, the proper preparation of baits, and the latter's placement in shaded wind-calm areas of the islands. Because such sites are generally out of sight of the public, baiting has instead shifted to populated areas, where only very conspicuous but non-pestiferous species of flies are attracted to the baits in large numbers. Sometimes, even ammonia baits were substituted that attract harmless blow fly species but not the targeted bush fly.

Aquatic Weed Management by Fish in Irrigation Systems

Imported fish species have been used for clearing aquatic vegetation from waterways, which has also reduced mosquito and chironomid midge abundance. In the irrigation systems, storm drainage channels, and recreational lakes of southern California, the California Department of Fish and Game authorized the introduction of three species of African cichlids: *Tilapia zillii* (Gervais), *Oreochromis (Sarotherodon) mossambica* (Peters), and *Oreochromis (Sarotherodon) hornorum* (Trewazas). These became established over some 2000 ha of waterways.[22] Their establishment reduced the biomass of emergent aquatic vegetation that was slowing down the distribution of irrigation water but that also provided a habitat for such encephalitis vectors as the mosquito *Culex tarsalis* Coquillet. Previous aquatic weed reduction practices had required an expensive physical removal of vegetation and/or the frequent application of herbicides.

One species, *T. zillii* can reduce mosquito populations by a combination of direct predation and the consumption of aquatic plants by these omnivorous fishes.[23–25] As Legner and Sjogren[22] indicated, this is a unique example of persistent biological suppression and probably applicable only for relatively stable irrigation systems where a permanent water supply is assured and where water temperatures are warm enough in winter to sustain the fish.[26] A threefold advantage in the use of these fish is as follows: 1) clearing of vegetation to keep waterways open; 2) mosquito abatement; and 3) a fish large enough to be used for human consumption. However, optimum management of these cichlids for aquatic weed reduction often is not understood by irrigation district personnel,[27–28,19] with the result that competitive displacement by inferior cichlids minimizes or eliminates *T. zillii*, the most efficient weed-eating species.[29]

The three imported fish species varied in their influence in different parts of the irrigation system. Each fish species possessed certain attributes for combating the respective target pests.[30,31] *T. zillii* was best able to perform as both a habitat reducer and an insect predator. It also had a slightly greater tolerance to low water temperatures, which guaranteed the survival of large populations through the winter months; at the same time, it did not pose a threat to salmon and other game fisheries in the colder waters of central California. It was the superior game species and most desirable as human food. Nevertheless, the agencies supporting the research (mosquito abatement and county irrigation districts) acquired and distributed all three species simultaneously throughout hundreds of kilometers of the irrigation system, storm drainage channels, and recreational lakes. The outcome was the permanent and semipermanent establishment of the two less desirable species, *S. mossambica* and *S. hornorum,* over a broader portion of the distribution range. This was achieved by the competitively advantaged *Sarotherodon* species that mouth-brood their fry, while *T. zillii* did not have this attribute strongly developed. It serves as an example of competitive exclusion such as conjectured by Ehler.[32] In the clear waters of some lakes in coastal and southwestern California, the intense predatory behavior of *S. mossambica* males on the fry of *T. zillii* could be easily observed, even though adults of the latter species gave a strong effort to fend off these attacks.

This outcome was not too serious for chironomid reduction in storm drainage channels because the *Sarotherodon* species are quite capable of permanently suppressing chironomid densities to below annoyance levels.[23,26] However, for the management of aquatic weeds, namely, *Potamogeton pectinatus* L., *Myriophyllum spicatum* var. *exalbescens* (Fernald) Jepson, *Hydrilla verticillata* Royle, and *Typha* species, they showed little capability.[31] Thus, competition excluded *T. zillii* from expressing its maximum potential in the irrigation channels of the lower Sonoran Desert and in the recreational lakes of southwestern California. Furthermore, as the *Sarotherodon* species were of a more tropical nature, their populations were reduced in the colder waters of the irrigation canals and recreational lakes. Although *T. zillii* populations could have been restocked, attention was later focused on a potentially more environmentally destructive species, the white amur, *Ctenopharyngodon idella* (Valenciennes), and other carps. The competitively advantaged *Sarotherodon* species are permanently established over a broad geographic area, which encumbers the reestablishment of *T. zillii* in storm drainage channels of southwestern California.

Management of Filth Fly Abundance in Dairies and Poultry Houses

The most important of muscoid fly species are broadly defined as those most closely associated with human activities. Breeding habitats vary from the organic wastes of urban and rural settlements to those provided by various agricultural practices, particularly ones related to the management and care of domestic animals. Their degree of relationship to humans varies considerably with the ecology and behavior of the fly species involved. Some are more often found inside dwellings.

Research to reduce fly abundance has centered on the highly destructive parasitic and predatory species, such as the encyrtid *Tachinaephagus zealandicus* Ashmead, five species of the pteromalid genus *Muscidifurax,* and *Spalangia* species that destroy dipterous larvae and pupae in various breeding sources. The natural enemies are capable of successful fly suppression if the correct species and strains are applied in the right locality.[24,33–36] Other approaches have included the use of pathogens and predatory mites and inundative releases of parasites and predators.[37,38] Although partially successful, none of these strategies has become the sole method for fly abatement, and the choice of a ineffective parasite strain may have detrimental results.[19] Instead, the focus is on integrated management including habitat reduction, adult baiting, and aerosol treatments with short residual insecticides. Also, it is generally agreed that existing predatory complexes exert great influences on fly densities[39] and that many natural enemies of these flies have a potential to significantly reduce their abundance if managed properly.[29,40] Because climatic and locality differences dictate which abatement strategies are effective, simple instructions to the public are impossible, and the involvement of skilled personnel is required. Of primary importance for successful management is the provision of relatively stable breeding habitats and their natural enemy complexes. Periodic cleaning operations should stress the partial removal of breeding sites and the deposition of such waste into large stacks, which favors the generation of destructive heat while minimizing the area and attractiveness for fly oviposition. Nevertheless, this management procedure is difficult for abatement personnel to grasp in the absence of competent supervision.

Pest Management: Ecological Agriculture

Barbara Dinham

Introduction

Strategies to develop ecological farming methods stem from economic, health, environmental, and practical concerns with chemical pesticides. Ecological agriculture, also called sustainable agriculture,[1] agroecology, low-external input, regenerative agriculture,[2] and farmer-participatory integrated pest management (IPM), has no single definition.[3] The Food and Agriculture Organisation (FAO) of the United Nations suggests that such sustainable development (in the agriculture, forestry, and fisheries sectors) conserves land, water, plant, and animal genetic resources, is environmentally nondegrading, technically appropriate, economically viable, and socially acceptable.[4]

Ecological agriculture implies approaches to prevent or minimize application of chemical pesticides, which promote local inputs, and where increased farmer knowledge becomes the basis of managing pests and improving yields and sustainability.[5] Organic agriculture is distinctive in requiring an approved body to certify that no chemical fertilizers or pesticides have been used. This provides a guarantee for consumers, and can enable farmers to receive a premium for their crops.

Pest Management Strategies

Ecological pest management practices have been adopted in both industrialized and developing countries. Most farming systems still use certain aspects: crop rotation, field clearance to destroy pest refuges, resistant varieties, early or late planting regimes. More specific ecological strategies employed by farmers vary widely, according to the cropping system, whether the farmer is in an industrialized or a developing country, and the locally available inputs.

As interest in ecological pest management grows, it is increasing the demand for biological technologies. The biological control agent in most widespread use, *Bacillus thuringiensis* (Bt) can be easily produced in large quantities, and can be used like a chemical. As a result it is applied in both conventional and organic agriculture in many countries. Bt has proved extremely effective in controlling persistent pests such as the diamondback moth, which plagues cabbages and related crops, and has led to a pesticide treadmill in many areas.[6]

Biological pest controls require the development of breeding centers for insect predators and parasitoids. Cuba has the most advanced program globally with a countrywide network of over 300 centers for the reproduction of entomopathogens and entomophages supplying bacteria, fungi, viruses, and insect parasitoids. These include *Lixophaga diatraege* for cane stem borer, the parasitic wasp *Trichogramma*, and the fungal disease *Beauvaria bassiana* against a total of seven pests.[7]

Particularly in developing countries, many indigenous plants and locally adapted technologies are used against a variety of pests. Most widely known is the neem tree (*Azardirachta indica*), native to India and also found in parts of Africa, whose leaves are effective against many pests. Other common solutions are pyrethrum, chili peppers, wood ash, and castor oil seeds.[8,9]

Spreading Ecological Practices

Ecological strategies for pest management are characterized by a holistic approach and not only the substitution of biological controls for chemical pesticides. Management strategies include soil conservation, seed selection, and maintenance of agricultural biodiversity. Participation of the women and men farmers to ensure cultural and local appropriateness is of central importance in the development of new strategies. Farmer field schools (FFS) have proved a successful training approach, where training takes place at field level, focusing on recognition of pests and predators and their life cycles. Designing in-field experiments, examining economic losses from pest damage, and encouraging observation of local plants that may act as a trap crop for pests or have repellent properties, become part of the armory.[10]

Ecological Diversity for Diverse Cropping Systems

Fragile tropical soils may benefit most from ecological strategies, but these farming approaches are not restricted by crop, climate, or continent. Table 1 indicates a range of cropping systems and countries that have benefited from IPM programs. One of the most successful examples is in European glasshouses where 70% of commercial glasshouses have been managed through IPM based on biological controls for more than 15 years. In these intensive production systems, IPM enables growers to control all major pests and avoid most pesticide use.

Cotton is the crop that uses the most chemical insecticides worldwide. Nevertheless, cotton IPM and organic strategies have demonstrated that ecological alternatives are successful. An FFS trainer- and farmer-training program in Pakistan prevented insecticide applications in the first 8–10 weeks after planting, allowing natural enemy populations to build up, and giving higher yields in seven of the 10 demonstration plots.[11] Similar successes have been achieved in India, Zimbabwe, and elsewhere.

Adverse environmental impacts of pesticide use in conventional cotton systems and the problems of insect resistance to pesticides have encouraged farmers to invest in organic systems. While still a small proportion of overall cotton production, the growing consumer support for ecological fiber is likely to further encourage producers. The United States is the largest single producer with 32% of the total certified organic cotton fiber production in 1997, followed by Turkey with 22%. Organic cotton production is well suited to small-scale cropping systems and in the same year 15% of certified organic cotton fiber came from India, 19% from Africa, and 11% from Latin America (mainly Peru).[12]

In Indonesia IPM strategies based on improving farmers' knowledge of ecological pest management were highly successful against infestations of brown rice-hopper that decimated the rice crop in the mid-1980s. An IPM rice program supported by the FAO in South and South East Asia that began in 1980 has targeted farmers using high chemical inputs. More than 500,000 farmers have been trained and now save on average $10 per hectare per season, while maintaining or increasing yields.[13]

Farmers develop their own strategic improvements. In an area of low rainfall and high soil erosion in Burkina Faso, local groups and villagers worked with the government and local organizations to develop an ecological approach ranging from tree planting to increased use of manure. Covering more than 200 villages, farmers increased sorghum yields from 870 kg/ha to 1650–2000 kg/ha. In the semi-arid

TABLE 1 Impact of Selected IPM Programs on Pesticide Use, Crop Yields, and Annual Savings

Country and Crop	Average Change in Pesticide Use (as % of Conventional Treatments)	Changes in Yields (as % of Conventional Treatments)	Annual Savings of Program $1000
Togo, cotton	50	90–108	11–13
Burkina Faso, rice	50	103	No data
Thailand, rice	50	No data	5–10,000
Philippines, rice	62	110	5–10,000
Indonesia, rice	34–42	105	50–100,000
Nicaragua, maize	25	93[a]	No data
United States, nine commodities	No. of applications up, volumes applied down	110–130	578,000
Bangladesh, rice	0–25	113–124	No data
India, groundnuts	0	100	34
China, rice	46–80	110	400
Vietnam, rice	57	107	54
India, rice	33	108	790
Sri Lanka, rice	26	135	1,000

[a] Lower yields, but higher net returns.

Source: Pretty.[2]

Machakos region of Kenya farmers developed appropriate agricultural techniques, building terracing, selective animal grazing, and manure collection, significantly increasing soil fertility and yields.[14]

The major physical constraints to adoption of ecological pest management relate to agricultural production systems rather than crops, regions, and climate. Large-scale monoculture, for example, does not easily lend itself to ecological approaches because of dependence on single varieties, loss of natural soil fertility, and emergence of specialized pests that kill natural enemies. The most sustained improvements can be found when government policies support ecological practices.

Environmental and Economic Benefits

Because of the many starting points, farmers have different motivations for adopting ecological approaches. In industrialized countries, where farmers generally rely heavily on external inputs, ecological practices may lower yields, but improve the environment.

In developing countries, some 2.3–2.6 billion people are supported by agriculture using the higher inputs of green revolution technologies and in these areas farmers would generally stabilize or achieve slightly higher yields with ecological pest management, also gaining environmental benefits. The remaining 1.9–2.2 billion people are largely fed by traditional agriculture and farmers. Here, ecological management strategies can substantially improve yields and income.[15]

The environmental benefits of ecological agriculture stem from reductions in chemical inputs, which threaten biodiversity, pollute water sources, and kill fish and other nontarget beneficials, often including cattle or domestic animals. Some entomologists believe that a significant proportion of the most serious insect pest problems have been introduced or worsened as pesticide use eliminates local natural enemies.

Economically, dependence on pesticides and poor management strategies can have devastating impacts, and the health and environmental costs of pesticide use are rarely calculated. In India cotton production accounts for more than 50% of pesticides used and poor application practices have resulted in insect pest resistance to chemicals. Farmers lacked the know-how to develop alternatives, and became deeply indebted to money lenders and pesticide dealers. The FAO has estimated that IPM could reduce pesticide use in Asian rice crops by 50% or more, without compromising yields, and maintain or improve net returns to the farmer—savings could amount to $1 billion.[16]

In areas of fragile and problem soil, intensive agriculture can lead to desertification, while resource-conserving systems in arid and semi-arid regions can deliver sustainable and often increasing yields. Farmers in these regions can rarely afford the external inputs and small improvements in yield would have profound impacts on the lives of the largely poorer populations that these agricultural systems support.

Risks in Adopting Ecological Strategies

The risks involved in adopting ecological pest management strategies are lower for small-scale farmers who are not yet using chemical inputs, and for farmers on a pesticide treadmill caused by high dependence and pest resistance to chemical inputs. In these instances the main risks are from short-term projects imposed without involvement of women and men in the farming communities who may swap one kind of dependency for another—the goodwill of donors. Farmers need knowledge to transfer to more ecological pest management strategies, and even successful IPM training can be limited by lack of funds for follow up.

Farming systems in industrialized countries that are effectively managing pesticide usage are likely to lose yields when adopting ecological strategies, particularly during the transitional stage. These farmers are also likely to face higher labor costs, though offset to some extent by lower input costs. The benefits are longer term and less tangible: improvements to the environment and to health, and in maintaining yields over time. For farmers who adopt organic practices and seek certification, the initial lower yields can be offset by a premium for their crops.

Pest Management: Ecological Aspects

David J. Horn

Introduction

Every animal and plant population is surrounded by an interactive biotic and physical environment, and these enormously complex interactions often stabilize population densities to reduce the probability of a pest outbreak. However, ecological interactions are often disrupted, simplified, or overridden in managed ecosystems, reducing the impact of naturally-occurring pest population regulation and leading to outbreaks. Understanding how ecological interactions may either cause or prevent pest outbreaks can lead to crop and landscape management activities that achieve relative stability of pest populations below damaging levels without resorting to widespread and environmentally disruptive intervention. Increasing environmental complexity can enhance pest management. Intelligent environmental management with due regard for the place of a pest within a complex and interconnected ecosystem reduces pest outbreaks when attention is given to 1) increasing species diversity within cropping or landscaped ecosystems, 2) crop rotations and use of short-term, rapidly-maturing cultivars, 3) reducing field size and encouraging intervening areas of uncultivated and undisrupted vegetation, 4) reduced tillage and tolerance of weedy backgrounds, and 5) increased genetic diversity within the crop.

Pest Population Dynamics and Species Diversity

Apparently simple ecosystems such as annual agricultural crop monocultures are complex, and the relative impact of alternate crops, weeds, natural enemies, competitors, and associated organisms on pests may be highly variable. Pest populations and their effective environments are constantly changing in space and time, and events impacting one population at one location and time interval usually do not duplicate events in the same population at another time and place. Despite ecosystem complexity, seasonal agricultural crops that are periodically disrupted due to harvesting and tilling may never achieve a steady, sustained state typical of later stages in ecological succession. Annual or more frequent disruption selects for pests that can locate and exploit resources quickly and efficiently. Colonizing species of plants and insects display rapid dispersal and an ability to increase numbers quickly when suitable habitat is located. The ancestors of many crop plants are typical of early stages of ecological succession, as are their associated insect pests. Conventional agriculture invites early- successional species that are likely to undergo uncontrolled population outbreaks. Populations of such pests are rarely in equilibrium at any given place and time, but are maintained by a loose balance of colonization and extinction over a large geographical area. Equilibrium is more likely to be reached in populations occupying longer-lasting ecosystems such as orchards and forests. Population fluctuations in these more complex ecosystems are partly buffered by the complex interactions within food webs, so there is less likelihood of outbreak of any particular pest species.

Species diversity is formally measured as an index combining numbers and proportion of each species present in an ecosystem. A species diversity index reflects the number of links in a food web, and the overall stability of any ecosystem is partly a function of the number of interactions among plant, pests, natural enemies, and pathogens. Ecologists and pest managers debate over whether there exists a direct relationship between species diversity and stability of individual populations within an ecosystem. It is often presumed that pest outbreaks are suppressed in more complex (and therefore more diverse) ecosystems. The so-called "diversity–stability hypothesis" holds that ecological communities with a higher species diversity are more stable because outbreaks of pest species are ameliorated by the checks and balances and alternative pathways that exist within a large and integrated food web. Evidence supporting this view comes from experiments that mix several plant species with the primary host of a specialist herbivore, resulting in reduced populations of the specialist herbivore. This observation is termed the *resource concentration hypothesis,* which holds that insect herbivores are more likely to locate and to remain on hosts growing in dense or pure stands, and the most specialized species frequently attain highest densities in ecosystems with low plant species diversity. Biomass becomes concentrated in a few species, with a concomitant decrease in species diversity of herbivores in monocultures. Increases in herbivore populations in crop monocultures generally result from higher rates of colonization and reproduction along with reductions in dispersal, predation, and parasitism. As species diversity increases in agroecosystems, more internal links result within food webs and these links promote greater stability, resulting in fewer pest outbreaks. Structural diversity is an important physical component of overall diversity; for instance, cropping systems with taller plants (such as corn among beans and squash) present more physical space to arthropods and this increases the variety of prey and provides greater shelter for predators.

Monoculture and Polyculture

Monoculture is the planting of a single species of crop plant, which often results in increased populations of specialist herbivores, a result consistent with the resource concentration hypothesis. Polyculture, the planting of more than one crop species in the same local area (often the same field), may reduce impact of herbivorous pests because the presence of a variety of plants disrupts orientation of specialist herbivores to their hosts. For example, cabbage flea beetles and cabbage aphids that locate their hosts via specific chemical cues (such as the alkaloid sinigrin) are less effective in locating their host plants when these are intermingled with a variety of other plant species. The result is lower populations of the flea beetles and aphids. Local movement of cucumber beetles and lady beetles is enhanced when cucumbers are interplanted with corn and beans as compared with these insects' movement in monocultures, where they tend to remain on individual plants. Numbers of specialist herbivores (cabbage aphids, diamondback moth, and imported cabbageworm) on collards planted in weedy backgrounds are lower than populations of these same herbivores on collards planted against bare soil or plastic mulch. This influence of weeds intensifies once the weeds become as tall as the collards, effectively allowing the collards to escape herbivory by concealment among the weeds. The frequent replacement of one crop by another in crop rotation maintains populations of specialist herbivores below damaging levels. Field crop producers in the midwestern U.S. can prevent the increase of corn rootworm populations by rotating from corn to soybeans every 2 or 3 years.

Open and Closed Ecosystems

Ecosystems may be considered to be *open* (subsidized) or *closed* depending on the amount of nutrient and energy exchange with ecosystems outside themselves. Open ecosystems are characterized by regular input of energy and nutrients, followed by removal of a large proportion of nutrients. In maize fields in the midwestern U.S. heavy importation of mineral fertilizer occurs at planting and subsequent energy is input when the crop is tilled and pesticides are applied. Most of the nutrients in a maize field are removed at harvest, as yield or crop residue. In landscaping towns and suburbs we fertilize (providing input) and rake leaves and remove mowed grass (exporting nutrients) to maintain a pleasing appearance.

The assemblage of species within a maize field is artificial, with novel interspecific associations. Many of the major insect pests are of exotic origin, and the association with maize is relatively recent. For instance, the European corn borer arrived in North America around 1910, before which maize (native to Mesoamerica) had no ecological association with the corn borer. It may take many years for native natural enemies to expand their host or prey range to include exotic organisms. Most anthropogenic agroecosystems and landscaped ecosystems are artificial assemblages and open ecosystems. The species assemblage in planned landscapes often includes a preponderance of exotic species.

In a closed ecosystem, such as a deciduous forest, most nutrient movement remains localized with little import and export. For example, the nutrients and energy in the forest canopy fall to the ground as leaves and frass, or leaves are converted into caterpillars, which in turn are eaten by insectivorous birds, predatory insects, and parasitic wasps. There is little "leakage" of nutrients from closed ecosystems into surrounding environments. The species assemblages of many closed ecosystems have been associated for millennia, resulting in multiple trophic links and close ecological associations among mostly native species. Such ecosystems are relatively "immune" to invasion by exotic species (although there are exceptions, such as the successful invasion of the gypsy moth into the forests of eastern North America).

Examples

The Mexican bean beetle overwinters in hedgerows and along field edges, so that soybean fields nearest overwintering sites are likely to become infested earlier and bean beetle populations subsequently will be higher. Soybeans located near bush and pole beans (which are more suitable hosts for the bean beetle) are also likely to develop economically damaging infestations earlier. Natural enemies often move from unmanaged field edges and nearby hedgerows and forests into adjacent farm fields and the nature of this movement may be very important to local suppression of pests. Many studies have shown that there are increased numbers and activity of natural enemies near field borders when there is sufficient natural habitat to provide cover and alternate prey and hosts, as well as food in the form of nectar and pollen. This function of wild border areas significantly enhances biological control.

Weedy vegetation in or near crop fields support a diverse fauna, including natural enemies of pests on the crop plants. This depends on the species of weeds present; for instance, if the weeds were particularly attractive to aphids and their natural enemies, this enhances aphid control on a commercial crop. Weeds such as pigweed *(Amaranthus),* lambs quarters *(Chenopodium),* and shepherd's purse (*Capsella*) when heavily infested with aphids serve as "nurseries" for production of aphid predators and parasitoids, which move onto neighboring crop plants when these are located near these weeds.

Growing several crops in the same space reduces pest problems relative to monocultures of the same species. When blackberries are planted among grapevines in central California, the parasitoid *Anagrus epos* attacks the eggs of both grape leafhopper and the leafhopper *Dikrella cruentata* on blackberry. By encouraging blackberries between alternate grape arbors, a constant supply of eggs of both leafhoppers are available to the parasitoid, which persists in populations high enough to bring the grape leafhopper under biological control.

Floral undergrowth in orchards provides resources to adult parasitic wasps and flies and increases parasitism of phytophagous insects (particularly Lepidoptera) on the trees. The presence of nectar and pollen along with alternate prey is particularly favorable to populations of generalist predators such as the lady beetle *Coleomegilla maculata* resulting in lower aphid populations. In relay cropping, two (or more) different crops are grown on the same area in successive seasons. The seasonal change from one crop to another prevents the increase of specialist pests especially if the crops are evolutionarily distantly related (such as legumes and grasses). When soybeans are relay cropped after winter wheat, pests of soybeans are less abundant than when soybeans are cropped alone.

Planting and harvesting corn and beans in alternating plots rather than solid monocultures reduces pest numbers on both crops, and this management approach is widely practiced in traditional agriculture. Where alfalfa can be grown throughout the year it is possible to harvest on a 3–4 week rotation when half the field is cut in strips. Natural enemies of the alfalfa weevil, alfalfa caterpillar, and aphids are conserved in the regrowth, and there are alternative food sources and hiding places for these predators and parasitoids all year, so they are always present to suppress pest populations below damaging levels. By planting alfalfa adjacent to cotton, control of *Lygus* bugs is achieved by allowing increase of natural enemies of *Lygus* in the alfalfa. These natural enemies move into the cotton and control *Lygus* bugs there.

Pest Management: Legal Aspects

Michael T. Olexa
and Zachary
T. Broome

Introduction

To promote public health, personal safety, and environmental protection, pesticides and their use are extensively regulated. Pesticide regulation is primarily decided at the federal level and enforced by the Environmental Protection Agency (EPA). Although the states generally copy the federal laws, some state laws are more restrictive than federal laws. Both federal and state laws provide for criminal prosecution and can impose penalties such as fines or imprisonment. In addition, common law actions are used to regulate pesticide use. Common law actions are civil claims brought by private citizens based on an allegation of improper pesticide production or use. When a pesticide manufacturer or user causes personal injury or property damage, the victim initiates a civil action to recover financial compensation for the harm.

This entry will detail the federal regulatory framework of pesticides, including product registration and methods of enforcement. This entry will also address the conflicts between pesticide regulation and other federal environmental law, and the current preemption guideline for conflicts between federal and state regulations. Finally, this entry will address various common law remedies available as private forms of pesticide regulation, to ensure pesticide users and manufacturers act reasonably and limit potential harm to humans and the environment.

Statutory Law and Regulation

Statutory laws are the formal acts of federal and state legislatures. Although statutory laws often provide general directions, technical details are assigned to a regulatory agency. The agency rules specify how the statute passed by Congress will be implemented and enforced by the agency. These rules have the force of law. Regulatory agencies implement their rules by requiring permits or licenses, and enforce those rules through civil and criminal penalties.[1]

Federal Law

Overview

Pesticides were first subject to federal laws by the Insecticide Act of 1910.[2] This law protected farmers from sellers of adulterated or misbranded pesticide products. Following a surge in the development of new pesticides during the Second World War, Congress repealed the Insecticide Act of 1910 and enacted the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) of 1947.[3] FIFRA broadened federal control of pesticides by requiring the United States Department of Agriculture (USDA) to register any pesticide before its introduction into interstate commerce. In 1970, Congress transferred the administration of FIFRA to the newly created EPA. Thereafter, Congress enacted the 1972 Federal Environmental Pesticide Control Act (FEPCA) to address public concerns about pesticides' environmental impact and to ensure greater pesticide use regulation.[4] As a result, federal policy shifted from regulation of pesticides for reasonably safe use in agriculture to regulation of pesticides to prevent unreasonable risks to people and the environment. Subsequent amendments to FIFRA (1988, etc.), have clarified the EPA's duties and responsibilities.[5]

The Federal Food, Drug, and Cosmetic Act (FDCA), and 1954 Miller Amendments, required the government to establish tolerances (maximum allowable pesticide residue limits) for all pesticides used on food and feed crops.[6] The 1996 Food Quality Protection Act (FQPA) amended the FDCA and FIFRA, especially the process of establishing tolerances for pesticide residues in food and feed.[7] For example, the EPA now uses a single standard to evaluate pesticide residues on raw and processed foods. FQPA represents the single largest shift in federal pesticide policy and process ever undertaken. The FQPA established a new safety standard to be met when establishing tolerances for a reasonable certainty of no harm from aggregate exposure. It also required all existing tolerances to be reassessed under the new standard and required the EPA to make an explicit determination that tolerances for residues in food are safe for infants and children.[7]

The heart of the regulatory scheme for pesticide application, storage, and disposal is the FIFRA provision making it unlawful to "… use any registered pesticide in a manner inconsistent with its labeling."[8] Thus, courts consider pesticide label instructions legislative regulations having the force of law. For pesticide users, labeling is the primary basis for enforcement of FIFRA. Hence, every person using a pesticide has a legal obligation to read and follow all label instructions attached to the product and all product usage directions contained in any printed materials mentioned on the label.

Pesticide Product Registration

The EPA retains primary oversight for providing guidance to major pesticide producers for what data are needed before the product is federally registered. Some states also conduct a review of scientific data before registering a pesticide in their state. State agencies generally identify product registration violations during their inspections and refer them to EPA for enforcement.[5] However, states also have the ability to regulate pesticide use with state-level registration, although the registration only applies within the regulating state.[9]

The federal government controls which pesticides are put on the market by requiring pesticide registration under FIFRA.[10] Unless exempt, all pesticides must be registered with the EPA administrator before being distributed or sold.[11] A pesticide will not be registered by EPA unless the agency's review of the registration data shows the pesticide will perform its intended function without "unreasonable adverse effects on the environment."[12] Pesticides are registered for general use or restricted use, depending upon the potential for adverse side effects.[13] If EPA determines that a pesticide generally will not have adverse effects on the environment or injure the applicator, then the pesticide is safe for general use.[14] This means that the product can be purchased by an unlicensed applicator. If EPA determines that a pesticide requires additional care or specific training in use, then the pesticide is defined as a restricted use product (RUP).[15] RUPs are subject to additional regulations and limited to use by a certified and licensed applicator.[16] Although many pesticides predated 1947, and were therefore exempt from registration, FIFRA was amended to require the reregistration of all pesticides "containing any active ingredient contained in any pesticide first registered before November 1, 1984."[17]

Most states require the federally regulated products to be registered in each state as well. A state also may regulate the registration of EPA-registered pesticides for additional distribution or use within that state, so long as the registered state use does not violate FIFRA.[18] For instance, a state can make it illegal to use a product registered by EPA, or limit the use of a registered pesticide. Unless the EPA administrator has denied the state's registered use, state registration of pesticides is equivalent to federal registration, but only within that state. State registrations are subject to disapproval by the administrator, who may also suspend a state's registration authority if the state issues registrations that violate either FIFRA or FDCA.[19]

Not all pesticides are regulated by the EPA. If the EPA administrator determines that a pesticide does not require regulation, then the administrator, by regulation, may exempt that pesticide from the registration requirements.[20] The pesticides that do not require regulation are natural substances and minimum-risk pesticides, such as cedar or geraniol, as well as substances treated with pesticides, pheromones, and biological preservatives.[21]

Pesticide Use Enforcement

Although EPA does have enforcement power, in many cases EPA delegates enforcement of pesticide use violations to the states, under cooperative agreements. Each state's agencies are responsible for administering pesticide regulations under state and federal statutes. States occasionally refer pesticide use violation cases to the EPA for enforcement.[22]

Enforcement of pesticide regulations is based on a hierarchy of state and federal agencies, beginning with the EPA Office of Pesticide Programs (OPP). OPP is the EPA entity responsible for registering all pesticides and formulating the label requirements that restrict pesticide use.[23] EPA in Washington works through 10 regional field offices (Regions) of EPA, which serve as liaisons between the states and OPP. The Regions work with the states to develop cooperative agreements, examine cases, answer questions, and conduct joint inspections.

Although EPA is the ultimate arbiter of pesticide regulation, states have the primary responsibility to enforce those regulations.[24] Each state has a designated lead agency responsible for meeting the OPP goals. The lead agencies investigate all major pesticide use sites, such as agricultural and urban operations, to ensure that registered pesticides are used according to the labels approved by OPP. The lead agencies are also responsible for investigating sites of pesticide misuse and taking appropriate enforcement information.[24]

Some Native American tribes have pesticide lead agencies that function the same as state lead agencies, and those tribes work with their EPA regions to develop pesticide field programs. Although the tribal enforcement programs are created in the same manner and with the same goals as state programs, OPP and the regions must treat the process with a high degree of deference to a tribe's sovereign treaty rights.[25]

If a pesticide user or manufacturer violates any FIFRA regulation, EPA and the state can stop the sale or use of the pesticide, seize the pesticide, and seek civil and criminal penalties.[26] If a pesticide manufacturer or distributor violates FIFRA, EPA can seek a $5000 civil penalty for each offense, or a criminal penalty of a $50,000 fine or 1-year jail term.[27] If a pesticide user violates FIFRA, EPA can seek a $1000 civil penalty for each offense, or a criminal penalty of a $1000 fine or 30-day jail term.[27] The most drastic enforcement procedures, in regard to pesticide manufacturers, are the cancellation or modification of a pesticide registration. Once a pesticide is registered under FIFRA, the applicant is not guaranteed permanent registration or classification. If EPA determines that a registered pesticide, or its labeling, does not comply with FIFRA or causes unreasonable adverse effects on the environment, the administrator may cancel the pesticide's registration, change its classification, or alter the label.[28]

Enforcement of Tolerances for Pesticides in Food

One important consideration in regulating pesticide use is the level of pesticide residue left on agricultural products that can be consumed by humans. The Food and Drug Administration (FDA) monitors raw and processed commodities for compliance with residue tolerances. The USDA monitors meat, milk, and eggs for residue tolerance compliance. The FDA and USDA programs cover both domestically produced and imported commodities. A few states, such as California and Florida, have additional residue monitoring and enforcement programs, but all states have the authority to enforce federal regulations against food located within each state.[29] States cannot impose regulatory limits on pesticide residue, however, unless the residue limits are identical to the federal levels or the state successfully petitioned the federal government for authorization to change the regulation.[30]

Under the FDCA, introducing adulterated food into interstate commerce is prohibited.[31] A claim for violating the FDCA can be brought in an appropriate federal district court, where the court can punish the guilty party with injunctive relief, criminal prosecution, or seizure.[32] The key for pesticide regulation is whether food containing pesticide residue constitutes adulterated food. Normally, a food is adulterated if it contains any poisonous substance or chemical.[33] Pesticide chemical residues, however, are specifically exempted from blanket regulation.[34] If the EPA has established a tolerance level for a pesticide, or exempted a pesticide from regulation, then the food product is not considered adulterated.[35] The EPA administrator can only establish a pesticide tolerance if consumption of the residue poses little risk to the consumer.[36] The consumption is safe so long as "there is a reasonable certainty that no harm will result from aggregate exposure to the pesticide chemical residue."[36] Once the EPA has established the tolerance level for a pesticide residue, the FDA enforces compliance because noncompliance residue that exceeds established tolerances constitutes food adulteration.

The FDA not only monitors U.S. pesticide residue but also develops cooperative agreements with foreign countries that export agricultural products into the United States.[37] These agreements require imported food to meet the FDCA standards for pesticide tolerance.[37]

While the EPA determines if the amount of pesticide residue found in the food is of "negligible risk" or below tolerable levels, there is a danger from consuming certain pesticide residues that the EPA has deemed carcinogenic.[38] Consumption of pesticide residue is also dangerous because of the pesticides that act as endocrine- disrupting chemicals (EDCs).[39] Evidence has established a link "between EDCs and decreased sperm counts; breast, testicular, and prostate cancer; and neurological disorders."[39] In fact, many of the chemicals found in pesticide residue have been banned in the European Union because of the danger to humans.[40]

Pesticide Regulation Interaction with Other Federal Regulations

One problem for the EPA is registering pesticides that conflict with other federal environmental law the EPA is charged with enforcing, especially the Endangered Species Act (ESA) and the Clean Water Act (CWA).[41]

Under section nine of the ESA, all persons, including federal agencies, are prohibited from causing the "take" of any endangered species.[42] While pesticides may threaten endangered species, EPA did not have a formal process to evaluate the potential impact of pesticides on threatened and endangered species, but EPA had never been liable for registering the pesticides.[43] In 1989, however, the Eighth Circuit held the EPA liable for approving the registration of a pesticide that later harmed a protected species.[44] According to the Eighth Circuit, an action solely based on pesticide regulation ordinarily should be brought under FIFRA, but a claim based on pesticide harm to an endangered species could be brought under the ESA.[45] Because EPA did not dispute the distributed pesticide caused the death of an endangered species, killing an endangered species is a taking, and pesticide distribution cannot legally occur without an EPA registration, the Eighth Circuit held EPA liable for a taking.[46]

Similarly, section seven of the ESA requires all federal agencies to conserve endangered species, which usually requires a consultation with the Fish and Wildlife Service or National Marine Fishery Service to ensure agency actions will not "jeopardize the continued existence of any endangered species."[47] In 2004, the Ninth Circuit ruled EPA violated section seven of the ESA by failing to obtain a "jeopardy" consultation before registering pesticide uses around listed salmon habitat.[48] EPA argued that any cancellation or modification of a pesticide's use must conform to FIFRA, and FIFRA's standard for registration and cancellation already accounted for an effect on listed species.[49] According to the Ninth Circuit, however, FIFRA does not exempt EPA from the ESA regulations, since the two statutes have different purposes, and EPA must comply with the ESA if its registration of pesticides will affect listed species.[49] In addition, EPA has an ongoing duty to ensure all registered pesticides do not violate the ESA, because EPA always has the discretion to cancel a pesticide's registration.[49]

EPA also has to consider the impact that registered pesticides may have on waterways, to ensure the pesticides will not violate the CWA.[50] Under the CWA, any discharge of a pollutant into the nation's waters requires the discharging entity to obtain a National Pollutant Discharge Elimination System (NPDES) permit.[51] The pesticide manufacturer claimed that EPA did not include a requirement for a NPDES permit in the FIFRA registration process, and since water-related usage restrictions were placed on the pesticide as part of the FIFRA registration, the manufacturers did not need additional permit- ting.[52] According to the Ninth Circuit, however, the CWA and FIFRA have different and complementary purposes, so the statutes should be treated as distinct entities.[52] FIFRA's objective is to protect human health and prevent environmental harm from pesticides through cost–benefit analysis, while the CWA's objective is to restore and maintain waterways by limiting pollution discharge.[52] Therefore, the court ruled that pesticide users are not exempt from CWA permitting requirements because they obtain FIFRA registration.[52]

This dual responsibility creates a tension for EPA, which is responsible for establishing water quality standards that dictate the permit requirements for a CWA permit.[53] Until recently, EPA had a Final Rule that exempted all FIFRA-compliant pesticides from NPDES permitting when those pesticides were put into water, or ran off property into water, as part of the pesticide's intended use.[53] The Sixth Circuit rejected this analysis, citing the CWA requirement that no pollutant could be discharged into any navigable water unless EPA determined the discharge would not cause undue harm to water quality and issued the discharger a NPDES permit.[54] Although the court agreed FIFRA-compliant chemical pesticides did not require a NPDES permit if put into water to work as a pesticide, because the pesticide was not being discharged as a waste and EPA only approves pesticides that "will not generally cause unreasonably adverse effects on the environment," the court cautioned that any introduced pollutant discharged with excess chemicals or residue required a NPDES permit.[55] In addition, all biological pesticides, regardless of whether or not it is excess pesticide or residue, always require NPDES permits because the CWA requires a permit for all biological material, not just waste.[56] While the court rejected EPA's Final Rule exempting pesticides from NPDES permitting, the court noted EPA and state authorities may grant general permits that allow for the discharge of a specific pollutant or type of pollutant across an entire region.[57] Once EPA or a state agency issues such a general permit, pesticide dischargers do not have to meet any additional requirements to comply with the CWA.[57] This issue is currently being worked on between EPA and the states, as they try to implement a national and state plan.

Preemption

Because of the interaction between state and federal regulations, preemption is a fundamental concern for pesticide regulation. Under FIFRA, the states are allowed to regulate the sale and use of federal pesticides, but precluded from passing additional regulations on pesticide labels.[58] This preemption applied to both state regulations and common law tort claims that "directly or indirectly attacked the adequacy of the warnings on the EPA approved pesticide label."[59]

Background

When a manufacturer submits an application to register a new pesticide, the manufacturer must include a proposed label, and the EPA will only register the pesticide if the data support the registration and its label complies with the statute's misbranding prohibition. A pesticide is "misbranded" if its label contains a statement that is "false or misleading" or lacks adequate instructions or warnings.[60] Although preemption was originally restricted to state regulations, in 1992, the federal courts began applying preemption to common law tort claims.[61] Although the Supreme Court never ruled on FIFRA-specific preemption, after *Cipollone,* most state and federal courts would reject any common law claim that was premised on "failure to warn."[62] A common test for preemption, which led to *Bates v. Don Agrosciences, LLC,* was whether it was reasonably foreseeable that a tort claim against a pesticide manufacturer would "induce it [the manufacturer] to alter its product label."[63] If the litigation would give the manufacturer a "strong incentive" to change the pesticide label, then the claim was preempted.[63]

Current Law

In *Bates V. Don Agrosciences, LLC,* the U.S. Supreme Court held that FIFRA's express preemption clause did not preempt state common law claims merely because an adverse judgment on the claim might impel a manufacturer to change a product label.[64] According to the Court, "private remedies that enforce federal misbranding requirements would seem to aid, rather than hinder, the functioning of FIFRA" because the claims serve as catalysts for evaluating harm and pesticide performance.[65] Although the Court acknowledged the lack of uniformity in national FIFRA regulation, the Court maintained that Section 136v still prevents states from imposing labeling requirements different from FIFRA.[66]

Applying *Bates* to future pesticide litigation and regulation will be necessarily fact specific. In *Bates,* the Court parsed the plaintiffs' tort claims against the pesticide manufacturer into two categories, design defect and failure to warn.[67] The Court held that design defect claims, formerly preempted under the "inducement" test, were not preempted because a successful claim would incentivize a manufacturer to change its label or ingredients, but the claim placed no requirement on the labeling.[67] The plaintiffs' fraud and negligent failure-to-warn claims, however, were premised on common law rules that qualify as "requirements for labeling and packaging," but the Court established that Section 136v(b) only prohibits state law labeling and packaging requirements that are "in addition to or different from" the labeling and packaging requirements under FIFRA.[66] Therefore, any preemption analysis begins with the plaintiff's claim and "calls for an examination of the elements of the common law duty at issue."[68] After *Bates,* only tort claims that impose liability for a labeling requirement that is in addition to or different from EPA labeling requirements would be preempted.[59]

Common Law

Common law actions do not depend upon statutes for their authority. Instead, common law arises from the generalized legal duty individuals in a law-abiding society owe to one another. Every adult person is obligated to a certain duty of care for the personal and property rights of others. A violation of this obligation can become a basis for a common law action. Common law theories generally encountered in actions resulting from pesticide use include negligence, trespass, nuisance, and strict liability.[68]

Negligence

Negligence is a legal standard applied to an individual who fails to act in a reasonably prudent manner.[69] To establish a negligence claim, the plaintiff must prove that the defendant owed the plaintiff a duty, the defendant breached that duty, the breach was the direct and proximate cause of harm to the plaintiff, and plaintiff's harm actually resulted in compensable damages.[69] Negligence actions can be used as regulatory tools against both pesticide users and the pesticide producers, to ensure pesticides are used reasonably to prevent damage to human health and the environment.[70]

A pesticide user can be liable for negligence if the user fails to exercise a reasonable duty of care in applying a toxic pesticide, and others are injured as a direct result of the negligent behavior.[70] A pesticide manufacturer can be liable for negligence if the manufacturer's label is defective, or if the manufacturer's label constitutes a failure to warn, and a person is injured because of the improper label.[67] The common law duty for pesticide use or production generally stems from the industry-established standard of care. However, because pesticides are heavily regulated at the state and federal level, statutes or administrative regulations generally define the applicable standard of care in a jurisdiction. These regulations also create a cause of action based on negligence per se, so any violation of a law regulating the manufacture, label, or use of a pesticide that results in harm is negligence.[71] In making a negligence claim for pesticide use, res ipsa loquitur can be a successful argument in cases where a pesticide, used as intended, was the direct cause of an injury.[72] Res ipsa can be difficult to prove, however, since many factors other than negligence of a manufacturer or user could cause or contribute to such injuries.

In negligence cases based on pesticide use, breach of duty and causation often relate to the same action—the pesticide dispersal. Pesticide users have a duty to act carefully when applying pesticides, so as to avoid applying pesticide on unintended targets. If a pesticide user does not breach that duty, then it is unlikely the pesticide caused a plaintiff's injury. To prove causation, the plaintiff must prove exposure to the pesticide and have an expert testify that exposure to the chemicals in the pesticide caused plaintiff's injury.[73] Generally, an expert can establish causation by using clinical studies where a certain level of pesticide caused certain chemical reactions, such that plaintiff's alleged exposure to that pesticide would likely result in plaintiff's injury. Experts can also establish causation by diagnosing the plaintiff's symptoms, and then eliminating all alternatives except the pesticide exposure.[70]

In actions based on pesticide use, damages are usually related to personal injury or property damage. Personal injury damages result from exposure to the toxic chemicals in pesticides and usually relate to health problems with the lungs and respiratory systems, skin rashes, swelling, discoloration, and lesions, as well as nervous system disorders, such as numbness or headaches, confusion, and memory loss.[70] Agricultural pesticide users often sue when a product malfunctions, so property damages are usually for harm to currently growing crops, although in certain cases, damages can be sought for the loss of property utility, if the pesticide causes property to lose agricultural value.[70] The same injury and damage rules apply to livestock and other "farmed" animals.[70]

Trespass

Trespass is an unauthorized entry onto the property of another by a person or thing that causes damage.[74] Pesticide application can result in liability for trespass if the pesticide, its residue, or container becomes deposited on another's land (through dumping, drift, runoff, incineration, or other means) and causes substantial damage to the property. Although trespass normally requires intent for liability, if the pesticide reached a plaintiff's property because the pesticide user behaved negligently or used the pesticide in an abnormally dangerous manner, then there is no requirement to prove intent.[75] The invasion element of pesticide occurs by either airborne drift or migration through soil or water.[76]

Nuisance

A nuisance is substantial interference with another's use and enjoyment of land.[77] A nuisance lawsuit requires no physical invasion, only a substantial interference with the possessor's enjoyment of land. Pesticide use resulting in offensive odors can be grounds for a nuisance suit. In almost all states, state "right-to-farm" statutes provide limited protection from nuisance actions. The farmer's "right-to-farm" defense is limited to nuisance actions.[78] Nuisance claims can be brought as either private or public actions, although most pesticide-based claims are for private nuisance, because a plaintiff cannot collect damages for a public nuisance claim.[79]

A private nuisance is a nontrespassory invasion of another's interest in the private use and enjoyment of land.[80] Generally, property owners bring private nuisance claims because some property use is prevented by a neighboring property owner's use of pesticides.[81] A private nuisance claim is often used to enjoin a defendant from continuing a certain action, although damages are often sought as compensation for harm already done by the defendant. Because nuisance is a common tort, and has been regularly applied to instances of pesticide drift, most courts will not bar a provable claim for nuisance. In addition, when the plaintiff is unable to prove which pesticide user out of several caused his or her particular harm, courts often allow the plaintiff to proceed on joint liability, so the defendants share the damages burden. However, a nuisance claim requires an ongoing pattern of pesticide application, so a single pesticide use is not actionable under this particular theory.[81]

A nuisance suit against a farmer for the use of pesticides often violates state right-to-farm laws.[78] Right-to-farm laws protect farmland in a variety of ways, including reducing farmer exposure to liability for common law claims based on farming operations.[78] One protection is the coming to the nuisance defense, which prevents a plaintiff from moving near a farm then claiming harm from an ongoing farm activity.[81] The coming to the nuisance defense only protects the farmer from reasonable actions, however, so using pesticides in a negligent manner could result in liability. In addition, coming to the nuisance only protects farm activities that were ongoing before the plaintiff's arrival. If the farmer did not apply pesticides until after the plaintiff's arrival, then the farmer could be subject to nuisance liability.[81]

Strict Liability

Some states hold pesticide applicators absolutely responsible for their pesticide application activities, regardless of fault, without a showing of negligence. This is known as strict liability.[82] Strict liability is normally associated with inherently dangerous or ultrahazardous activities. Whether an activity is inherently dangerous, and therefore subject to strict liability, usually depends on the degree of risk, likelihood of serious harm, inability to eliminate risk, commonness of usage, appropriateness of activity to area, and its value to the community.[83] Most misuse of pesticide claims are brought under the theory of negligence, but a few states allow strict liability claims against the aerial spraying of pesticides.[81]

A common strict liability claim is for a manufacturing defect in the pesticide, where some contaminant in the pesticide caused damage during the pesticide use.[84] Because FIFRA registration requires a manufacturer to register the exact chemical makeup of a pesticide product, the presence of any other chemical in the pesticide is a statutory violation that exposes the manufacturer to strict liability.[85] To bring a strict liability claim against a pesticide manufacturer, a plaintiff must be able to prove that he or she suffered injuries as a result of the use of a pesticide, the defendant was engaged in the manufacture and sale of the harmful pesticide products, the plaintiff purchased the particular pesticide that caused the alleged injuries, the pesticide had not been contaminated after leaving the manufacturer, and the pesticide was unreasonably dangerous to any user.[86]

Regulatory Trends

For the foreseeable future, current and emerging societal issues will continue to stimulate regulatory action. EPA's regulatory focus is found in the National Pesticide Field Program, which establishes EPA's guideline for action to meet the statutory requirements to protect human health and the environment. Currently, EPA regulations focus on worker safety, water quality, and endangered species protection, and promoting pesticide stewardship.[87]

EPA regulation of worker safety is done to minimize occupational risks from pesticides, as outlined in the Worker Protection Standard. The potential danger of pesticide exposure is especially prevalent in agricultural operations, because workers have high occupational exposure to pesticides. In large-scale commercial agriculture operations, workers are often in such close contact with pesticides that they develop serious health problems.[88] Regulating worker safety also gives regulatory bodies an additional "watchdog" group of on-site workers trained in appropriate pesticide manufacture and application, as EPA hopes that the educated workers will report pesticide misuse to mitigate health risks.[89]

Another regulatory trend is reducing environmental risks from registered pesticides, in order to reduce EPA liability under federal environmental protection statutes. Courts have repeatedly held that EPA has a duty to comply with complementary environmental statutes when issuing FIFRA registrations, so two of the focal points for EPA regulation are compliance with the ESA and CWA water quality controls.[89]

Finally, EPA promotes better performance regulation as a part of an incentive plan to encourage agricultural pesticide users to move away from high-risk pesticides. EPA is currently collecting funds for grants and collaborating with the USDA to establish the best environmentally and socially sound pesticide use policies, and EPA plans to implement those policies by giving incentives to pesticide users. To establish which users are successful, and deserve grants, EPA is continually altering alternative regulations to establish baseline performance standards.[89]

Conclusion

To promote public health, personal safety, and environmental protection, pesticides and their use are extensively regulated. Pesticide regulation is primarily decided at the federal level, and enforced by the EPA. Although the states generally copy the federal laws, some state laws are more restrictive than federal laws. Both federal and state laws provide for criminal prosecution and can impose penalties such as fines or imprisonment. In addition, common law actions are used to regulate pesticide use. Common law actions are civil claims brought by private citizens based on an allegation of improper pesticide production or use. When a pesticide manufacturer or user causes personal injury or property damage, the victim can initiate a civil action to recover financial compensation for the harm.

Regulating the manufacture and use of pesticides is necessary to protect human health and the environment, but those regulations require enforcement. Although EPA penalties are a deterrent, the specters of cancelled registration or toxic tort litigation offer successful alternatives, especially in light of the Supreme Court's relaxation of the limitations on state tort claims. In addition, the recent bout of environmental litigation compelling increased EPA enforcement of pesticide regulations has clearly impacted EPA's model of enforcement, which will hopefully lead to overall social benefit.

Acknowledgments

Special thanks to Fred Whitford, coordinator of Purdue Pesticide Programs, and Dr. Fred Fishel (University of Florida/Institute of Food and Agricultural Sciences) for reviewing this entry.

Acid Sulfate Soils: Formation

Martin C. Rabenhorst, Delvin S. Fanning, and Steven N. Burch

Introduction

Soils containing sulfide minerals that have not yet been oxidized through acid sulfate weathering are referred to as potential acid sulfate soils (potential acid SS). The processes involved in the formation and accumulation of sulfide minerals in soils leading to the formation of potential acid SS will be discussed first. Subsequently, processes related to the oxidation of sulfides in the formation of active acid SS will be examined. The extent of acid SS worldwide has been estimated to be approximately 12–15 MHa.[1]

Potential Acid Sulfate Soils and Sulfide Mineral Formation—Sulfidization

Biogeochemistry of Sulfide Mineral Formation

Several factors are required for sulfate reduction. These include a source of sulfate, a source of oxidizable carbon, reducing conditions and the presence of sulfate reducing bacteria.[2] Any of these components could theoretically limit sulfate reduction. In saturated soil or sedimentary environments where the required factors are present, heterotrophic microbes utilize sulfate as an electron acceptor that becomes reduced to sulfide according to Eq. (1).

$$\mathrm{SO_4^{2-}} + 10\mathrm{H}^+ + 8_e^- \rightarrow H_2\mathrm{S} + 4H_2\mathrm{O} \qquad (1)$$

Sulfate

Provided that the other required factors are met, the quantity of sulfate may limit the rate of sulfate reduction. Gold-haber and Kaplan[3] reported sulfate reduction to be independent of concentration when sulfate levels are above 10 mM (320 mg/L). Work by Haering,[4] in Chesapeak Bay, indicated that sulfate levels may begin to limit sulfur accumulation in marsh soils when levels drop below 1 mM (32 mg/L). Some degree of sulfate reduction will continue as long as sulfate is present at minimal levels (>5–20 μM, 0.16–0.6 mg/L).[5] Because sulfate-reducing bacteria are better able to complete for electron-donating substrates than are methane-generating bacteria, methanogenesis is of minimal significance so long as sulfate levels are above 0.03–0.4 mM.[6] Therefore, sulfate reduction dominates in brackish systems. In freshwater, sulfate reduction may become overshadowed by methanogenesis as sulfate is depleted.

Oxidizable Organic Carbon

The oxidation of organic matter provides the energy microorganisms need to facilitate sulfate reduction. Plant materials rich in labile components are more easily decomposed than humified soil organic matter or peat. In sediments low in organic matter, sulfate reduction may be limited by the paucity of oxidizable carbon. This can be demonstrated in thin sections from mineral horizons in tidal marsh soils where iron sulfide minerals have accumulated in pores occupied by decaying plant roots (Figure 1). The intimate association of pyrite with the decomposing organic minerals, and its near absence from the surrounding soil matrix suggests that organic matter is limiting the formation of sulfide.[7]

Reducing/Saturated Conditions

Because diffusion of gases through saturated soils and sediments is very slow, oxygen becomes depleted under saturated conditions and microbes which utilize other electron acceptors become active. Nitrate, Mn(IV) and Fe(III) are so utilized as the environment becomes progressively reduced (Figure 2). If the conditions permit the entry of oxygen, then redox potentials may never become sufficiently low to foster sulfate reduction. More typically, diffusion of oxygen into a saturated soil or sediment is sufficiently slow, and if other necessary factors are present, sulfate reduction will occur. Figure 2 illustrates that pH, as well as E_h, must be specified in assessing sulfur phase equilibria. For example, as the pH increases from 5 to 7, the minimum E_h at which sulfate reduction is expected decreases from approximately −50 to −200 (based on a SO_4^{2-} concentration of 10 mM and a pH_2S of 0.0001 atm).

Sulfate-Reducing Bacteria

Some 15 genera of bacteria have been recognized as sulfate reducers including *Desulfovibrio, Desulfotomaculum,* and *Desulfobacter.*[8,9] These organisms thrive under strongly reducing conditions,

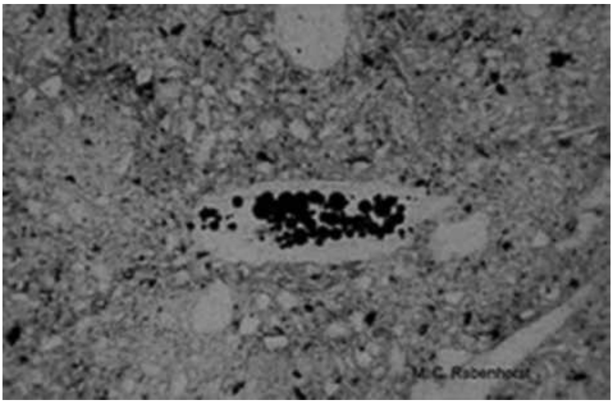

FIGURE 1 Micrograph of a thin section from the mineral (Cg) horizon of a tidal marsh soil illustrating accumulation of pyrite framboids in the channel occupied by decaying plant roots. Plane polarized light; frame length 1.2 mm.

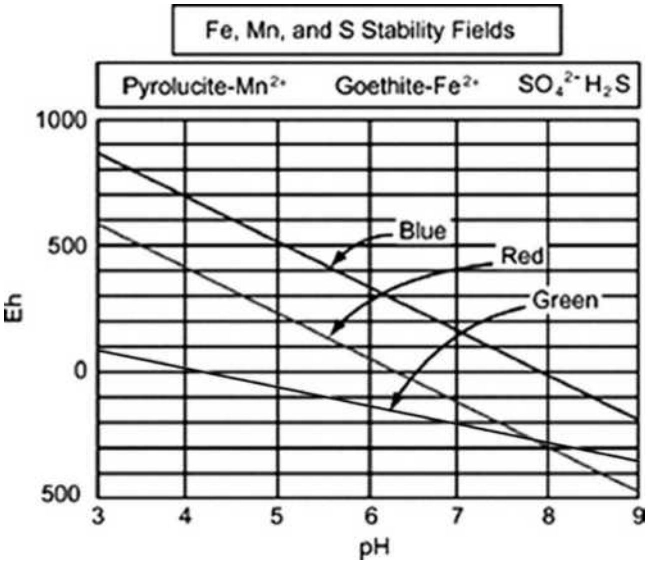

FIGURE 2 pe-pH diagram illustrating location of stability fields for redox sensitive components. The sulfate-sulfide lines (Green) is based on a $(SO)_4^{2-}$ concentration of 10 mM and a pH_2S of 0.001 atm. (Blue line separates the pyrolucite-Mn^{2+} stability fields; red line separates the goethite-Fe^{2+} stability fields.)

but many are able to persist in aerobic conditions for significant periods of time. Thus, if the other factors necessary for sulfate reduction are present, sulfate reducing bacteria will also become active.

As with most heterotrophic bacteria, rates of sulfate reduction are temperature dependent. Optimum temperature for most sulfate reducers is 30–40°C,[8] and the rate of sulfate reduction generally increase with temperature across this range. Some groups of sulfate reducers are thermophyllic and can function at temperature up to 85°C. Thus, in tropical coastal wetlands, sulfate reduction occurs all year round. In higher latitudes, where soil and sediment temperatures may approach biological zero, rates may become very slow during winter.

Reactive Iron

Once formed, sulfide is available to form a variety of minerals provided there is adequate reactive iron present. Most of the iron enters coastal environments as iron oxides sorbed to the surface of clay and silt particles. When iron oxides in the sediments and marsh soils become reduced to Fe(II), they can form iron sulfide minerals. While monosulfide species may form first [Eq. (2)], and minerals such as greigite (Fe_3S_4) may persist in recent sediments, disulfide forms such as pyrite are energetically more stable and will form at the expense of the monosulfides.

$$\mathrm{FeS_2} \text{ and } \left(+\mathrm{S_x^{y-}}, \text{loss of } \mathrm{e^-}, \text{or} + \mathrm{H_2S}\right) \tag{2}$$

$$\rightarrow \mathrm{FeS_2} + \text{various} \tag{3}$$

Mechanisms for pyrite formation may follow several possible pathways including 1) reaction of monosulfide with polysulfide; 2) partial oxidation of monosulfide; and 3) reaction of monosulfides with H_2S[10] (Eq. 3). Sulfide itself has the ability to reduce Fe(III) to Fe(II) on the surface of iron oxides.[11] Pyrite can occur either as small (<2 μm) individual crystals or as spherical clusters of crystals called framboids. In low organic mineral sediments, reactive iron is usually present in excess, resulting in a low degree of pyritization.[12] However, in organic-rich soils iron may limit the accumulation of sulfide minerals, and the degree of pyritization is generally high. This has been demonstrated experimentally in salt marsh Histosols.[13]

Environments of Sulfide Formation and Accumulation

It is clear that in environments which provide a source of oxidizable carbon and sulfate and which are sufficiently saturated to enhance reducing conditions, sulfate reducing bacteria will generate sulfide. If reactive iron is present, then solid phase ferrous minerals will accumulate. This process of *sulfidization*[14] is shown schematically in Figure 3. The obvious settings for these processes are coastal marine and brackish environments, where sulfate is abundant. Under permanently submersed conditions, detrital carbon is added by flora and fauna to the sediment. In shallow water settings (<3 m) where various pedogenic processes are at work, these accumulated sediments have been recognized as subaqueous soils[15] and are classified to reflect the sulfide components.

The soils of coastal marshes (in temperate environments) and mangroves (in tropical settings) also are ideal for sulfide formation and accumulation. The high primary productivity of these ecosystems (up to 3 kg m^{-2} yr^{-1} in marshes and up to 5 kg m^{-2} yr^{-1} in mangroves)[16] makes these an exceptionally good environment for sulfate reduction. Such soils may contain up to 20–30 g/kg of pyrite sulfur, and estimates of pyrite S accumulation rates in estuarine marshes are as high as 7 g m^{-2} yr^{-1}.[17]

Sulfate reduction can occur in other settings, so long as a source of sulfate is available. While generally small, atmospheric deposition of sulfate may be enough to induce sulfate reduction in the sediments of some interior freshwater lakes. Sulfate reduction has also been documented in prairie potholes where sulfate has apparently been contributed by the weathering of sulfur-bearing shales.[18]

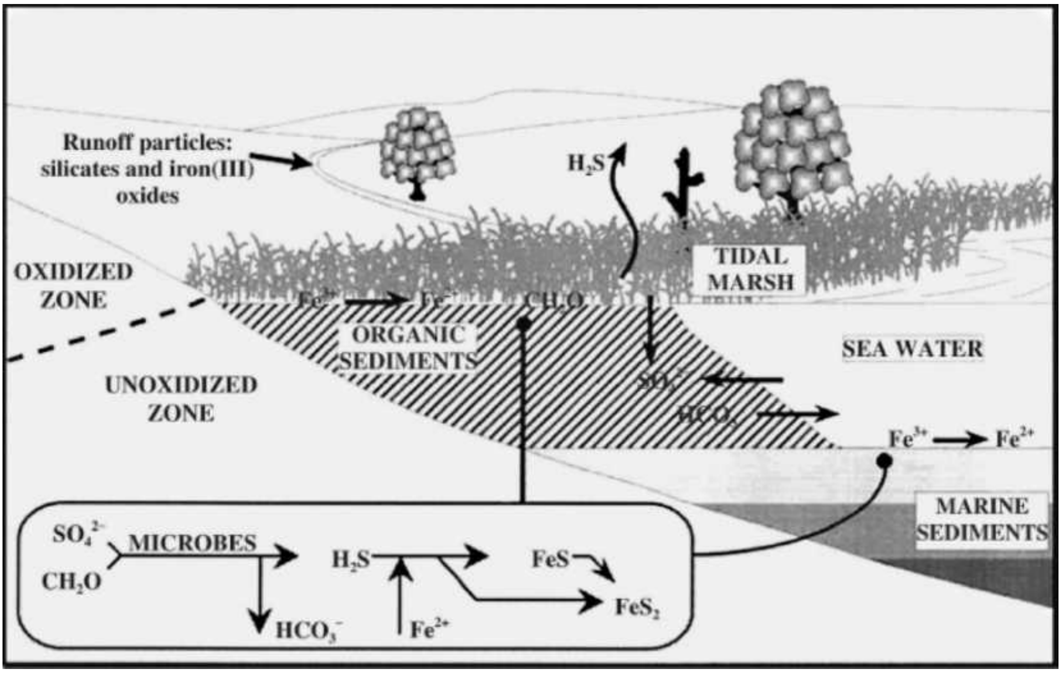

FIGURE 3 Schematic diagram illustrating the generalized process of sulfidization which leads to the formation of iron sulfide minerals and potential acid SS.
Source: Fanning et al.[26]

Formation of Active Acid Sulfate Soils—Sulfuricization

Chemistry of Sulfide Oxidation

Sulfides begin to oxidize once they are exposed to more oxidizing conditions. This occurs most often as a result of such human activities as drainage or dredging of sulfide bearing soils or sediments, or the mining of sulfide bearing coal, but may also occur due to tectonic uplift or oceanic regression. Under humid or moist aerobic conditions, sedimentary sulfide minerals can oxidize chemically[19] but this is a slow process, probably due to particular rate-limiting reactions. Various microorganisms are adapted to oxidize sulfides either directly through sulfur transformations or by facilitating (catalyzing) such rate-limiting reactions as the oxidation of Fe(II) to Fe(III).[20] While there are many possible intermediate reactions in the oxidation of pyrite, the overall reaction is summarized in Eq. (4). One mole of pyrite eventually yields two moles of sulfuric acid and a mole of iron hydroxide.

$$\mathrm{FeS_2} + 3\frac{3}{4}\mathrm{O_2} + 3\frac{1}{2}\mathrm{H_2O} \rightarrow 2H_2\mathrm{SO_4} + Fe(OH)_3 \tag{4}$$

The oxidation of pyrite proceeds along two fronts (Figure 4). First the S is oxidized (through intermediates) to sulfate yielding sulfuric acid and the remaining Fe(II). The generated Fe(II) sulfate salts are very soluble and potentially mobile. Secondly Fe(II) is oxidized to Fe(III), which when hydrolyzed produces additional acid. At high pH, the oxidation of sulfide is accomplished with oxygen, but under low pH conditions sulfide is oxidized by Fe(III). Microorganisms such as *Thiobacillus ferrooxidans* facilitate this reaction by oxidizing Fe(II) to Fe(III). For more details refer to Gagliano and Bigham.[21]

Other Aspects of Sulfuricization and Properties of Acid Sulfate Soils

Sulfuricization is the overall process by which sulfide bearing minerals are oxidized, minerals are weathered by the sulfuric acid produced and new mineral phases are formed from the dissolution products.[14,21] When $CaCO_3$ minerals are present, the sulfuric acid reacts with them to form the mineral gypsum, according to Eq. (5).

$$\begin{aligned} &\mathrm{CaCO_3} + \mathrm{H_2SO_4} + \mathrm{H_2O} \\ &\rightarrow CaSO_4 \cdot 2H_2\mathrm{O} + \mathrm{CO_2} \end{aligned} \tag{5}$$

As long as sufficient $CaCO_3$ is present, the pH is prevented from becoming very low and the soil does not become acid. When insufficient acid neutralizing minerals are present, the oxidation of pyrite in soils will lower the pH. The pH of active SS commonly drops to below four and in extreme can go below two. As iron is oxidized and hydrolyzed, various iron minerals form in the soil including ferrihydrite, schwestmannite and goethite. If the soil pH falls below four while maintaining an oxidizing environment ($E_h > 400\,\mathrm{mV}$) then the mineral jarosite ($KFe_3(SO_4)_2(OH)_6$) can form.[23] Because jarosite forms under conditions of high E_h and very low pH, which can only develop from the generation of sulfuric acid, it is considered a diagnostic mineral for acid SS.[24]

Jarosite has been reported in soils, which are not extremely acid and which may even contain carbonates.[22] These are interpreted to be “postactive” acid SS, meaning that earlier in their pedogenic history, they had undergone acid sulfate weathering. Subsequently, the soil pH has risen due to weathering of silicate minerals or addition of eolian carbonates. Because the redox potential has remained strongly oxidized, the jarosite has persisted as a metastable species. A recent review of acid sulfate soils including a discussion of the modeling of associated processes was recently completed.[25]

Erosion and Sediment Control: Vegetative Techniques

Samson D. Angima

Introduction

Soil detachment and erosion occur when soil is disturbed by either human activity or natural conditions such as extreme weather. As a result of this, the soil is being moved from one point to another by either wind or water. Practices such as road construction, suburban and industrial developments, stream channel and other types of construction on sloping lands, inadequate drainage facilities, poor grading practices, deforestation, cultivation on sloping lands, and general lack of adequate planning by land users cause soil erosion. Consequences of soil erosion include water and air pollution, reduced land productivity from loss of topsoil and nutrients, and degradation of the environment. Soil erosion by water is controlled mainly by earthworks and engineered constructions such as terracing aimed at reducing the slope and at collecting and storing moisture while reducing runoff to acceptable limits. Vegetative barriers are grass, shrubs, or small trees grown in close rows that can be used to control both water and wind erosion by providing protection from soil and dislodging sources such as rainfall, and offering a semipermeable barrier to erosion agents resulting in soil deposition. The resultant vegetation also shields the soil surface from overland flow and decreases the erosive capacity of water flow by reducing its velocity.

Vegetative Materials for Soil Erosion and Sedimentation Control

Vegetative cover is essential for the design and stabilization of many structural erosion-control devices (Figure 1). Proper vegetative cover provides excellent erosion protection and sedimentation control. Vegetative barriers are planted in close rows along contours on slopes to intercept water runoff, or are planted perpendicular to the direction of wind to retard wind movement, resulting in soil deposition. Plant roots and lateral stems provide a structure to hold soil particles in place. These features also

FIGURE 1 Vegetative barriers/strips hold the terraces intact for agricultural production in Kabale, Uganda. (Courtesy of Samson Angima.)

improve the soil's physical properties and increase infiltration rate, thereby decreasing runoff. Plant transpiration reduces soil moisture levels, which increases soil absorption capabilities. Not every plant material can serve as a soil erosion-control agent. Those plants that do possess some bioengineering characteristics in both the root and the shoot systems that encompass both living plants and organic materials as construction elements for erosion control. Such properties include noncompetition with adjacent crops or fruit trees for moisture or nutrients, a rooting system that reaches deep down to anchor the plant and also extract leached nutrients from the subsoil, and shade tolerance. The plants must be perennials with high seed vigor, have the ability to increase soil organic matter and reduce surrounding soil bulk density to allow faster water infiltration, and have strong woody stalks to withstand pressure from erosive agents.

Vegetative materials used for soil erosion control include grass species, legumes, trees, shrubs, vetches, and sods. Common grass species that bunch during growth include tall fescue, perennial ryegrass, orchardgrass, timothy, switchgrass, weeping lovegrass, deertongue, and big bluestem. Bunching legumes include birdsfoot trefoil and serecia lespedeza. Cereals such as winter wheat, winter rye, spring oats, sudangrass, and Japanese millet are also used. Sod-forming species include grasses such as redtop, fine fescue, Kentucky bluegrass, smooth bromegrass, and legumes such as crownvetch and flatpea.[1] Shrubs and small trees that are used as barriers in erosion control include *Calliandra calothyrsus, Sesbania sesban, Leucaena leucocephala, Gliricidia sepium, Cassia siamea, Eucalyptus* spp., *Casuarina* spp., *Acacia* spp., *Azadirchta indiaca,* and *Grevillea robusta*.[2] Tree species selection depends on local landuse and climatic conditions that favor establishment.

Mass Planting of Vegetative Cover

Mass planting of vegetative cover is done where land that is susceptible to erosion is converted from cropland to vegetative cover such as in the conservation reserve program (CRP). In this program, trees as well as sod are planted in strategic places, where they will provide maximum protection to the soil resource, and the landowner agrees to leave the areas under vegetation for a given period of time for land stabilization to occur. The vegetative cover also reduces water pollutants such as fertilizer nutrients, pesticides, and herbicides in the runoff water, increases oxygen levels, reduces greenhouse gases and evaporation rates, and provides shade and buffers against high winds.[2]

Vegetative Strips

Vegetative strips constitute different types of filter strips that reduce runoff velocity and provide differing degrees of filtering action depending on the species used. Larger soil particles tend to settle out readily, leaving only clay particles suspended and thereby reducing pollutant transfer to ponds, rivers, and lakes. Filter strips can be classified as grass strips, vegetated waterways, filter strip terraces, buffer and riparian strips, and settling basins.[3]

Grass Strips

Grasses are by far the most important vegetative materials used to control erosion. Bands of grass about 1–2 m in width are planted along the contours and spaced every 10–100 m depending on the slope (Figure 2). Prior to planting, the land is roughened by disking, harrowing, or raking, and then limed, fertilized, and seeded with mixtures of adapted grasses and legumes to enhance a good stand.[4] Vetiver grass (*Vetiveria zizanioides*), napier grass (*Pennisetum purpureum*), and stiff grass (*Miscanthus sinensis*) are the most commonly used species.[2] These are upright, tufted, deep-rooted, and very dense grasses that are by far the most important in erosion control, particularly in tropical countries. Vetiver is a bunch grass with very rapid growth in warm and moist conditions. It grows to more than 2 m in height and has a remarkably dense and vertical rooting system, growing deep (3–5 m). Napier grass is a tall perennial reaching over 3 m high. It is resistant to drought, and grows at altitudes up to 2400 m. Stiff grass has dense roots and coarse stems that withstand erosive agents. These grass hedges present a virtually impenetrable barrier through which soil can hardly pass and only water, with much reduced velocity, passes.[5] As silt builds up behind the grass, other grass shoots arise from the nodes above the deposited silt to form a natural terrace. Weeds and undesirable foreign grasses are unable to penetrate through a well-established grass hedge. Studies carried out in Mississippi, using stiff grass (*M. sinensis*) on no-till and conventional tillage, [6] showed that grass strips help reduce sediment losses by up to 88% on conventional tillage and 57% on no-till cotton plots (Table 1). Other grass species include Buffalo grass (*Buchloe dactyloides*), grama or mesquite grasses (genus *Bouteloua*), switch grass (*Panicum virgatum*), and *Phalaris aquatica*.

Vegetated Waterways

Vegetated waterways are channels or waterways that transfer runoff from a higher to a lower elevation over a short distance without allowing erosion to occur (Figure 3). In addition to dissipating flow energy,

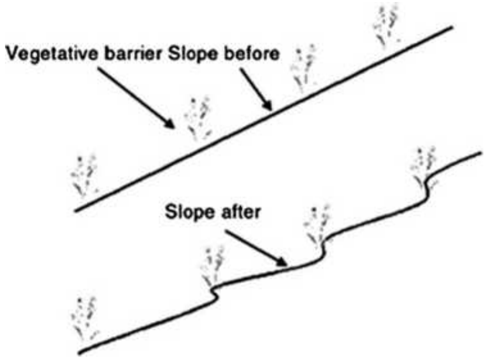

FIGURE 2 Schematic sketch of vegetative barriers illustrating expected change in land slope over time resulting from tillage and erosion deposition process.

TABLE 1 Sediment Loss with and without Grass Strip (*M. sinensis*) under No-Till and Conventional Tillage Cotton at 5% Slope

	Sediment loss (t/ha)				
Period	No-Till with Grass Strip	No-Till without Grass Strip	Conventional Tillage with Grass Strip	Conventional Tillage without Grass Strip	No-Till with Winter Wheat Cover
1992	2.6	4.5	12.3	60.3	2.9
1993	0.9	1.6	5.4	21.9	1.2
1994	3.2	9.6	18.6	63.2	1.9
Average	2.2	5.2	12.1	48.5	2.0

some structures also act to retain soil. They are especially effective in arresting gully development, a situation that might need both structure(s) and some vegetated channel. They have many uses in comprehensive conservation plans, but they primarily collect and concentrate flows and then safely transport the water to major drainage systems. Dense vegetation is used to minimize the area required, i.e., the protective action of the vegetation permits higher flow velocities and thus smaller waterway cross-sections. Most vegetated waterways run directly down a slope; however, they can also be constructed somewhat across the slope as diversions or sometimes just to reduce channel slope. Vegetated channels are not used where continuous flow occurs because the vegetation will die out. Tillage near a waterway is accomplished in a direction across the waterway. Sodforming, cool-season grasses such as smooth brome or western wheatgrass are used in grass waterways. Grass waterways are usually designed to carry runoff of a 24 hr storm of the intensity that happens once every 10 years. In areas with prolonged water flows, high water tables, or seepage problems, a rock-lined center is added.[1]

Filter Strip Terraces

Filter strip terraces are strips of grass sod, legumes, and other vegetation on the contour that surface water runoff crosses as it runs downhill. They serve as an alternative to earthen terraces but do not have a channel to conduct water along the contour, as earthen terraces do. Filter strip terraces are excellent removers of sediment, pesticides, organic matter, and other pollutants. They are better than grass waterways because water enters the strip uniformly and over a wide area.[3] The width and type of vegetation established in the filter area are determined by site conditions including soil type, land slope, and type of runoff entering the filter.

Small trees and shrubs are also used as conservation hedges in erosion control. These are planted close together and are periodically pruned to maintain height while the cut branches are inserted upslope of the hedge to trap more sediment. Trees that have been used successfully in erosion control, especially in agroforestry systems in the tropics, include *C. calothyrsus, S. sesban, L. leucocephala, G. sepium,* and *C. siamea*. Trees used for windbreaks include *Eucalyptus* spp., *Casuarina* spp., *Acacia* spp., Neem tree (A. *indiaca*), and *G. robusta*[7] In the temperate zone, thorny hedge plants include barberry, Osage orange, buckthorn, and hawthorn. Evergreen hedge plants are box, privet, azalea, yew, arborvitae, rhododendron, mountain laurel, and holly.[8] Decorative deciduous shrubs often used are lilac, forsythia, mock orange, spiraea, euonymus, and viburnum. *Rosa rugosa* can be planted along the highway embankments, and rows of poplars, hemlocks, and other trees can be used as shelterbelts. Vegetative or biological measures may include log bundles anchored to the stream bank or the planting of herbaceous or woody plants, which can withstand high velocity flow, while the roots form a protective net for the soil.

Buffer Strips and Riparian Strips

Buffer strips at lower elevations of fields (Figure 4) and Riparian strips along stream banks, ponds, and lakes (Figure 5), intercept surface runoff water from crop fields. Buffer strips may constitute ordinary grassed fencerows or strips of grasses, shrubs, and trees lining hillsides or banks of rivers. Runoff water must flow in a shallow, even layer across the buffer strip to remove sediments. Most common grasses used in buffer strips are Bluestem and Indiangrass. Riparian strips are planted so that surface and subsurface runoff must filter through them before it reaches a pond, lake, or stream.[1] The body of water can be permanent or temporary. Riparian strips can also be placed next to wetlands, such as marshy or swampy areas, and additional vegetation can be placed uphill if excessive amounts of sediments enter the waters.

Settling Basins

Settling basins are constructed around inlets to tile-outlet terraces. These are important in reducing soil sediment loads and also act as setback zones for herbicides such as Atrazine. The basins are designed to retain water for up to 24 hr, giving most of the larger sediments time to settle out.[3] These are common where tile lines have been installed.

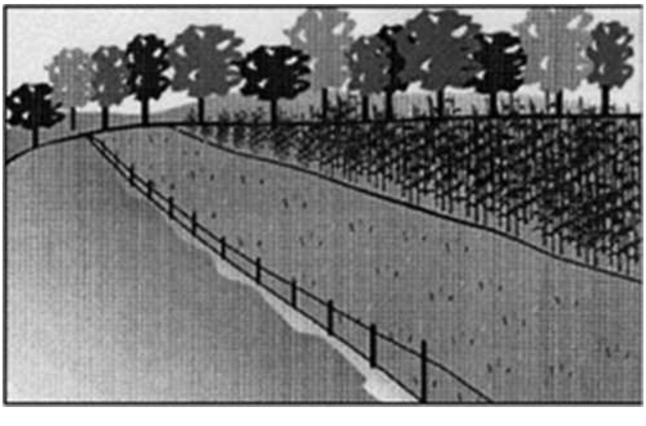

FIGURE 4 Buffer strips at lower elevations of fields intercept surface runoff water from crop fields.
Source: Regehr.[3]

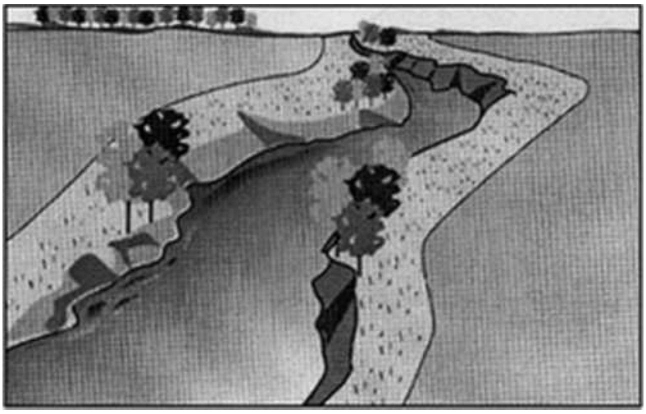

FIGURE 5 Riparian strips along stream banks intercept surface runoff water from crop fields.
Source: Regehr.[3]

Conclusions

Vegetative techniques for erosion and sedimentation control offer a wide range of tools for use by a wide range of land users especially those that cannot afford engineered or earthen structures. However, for these tools to work well in erosion prevention, they have to be regularly maintained and landowners need to understand that they require time to effectively control enough sediment that can gradually change slope. Research is adding more species of grass and/or shrubs that can be multipurposely used to control erosion and at the same time provide other uses beneficial to the land owner. When used well in conjunction with best management practices, vegetative techniques can substantially contribute to overall water and wind erosion control.

Precision Agriculture: Engineering Aspects

Joel T. Walker,
Reza Ehsani, and
Matthew O. Sullivan

Introduction

Information technology is playing an increasingly important role in today's agricultural production systems of all sizes, commodities, and management philosophies. Precision agriculture[12,14,17] or site-specific management is an information- based management technique that has the potential to improve profitability[7] and reduce the environmental impact[19] of crop production. It also has the potential to improve the quality and nutrient content of the product. Precision agriculture, rather than the "one-size-fits-all" management strategy, provides for differential treatment of selected areas of a production field, called management zones, based upon expectation of increased yield, profit, or some other agronomic goal.[2–4,18] Management zones may be selected for differential treatment based upon various documented differences such as soil type, soil fertility or pH, yield history, presence of weeds, insects, or diseases, or other measures for which a differential treatment helps the producer achieve a selected goal. The ability to provide differential treatment to management zones, also called site-specific management, depends upon availability of both proper equipment and effective treatment algorithms.

What Makes It Possible?

Precision agriculture techniques have been made possible by the advent of global positioning systems (GPS) and high speed computer processing. GPS provides real-time location information to a computer that, from stored information, determines the current management zone, selects appropriate treatment for that management zone, and controls mechanisms to provide the treatment. Figure 1 is a graphic representation of the precision agriculture paradigm. GPS provides position information for a variety of data gathering processes or for control of site-specific treatments. Information of various types (shown as layers) may be used in analysis of yield results or to develop an application map to control site-specific treatments. The whole system taken together is often called precision agriculture or site-specific agriculture. Note that a feedback loop is implied where results of the previous growing season (yield) become part of the information that influences current treatment practices. Given the proper

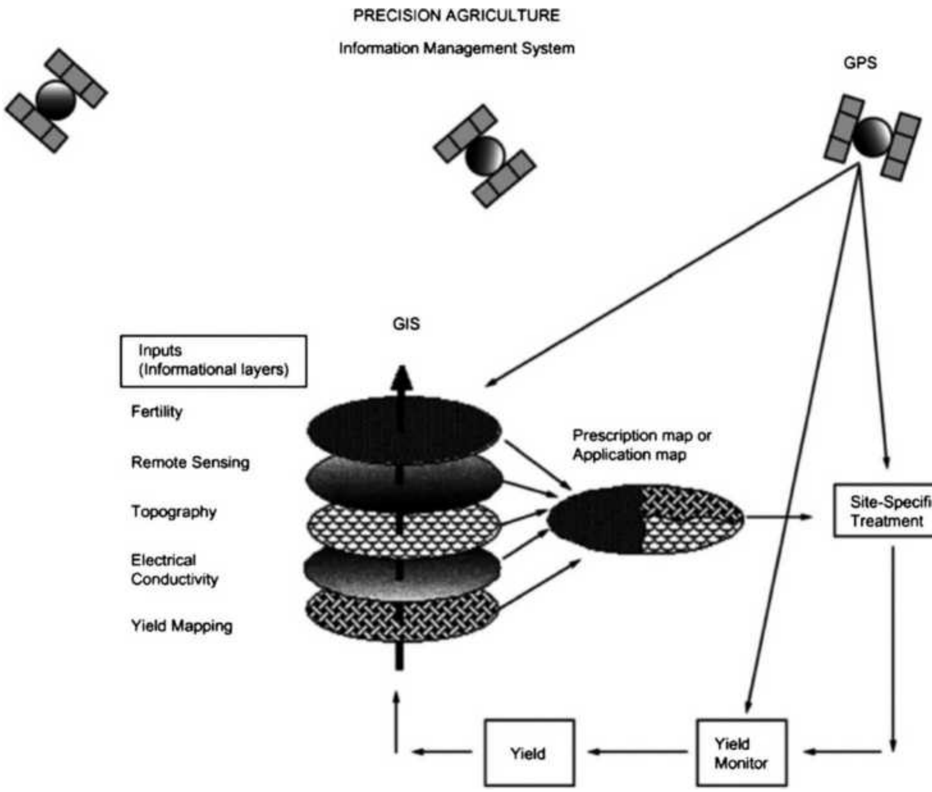

FIGURE 1 Paradigm for precision agriculture.

treatment algorithms, current treatment practices may optimize the goal parameter. Maximum yield is not necessarily the best goal because the cost of treatments required to achieve that yield may be greater than the increased crop value.[4,18]

GPS consists of a minimum of 24 satellites orbiting the Earth and sending signals to a local receiver for which location is desired.[9] Each and satellite broadcasts encoded information with particular timing. By measuring the time a signal travels (at the speed of light) to reach the receiver, the distance from a satellite to the receiver may be calculated. Determining distances from four or more satellites of known location may establish the receiver's location (latitude, longitude, and elevation). Even simple, inexpensive receivers are capable of accuracy better than 15 m, close enough to return to a favorite fishing spot. With specialized transmissions containing information to correct for known errors (called differential signals), accuracy better than 1 m may be achieved. Specialized local transmitters make possible real-time kinematic (RTK-GPS) systems with accuracy of better than 1 cm. RTK systems are used in surveying, guidance, and where the fine precision may justify a relatively high equipment cost.

High-speed computer processing systems have also played an important role in the advent of precision agriculture. Precision agriculture requires collection and storage of data, decision-making computation, and controlling of equipment by computers operating at billions of operations per second. GPS locations are recorded in realtime by the computer. Digital maps of field conditions and parameters are carried in memory or storage media. Digital data such as digital still or video images of weeds, insects, or disease damage, soil properties, crop spectral reflectance, or climactic conditions may also be collected in real-time by the computer. Using such information, the computer may work through a response model to decide what actions should be taken with current equipment. For example, a precision agriculture capable planter may be able to adjust planting rate and depth or change the seed variety on-the-go. Thus, the computer may decide that areas with a selected soil type and relative elevation will get a reduced population (investment of seeds) because less yield is expected. The computer may dictate that another soil type with a high yield potential and high existing moisture content will get a different variety planted to a shallower depth. Across an entire field, many combinations of the controlled variables will be chosen to optimize the desired result (yield, profit, or other goal). A large field would require constant decisions and adjustment of the equipment that would not be possible without computerized systems. Finally, volumes of data may be produced by precision agriculture techniques and computer methods are being developed to extract useful information; and models form this data[5,6,10,11,15,16] and present it to the public in readily accessible form.[13]

Sensing for Precision Agriculture

Real-time sensors will be important to many precision agriculture systems.[8] A real-time sensor provides data in a nearly constant stream as the machine traverses the field. For example, a camera may provide digital images from which the presence of weeds may be determined. A sprayer may then be directed to spray only where weeds are present. Organic matter and moisture levels in soil affect the performance of some herbicides. Sensors that measure organic matter and/or moisture on-the-go allow for optimum rates of chemical application—adequate to control the weeds, but no more than necessary to preserve environmental quality.

One of the most popular real-time sensors measures grain yield on combines.[12] Yield sensors are also available or are being developed for a variety of crops such as cotton, potatoes, tree fruits, and strawberries. Yield sensors provide a measure of yield over a whole field. Areas of the field with unusually high or low yield may be identified and corrective action (subject to some predictive model created by the producer or by computer) can be taken for the following year. This one aspect of precision agriculture has created a lot of activity in adjusting soil drainage and fertility and crop management decisions such as the relative value of fertilizer or chemical inputs.

For many agronomic parameters, site-specific soil sampling is more practical, either because a real-time sensor is not yet available, or because the spatial variation of the parameter is more gradual and can be estimated with a few site samples. Soil samples to determine fertility are common. The values of pH (acidity/alkalinity), nitrogen, potassium, and phosphorus are particularly important in prediction of yield levels. Soil type is another parameter that is often determined by a site visit.

Remote sensing is becoming increasingly important to precision agriculture. Early data that came from random satellite observations had low resolution and limited value. Now specially equipped satellites and aircraft may be hired to collect specific crop or soil information. Crop growth or health may be deduced from this data. Certain wavelengths of the electromagnetic spectrum are particularly helpful. The visible light frequencies provide some information. Unhealthy crops tend to reflect more yellow and red light. Various frequencies in the infrared range also have been correlated with plant health and soil moisture conditions. Multi-spectral systems provide data on the visible spectrum (often three primary colors) and a limited range of the infrared. More sophisticated equipment, called hyper-spectral, can provide data from a much broader range of the spectrum and from narrower sample bands. This type of data offers greater opportunity to correlate specific crop or soil conditions to measured spectral data.

Other types of remote sensing are becoming available. Light detection and ranging (LIDAR), for example, is a laser ranging technique that may be used to measure topography and plant height simultaneously.[1] Currently applied to the forest industry and relatively expensive, this method holds promise for rapid feedback of information on crop growth problems to the producer, perhaps allowing solution of the problem before yield is permanently affected. For example, nematodes in soybeans are a common cause of reduced vigor and yield if left untreated. Conventional crop scouting or remote sensing may not detect small areas of infestation or provide feedback in time to take corrective action. With regular LIDAR imaging, a producer could detect and treat such trouble spots in a timely and efficient manner.

Geographic Information Systems

Geographic information systems (GIS) techniques are an integral part of precision agriculture. Basically, GIS is a storage system for geographically referenced digital data. Many of the data types discussed above can be digitized (if not already in digital form) and referenced to specific locations in a field. Each parameter or variable then may be represented as a layer of information. Geographic position of the information matches the position on a map of the field. The value of a parameter may be represented on a map as a shade of gray or a color. So a GIS information layer representing soil type can be drawn in the physical shape of the field with patches of color—each color representing a different soil type. Many such layers may exist in a GIS dataset for a particular field. Depending upon the need, these layers may be viewed as overlays—simultaneous presentation of several variables in one field. As many layers of information are added to the GIS system, it becomes apparent that human vision is inadequate to detect the important patterns. Computers, however, are infinitely more able to "see" data patterns with a potential to produce an economic advantage.

Future

The future of precision agriculture depends on economic results. Can the cost of additional equipment and operations be more than offset by increased economic return and value of environmental protection? It seems possible that all agricultural operations could be monitored and recorded, linked by digital transmissions to databases containing weather, remote sensing, and historical data, and controlled through a general model of the crop's predicted response to specific inputs. Such a system may not only control specific agricultural operations, but also be involved in scheduling, ordering seed, fertilizer, and supplies, providing records to regulating agencies, and feeding valuable information back into the research system for further refinement of the control model. Already, manufacturers are producing prototype agricultural machines that perform without an operator. These machines are guided by GPS, are controlled by computer, and have onboard sensors to detect obstructions or people in the way. The advancement of agriculture will come with technology—technology to feed the world.

Sodic Soils: Reclamation

Jock Churchman

Introduction

Two main mechanisms are involved in the reclamation of sodic soils: 1) improvement in water flow; and 2) displacement of exchangeable Na ions.

Improvement in Water Flow

Sodic soils show a low permeability to water. Their permeability can be improved quite rapidly by increasing electrolyte concentrations[1,2] (the "electrolyte effect"). Ions in solution tend to inhibit the swelling and dispersion of fine clay particles by compressing the electric double layers of adjacent particles (Figure 1). The volume around the particle surfaces within which repulsion takes place is reduced, ultimately to zero.

It has been found[2] that there is no swelling and dispersion when the total electrolyte concentration exceeds a critical level, i.e., the "threshold electrolyte concentration" that depends on soil properties.[1,3]

Displacement of Exchangeable Na Ions

The deleterious effects of exchangeable sodium reflect the more extensive hydration of the sodium ion than that of other common exchangeable cations on soil particles (Figure 2). Exchangeable sodium, which forms an ionic association with the clay surface, causes hydration, dissociation of particles, and hence swelling and dispersion. By contrast, exchangeable calcium forms polar covalent bonds with the clay surface.[4] Calcium shows only limited hydration and dissociation of particles, and therefore causes only limited dispersion and swelling.[4] Na^+ on exchange sites is replaced by Ca^{2+} for the longer term remediation of sodic soils.

Chemical Améliorants

Gypsum

Soluble sources of calcium ions are the most suitable sodic soil ameliorants. While gypsum is used most often, not all sources of gypsum are similarly effective or similarly suitable for each specific problem from sodicity. It was found[1,5] that only "by-product" gypsum, as a surface application, could prevent crusting. Mined gypsum was too slowly soluble for the purpose.[1] Gypsum is a by-product of many industrial processes.[5] Furthermore, gypsums from different mines can differ quite markedly in purity[6] They can also differ in dissolution rate. A finer particle size generally provides a greater solubility.[5] As well, sodium salts associated with gypsum (Table 1)[6] decrease its efficiency for amelioration.[7]

Lime

Lime has also been used as an ameliorant for sodic soils.[6,8,9] While generally less soluble than gypsum, lime may provide a useful incidental source of calcium ions when used to raise the pH of acid sodic soils. It may provide a cheaper alternative to gypsum or else be used in association with gypsum to extend the lifetime of the calcium reserves.[6] Because of its increased solubility in the presence of sodium salts, it may be more effective than gypsum for the reclamation of saline sodic soils. Lime also contributes less to the salt load than gypsum.[9]

Reclamation of Calcareous Sodic Soils

Calcareous sodic soils have an abundance of Ca, but it is present as $CaCO_3$, hence is insoluble at the high pH of these soils. Their sodicity is often overcome through acid additions,[10,11] either directly, or indirectly. Additions of elemental sulfur, pyrite (FeS_2), iron and aluminum sulfates,[10,12] and also organic matter[13] each provide acid through microbial activity for indirect acidification. Plant growth can also help dissolve native calcium carbonate.[12]

Miscellaneous Chemical Ameliorants

Sodic soils may be reclaimed with soluble sources of Ca that include waste materials, e.g., acidic cottage cheese whey,[1] acid resin by-products of the oil industry, and also $CaCl_2$ as an industrial by-product.[3] Addition of polymers can also increase the permeability of soils.[1]

Role of Biology and Organic Matter

Effects of Plant Growth

Rice culture ameliorates sodic soils through the buildup of carbon dioxide and hence dissolution of calcium carbonate, among other effects.[10] Among crops, rice is particularly tolerant to sodicity, and some grasses are also highly tolerant[10,12] (Table 2).

Ameliorants are readily leached out of soils, so losing the benefit of the electrolyte effect. In addition, Na^+ from sodium salts often present in soils can replace exchangeable Ca^{2+}. Therefore long-term reclamation probably requires increased plant growth, hence enhanced biological activity[13] and stabilization of soil structure. This occurs partly through transient binding agents, e.g., roots, hyphae, polysaccharides, and hydrophobic binding[13] and partly through associations between soil organic matter and Ca^{2+} in the soil system. Organic matter has a stronger affinity for Ca than for Na,[13] so is most effective when used with gypsum or lime to help restore a stable structure to soils.[13] There is a resulting increase in stable pores for the transmission of water and nutrients, root growth, and soil stability.

TABLE 2 Relative Tolerance of Crops to Sodicity

ESP Range	Crops[a]
10–15	Safflower, mash, pea, lentil, pigeon-pea, curd bean
16–20	Bengal gram, soybean
20–25	Groundnut, cowpea, onion, pearl millet
25–30	Linseed, garlic, guar
30–50	Indian mustard, wheat, sunflower, berseem, hybrid napier, guinea grass
50–60	Barley, sesbania, saftal, panicums
60–70	Rice, para grass
70+	Karnal, rhodes, and bermuda grasses

[a] Yields are about 50% of the potential yields in the respective sodicity ranges.
Source: Gupta and Abrol[10] and Oster and Jayawardene.[12]

Effects of Additions of Organic Matter

Due to its stabilizing effect on soil structure, organic matter can also help to reclaim sodic soils when added to soils, even though additions of organic matter can sometimes also enhance their dispersion, with resulting physical problems.[13] The different effects vary with types of soils and also of organic matter.[13] The addition of readily decomposable organic matter tends to reduce the pH of calcareous sodic soils, and hence aid their reclamation.[13]

Strategies for the Reclamation of Sodic Soils

Reclamation without the Addition of Ameliorants

Reclamation can be achieved slowly without ameliorants by many cycles of irrigation and cropping.[10] As well, underlying calcareous or gypsiferous layers may be incorporated into upper parts of the soil profile through deep plowing.[3]

Optimal Supply of Ameliorants

The effectiveness of gypsum can be increased by its placement in cracks for their stabilization so that they remain open to conduct water, air, and plant nutrients when soils become wet.[1] Water flow to subsoil layers, and also aeration, hence higher crop yields, were achieved by incorporating gypsum in narrow tilled slots.[12] More generally, gypsum is often incorporated into subsoil layers by tillage.

Ameliorants may also be used in association with other additions. Only a little gypsum applied with acidifying nitrogenous fertilizers led to effective reclamation of a saline-sodic soil.[1] This combination confers immediate benefits through a higher electrolyte concentration and also medium-term benefits through an increased supply of exchangeable Ca ions. Enhanced plant growth from fertilizer use provides long-term benefits.

Supply of Water for Reclamation

Ameliorants are only effective when dissolved. A supply of water and its flow through the profile are required for effective amelioration. Irrigation and/or rainfall may supply water but the quality of water available for irrigation can vary. Gypsum can be supplied in electrolyte-free irrigation water, as in parts of California.[12] Saline-sodic irrigation water, including water commonly derived from groundwater sources, may exacerbate the deleterious effects of sodicity when its application during the dry season is followed by rains, as can occur in Israel.[12] In this case, (by-product) gypsum is applied to the surface prior to the rainy season.[12] Adequate drainage to beyond the root zone should accompany irrigation in order to leach displaced electrolyte but this should not cause increased salinity in underlying groundwater.[11]

As long as there is provision for the disposal of the salt water, dilution with salt water[3,11] is also useful in sodic soil reclamation. Its immediate effect is to increase the hydraulic conductivity of sodic soils by the electrolyte effect, but long-tern reclamation will occur provided it also contains sufficient Ca (Ca : total cations ≥ 0.3). This can be added as gypsum.

Rate of Supply of Ameliorants

All additives increase costs so their optimal use is required. The cost of transporting gypsum often limits application rates. Recommendations from field trial results of the most effective application rates for ameliorants are necessarily specific to soil type and climate, among other factors. Nonetheless, both simulations[9,14,15] and laboratory studies[16] have shown that the solubility of gypsum increases as the proportion of exchangeable sodium on the soil increases. They have also shown that gypsum is more effective when mixed throughout the soil than when applied to the soil surface alone. Simulations[9] have shown that reclamation is primarily limited to the depth interval in which gypsum was applied (Figure 3A). They have also shown (Figure 3B) that the electrical conductivity EC of the solution within and below the gypsum-amended layer decreases as the exchangeable sodium percentage (ESP) within that layer decreases.

Nonetheless, calculations of gypsum requirements have been based on 1) exchange of Na by Ca, rather than the attainment of a sufficiently high electrolyte concentration EC to maintain a low permeability; and 2) assumptions of chemical equilibrium. The gypsum requirements for the achievement of a suitable permeability by the electrolyte effect also depend on the inherent EC of the soil solution.[11] Because mineral dissolution can maintain a high EC throughout most of the soil profile, gypsum often needs to be added to the soil-surface only, mainly to prevent crusting. Assumptions of equilibrium, while strictly invalid, have probably been useful for the calculation of gypsum requirements because of low flow rates of percolating solutions and high surface areas of gypsum particles.[10] Models of soil and water flow, e.g., UNSATCHEM[16] which consider equilibrium and kinetic expressions for ion exchange and the dissolution and precipitation of minerals and also ameliorants, may enable more robust calculations of requirements for ameliorants.

Ultimately, the main purpose of reclaiming sodic soils is to obtain the maximum possible improvement of yield of the particular crop in relation to the cost of ameliorant applied. Work in the Australian

sugar industry[17] has established a quantitative relationship between percentage increase in ESP and consequent loss in sugarcane yield. Sugarcane yield decreased by 1.5–2.1 ha^{-1} for every 1% increase in ESP.[17] This relationship forms the basis of a cost–benefit analysis for calculating gypsum application rates from the ESP, the quality of the gypsum used, the quality of irrigation water and economic factors. These include the cost of gypsum and its application, the price for the product (sugarcane) and the discount rate.[18] Clearly there are opportunities for more practical calculations of this kind to be carried out for other crops and in other soil and climatic environments.

Tillage Erosion: Terrace Formation

Seth M. Dabney and
Dalmo A.N. Vieira

Introduction

All tillage moves soil laterally as well as vertically. While a few implements such as a moldboard plow or a one-way disk plow throw soil to only one side, most tillage implements—including tandem disks, chisel plows, harrows, and cultivators—throw soil to both sides. With such implements, a tillage operation along the contour moves some soil uphill, more soil downhill, and still more soil along the contour in the direction of travel.[1–3] Within an undulating field, each tillage operation flattens the topography as soil is progressively removed from convexities and is deposited in depressions and other concavities.

Field boundaries interrupt soil fluxes caused by tillage and can result in the formation of two distinct classes of terraces. On sloping land with untilled strips, tillage moves soil toward a down-gradient untilled strip and away from an up-gradient untilled strip. This leads to aggradation of soil upslope of untilled strips and degradation of soil downslope of them and causes the gradual formation of bench terraces. The speed of bench terrace formation is greater where the spacing between the untilled strips is narrower, where the initial slope is steeper, and where tillage is more intense. The other class of terraces formed at field boundaries is due to local ridges and furrows. Depending on tillage tool design and operation, some soil often leaves the tilled zone in the form of clods deposited along field borders. The combination of clods thrown from the tilled area and dead furrows left behind creates small terrace channels at the margins of tilled areas that can intercept and alter runoff flow patterns. The impact of these small gradient terraces on hydrology is greatest on gently sloping lands. This entry reviews research into terrace formation by tillage, identifies ways in which these terraces can be advantageous to soil and water conservation, and discusses problems that have been recognized with tillage terraces.

Ancient Lynchets

Archeologists use the term "lynchets" to refer to soil banks that are believed to be remnants of ancient agricultural activities. These ancient soil banks have been studied intensively for over 100 years. Lynchets dating from the bronze age, iron age, and medieval periods are all generally recognized to be the morphological response on a hillslope to the presence of field boundaries in cultivated landscapes.[4] While medieval lynchets tend to be oriented along the slope, older "Celtic fields" were often square and bounded by lynchets on all sides,[5] and some lynchets are oriented up and down the slope.[6] Lynchets form at all field boundaries whether bounded by untilled grass strips (balks), hedge rows, paths, fences, or ditches.[6,7] Frequently, lynchets contain piles of stones at their core. These stones may have marked property boundaries or may simply represent convenient disposal locations as stones were removed from fields.

Contemporary Lynchets

Contemporary lynchet formation has been observed and described around the globe.[7–23] The presence of a physical boundary such as field borders, fences, hedge rows, or vegetative barriers creates a local interruption of the soil movement created by tillage, resulting in morphological changes in the vicinity of the boundary. Erosion or deposition occurs depending on the orientation of terrain slopes with respect to the boundary. When the tilled terrain slopes away from the boundary, the net soil translocation in the downhill direction creates erosion near the boundary, while soil deposition occurs where the terrain slopes toward the boundary. Localized erosion also occurs wherever tillage implements first engage the soil, and deposition occurs at locations where tillage tools are removed from the ground and turned around. The aggrading side of a field boundary is often termed a "positive lynchet," while the degrading side (the upslope edge of a tilled area) is termed a "negative lynchet" (Figure 1). Positive lynchets have deeper, more fertile, and more productive soils than those on negative lynchets, where subsoil may be exposed.[12,19,21,22,24]

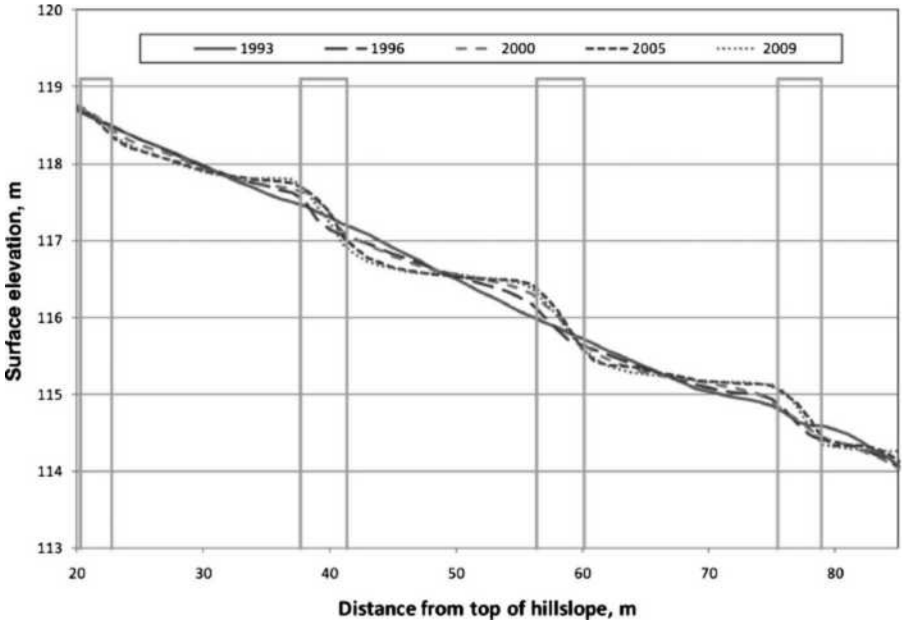

FIGURE 1 Patterns of erosion and deposition created by tillage and water erosion and deposition in a field near Coffeeville, Mississippi, United States. Tillage translocation leads to erosion downslope of each grass hedge, creating the negative lynchets, while deposition due to tillage and water transport reinforces the positive lynchet.

A modern example of lynchet formation is provided by a field subdivided by grass hedges planted on the contour in North Mississippi, United States, that was surveyed periodically over 16 years (Figure 1). Tillage between the hedges led to erosion in the downslope side of each hedge as soil was displaced in the downhill direction by tillage, and the hedges caused deposition of sediment transported by water and tillage on their upslope side. Lynchets developed rapidly once contour tillage with disks and chisel plows began between the grass hedges.[25,26] Changes in elevation reflected the combined influences of tillage and water erosion. At each grass hedge, lynchets of up to 0.8 m formed during a period of 16 years, and the average slope of field was reduced from 7.2%, when the hedges were first established, to 3.7%.[27]

Hand tillage with a hoe differs from that associated with draft animals or tractors because soil usually moves in a direction opposite of the workers' travel. Because hoeing is hard work, it is common for soil to move mainly downhill, with work starting at the bottom of a field and proceeding upslope.[19] Again, the net result is gradual terrace formation.

Soil erosion by water generally increases with increasing slope length because of an accumulation of runoff. This should lead to the development of concave hillslope profiles with little change in elevation near hilltops.[28] In contrast, the quantity of soil moved by tillage is independent of field size and leads to rapid soil loss at upslope field boundaries. Since erosion rates are generally considered in terms of mass per unit area, the amount of soil "eroded" by tillage is much greater on narrow fields than on long slopes.[19,23,29] Thus, the more strips into which a field is divided, the greater the contribution of tillage translocation to terrace formation, and the more rapid terrace formation will be.

Engineered Terraces

Engineered terraces are designed to manage runoff from a certain contributing area. Therefore, when a field is to receive more than one terrace, it is common practice to start at the top of the field and work down so that the bottom terrace does not get overloaded by a storm that might occur before upslope terraces are completed. While specialized equipment such as bulldozers and scrapers are generally used for terrace construction, ordinary farm machinery can also be used to form broad-base terraces,[30] and proper tillage operations are needed as part of routine maintenance to preserve functionality of all terraces.[8]

Bench Terraces

For deep soils, tillage translocation can be used to reduce the cost and increase the farmability of bench terraces. On irregular fields, starting at the bottom of the slope may facilitate efficient development of straight parallel terrace systems. First, a bulldozer pushes up soil from below into a terrace with extra height where it crosses existing gullies.[31,32] A tile outlet near the thalweg drains impounded runoff, leaving sediment trapped in the low area. When the thalweg area is sufficiently filled (up to 5 m of fill in 3 years), further sediment is cut off by construction of the next upslope terrace, parallel to the first. In one case, downhill moldboard plowing between terraces accounted for 50% of the soil moved, reducing a slope from 14% to 4% over a 15 years period. Similar to the natural development of lynchets that occurs when tillage is performed between strips of permanent vegetation, bench terraces can be developed by soil moved by tillage operations. Tillage smoothes the benches, and the vegetation conserves soil and water while benches gradually develop.

A similar process occurs when fields are tilled between parallel vegetated strips, as described with reference to lynchet formation. The vegetation conserves soil and water while benches gradually develop. This process has been formalized by the U.S. Department of Agriculture–National Resources Conservation Service (USDA-NRCS) in the vegetative barrier national conservation practice standard.[33] The vertical interval between vegetated strips should not exceed 2 m, and the planned vegetated back slope should not be steeper than 1 on 2, horizontal to vertical, which is consistent with historical practice.[8]

Gradient Terraces

Gradient terraces are ridge-and-channel systems that reduce erosion by intercepting surface runoff and redirecting it to a stable outlet at reduced velocities. Tillage adjacent to vegetated strips may create small berms that form when soil is thrown beyond the implement width into and against the vegetation and deposited next to it and within it, later coalescing into a stable ridge. If the tillage boundary remains unchanged, subsequent operations increase the berm height until soil cannot be thrown atop the berm. When the vegetated strip deviates from the contour, these tillage induced channels can act as gradient terraces and divert an appreciable fraction of runoff.

A microtopography survey was conducted at 28 locations along the upslope edge of several grass strips in a field with 6%–9% slope steepness,[25] farmed with tandem disks and chisel plows. At every location, asymmetrical triangular channels (Figure 2) formed during 7 years of commercial farming. The hydraulic radius of the smallest channel was 0.04 m. At 0.2% grade and Manning's n = 0.025, this smallest channel could carry 25 mm/hr of runoff from a 15 m–wide cropped strip more than 100 m long. Since the distance between local depressions in the field is usually less than 200 m, these tillage-induced channels could divert most of the fields' runoff to these depressions, where a stable outlet could be provided. Reducing downslope runoff accumulation interrupts slope length and reduces soil erosion by water.

A more detailed study showed that when tillage was conducted with tandem disks and chisel plows immediately adjacent to the vegetation, berms quickly formed along grass hedges planted close to the contour at the bottom of experimental plots with 22.1 m–long, 5% slopes.[27] Four years after tillage adjacent to hedges had begun, berms of triangular shape attained an average height of 0.13 m (Figure 3), forming a shallow channel in the upslope side of the vegetation that diverted runoff. Observations indicated when no soil berm was present, most (>95%) runoff passed through grass hedges planted on 0.3% gradient from a true contour. Once tillage berms were formed, however, runoff from small storms no longer crossed the vegetation but was diverted to flow along the upslope side of the berm and grass hedge. The resulting berms diverted more than 70% of runoff from runoff events less than 10 mm/d and more than 55% for events less than 80 mm/d.[34]

Tillage berms may or may not form, depending on the design and adjustment of tillage tools, which affect how soil is displaced to the sides. When soil is thrown beyond the implement's width, a line of deposition is created; if soil is moved away from the boundary, a dead furrow is formed. The presence of a grass hedge or other fixed boundary ensures that the position of the first pass near the boundary

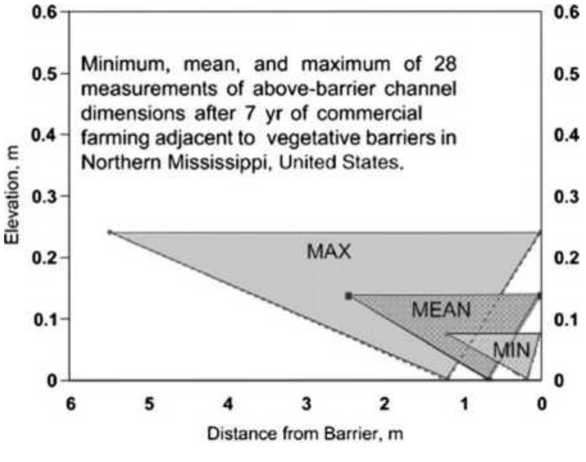

FIGURE 2 Typical channel cross sections observed after several years of tillage with disks and chisel plows. When vegetated strips deviate slightly from the contour, small channels can act as small gradient terraces and divert an appreciable fraction of the runoff.

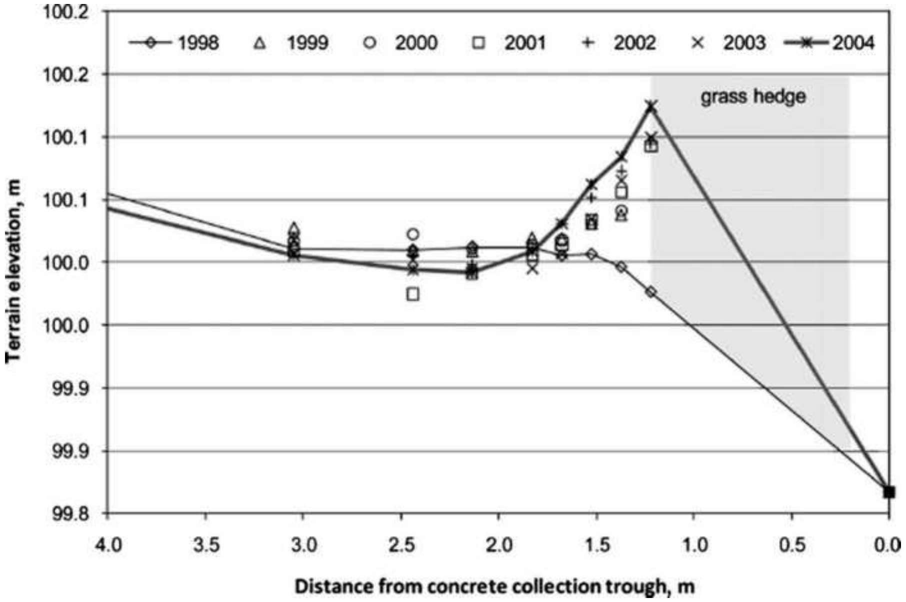

FIGURE 3 Evolution of topography in the lowest 4 m of research plots with grass hedges and an average contributing area steepness of 5%. Chisel and disk tillage was kept a distance away from hedges from 1996 through 2000 and was moved adjacent to the hedges from 2001 through 2004.
Source: Vieira and Dabney.[27]

is maintained, facilitating the formation of berms or furrows. Tillage implement type and speed, slope steepness, and the superposition of sequential tillage operations determine the formation of berms and their dimensions. On flat lands, the creation of dead furrows and ridges associated with the layout of lands used to till the fields makes the tillage patterns clearly visible in light detection and ranging topographic data[35] and can greatly alter surface hydrology.

Terrace Benefits and Problems

Bench terraces facilitate contour farming operations. On very steep slopes, mechanical cultivating is difficult, and contour plowing can be dangerous due to the risk of overturning. The formation of bench terraces reduces the slope steepness and therefore makes contour tillage easier and safer. When tractor or animal power is limited, it may be easier to plow or hoe downhill.[11,29] However, when sufficient power is available, it is most efficient to plow on the contour because a uniform load can be matched to a tractor or team of animals.

Contour tillage reduces runoff and soil erosion, thereby conserving plant nutrients and making more water available to grow crops.[36] On the other hand, large fertility differences can develop between the negative and positive lynchets.[12,19,24] This reduces uniformity of crop growth where fertilizer and liming amendments are not available. In these situations, farmers often cut soil from the terrace back slope and distribute it on the degraded negative lynchet. If the upper field is owned by a different landowner, an entire terrace may be undermined in this fashion.[12] Manuring, fertilization with seaweed, and liming with marl were ancient responses to similar problems.[37]

While tillage berms acting as gradient terraces can improve soil conservation where runoff is diverted to a stable outlet, they can have negative consequences on the effectiveness of some conservation practices. For example, if berms keep a significant fraction of runoff water from entering a grassed waterway, erosion on the margin of the waterway may be increased. Tillage berms may keep water from entering a vegetated filter strip on very flat fields (Figure 4), which may preclude the filter from improving water

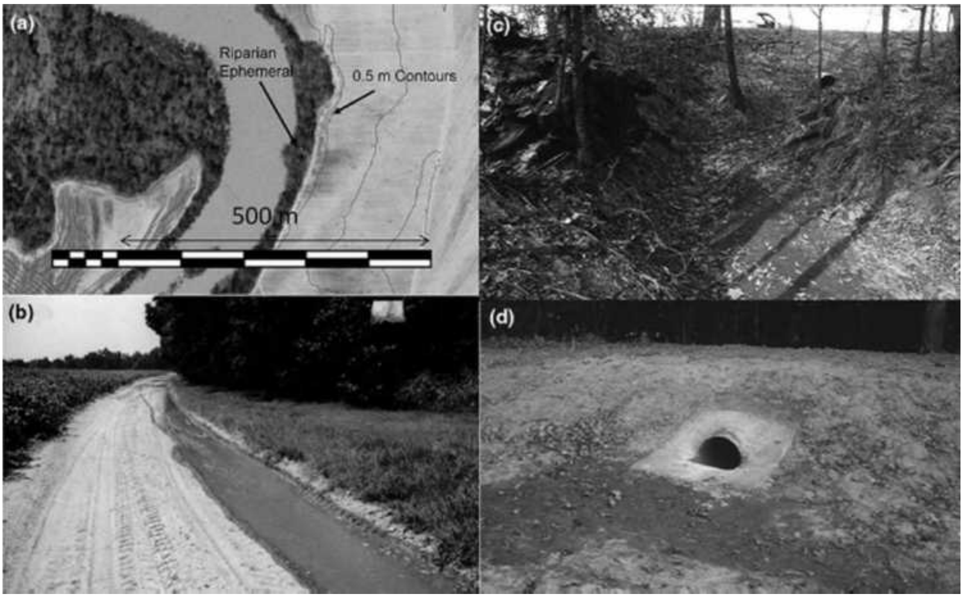

FIGURE 4 Runoff reaching (a) a filter strip/riparian forest buffer surrounding an oxbow lake in the Mississippi Delta was (b) redirected by a small tillage berm to (a and c) a riparian ephemeral flow channel. Storm flow through this channel was controlled by (c and d) a slotted inlet pipe and associated earthen pad, which created backwaters that allowed the riparian buffer to function (**Source:** Dabney, Moore, and Locke.[38])

quality from small runoff flows. This problem is the main reason why the USDA-NRCS restricts the establishment of filter strips to fields with an upslope contributing area steepness greater than 1%.[39] Tillage berms are also implicitly recognized in the USDA-NRCS contour buffer strip standard[40] that states, “If sediment accumulates just below the upslope edge of the buffer strip to a depth of 6 inches or more … relocate the buffer/cropped strip interface location.”

Conclusions

Tillage erosion has come to be recognized as an important contributor to the evolution of agricultural landscapes and, in some cases, the degradation of soil resources. With each tillage operation, a tilled area becomes flatter, and some soil leaves the tilled zone in the form of clods deposited along field borders. Over time, these clods, along with stones removed from the tilled area and sediment deposited by runoff, coalesce to form terraces or lynchets. If a field is divided into several tilled strips, then the consequence will be the gradual development of bench terraces, unless the untilled areas are periodically relocated. Also, tillage-induced berms located at the upslope edge of the untilled areas may act as small gradient terraces that alter runoff flow patterns. On flat lands, tillage berms may dominate surface drainage patterns. The formation of such bench and gradient terraces due to agricultural tillage operations may or may not be desirable but can hardly be avoided if field boundaries on sloping lands are fixed for long periods of time.

Erosion by Wind-Driven Rain

Gunay Erpul, L. Darrell Norton and Donald Gabriels

Introduction

Wind-driven rain can be described as raindrops falling through a wind field at an angle different from the vertical under the effects of both gravitational and drag forces. Schematic representation of wind-driven rain incidental to a sloping soil surface is given in Figure 1.

A study of wind-driven rain erosion is an attempt to investigate the combined effect of wind and rain on soil erosion processes in situations where wind and rain occur at the same time.

Effects of Wind on Physical Characteristics of Rains

Raindrop Size Distribution

In the assessment of the distribution of small-simulated raindrops in a wind tunnel, Erpul, Gabriels, and Janssens[1] obtained a narrower raindrop distribution and observed a distinct increase in mean drop diameter under wind-driven rain compared to windless rain. Collisions between small drops occurred more frequently as a result of their greater number per unit volume in air leading to an increase in mean drop size. For large drops, however, this would not occur, as large drops are less stable and the wind caused some of them to break up into smaller drops.[2,3] Basically, the effect of wind on raindrop size distributions is a potentially important effect that needs to be considered when estimating the rainfall erosivity.

Raindrop Impact Energy

Wind-driven raindrops gain some degree of horizontal velocity, which increases their resultant impact velocity. The kinetic energy load of the rainfall may be expected to change as a result of increased velocity and the altered size of the raindrops. The exponential relationship between the horizontal wind

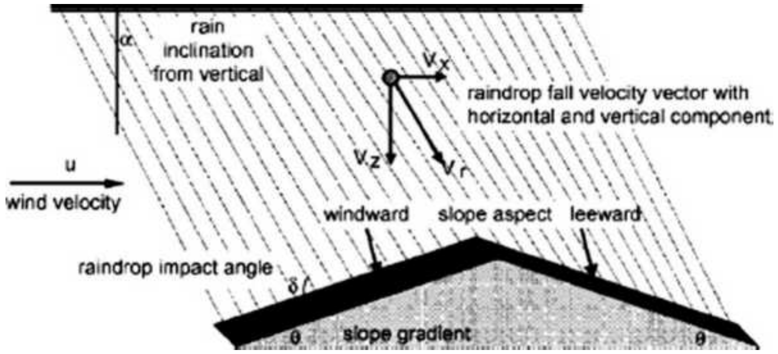

FIGURE 1 Schematic representation of wind-driven rain with an angle from vertical and incident on sloping soil surface.

velocity and the kinetic energy of raindrops was found in natural rains.[4] The effect of the wind on the horizontal component of small raindrops would be greater, so a greater percentage increase in kinetic energy would be expected for small raindrops than large raindrops.[5]

Raindrop Impact Angle

Wind-driven raindrops strike the soil surface with an angle deviated from the vertical because of their horizontal and vertical velocities. This inclination depends on the magnitude of wind velocity. In mid-latitudes rain mostly falls at considerable inclination from the vertical, and resultant angles of 40–70° have been found in rains driven by wind velocity of 10 m/s.[6] Gabriels et al.[7] reported that the mean angles of rain inclination were 52°, 66°, and 67° for the simulated rains in a wind tunnel driven by 6, 10, and 12 m/s of wind velocities, respectively. For these rains, a median drop size was approximately 1.50 mm. Little is known about the physical impact of raindrops on a soil in situations where this impact is not vertical. It is also not known if inclined raindrops have stronger erosive effects than vertical ones. The extent and magnitude of the rain-splash detachment increased as the angle of deviation increased within the range of 5–30°;[8] whereas, with greater deviations, the impact angle could be so small that raindrops would hardly hit the soil surface. Especially when impact angles were less than 30°, the rain-splash detachment rate decreased greatly (Table 1).

Raindrop Impact Frequency

The distribution and the intensity of rain on sloping surfaces differ depending on wind direction and velocity. In fact, the angle of rain incidence ($\boldsymbol{\pi}$), which is a function of rain inclination ($\boldsymbol{\alpha}$), slope gradient ($\boldsymbol{\theta}$), and slope aspect, determines the rain intensity in wind-driven rains. As an example, a windward facing slope can receive two times more rain intensity than a leeward facing slope, or even exceed it in extreme cases for rain inclinations of 40–70°.[6] When the rain inclination and the slope gradient increase, the discrepancies in the rain intensity between wind slope and leeward slope become greater (Table 1).

Effects of Wind on Rainsplash Detachment and Transport

Rainsplash Detachment

Similar to effects on rain characteristics, wind movement and velocities can have a profound effect on some aspects of the soil erosion process. When wind accompanies rain, rainsplash detachment tends to increase owing to the increased energy of raindrops. Pedersen and Hasholt[4] obtained a better

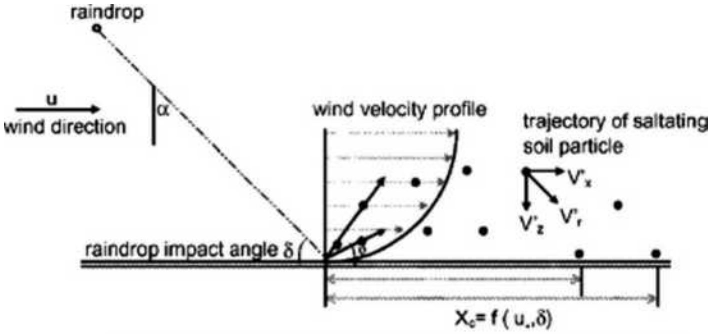
u, horizontal wind velocity; KE, kinetic energy [the exponential relationship found between KE and u is $E(u) = 1.9723\ e^{0.1796u}$ (the relationship between columns 1 and 2)]; α, rain inclination from vertical; *θ*, slope gradient; π, angle of rain incidence calculated using rain inclination, slope gradient, and slope aspect by cosine law: $\cos(\pi) = \cos(\alpha - \theta) = \cos \alpha \cos \theta + \sin \alpha \sin \theta$ for windward slopes and $\cos(\pi) = \cos(\alpha + \theta) = \cos \alpha \cos \theta - \sin \alpha \sin \theta$ for leeward slopes; I, rain intensity; *D*, rainsplash detachment rate; X_c, mean rainsplash distance calculated by center of gravity of mass distribution curves; qs, rainsplash transport estimated by $q_s = DX_c$.

correlation between the rainsplash detachment and erosivity indexes, when wind velocity was taken into account in the kinetic energy calculation. However, the wind not only increased the raindrop impact energy but also altered the angle of rain incidence, resulting in the variations in the raindrop impact frequency and the raindrop impact angle. In other words, raindrop impact energy, impact frequency, and impact angle determine the magnitude of rainsplash detachment under wind-driven rainfall. The influence of each factor on the process is not exclusive and not clearly distinguished, because all are closely related and each factor is a function of the wind speed. The highest rainsplash rate occurred with the highest impact frequency and the highest impact angle at a given raindrop impact energy under wind-driven rains (Table 1).

Rainsplash Transport

Wind, as well as slope and overland flow, is another possible factor capable of transporting detached particles by raindrop impact. It is possible to find similarities between the movement and trajectory of sand saltation by wind and the movement and trajectory of soil particles by rainsplash under wind-driven rainfall. In saltation, the hitting sand grains, once ejected, initiate the motion of uplift,[9] whereas hitting raindrops on the soil surface with an angle initiate a jumping movement of soil particles in wind-driven rainfall.[10] A threshold is given by impacting raindrops, and wind does not account for the upward movement except that it changes energy, frequency, and angle of raindrop impact. Once soil particles are entrained in the splash droplets that have risen into the air by raindrop impact, wind velocity gradient will transport these particles. It is found that, together with wind velocity gradient, the impact angle is also playing a significant role in determining the extent of the process. At the same wind speed, longer mean rainsplash distances (X_c) were observed as the impact angle became greater (Table 1). There was a very discernible decrease in X_c in leeward slopes, which was mostly associated with the impact angles of less than 30°. These results showed that the raindrop impact angle might determine the soil particle ejection angle.

As mentioned above, the amount of soil particles to be transported by the wind will depend upon the raindrop impact energy, impact frequency, and impact angle. Subsequently, the soil particle ejection angle and the wind velocity gradient will determine the extent of the process (Figure 2).



V'_x: the horizontal component of the ejected soil particle velocity;
V'_z: the vertical component of the ejected soil particle velocity;
V'_r: resultant fall velocity of the ejected soil particle;
φ: soil particle ejection angle;
X_c: mean rainplash distance;
u_*: wind shear velocity;

FIGURE 2 Rainsplash transport: raindrop-induced and wind-driven splash trajectories of soil particles falling through a wind profile.

Conclusions

Wind could make significant changes in physical characteristics of rains and hence in soil erosion processes. The rainsplash detachment and transport under wind-driven rainfall would differ from that under windless rain. The rainsplash transport could be a significant process to the extent that it may not be negligible in accurately predicting water erosion, and this process could result in a net transportation in the prevailing wind direction.

Organic Matter: Global Distribution in World Ecosystems

Wilfred M. Post

Introduction

Globally, the amount of organic matter in soils, commonly represented by the mass of carbon, is estimated to be 1200–1500 Pg C (1 Pg C = 10^{15} g carbon) in the top 1 m of soil.[1,2] This is 2–3 times larger than the amount of organic matter in living organisms in all terrestrial ecosystems.[1] The exact ratio between living and dead organic matter in terrestrial ecosystems varies, depending on the ecosystem. The amount of carbon stored in soil is determined by the balance of two biotic processes—the productivity of terrestrial vegetation and the decomposition of organic matter. Each of these processes has strong physical and biological controlling factors. These include climate; soil chemical, physical, and biological properties; and vegetation composition. Interactions among these controlling factors are of particular importance. These biological and physical factors are the same as the ones that influence the above ground structure and composition of terrestrial ecosystems, so there are strong correspondences between soil organic matter content and ecosystem type.

Organic Matter Inputs

Quantity

The amount of carbon stored in soils is to a great extent determined by the rate of organic matter input through litterfall, root exudates, and root turnover. The main factors that influence vegetation production are suitable temperatures for photosynthesis, available soil moisture for evapotranspiration, and rates of CO_2 and H_2O exchange. Dry and/or cold climates support low vegetation production rates

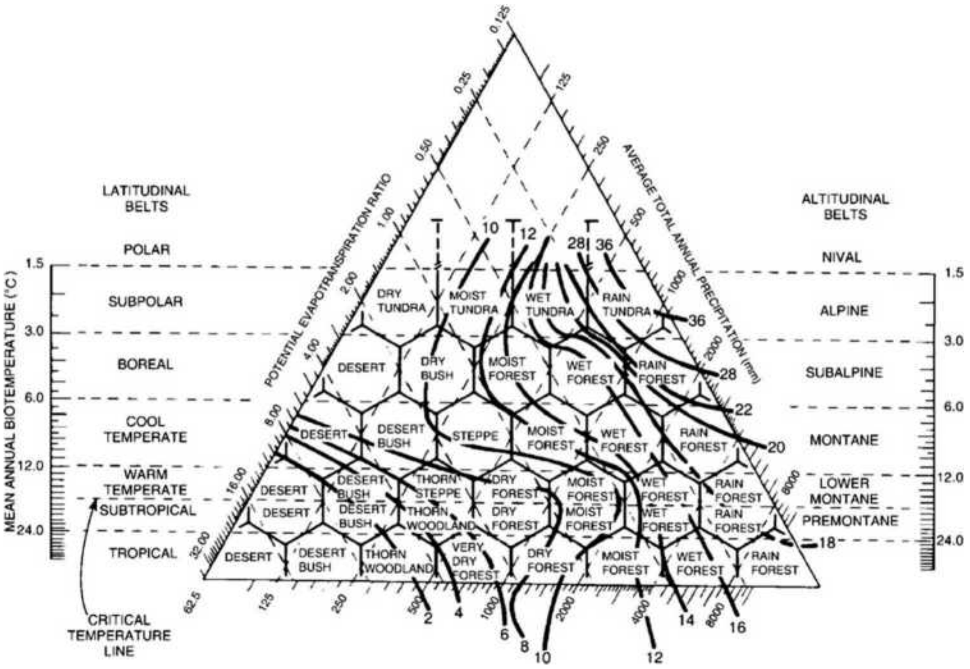

FIGURE 1 Contours of soil carbon density (kg m^{-2}) plotted on Holdridge diagram[3] for world life-zone classification. Values of biotemperature and precipitation uniquely determine a life zone and associated vegetation. Contour lines for mean soil carbon content in the surface meter of soil are determined from data derived from over 3000 soil profiles.[4,5]

and soils under such climates have low organic matter contents. Where climates are warm and moist, vegetation production is high and soil organic matter contents are correspondingly high. Figure 1 shows the striking correspondence between soil organic matter content and general climate measurements that results from the relationship between vegetation production and suitable moisture and temperature conditions.

Vegetation production depends not only on climate but also on nutrient supply from decomposition and geochemical weathering. Walker and Adams[6] hypothesized that the level of available phosphorus during the course of soil development is the primary determinant of terrestrial net primary production. Numerous workers have examined this hypothesis. Tiessen, Stewart, and Cole[7] and Roberts, Stewart, and Bettany[8] found that available phosphorus explained about one-fourth of the variance in soil organic matter in many different soil orders. The relationship between phosphorus and carbon is strongest during the aggrading stage of vegetation–soil system development.[9] Initially, the production of acidic products by pioneer vegetation promotes the release of phosphorus by weathering of parent material. Organic matter builds up in the soil, increasing the storage of phosphorus in decomposing organic compounds. Nitrogen fixing bacteria populations, which depend on a supply of organic carbon and available phosphorus, can grow to meet ecosystem demands for nitrogen. Plant growth is enhanced by this increasing nitrogen and phosphorus cycling, resulting in increased rates of weathering. This process continues until the vegetation is constrained by other factors affecting phosphorus availability: Leaching losses become larger than the weathering inputs;[10] or an increasing fraction of the phosphorus becomes unavailable by adsorption or precipitation with secondary minerals;[11] or nitrogen availability (denitrification or leaching is affected) reaching or exceeding nitrogen inputs and fixation.[12] In mature soils, net primary production is more likely to be limited by nitrogen. Availability of other nutrients that are largely derived from parent materials, such as most base cations, may also influence soil organic matter accumulation during early soil development.[13] Soils derived from base cation rich volcanic parent materials (Andisols) have much higher carbon contents on average than soils from other parent materials.[4]

Species Composition

Biotic factors, in particular plant species composition, also affect soil organic matter dynamics. Production and decomposition rates are to some degree controlled by species composition. Each terrestrial plant species produces different amounts and chemical compositions of leaves, roots, branches, and wood of varying decomposability. This range of decomposability may be summarized by the lignin and nitrogen content of the organic material.[14,15] Litter decay rate is inversely related to C : N and lignin: N ratios and positively related to N content. Species with tissues that have low nutrient or high lignin content produce litter that is slow to decay. Nitrogen is made available to plants during the decomposition process. Nitrogen is a limiting element for productivity in most terrestrial ecosystems so the rate at which it is released during decomposition is an important factor in ecosystem production. Thus, the interactions between processes regulating plant populations and their productivity and microbial processes regulating nitrogen availability result in some of the observed variation in soil carbon and nitrogen storage.[16–19]

Placement

The deeper that fresh detritus is placed in the soil, the slower it decomposes. This is a result of declining decomposer activity and increased protection from oxidation with depth in the soil. Prairies have a somewhat lower productivity than forests and produce no slowly decomposing woody material. Nevertheless, prairies have a very high soil organic matter content because prairie grasses allocate twice as much production to belowground roots and tillers than to aboveground leaves.[20] The result is high soil organic matter contents with a uniform distribution in the upper 1 m of soil (Figure 2). In contrast, a spruce-fir forest contains 50 percent of its soil organic matter in the top 10 cm. There are interesting exceptions to the rule that above-/belowground plant allocation determines soil organic matter distribution patterns in soil. Tropical moist forest soils show a uniform depth distribution similar to the depth distribution of temperate grasslands, however, in tropical forests this is largely due to a long-term accumulation of recalcitrant organic materials at lower depths in the soil rather than increased allocation to roots. Alpine tundra soils support a largely herbaceous flora but show a similar depth distribution as forest soils because of inhibition of surface litter decomposition by low temperatures and high water saturation.

Decomposition

Climate

Organic matter decay rates can be related to environmental parameters such as temperature and soil moisture. Climatic indices that correlate well with decay rates include plant moisture and temperature indices,[21,22] linear combinations of temperature and rainfall,[23] and actual evapotranspiration.[15] Warm temperatures and available soil moisture enhance microbial, and micro-and macro-invertebrate activity. These environmental conditions are also correlated with plant production. As a result, the amount of organic matter present in soil is highest in vegetation types with the highest rates of organic matter production. These are ones found in the warm, moist climate regions. The contours of soil carbon density displayed in Figure 1 reflect the balance of input by vegetation production and loss from decomposition imposed by climate. Soil carbon content increases from lower left to the upper right in Figure 1 as the temperature decreases in the cool temperate, boreal, and sub-polar life zones and as precipitation increases in the warm temperate, subtropical, and tropical life zones.

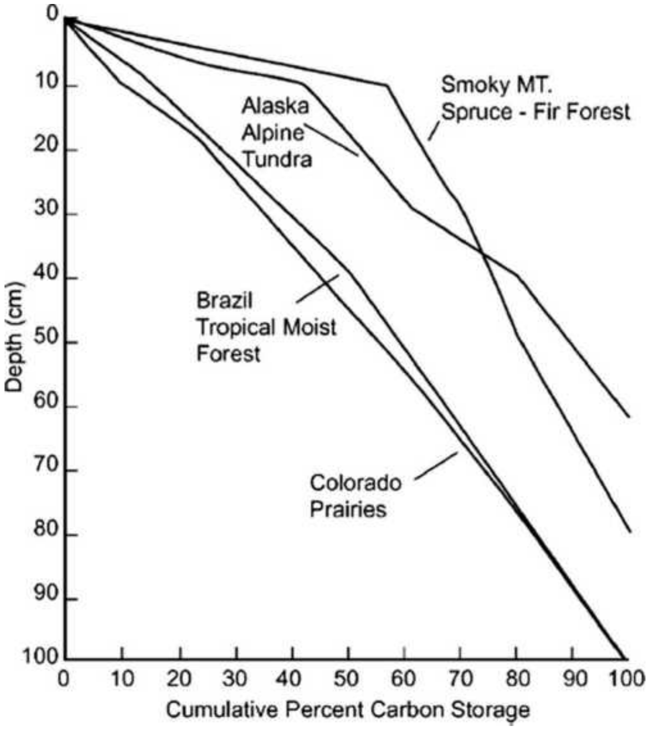

FIGURE 2 Cumulative carbon storage as a function of depth for four ecosystems. Refer text for explanation of these patterns.
Source: Zinke et al.[4]

The combined influence of temperature and precipitation is presented by the third axis of the Holdridge diagram (Figure 1) as the ratio of potential evapotranspiration (PET) to annual precipitation. When this ratio is less than 1.0, rainfall exceeds PET and vice versa. Life zones bordering the line with the PET is equal to precipitation (PET ratio = 1.0) have soil carbon contents around 10 kg m^{-2} except in warm temperate and subtropical zones where strong seasonality limits production, but decomposition conditions are favorable for most of the year. Soil carbon content increases as the PET ratio decreases indicating that productivity increases faster than the rate of decomposition with increasing moisture availability.

Organic Matter Quality

On global scale, climate may be the most important factor controlling decay rates, but within a given region, substrate chemistry is the more important factor.[15,24,25] Decay rate is often negatively related to substrate C : N ratio. Litter C : N is initially much greater than microbial C : N but approaches microbial C : N as the microbes release the carbon as CO2 while taking up nitrogen (nitrogen immobilization). The further the initial litter C : N is from microbial C : N, the slower the decay rate. Lignin content or lignin: N ratios may be better predictors of decay rates because lignin itself is difficult to decompose, and it shields nitrogen and other more easily degraded chemical fractions from microbes. Concise and simple models of decay rate are based on a combination of chemical and climatic indices.

The effect of litter quality on soil organic matter content is most dramatically expressed in Podzols (Spodosol in the United States Department of Agriculture classification). These occur over large areas in boreal zones dominated by evergreen conifers, but often occur in other regions on shallow or sandy soils. Low nitrogen content of organic matter inputs and cool temperatures reduce decomposition and soil animal activity. As a result, large surface organic matter accumulations occur over a thin A horizon. Low temperatures combined with leaching of organic acids result in podsolization as the predominant soil-forming process. Leaching of iron, aluminum oxides, and organic matter result in a distinct E horizon near the surface where these materials are removed and deposited in the B horizon. If the surface organic layers are included, these soils can have substantial organic matter contents, exceeding the expected amount for the climate conditions. Batjes[2] gives an average value for Podzols of 24.2 kg m^{-2} for the surface meter which is considerably above the mean for most other soil types (see Table 1).

Significant Physical and Chemical Influences

There are several notable exceptions to the climate-based explanation of variation in soil carbon content. There are two in particular that have lower rates of decomposition and therefore higher accumulations of organic matter than expected (Table 1). These include Histosols due to hydrological conditions and Andisols due to parent material chemical effects.

TABLE 1 Mean Organic Carbon Contents (kg m^{-2}) by FAO–UNESCO Soil Units to 1 m Depth

Soil Unit	Mean C (kg m^{-2})
Acrisols	9.4
Cambisols	9.6
Chernozems	12.5
Podzoluvisols	7.3
Ferrasols	10.7
Gleysols	13.1
Phaeozems	14.6
Fluvisols	9.3
Kastanozems	9.6
Luvisols	6.5
Greyzems	19.7
Nitosols	8.4
Histosols	77.6
Podzols	24.2
Arenosols	3.1
Regosols	5.0
Solonetz	6.2
Andisols	25.4
Vertisols	11.1
Planosols	7.7
Xerosols	4.8
Yermosols	3.0
Solochaks	4.2

These soil units generally span a wide range of climate conditions and therefore present a different view of soil organic matter content based on additional soil factors. In particular, the high C content of Podzols, Histosols, and Andisols is apparent. Refer text for additional explanation of biological, chemical and physical factors responsible.

Source: Batjes.[2]

Histosols

In landscape positions where water accumulates at or above the surface of the soil for an appreciable part of the growing season, decomposition can be reduced to such an extent that large amounts of undecomposed organic matter can accumulate. This soil type is called a Histosol and can be found in any region in wetlands where decomposition is restricted. The soil-surface of mature or old-growth boreal forests over shallow water tables are often covered with *Sphagnum* moss which may also lead to development of Histosols. Histosols with the largest areas and thickest accumulations occur in lowland tundra where a mixture of sedges, lichens, and mosses grow at the northern limit of vegetation in the northern hemisphere. Production, decomposition, and evaporation are limited by low temperatures and water-saturated soils. In these cold regions, deeper layers may freeze and not become thawed during the short growing season (permafrost). As a result, Histosols have carbon contents over 70 kg m^{-2} in the surface meter (Table 1). Some regions have been accumulating organic matter since the last glacial period without any substantial decomposition. Histosols in such regions may be several meters thick and contain over 250 kg C m^{-2}.[2] Globally it is estimated that boreal and sub-arctic Histosols contain 455 PgC that has accumulated during the postglacial period.[26]

Andisols

Andisols form on young volcanic stone (basalt lava) rich in nutrients and alkaline. Andisols are weakly weathered soils associated with pyroclastic parent materials that are rich in allophane, ferrihydrite, and other minerals that readily form complexes with humus molecules. These chemical constituents provide conditions promoting high vegetation production and also the retention of organic matter in soil. As a result, Andisols typically have higher soil carbon contents (25.4 kg m^{-2}, Table 1) than soils with the same environmental conditions but different parent materials.

Conclusions

Over long periods of time, organic matter in soils is the result of climatic, biological, and geological factors. These factors are not independent. In particular there exists a strong relationship between climate and vegetation type. In Figure 1, the Holdridge climate based life zones have names that depict the dominant vegetation of climates. Jobbágy and Jackson[27] provide a summary of soil data based on biomes that demonstrates similar soil carbon distribution as that based on climate (Table 2).

TABLE 2 Mean Organic Carbon Content (kg m^{-2}) by Biome to 1 m Depth

Biome	Mean C (kg m^{-2})
Boreal forest	9.3
Crops	11.2
Deserts	6.2
Sclerophyllous shrubs	8.9
Temperate deciduous forest	17.4
Temperate evergreen forest	14.5
Temperate grassland	11.7
Tropical deciduous forest	15.8
Tropical evergreen forest	18.6
Tropical grassland/savanna	13.2
Tundra	14.2

Note: Biome classification is based on Whittaker.[28]

Source: Jobbágy and Jackson.[27]

Over shorter periods of time soil carbon varies with vegetation disturbances and changes in land use patterns that affect rates of organic matter input and its decomposition. Various land uses result in very rapid declines in soil organic matter from the native condition.[29–32] Losses of 50% in the top 20 cm and 30% for the surface 100 cm are average. Much of this loss in soil organic carbon can be attributed to erosion, reduced inputs of organic matter, increased decomposability of crop residues, and tillage effects that decrease the amount of physical protection to decomposition. Evidence from long-term experiments suggest that C losses due to oxidation and erosion can be reversed with soil management practices that minimize soil disturbance and optimize plant yield through fertilization. These experimental results are believed to apply to large regions and that organic matter is being restored as a result of establishment of perennial vegetation, increased adoption of conservation tillage methods, efficient use of fertilizers, and increased use of high yielding crop varieties.[33,34] Additionally, when agricultural land is no longer used for cultivation and allowed to revert to natural vegetation or replanted to perennial vegetation, soil organic carbon can accumulate by processes that essentially reversing some of the effects responsible for soil organic carbon losses initially—from when the land was converted from perennial vegetation—and return them to typical amounts for the climate, vegetation, landscape position, and parent material conditions.[35,36]

Permafrost

Douglas Kane
and Julia Boike

Introduction

On an extended south-to-north transect at northern latitudes, a transition from ground that never experiences seasonal freezing, to those that occasionally freeze during the winter, to those that freeze every year, to those that may remain frozen for an extended time could be encountered. The topic of discussion here is those surface soils and deeper geologic layers that remain at or below freezing for a duration of two years or more and how they impact people living in this environment. Such frozen ground, both unconsolidated and bedrock, are commonly referred to as permafrost.[1] Although at or below the freezing point of bulk water (0°C), the term "permafrost" neither implies that water is present or that water, if present, is frozen. In fact, it is possible for significant amounts of water to remain unfrozen in permafrost; this is also true for water in seasonal frost.

Permafrost Characteristics

Spatially extensive permafrost can be found in Russia and Canada as far south as 45°N, and even farther south on the elevated Tibetan Plateau and Himalayan Mountains.[2] Approximately 25 million km^2 of permafrost exist in the northern hemisphere. In the higher latitudes, permafrost is continuous under the land surfaces. At intermediate latitudes permafrost is discontinuous or sporadic. Legget[3] reported that 20% of the land surface of the world is underlain by permafrost. More than 50% of Russia and Canada are underlain by permafrost. Alaska has continuous permafrost in the northern 1/3 of the state and discontinuous permafrost in the rest of the state, excluding the coastal areas from the Aleutian Islands to southeastern Alaska (Figure 1). In the southern hemisphere, permafrost distribution is confined to Antarctica and high alpine or mountainous regions. Isolated permafrost is common at higher elevations, and evidence of past permafrost is common in areas that no longer have permafrost. The thickness of permafrost can vary from a thin lens of less than 1 m to greater than 1000 m (Figure 1). Permafrost can also be found in coastal areas at the bottom of seas.

Permafrost ground is interesting to the engineer and scientist because the medium is usually composed of two solids (porous medium and ice) and two fluids (air and liquid water). The more components that are present in a mixture, the more difficult it is to predict the medium's response to an input of energy or mass. The amount of unfrozen water in saturated ground is strictly a function of the grain

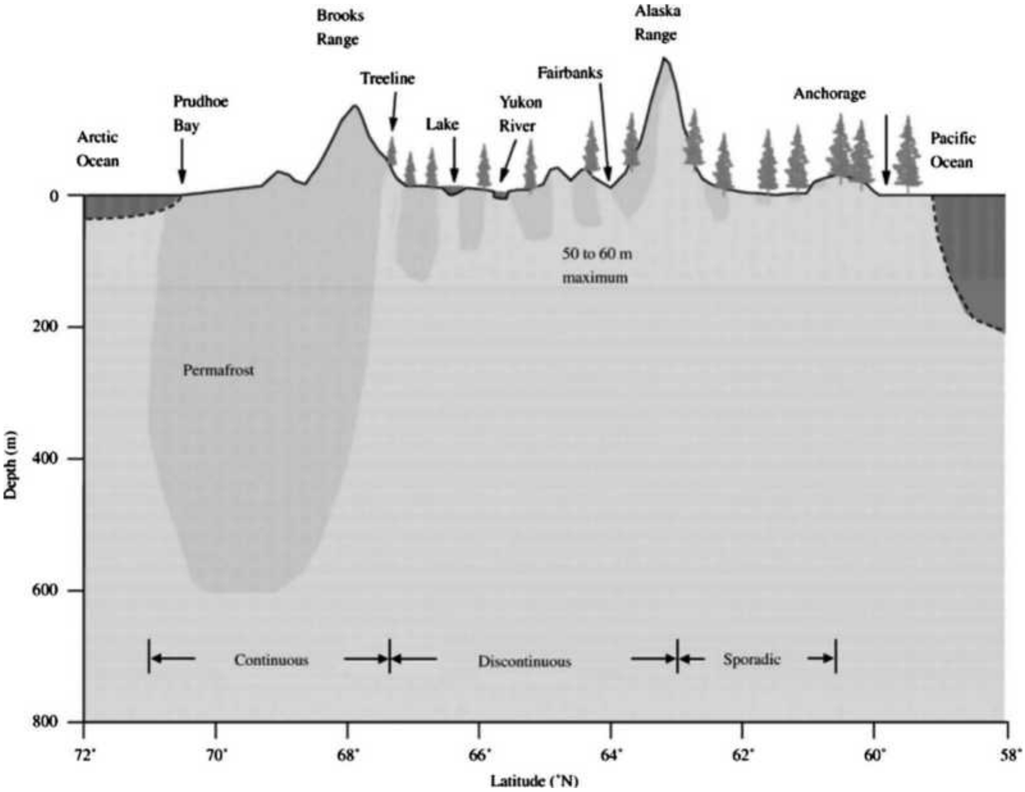

FIGURE 1 Schematic of permafrost distribution in Alaska on a south-to-north transect.

size (more specifically surface area) and the freezing temperature. A fine-grained soil such as clay has a very high surface area relative to coarse-grained soils such as sand; in frozen ground, this translates into much higher unfrozen water contents at the same temperature. The unfrozen water found in permafrost exists as a film of water around each soil particle. It is via these unfrozen films that water moves in permafrost. Frozen clay can have as much as 5%–7% unfrozen water by volume at –15°C. As the temperature decreases the amount of unfrozen water also decreases. Thermal and hydraulic properties of permafrost are quite variable and depend upon the percentages of the various ground components. Most heat transfer in permafrost is by conduction and can be modeled by Fourier's law, although simpler methods have been developed.

A typical temperature profile of permafrost appears in F2. Since there is a geothermal flux outward from the center of the earth, this heat has to be successfully transferred to the ground surface or the permafrost will warm and melt. In order to maintain the thermal integrity of the permafrost, the soils above the top of the permafrost table must completely freeze during the winter so there is a continuously decreasing thermal gradient along which the geothermal heat can be transferred to the surface by conduction (Figure 2).

The seasonally thawed soil layer at the ground surface that goes through freezing/thawing annually and mantles the permafrost is called the active layer (Figure 2). This layer acts as a buffer to heat and mass transfer to the permafrost. A typical active layer in the continuous permafrost zone would typically thaw to a maximum depth of 60 cm. The top 15–25 cm of these soils are generally composed of organic material, with the deeper soils being mineral. Organic soils are good thermal insulators and, when coupled with snow cover during the winter months, they minimize heat loss from the ground. The thermal balance of the permanently frozen ground is maintained by heat loss to the atmosphere that occurs at high latitudes over the extended winter months.

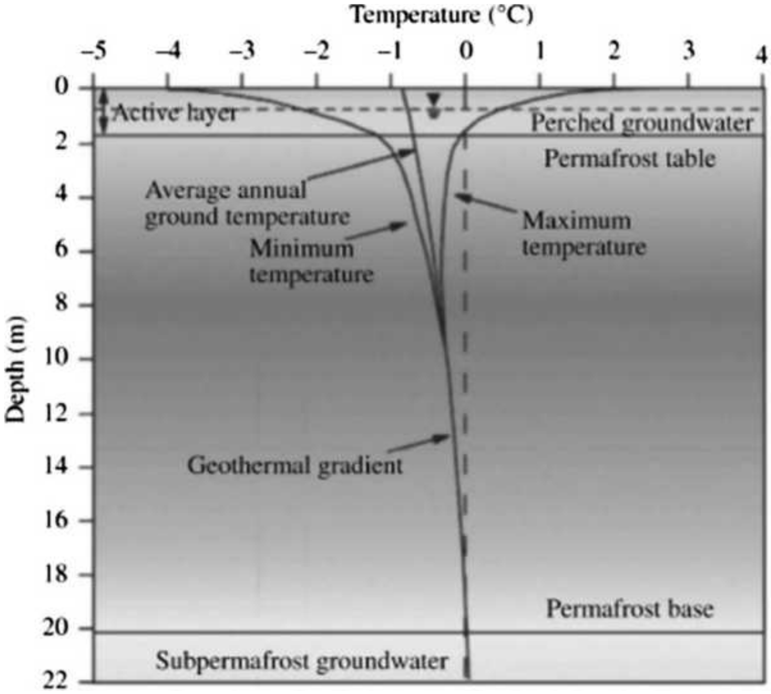

FIGURE 2 Typical temperature profile for permafrost, with annual variation indicated near the ground surface.

Permafrost is usually considered to be impermeable to water movement. This is usually a good assumption for short durations of days or even a few months. For longer periods of time, the redistribution of water within permafrost can be appreciable. During snowmelt and major rainfall events, considerable water enters the active layer. Most of this water resides in the organic soils as the mineral soils are usually already near saturation. Since permafrost has relatively low hydraulic conductivity, there is no hydraulic connection between the perched water above the permafrost (suprapermafrost groundwater) and the subpermafrost groundwater below the permafrost (Figure 2). In continuous permafrost, the subsurface hydrology is confined to the active layer. For areas of discontinuous permafrost, the subsurface hydrology is a combination of shallow flow over the frozen ground and deeper flow around and under it.

Surface Energy Balance

Any time the ground surface is disturbed, the surface energy balance that sustains permafrost is upset. This generally results in warming of the permafrost and thickening of the active layer. Much sporadic and discontinuous permafrost is maintained at temperatures just below freezing; climatic warming of just a few degrees would result in the melting of this frozen ground and warming of colder permafrost. Also where permafrost exists, surface disturbances such as removing vegetation or surface soils and ponding of water are sufficient to alter the surface energy balance and cause permafrost degradation. Permafrost generally appears where the mean annual surface temperature is at least a few degrees Celsius below freezing; for instance, Hay River, NWT, Canada has sporadic, shallow permafrost with a mean annual temperature of –3.4°C.

In areas of discontinuous permafrost, the south-facing slopes are generally permafrost-free (Figure 1) while north-facing slopes have permafrost; the east- and west-facing slopes and valley bottoms may or may not have permafrost, depending upon subtle site-specific conditions that impact the energy balance (vegetation, slope, moisture content, etc.). Because it took thousands of years for permafrost to develop, deep permafrost is a particularly good recorder of past climates, and changes in the temperature profile will reflect these impacts. Many general atmospheric circulation models (GCM) predict variable global warming in the high latitudes, and in some areas there is already field evidence of atmospheric warming[4] and permafrost warming.[5] To sustain permafrost, the geothermal heat radiating out from the core of the earth must be removed; this only occurs if the active layer is completely frozen during winter.

Living with Permafrost

Permafrost influences many facets of everyday living that are often taken for granted in warmer climates. Permafrost negatively impacts both the quality and quantity of the available groundwater and limits the potential for infiltration of wastewater. As a result, housing units with individual water and wastewater systems must be designed with innovative options to replace the traditional groundwater well and septic system for wastewater treatment. Utilities that are typically buried are often placed in aboveground utilidors. Also as roadways age, they become very bumpy as differential movement of the road surface occurs.

The significant property of permafrost from an engineering viewpoint is the ice content. The amount of ice can range from essentially none in well-drained ground to values that exceed the porosity of poorly drained ground. Within the permafrost, segregated ice with minimal entrained soil exists as ice lenses and wedges. As long as the permafrost stays frozen, the ground is relatively stable. However, thawing of ice-rich permafrost causes ground to settle or subside. This thaw settlement compromises the structural integrity of buildings, roadways, pipelines, and other structures built on it. For areas where construction must take place on frozen ground, special efforts—for example the use of insulation and thermosyphons—are necessary to maintain the structural integrity of the permafrost. Thermosyphons are vertical devices for removing heat from the ground, and they are used extensively under buildings and pipelines to maintain below freezing conditions in the ground.

Soil freezing causes additional engineering problems near the ground surface when strong thermal gradients induce water movement from warm ground to cold ground through unfrozen films of water on the surfaces of soil particles, regardless of whether it is frozen or not. This process causes "frost heave," as it results in an accumulation of ice in the form of lenses that can cause the ground to expand and deform. Surface heaving becomes significant over time periods of several years, and it is important for those engineering structures with design lives of tens of years to compensate for this additional stress.

Conclusions

Permafrost and seasonally frozen ground are very extensive in the high latitudes of Earth. Also, resource development and population in these areas is increasing. Initial efforts directed at building an infrastructure (roads, airports, water and sewer distribution, etc.), on permafrost assumed that the frozen ground was in thermal equilibrium. It is now obvious that because of climatic change that the permafrost is not in thermal equilibrium. Instead, it is warming in many areas and this needs to be considered in the present design criteria for all engineering structures built on permafrost. Warming, with subsequent thawing of permafrost, will affect the surface energy budget, water and gas fluxes (potential for release of greenhouse gases), and vegetation; hence, there is a direct feedback with the climate system. Just as it took a long time for permafrost to develop, it will take a long time for it to completely melt; but the consequences of thawing permafrost can impact our daily lives in the first or second season of melting.

Salt-Affected Soils: Plant Response

Anna Eynard,
Keith D. Wiebe,
and Rattan Lal

Introduction

Salt-affected soils can be defined as soils on which the growth of most crop plants is limited by an excess of easily soluble salts. Salts are considered easily soluble when they are more soluble in water than gypsum. Salts may include chlorides, sulfates, carbonates and bicarbonates of sodium, potassium, magnesium, and calcium. The salt concentration in the soil solution is usually measured by the electrical conductivity of the soil saturation extract (EC). A soil is saline if the EC of the extract is higher than 4 dS/m.[1] However, plant growth may be severely affected or inhibited at much lower levels of EC. Limiting EC values change with the ionic composition of the soil solution and with the plant species and variety grown. Sodic soils are salt-affected at EC <4 dS/m (Table 1). In sodic soils, the high sodium content relative to other cations is the main factor affecting plant growth. The amount of sodium is usually expressed as exchangeable sodium percentage (ESP) or sodium adsorption ratio (SAR). The critical level of ESP for growth reduction depends on many interacting factors and may vary from <6% to >15%. There is a continuum of plant responses to the continuous increase of salt stress with increasing salt or sodium concentrations in the soil. Saline and sodic conditions, although very different, are often both implicated in adversely affecting plant performance so that terms such as salinity, saline, and salinization are generically referred to soil conditions and processes leading to salt and sodium stresses on plants.[2]

TABLE 1 General Classification of Salt-Affected Soils

Soil Class	EC (dS/m)	SAR	ESP (%)
Nonsaline nonsodic	<4	<13	<15
Saline	>4	<13	<15
Saline–sodic	>4	>13	>15
Sodic	<4	>13	>15

Extent and Distribution

Salt-affected soils are most common in arid climates with evapotranspiration greater than precipitation for at least part of the year (aridic, ustic, or xeric soil moisture regimes), but they are present at any latitude and altitude. Salinization by improper irrigation management was a major cause of degradation of the Nile Delta, the Mesopotamian Plain, and the valley of the Yangtze and the Hwang Ho.[3] Estimates of the extent of soil salinity and sodicity problems vary from 5% to 10% of the world land area. Recent estimates of FAO-AGL[4] indicate that >800 million ha are salt-affected, i.e., >6% of the world land area (Figure 1). Salinization is a serious hazard in San Joaquin Valley, United States; Murray-Darling Basin, Australia; Euphrates Basin, Pakistan; Indo-Gangetic Basin, India; and Aral Sea Basin, Central Asia.[5] Global land area degraded by salt-affected soils may be 1 billion hectare (Bha),[6,7] and the world may be losing as much as 2000 ha/day.[5] Worldwide 20% of the cultivated land area and 33% of the irrigated lands are degraded because of salt-induced problems.[8,9] It is also estimated that salinized area may be increasing at the rate of 10% annually. Fifty percent of arable land may be salinized by 2050.[8] Crop growth and agronomic productivity in salt-affected soils is adversely affected[10] because of osmotic and drought stress,[11] degradation of soil structure especially in sodic soils, and alteration in soil enzymatic activity.[12] Salinity problems also affect greenhouse crops, mine spoils, and disposal areas. Part of the yield loss occurs on irrigated lands, which are otherwise highly productive. In the irrigation district of Ciudad Juarez Valley in Mexico, the productivity of 70% of the lands is hindered by salinity. On average, 25% of irrigated Mexican lands are salt-affected. The impact of yield losses is magnified at a local scale because salt-affected soils are not uniformly distributed, threatening the economic welfare of some regions and countries. In Bangladesh, 24% of the total land area is salt-affected with a rapid expansion

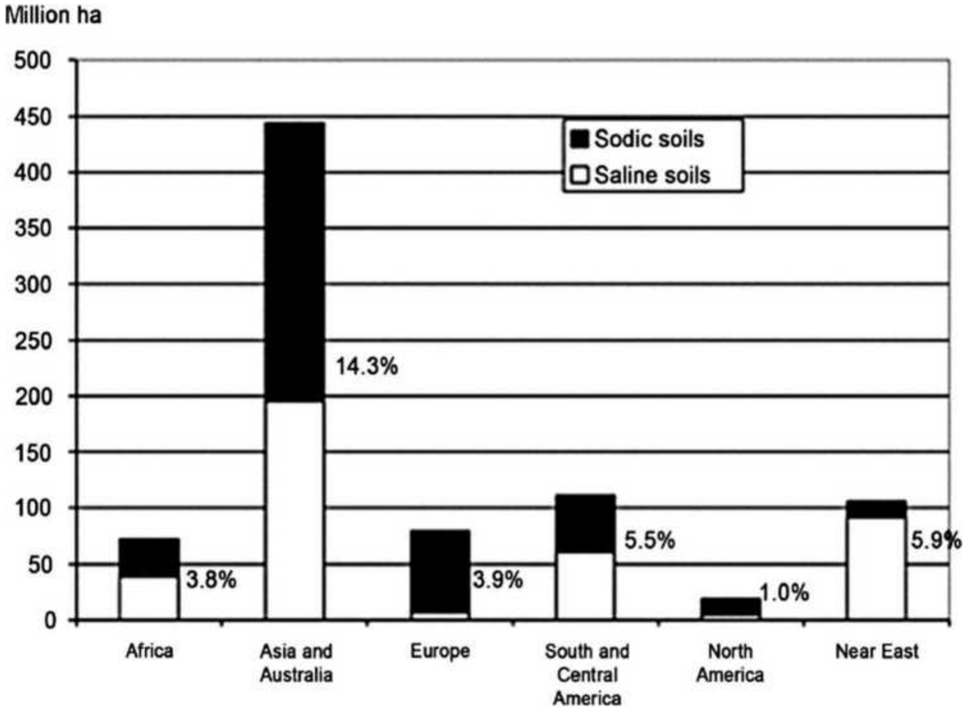

FIGURE 1 Distribution of salt-affected soils. The percentage of salt-affected soils on the total land surface is reported for each region of the world.
Source: FAO-AGL.[4]

during the last quarter of the 20th century from <1 million ha to >3 million ha. In Australia, almost 20% of the land is salt-affected.[4]

Salt-affected soils not currently used for crop production (e.g., salt flats) are a potential source of salts for salinization of surrounding fields. According to Oldeman, Hakkeling, and Sombroek,[13] the annual rate of loss of agricultural land by salinization, alkalinization, and waterlogging is about 1.5 million ha. Previous estimates reported 10 million ha of agricultural land loss per year.[14] The rate of increase is likely to vary widely across regions and from year to year, but all data suggest an increasing extent of salt-affected lands, especially where the natural resources are scarce and the growing human population increases pressure on soils. Changes in the global environment are likely to increase yield losses consequent to soil salinity. The predicted increase of the sea level from thermal expansion of seawater ranges from 15 to >50 cm by the year 2100.[15] The rise of seawater is likely to worsen salinity problems from tidal inundation of coastal lands. On the other hand, there is no evidence to suggest that elevated atmospheric CO_2 would increase the level of salinity suitable for plant growth.[16] Increased CO_2 is expected to increase plant growth only on nonsaline soils, magnifying yield losses due to soil salinity.

Crop Tolerance

Soil salinity and sodicity limit the potential area of growth of sensitive crops. All plants are sensitive to salts at some concentration, but the limiting concentration varies with plant species and variety. Crop tolerance is defined in relation to the level of salinity causing yield losses. High salt concentration may lead to plant death and no yield. Decreased growth occurs above a soil critical salt or sodium concentration (tolerance threshold). Crop yield reductions in salt-affected soils result from alteration of various metabolic processes in plants under salt stress. Negative effects of excess of salts in the soil solution include increased osmotic pressure limiting water uptake (physiological drought), abnormal pH and ionic competition limiting nutrient uptake, and ionic toxicity. Total salinity effects always depend on the specific soil ionic composition. The negative response of plants to low water potential may prevail in saline soils, while single ion toxicity or nutritional imbalance may be particularly severe in sodic soils. Soil structural impedance of plant growth is common in the absence of sufficient Ca^{2+}. Structural problems derive from crusting, formation of compacted layers, poor infiltration, and poor permeability to water and air. In waterlogged soils, anaerobic conditions may enhance salinity stresses.

In all plants growing on saline media, a part of the metabolic energy is diverted to ion transport, synthesis of organic osmolytes (contributing to osmotic adjustment to low water potential), and ion compartmentation preventing ion toxicity.[2] Osmotic adjustments in salt-tolerant plants need to follow seasonal changes in soil salinity and water availability. In general, plants that are more salt-tolerant tend to grow more slowly at low salinity levels than less-tolerant plants. Broadly adaptable plants can produce good yields where strong temporal changes of soil salinity occur in the soil. But such plants, tolerant to a wide range of salinities, perform less well at any salinity than less adaptable plants at their optimal salinity.[8] Reduced yield in tolerant plants can be related to (1) greater allocation of organic C in the roots of tolerant plants at the expense of leaf area, (2) decreased use of the solar radiation, and (3) low transpiration rate. Soil salinity interacts with climate and other edaphic factors in determining yield. Reduced availability of water in the soil is concomitant to higher evaporative demand in the leaves. Adaptation to soil salinity is a reduction in the capacity for photosynthetic carbon assimilation consequent to the necessity of minimizing evapotranspiration. In general, crops are less sensitive to salinity in glasshouse conditions than outdoors. At low soil fertility levels, plants may appear more tolerant to salinity than at high fertility levels if salinity is not the limiting factor of yield. On the other hand, nutrient deficiencies induced by salinity and sodicity can further reduce low yields due to low fertility.

In natural conditions, soil salinity varies with depth and time. Plants extract water from the least saline parts of the soil surrounding the roots. Plants may be able to tolerate high salinity levels in the root zone if occurring only for short periods of time during the growing season. Soil salinity may peak

TABLE 2 Classification of Crop Salt Tolerance Based on the Values of EC above Which Yield Loss Begins

Relative Tolerance	Critical EC (dS/m)	Examples of Crops
Sensitive	<1.3	Beans
Moderately sensitive	1.3–3.0	Rice, corn
Moderately tolerant	3.0–6.0	Wheat
Tolerant	6.0–10.0	Barley, cotton
Unsuitable	>10.0	Most crops

Source: Ayers and Wescot.[17]

TABLE 3 Classification of Crop Exchangeable Sodium Tolerance. Growth Is Usually Already Affected at Lower Values of ESP and Crop Production Is Usually Excluded at ESP>30

Relative Tolerance	ESP (%)	Examples of Crops
Sensitive	<15	Beans, corn
Semitolerant	15–40	Rice, wheat
Tolerant	>40	Barley, cotton

Source: Ayers and Wescot.[17]

at different stages of the crop, when plants may be more or less sensitive. Consequently, the critical point for yield reductions varies with duration of the salt stress and stage of development. Growth can be inhibited at any stage of the biological cycle. Severe reductions of yields can be due to low germination and limited early plant establishment. Yield reductions can be caused by reduced vegetative growth and/or by perturbation of the reproductive phases. Developmental shifts of relative salt tolerance are common during plant life and vary with cultivar and environment. Often, qualitative yield reductions enhance total yield losses.

Irrigated drylands are at a high risk of salinization,[18] and there are a wide range of reclamation measures.[19,20] A common classification of crop salinity tolerance distinguishes five categories (Table 2). Sodium is not considered a limiting factor in the above classification.

A classification of sodium tolerance of crops consists of three groups (Table 3). Sodium-tolerance tables are usually based on nutritional responses in absence of soil structural degradation, which generally excludes crop production at ESP >30.[9] These classifications are based on the agronomic criterion of comparing the relative yield of each crop on saline media to its yield on normal nonsaline media. Published tolerance tables provide a reference of relative salt tolerance of crops under irrigation without local climatic specifications. Such data refer to duration of salinity from late seedling stage to maturation with irrigation, fertilization, and pest control maintained optimal for each crop species and variety at the time of the experiment. Tolerance tables may apply to individual cultivars in the absence of interactions between soil salinity and other environmental factors.

Conclusions

Salt-affected soils decrease crop productivity at local and global scales. The extent of soil salt problems is likely to increase if no measures are taken to limit soil salinization and sodication. Management and reclamation of salt-affected soils require a combination of agronomic practices, including hydraulic, mechanical, amending, and cropping practices.[4] The selection of proper management practices is relative to the soil, water, crop, and human available resources.

Improved crop salt tolerance can contribute to the remediation of soil salt problems because:

- Extends the choice of crops that can grow at each soil salinity level
- Allows irrigation using more saline water
- Increases soil organic matter and improves soil structure.

Consequently, tolerant crops may assist in establishing a proper water balance and reduce the need and cost of reclamation measures such as leaching.

Information on crop response to salinity and sodicity needs to be updated in relation to changes of plant materials, agronomic practices, and climatic conditions. A range of values in the continuum of salt and sodium stresses would be better suited than a single critical value to represent the tolerance or sensitivity of a plant since the intensity of salt stress depends on many other factors determining yields.

List of Abbreviations

EC	electrical conductivity of the soil saturation extract in dS/m
ESP	exchangeable sodium percentage in %
SAR	sodium adsorption ratio = $Na^+/([Ca^{2+} + Mg^{2+}]/2)^{1/2}$, where concentrations are in mmol/L

Agricultural Runoff

Matt C. Smith,
David K. Gattie, and
Daniel L. Thomas

Introduction

Agricultural runoff is surface water leaving farm fields as a result of receiving water in excess of the infiltration rate of the soil. Excess water is primarily due to precipitation, but it can also be due to irrigation and snowmelt on frozen soils. In the early 20th century, there was considerable concern about erosion of farm fields due to rainfall. The concern was primarily related to the loss of valuable topsoil from the fields and the resulting loss in productivity. With the passage of the Federal Water Pollution Control Act Amendments of 1972, the potential for pollution of surface water features such as rivers and lakes due to agricultural runoff was officially recognized and an assessment of the nature and extent of such pollution was mandated.[1,2]

Agricultural runoff is grouped into the category of nonpoint source pollution because the potential pollutants originate over large, diffuse areas and the exact point of entry into water bodies cannot be precisely identified (see *Pollution: Point Sources,* p. 2190). Non-point sources of pollution are particularly problematic in that it is difficult to capture and treat the polluted water before it enters a stream. Point sources of pollution such as municipal sewer systems usually enter the water body via pipes and it is comparatively easy to collect that water and run it through a treatment system prior to releasing it into the environment. Because of the non-point source nature of agricultural runoff, efforts to minimize or eliminate pollutants are, by necessity, focused on practices to be applied on or near farm fields themselves. In other words, we usually seek to prevent the pollution rather than treating the polluted water.

Due to the great successes made in treating polluted water from point sources such as municipal and industrial wastewater treatment plants, the relative significance of pollution from agricultural runoff has increased. Agricultural runoff is now considered to be the primary source of pollutants to the streams and lakes in the United States. It is also the third leading source of pollution in U.S. estuaries.[3] The water pollutants that occur in agricultural runoff include eroded soil particles (sediments), nutrients, pesticides, salts, viruses, bacteria, and organic matter.

Agricultural Runoff Quantity

Agricultural runoff occurs when the precipitation rate exceeds the infiltration rate of the soil. Small soil particles that have been dislodged by the impact of raindrops can fill and block soil pores with a resulting decrease in infiltration rate throughout the duration of the storm. As the excess precipitation builds up on the soil surface it flows in thin layers from higher areas of the field towards lower areas. This diffuse surface runoff quickly starts to concentrate in small channels called rills. The concentrated flow will generally have a higher velocity than the flow in thin films over the surface. The concentrated flow velocity may become rapid enough to cause scouring of the soil that makes up the channel sides and bottom. The dislodged soil particles can then be carried by the flowing water to distant locations in the same field or be carried all the way to a receiving water body. If the quantity of flow and the velocity of flow are large enough, the rills can grow so large that they cannot be easily repaired by typical earth moving machinery. When this happens, the rill has become a gulley.

The quantity of runoff from agricultural fields is not usually listed explicitly as a concern separate from the quality of the runoff. However, it should be considered because it transports the pollutants and can cause erosion of receiving streams due to excessive flows. If less runoff is allowed to leave a field, there is less flow available to transport pollutants to the stream. Also, if more water is retained on the field, there is likely to be a corresponding reduction in the amount of supplemental water that will need to be added through irrigation. Runoff quantity varies significantly due to factors such as soil type, presence of vegetation and plant residue, physical soil structures such as contoured rows and terraces, field topography, and the timing and intensity of the rainfall event.

Some agricultural practices increase the infiltration capacity of the soil while other practices can result in decreases. The presence of vegetation and plant residues on a field reduce runoff due to improving and maintaining soil infiltration capacity. Actively growing plants also reduce the amount of water in the soil due to evapotranspiration, thus making more room for infiltrating water to be stored in the soil profile. Bare soils increase runoff because there is nothing except the soil surface to absorb the energy of the falling raindrops. The rain, therefore, dislodges soil particles that will tend to seal the surface and reduce infiltration.

Soil Erosion and Associated Pollutants

One of the primary pollutants in agricultural runoff is eroded soil. In 1975, 223 million acres of cropland produced 3700 million tons of eroded sediments or an average of 17 tons of soil lost per acre of cropland per year (see various *Erosion* entries, pp. 967–1103). It is estimated that cropland, pasture, and rangeland contributed over 50% of the sediments discharged to surface waters in 1977.[4] As noted above, the energy of raindrops can dislodge and transport soil particles. In the aquatic environment the eroded soil is called sediment. There are several concerns related to excessive sediments in aquatic systems. These include loss of field productivity, habitat destruction, reduced capacity in reservoirs, and increased dredging requirements in shipping channels.

Eroded sediments represent a loss of fertile topsoil from the field, which can reduce the productivity of the field itself. Soil formation is an extremely slow process occurring over periods ranging from decades to centuries.[5] Possible results to a grower from excessive erosion of their fields include increasing fertilizer and water requirements, planting more tolerant crops, and possibly abandoning the field for agricultural production.

A second concern is that many of these sediments are heavy and will settle out in slow moving portions of streams or in reservoirs. The settled sediments can dramatically alter the ecology of the streambed. Aquatic plants, insects, and fish all have specific requirements related to composition of the streambed for them to live and reproduce.[6] Sediments in reservoirs reduce the volume of the reservoir available to store water. This may result in reduced production of hydroelectric power, reduced water availability for municipal supply, interference with navigation and recreation, and increased dredging requirements to maintain harbor navigability.

Another concern with eroded sediments is that they can transport other pollutants into receiving waters. The plant nutrient phosphorus, for example, is most often transported from the fields where it was applied as fertilizer by chemically bonding to clay minerals. Many agricultural pesticides also bond to eroded clays and organic matter. Once these chemicals have entered the aquatic ecosystem, many processes occur that can result in the release of the pollutants from their sediment carriers. Phosphorus, when released, can contribute to the eutrophication of lakes and reservoirs (see the entry *Eutrophication,* p. 1115). Pesticides and their degradation products can be toxic to aquatic life and must be removed from municipal water supplies.

Erosion from animal agriculture such as feedlots and pastures can also result in the transport of sediments composed of animal manures (see the various *Manure Management* entries, pp. 1680–1695). These sediments can transport significant quantities of potential pathogens (viruses and bacteria). The animal manures are primarily organic in nature and can serve as a food source for natural bacteria in the receiving water. When these naturally occurring bacteria begin to utilize the organic matter in this way they may lower or deplete the water of dissolved oxygen as they respire and multiply. This use of oxygen by aquatic bacteria is known as biochemical oxygen demand (BOD). High levels of BOD can reduce stream oxygen level to the point that fish and other organisms that require dissolved oxygen suffer, die, or relocate, when possible, to more suitable habitats.[6]

Dissolved Pollutants

Agricultural runoff can carry with it many pollutants that are dissolved in the runoff water itself. These may include plant nutrients, pesticides, and salts. Since these pollutants are dissolved in the runoff, control measures are most often aimed at reducing the volume of runoff leaving an agricultural field, or making the pollutants less available to be dissolved into the runoff water.

One of the major pollutants of concern in agricultural runoff is the plant nutrient nitrogen. Nitrogen is a relatively cheap component of most fertilizers and is necessary for plant growth. Unfortunately, nitrogen in the form of nitrate is highly soluble in water. Thus nitrate can be easily dissolved in runoff water. Just as it does in an agricultural field, nitrogen can promote growth of aquatic vegetation. Excess nitrogen and phosphorus in runoff can lead to the eutrophication of lakes, reservoirs, and estuaries (see the entry *Eutrophication,* p. 1115). Nitrogen in the form of ammonia can be dissolved into runoff from pastures and feedlots. Ammonia is toxic to many aquatic organisms, thus it is important to minimize ammonia in runoff.[7]

Many agriculturally applied pesticides are also soluble in water. They can be dissolved in runoff and transported into aquatic ecosystems where there is a potential for toxic effects. These pesticides must also be removed from drinking water supplies and, if concentrations are high or persistent, such treatment can be difficult and expensive. Stable, persistent pesticides can bioaccumulate in the food chain with the result that consumers of fish from contaminated waters might be exposed to higher concentrations than exist in the water itself.[8]

Runoff from agricultural fields can contain significant concentrations of dissolved salts. These salts originate in precipitation, irrigation water, fertilizers and other agricultural chemicals, and from the soil minerals. Plants generally exclude ions of chemicals that they do not need. In this way, dissolved salts in irrigation water, for example, can be concentrated in the root zone of the growing crop. Runoff can redissolve these salts and transport them into aquatic ecosystems where some, naturally occurring selenium for example, can be toxic to fish and other wildlife.[9]

Transport of fertilizers and pesticides from their point of application can result in significant environmental costs. This transport, or loss from the field, can also have significant negative economic impacts on the grower. Fertilizers lost from the field are not available to promote crop growth. Agricultural chemicals lost from the field, likewise, are not available to protect the plants from pests and diseases. In both cases the grower is paying for expensive inputs and paying to apply them. It is always in the growers' and the environment's best interests, therefore, to keep agricultural chemicals in the field where they are needed and where they were applied.

Control of Agricultural Runoff

One of the most direct methods of controlling pollution by agricultural runoff is to minimize the potential for runoff to occur. Other methods can be employed to reduce the amounts of sediments and dissolved chemicals in runoff. As a whole, management practices designed to minimize the potential for environmental damage from agricultural runoff are called best management practices (BMPs), (see the entry *Nutrients: Best Management Practices,* p. 1829). Many times, practices aimed at controlling one aspect of agricultural runoff are also effective at reducing other components. This is due to the interrelationships between runoff volume, erosion, transport, dissolution, and delivery.

Maintaining good soil tilth and healthy vegetation can minimize runoff. This will promote increased infiltration and a resultant decrease in runoff. Other management practices such as terracing, contour plowing, and using vegetated waterways to convey runoff can result in decreased quantities of runoff by slowing the water leaving the field and allowing more time for infiltration to occur. Construction of farm ponds to receive runoff can result in less total runoff from the farm, lowered peak rates of runoff, and storage of runoff for use in irrigation or livestock watering.[2]

Control of water pollution by the mineral and organic sediments and associated chemicals in agricultural runoff is most effectively achieved by reducing erosion from the field. The primary method of reducing erosion is by maintaining a vegetative or plant residue cover on the field at all times or minimizing areas of the field that are bare. Techniques utilized to accomplish these tasks include conservation tillage, strip tillage, and the use of cover crops (see the entry *Erosion Control: Tillage and Residue Methods*, p. 1081). Additional measures that can be employed at the edge of the field, or off-site include vegetative filter strips and farm ponds.

Methods to control the loss of nitrogen and other plant nutrients from cropland include applying nitrogen in the quantity required by the crop and at the time the crop needs it (see the entry *Nutrients: Best Management Practices*, p. 1829). This requires multiple applications and can be difficult for tall crops. For this reason, most, or all, of the nitrogen required by the crop is often applied at planting. Nitrogen fertilizers have often been applied based on general recommendations for the type of crop to be grown. Since nitrogen fertilizers are relatively inexpensive, growers have tended to over apply rather than under apply. Soil tests can tell a grower how much nitrogen is already in the soil and how much needs to be applied for a specific crop. Efforts have been made to make the nitrogen less soluble by changing the form of nitrogen applied to the field so that it becomes available to the plants (and, thus available for loss in runoff) more slowly.[10]

One method of controlling the loss of agricultural chemicals is to minimize their solubility in water. Another is to minimize their use through programs such as integrated pest management (IPM) where some crop damage is allowed until it reaches a point that it becomes economically justified to apply pesticides.[11] And a third approach is to make the chemicals more easily degraded so that they do their job and then degrade into other, less harmful, chemicals so that they do not stay around long enough to be influenced by runoff-producing rainfall events.

Conclusion

Agricultural runoff is one of the leading causes of water quality impairment in streams, lakes, and estuaries in the United States. It can transport large quantities of sediments, plant nutrients, agricultural chemicals, and natural occurring minerals from farm fields into receiving water bodies. In many cases the loss of these substances from the field represent an economic loss to the grower as well as a potential environmental contaminants. There are many methods by which the quantity of agricultural runoff can be reduced. Many of these methods are referred to generically as BMPs. Adoption of BMPs can also improve the quality (reduce contaminant concentrations) of the runoff that does leave the farm. By reducing the quantity and improving the quality of agricultural runoff, it will be possible to improve the water quality in our streams, river, lakes, and estuaries.

Desertification

David Tongway
and John Ludwig

Introduction

The term *desertification* was coined in the 19708 to graphically represent the state of the Sahelian lands, on the southern margin of the Sahara Desert. This was a period when major drought accompanied by big increases in the human population served to cause the desert margins to apparently move into formerly more productive land.[1,2] The image of an encroaching desert is powerful and evocative and resulted in major international efforts to understand and deal with the problem. Since that time, the notion of desertification has been reworked in the light of additional information and improved conceptual frameworks to the extent that the desert is no longer seen as inexorably increasing in size, nor restricted to the Sahelian fringe of the Sahara.[3–5] Most rangeland areas in the world have suffered some sort of degradation due to the impact of disturbance regimes, and recent reviews[6] have shown the process to be not at all restricted to hot deserts or areas of high population density. This is not to deny, however, the major effects on the human populations using these lands, and no doubt, much human hardship has been endured. This entry describes a process whereby the degree of desertification can be assessed and then used to design restoration activities appropriate to local biophysical and socioeconomic constraints.

Desertification Redefined

This entry focuses on the biophysical aspects of desertification. Traditionally, easy to measure structural and functional attributes of vegetation, such as species composition and productivity, were the means by which desertification was initially assessed. These methods served to show the effect of desertification but did not provide a predictive understanding of how to combat it. However, recent advances in landscape ecology and restoration technology[7,8,10] have led to generic and practical approaches to study the basic nature and reversibility of desertification. Principally, this involves treating the affected landscapes as biophysical systems, comprised of sequences of processes and feedback loops and summarized in a conceptual framework (Figure 1).[8,9]

In this framework, vital resources such as water, nutrients, and topsoil are transported, utilized and cycled in space and time, and the processes are driven by processes such as runoff/runon, erosion/deposition, and plant litter de- composition.[8,11,12] Landscapes are said to be “functional,” or

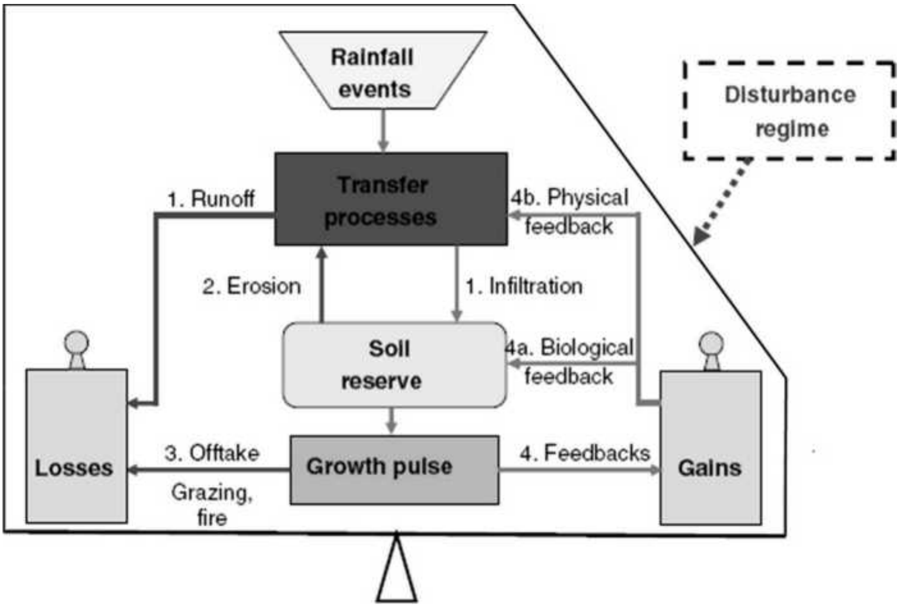

FIGURE 1 A conceptual framework summarizing landscape functioning. Numbers refer to the recommended sequence of assessing practical function. The disturbance regime shown is generic, and it may impinge on a number of landscape processes at the same time.
Source: A modification of Figure 2 in Tongway and Ludwig[9] (reproduced with permission).

non-desertified, if resources are substantially retained within the system and utilization and cycling processes are efficient. "Dysfunctional" or desertified landscapes are characterized by the depletion of the stock of some vital resources and the continued flow of these resources out of the system. This mind-set emphasizes the system attributes of processes acting in space, over time, in relation to applied stress and disturbance, rather than just changes in lists of species, or yields of marketable commodities. The role of vegetation as a significant regulator of energy and resources is integral to this approach.[13] Desertification should be viewed as a continuum ranging from slight to severe, rather than as a simple step function (Figure 2).

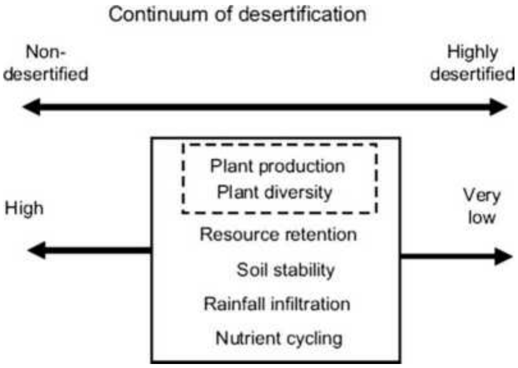

FIGURE 2 Desertification as a continuum. The four new biophysical parameters (bold) are added to the two existing desertification descriptors (dotted box) to locate any given landscape on the continuum.

Assessing the Degree of Desertification

If field sites are characterized according to "resource regulation" capacity, not only can the degree of desertification be assessed, but also the critical pathway of resource loss may be identified. Tongway and Hindley[14] and Tongway and Ludwig[15] have designed and implemented monitoring programs to quickly provide information about biophysical processes and edaphic properties related to plant habitat favorability at both landscape and plot or patch scales. Typically, the initial analysis examines the fate of rainfall into infiltrated water and runoff water. The data gathered need an interpretational framework to facilitate generic application. Graetz and Ludwig[16] proposed that system response to desertification be represented by a four-parameter sigmoidal or logistic curve. The curve form acknowledges upper and lower asymptotic plateaux, at the non- and highly desertified ends of the spectrum, respectively, and a gradual transition between those plateaux. This approach permits questions about whether a system was "fragile," i.e., easily made dysfunctional, with low restoration potential or "robust," or rather able to withstand stress and disturbance with only low attenuation of biophysical processes (Figure 3). Importantly, this curve type enables thresholds and milestones to be predicted and quantified using field indicators.[17]

Procedures to Reverse Desertification

Rehabilitation and restoration of desertified landscapes, under the functional biophysical system mind-set, require that processes that accumulate resources be reintroduced or augmented, thus providing a rational procedure in the repair and functional recuperation of desertified landscapes. The approach explicitly seeks to retain vital resources by ecological processes.[18–20] Once the analysis of resource regulation system has been completed, and the most affected process identified, remedial efforts can begin. For example, Rhodes and Ringrose-Voase[20] deduced that ponding water for extended periods on clay soils with modest swell/shrink properties would eventually result in soils with high infiltration and water store through sequences of swelling and shrinking processes permitting infiltration into greater soil depths. Recolonization and establishment of plants then began spontaneously, eventually cycling organic matter, so that open friable soils developed, colonized by soil macrofauna that further improved soil properties. Tongway and Ludwig[18,19] used piles of branches arranged on the contour in gently sloping country to trap water, sediment, and organic matter to effect substantial improvements to a range of soil properties, permitting perennial grasses to self-establish. In each of these cases, an analysis of the different underlying causes facilitated the selection of the most appropriate techniques to reverse

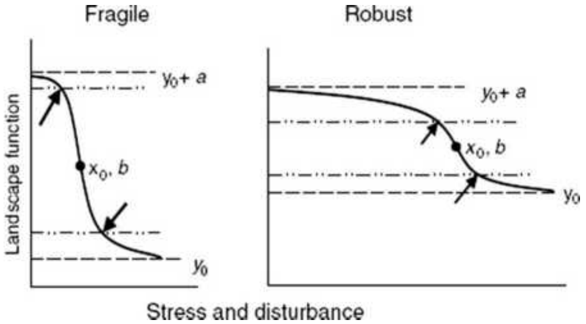

FIGURE 3 Examples of response curves for fragile and robust landscapes. The initial response of landscape function to stress and/ or disturbance is markedly different. A fragile landscape deteriorates with low applied stress and has a much lower base value (y_0) than the more robust landscape. Four-parameter sigmoid curves of the form $y = (y_0 + a)/1 + e^{(-x-x_0)/b}$ provide four practical values reflecting the nature of the landscape. Critical thresholds (arrows) for each index of desertification can be determined by curve analysis.

the observed desertification. Attempting to revegetate desertified areas by simply reseeding without understanding both the current and required edaphic properties needed for the desired vegetation mix frequently results in unexplained failure. In some instances, where the system function is close to the lower asymptote (Figure 3), simple treatments such as exclusion from grazing will be too slow or ineffective and active intervention may be needed to improve one or more functional processes.

Monitoring Rehabilitation

It is important to monitor the progress of processes set in train by the rehabilitation activities. Essentially, the degradation curves such as those in Figure 3 need to be driven "in reverse." The landscape assessment procedure proposed by Tongway and Hindley and Tongway and Ludwig[15,21] can also be used to follow the trajectory of improvement in ecosystem functioning. The procedures use simple, rapidly acquired indicators of processes of resource regulation. Data recording biota establishment and development are included in this procedure and interpreted in terms of the rising plane of delivery of goods and services to the whole system over time. It is important that monitoring should provide accurate information quickly and at low cost. Remotely sensed data, related to landscape function, is a cost-effective procedure,[22] and new products such as Google Earth may, in the future, provide synoptic assessment of restoration trends at coarse scales. The effect of rare stochastic events such as fires or storms may need to be assessed to see if the resultant stress and/or disturbance has set the system back beyond a critical threshold or not.

Conclusion

We have described an ecosystem-function-based set of data gathering processes by which the fundamental nature of desertification can be assessed and combated, using a framework that characterizes the biophysical status of the affected system. This can be simply expressed as "assessing the regulation of vital resources in space and time." In deploying the procedure, community groups can be easily instructed to "read the landscape." The procedure enables the user to design or adapt restoration or rehabilitation technologies appropriate to the problem at hand because of the predictive understanding acquired, rather than using a "recipe" from another type of landscape elsewhere. The information-gathering procedure can be adapted to a wide range of bioclimatic situations because it deals with the basic processes controlling the availability of vital resources to biota.

Desertification: Prevention and Restoration

Claudio Zucca,
Susana Bautista,
Barron Orr, and
Franco Previtali

Introduction

This entry provides a brief overview of the most significant approaches to prevent and reverse land degradation in drylands, with a special emphasis on conceptual frameworks and on methods to monitor and evaluate their impacts.

The entry first discusses the main underlying concepts, in light of recent developments on the conceptual framework of desertification. The methodological developments related to integrated and participatory evaluation are then presented. Finally, the implementation of mitigation and restoration programs is addressed, with particular reference to the constraints and risk factors and to the practical lessons learned in the field.

Desertification: The Underlying Concepts

Desertification is defined here as "land degradation in drylands resulting from various factors, including climatic variations and human activities," in conformity with the UNCCD (United Nations Convention to Combat Desertification).[1] Before the entry into force of the UNCCD in 1996, the term "desertification" had been given a number of different definitions.[2–6] The UNCCD definition has been and still is the subject of scientific debate; the related evolving concepts have been reviewed by a number of papers.[7–12]

The Millennium Ecosystem Assessment (MA) defines desertification as a persistent reduction in the provision of ecosystem services over an extended period.[13,14] The scientific discussion promoted in 2009 by the UNCCD in view of the First Scientific Conference of its CST (Committee on Science and Technology), building on the MA definition, resulted in a proposal to redefine desertification as "an end state of the process of land degradation; this process is expressed by a persistent reduction or loss of biologic and economic productivity of lands that are under use by people."[15] The ongoing discussion also focuses on the integrated sets of indicators needed for monitoring and assessing desertification, and on the related conceptual frameworks that would help scientists, practitioners, and policy makers organize, use, and communicate the results of that monitoring.[16–18]

While the definition of desertification continues to evolve, ecosystem services are increasingly seen as a unifying supporting concept. The MA states that "desertification results from a long-term unbalance between demand for and supply of ecosystem services" and that measurement of persistent reduction in the capacity of ecosystems to supply services provides a robust and operational way to quantify land degradation and desertification. The ecosystem services framework is increasingly thought to provide a basis to assess and value the impacts of land change and degradation, as well as the effects of the actions aimed at reversing it.[19–21]

Desertification manifests itself through different forms and processes in different ecosystems and socioeconomic contexts. Its direct causes are many and can be generally ascribed to different forms of land mismanagement, such as overgrazing, deforestation, overuse of irrigation, and non-resource-conservative agriculture and forest practices.[1,7,17] These are at the origin of the major land degradation processes that are globally affecting the provision of ecosystem services, including water and wind erosion, soil salinization, loss of vegetation cover and diversity, and degradation of the hydrological cycles.[13]

No satisfying estimates of the global extent and severity of desertification are available thus far; however, the new World Atlas of Desertification, which is based on multiscale integrated sets of indicators, provides global datasets that can be used to identify local or regional areas of concern.[22] Assessment and monitoring of desertification, as well as of the impact of the prevention and restoration interventions, still constitute a major research challenge[15] and for this reason are a primary focus of this entry.

Prevention and Reversal

Policy and management responses to desertification can be grouped under two major classes: prevention and reversal.[13] The boundaries between these ones are vague, as in practice they form a continuum of potential prevention, mitigation, and restoration actions, to be adapted to particular sites and dynamics through adaptive management approaches (Figure 1). Through integrated land use planning, the optimal spatial mix of prevention and reversal responses can be identified, so that in net terms, desertification can be controlled. This approach, which was endorsed by the country Parties of the UNCCD in 2017, is known as land degradation neutrality (LDN).[23–25]

Prevention actions can be considered as avoidance approaches either through proactive management efforts or through changes in land use and management currently leading to desertification.

Prevention, however, is not enough to address the challenges posed by desertification. Vast areas of drylands are already severely degraded, with reduced plant cover and species diversity, falling

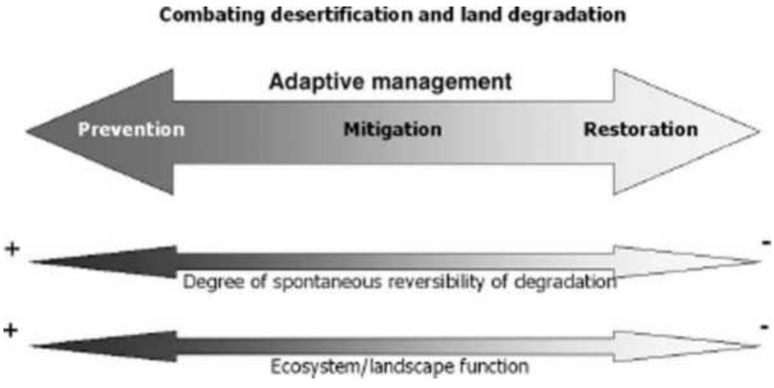

FIGURE 1 Continuum of actions to combat desertification and land degradation.

productivity, depleted or eroded soils, and very low potential for spontaneous recovery of ecosystem functions, even when degradation forces are no longer stressing the system. Many of these systems have changed at a level at which restoration is the only viable option to recover ecosystem services that have been lost.[26–28]

Examples of prevention and mitigation actions include measures to improve water management and agricultural practices. These are often referred to as soil and water conservation (SWC) or sustainable land management (SLM) practices. The FAO–LADA (Food and Agriculture Organization of the United Nations/Land Degradation Assessment in Drylands)[29] project and WOCAT (World Overview of Conservation Approaches and Technologies)[30] provide a framework for classifying and evaluating SLM actions. In view of the needs of the UNCCD, SLM has been recently defined as "land managed in such a way as to maintain or improve ecosystem services for human wellbeing, as negotiated by all stakeholders."[21]

Examples include long-term crop rotations with cereals/legumes; more efficient use of fertilizers; improvements in water-use efficiency; conservation-minded tillage methods; water-harvesting and water storage techniques; measures that protect soils from erosion, salinization, and other forms of soil degradation; improved crop–livestock integration, combining livestock rearing and cropping to allow a more efficient recycling of nutrients within the agricultural system; and in situ conservation of genetic resources and better resource use with efficient germplasm.[31] Creating viable livelihood alternatives, including the creation of economic opportunities in urban centers, can also help reduce current pressures on drylands.

For extremely degraded lands, rehabilitation and restoration approaches often involve the improvement in the quantity and/or quality of vegetation cover through, for example, the establishment of seed banks, reintroduction of selected species, control of invasive species, and reforestation programs.

Desertification is driven by a combination of proximate causes and underlying forces, including their interactions and feedback; these vary from region to region and change over time.[32] Approaches and strategies to prevent and reverse desertification need therefore to address the dynamic causal patterns and multiplicity of actors, factors, and scales involved. In general, developing the appropriate engagement between scientific and local environmental knowledge is critically important for efforts to prevent and reverse land degradation.[33] Desertification is framed within multiscale, coupled human–environmental dynamics, and so must be the approaches for desertification prevention and reversal.[34,35] The relationships between land degradation and its causal agents are non-linear and complex. Degradative and aggradative trajectories commonly exhibit thresholds and rapid shifts, as well as hysteresis dynamics, where the trajectories of degradation and recovery differ.[36–38] Understanding and monitoring these relationships are critical in the design of strategies to combat desertification.

In addition, socioeconomic conditions impose limitations on the technology and inputs available. Therefore, the approaches to combat desertification should incorporate both current conditions and scenario projections of socioeconomic and environmental constraints and opportunities.[13]

Finally, there is growing evidence that land degradation in desertification-prone areas is likely to increase with climate change.[22] Desertification is linked to biodiversity loss and global climate change through the regulation of water and carbon fluxes. Therefore, interlinkages in policy formulations aimed at combating desertification, mitigating the effects of climate change, and conserving biodiversity must be beneficially exploited by developing multifunctional strategies that address the three global environmental goals.

Implementing Solutions in the Field: Lessons Learned

Despite the availability of technological, institutional, and even financial resources, efforts to combat desertification often fail because of poor implementation. A list of "lessons learnt" is presented below to summarize a range of major constraints and risk factors that can hinder the successful implementation of the interventions, while highlighting the lessons learned and necessary improvements. Some of those issues stem from the concepts of adaptive management and multiscale human–environmental dynamics as introduced in the previous section. Others are more related to the issues of local participation and integrated assessment that will be discussed in the following section. Points 1 and 2 deal with the quality of the technical design and its degree of adaptation to local conditions and knowledge. Points 3–7 are related to the ability of the projects to cope with the long-term human–environmental dynamics. Points 8–11 are connected to the quality of the participatory processes implemented by the projects, while the last two points are linked to major, common organizational constraints.

1. Lack of awareness of actual land conditions. Sometimes, people (including decision makers) living in degraded areas do not realize that their land still maintains productive potential or perhaps are unaware of how that potential can be exploited. Preliminary land surveys should be done to support project design. These baseline assessments are necessary to guide subsequent actions. In some cases, "no-action" options could be considered. In the case of degraded rangelands, simple and cost-effective "self-learning" tests based on grazing exclusion and rotation can be proposed to local communities as a means to demonstrate the effects of pressure mitigation and sustainable management. Such tests allow hands-on learning and practical experience, and are much less risky than the direct introduction of often expensive "all or nothing" rehabilitation programs.
2. Schematic approach. Sometimes, large programs are extensively implemented by adopting schematic approaches, which are not able to adapt to specific local land characteristics and the needs of local people. In other cases, they target geographic areas where they are not necessary or inadvertently lead to negative side effects. Implementation protocols offering multiple technical solutions and integrating local stakeholder input on the perceived benefits (and unintentional consequences) are needed.
3. Lack of long-time planning in restoration. Often the long-term dynamics of the "restored human–environmental systems" are not fully considered. This is particularly relevant when the interventions are based on introducing fast-growing, income-generating alien species that may require a "renaturalization" strategy in the long term to balance ecological and social sustainability.
4. Inability to cope with natural crises. Especially in projects aimed at increasing plant cover, a poor or delayed wet season or recurrent droughts may cause the loss of part or all of the investment in a project. For example, this may happen in the case of fodder shrubs plantations, when farmers cannot avoid early grazing due to drought and unavailability of alternative feeding resources. Emergency/contingency funds, quick diagnostic and intervention mechanisms, and flexibility in project duration are necessary to mitigate against this risk.
5. Socioeconomic and demographic dynamics. Some projects have experienced labor shortfalls due to the out-migration of young people. In contrast, the return of people onto land previously "closed for restoration" may cause unsustainable pressure. Addressing economic constraints and associated demographic pressures such as migration prior to project implementation can reduce such kind of risks.
6. Market drivers. The dynamics of international and local market prices may completely and quite rapidly negate achievements produced by years of conservation programs.
7. Contrasting policies. A restoration initiative may be useful in practical terms and yet be overwhelmed by unrelated policies. A common example is farming incentives that come in conflict with the goals of mitigation programs, if not accompanied by adequate guidelines.
8. Passive community participation. Community participation should be strongly based on responsible awareness and sharing of project objectives, and participation in its planning, implementation, and evaluation. Cases where, for example, sectoral administration goals are implemented through prior agreement with land users (e.g., "I let you do on my land") may require or even force farmer action but, in the end, may not represent or address the key concerns or needs of local people.

9. Uncertain community commitment. Stakeholder engagement that fails to bring all parties to the table can have dire consequences. Comprehensive, balanced, and approved representation is not easy to obtain, but it is essential for success. The key question often raised is, "Who is committing on behalf of whom?" The commitment should include a community contribution or investment to cover the implementation costs, be linked to final results, and be based on taking ownership and responsibility after a project ends, rather than simply for the completion of individual tasks. Community commitment should be clearly defined in a way that can cope with changing community priorities.
10. Institutional commitment. Complex projects, in which the implementation is based on the support of local administration staff, need a formal and clear institutional commitment. This may take time and very rarely can be established before project approval: Projects should have an inception phase to set agreements.
11. Lack of transparency in the engagement process of the ultimate project beneficiaries. This is especially true (but not only) when the involvement of individual farmers or other land users in projects is not mediated by the community. Inappropriate or unrepresentative participation can lead to failure and loss of credibility. Transparent and objective selection mechanisms must be understood by all and be followed rigorously by project implementers.
12. Unrealistic project duration. Very often, the most common investment period imposed by donors (3–5 years) is too short to allow for adequate biophysical response and/or socioeconomic adaptation that would assure success. Of particular concern is enough time for effective "inception or learning phases" for community members to deal with the necessity to adapt to changing conditions and needs, to cope with unforeseen events, and most of all to monitor and assess impacts and sustainability.
13. Spending and reporting difficulties. Spending rules, procurement procedures, "exotic" rules imposed by the donors, or strict local rules, not well known by the local project management, often lead to delays and underperformance. More in general, the lack of flexibility can exacerbate the effects of most of the above-mentioned difficulties.

Finally, our capacity to design effective projects is often undermined by a lack of integrated assessment of the progress and success of the previous projects. Projects that are adequately implemented, monitored, and evaluated generate impact, and useful lessons that can feed into successful scaling strategies.[39]

Integrated Evaluation of Prevention and Restoration Actions

The development of integrated biophysical and socioeconomic analytical methods for evaluating progress and success, along with a framework for knowledge sharing and transfer, is crucial to combating desertification.[34] Furthermore, monitoring and evaluation are needed to demonstrate the benefits of sustainable dryland management, establish cost-effective thresholds for the various management alternatives, and identify priority areas where actions could be most effective.

In recent years, there have been a number of initiatives to develop common and comprehensive methodologies for assessing and evaluating the effectiveness of management and restoration programs.[40–44] These approaches focus on indicators that relate to ecosystem integrity and services, and human well-being (socioeconomic and cultural variables). Irrespective of the biophysical or socioeconomic attributes assessed, the selected indicators should be relevant, be sensitive to variations of environmental stress, have the capacity to respond to stress in a predictable manner, but also be simple and measurable with a reasonable level of effort and cost.[45,46]

Soil conditions and vegetation cover and composition are the most common metrics used for evaluating mitigation and restoration actions.[47,48] However, used in isolation, these indicators cannot always reflect how well an ecosystem is functioning. During the last decade, a variety of functional assessment approaches that relate to the spatial pattern of vegetation have been proposed.[49–51]

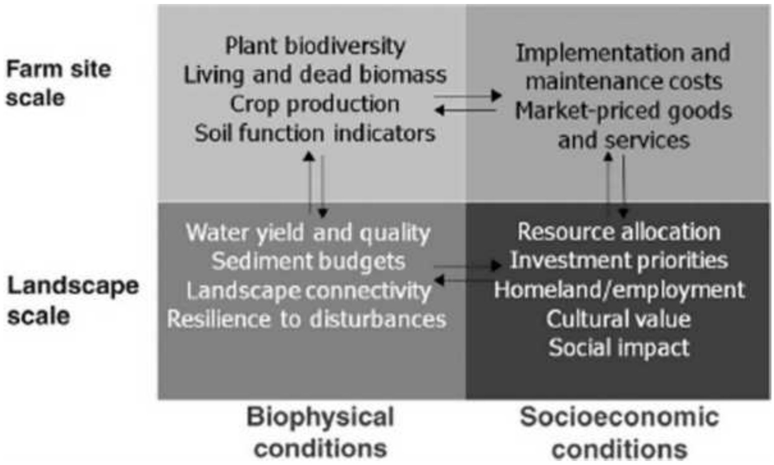

FIGURE 2 Example of a multiscale integrated framework and indicators for evaluating mitigation and restoration actions.

Some of these functional assessment methods also incorporate properties relative to the soil surface condition.[52,53] The theoretical framework for these approaches considers that landscapes occur along a continuum of functionality from highly patchy systems that conserve all resources to those that have no vegetation patches and leak all resources.[54] For semiarid ecosystems, it has been hypothesized that vegetation patchiness could be used as a signature of imminent transitions[55] and that changes in patch-size distributions may be a warning signal for the onset of desertification.[56]

Evaluation frameworks must account for the cross-scale and social–ecological interactions affecting the response of degraded lands to mitigation/restoration actions.[13] A multiscale approach is always advisable. Farm- and project-scale assessments focus on local resources and productivity, and a private economic valuation perspective (market-priced goods and services), while landscape- and program-level indicators address environmental benefits and public/social welfare considerations (Figure 2).

Because of the large spatial and temporal variability of ecosystems, particularly in drylands, it is critical to focus on "slow variables,"[57] so the assessment of long-term changes, and of the sustainability of land management, is not confused by short-term variations in land and socioeconomic conditions.[34] Assessment methods range from simple, qualitative assessments based on field observations to relatively complex protocols based on quantitative measurements of critical ecosystem and landscape attributes and socioeconomic surveys.[42] The development and accessibility of remote-sensing (RS) products have led some international bodies to recommend the integrated use of RS-based geospatial information with ground-based observations to assess land degradation.[13,15,58,59]

Participatory Approaches

While substantive progress has been made in developing more standardized and more relevant environmental assessment and monitoring approaches that reflect human–ecological interactions, the adoption of evaluation results at the local level remains challenging.[35,60] Though some suggest that local interests or even national policies outside the control of evaluators may partially explain this, environmental assessments tend to be independent, unilateral, and top-down, with results being delivered post-assessment. Stakeholder engagement is rare, or all-too-often limited to a period of "public comment" immediately before and/or after the assessment. In the same way that adaptive governance and ecosystem-based management approaches require local knowledge and continual stakeholder engagement, so too must the corresponding monitoring and evaluation if the goal is for results to be truly embraced and used.[61–63] Adaptive, ecosystems-based management is data intensive and requires a commitment to a variety of data sources, including local knowledge, which in turn necessitates more attention to knowledge integration and methods of analysis at different scales. Adoption of best practices that in theory come from a well-executed evaluation of a given desertification mitigation or restoration action can fail due to poor or limited communication and knowledge exchange among the involved actors. Essentially ignoring local knowledge increases the risk of missing essential key local factors, opportunities, or constraints.

Engaging stakeholders from the outset of an environmental assessment and maintaining the interaction throughout the process can result in the integration of local people and their perceptions into management, planning, and evaluation, helping develop feelings of ownership and representation while giving voice to locals in the process.[33,64,65] The potential benefits go beyond the assessment itself. Analysis of environmental conflict resolution processes suggests that ensuring all parties are at the table and are effectively engaged is directly correlated with often-sought outcomes like reaching an agreement, the quality of agreement, and improved working relationships among parties.[66,67]

An additional benefit to a participatory approach to the evaluation and the exchange of ideas among stakeholders, including researchers, is the learning that takes place. The collective self-reflection through interaction and dialogue among the diverse set of stakeholders involved with or affected by environmental challenge and the assessment of associated responses can result in the coproduction of knowledge.[68–70] Social groups that develop a shared understanding of a challenge can build up the experience necessary to improve linkages between knowledge and the environment, cope with change, and enhance adaptation because social learning helps solidify knowledge systems made up of the relevant sets of actors, networks, or organizations.[71] While the majority of discussion about the benefits of encouraging social learning has been focused on improving adaptive management, it is clear that the wealth of information explored during an evaluation suggests that an assessment period is an ideal time to encourage stakeholder interaction and knowledge exchange. In this sense, the evaluation itself becomes a tool for outreach and inreach, where land users, natural resource managers, and scientists all stand to learn from and potentially benefit from each other's insights. The process has the potential to empower individuals, build relationships, expand networks, and thereby enhance the relevance and impact of decision making.

Conclusion

Desertification is one of the major global environment and sustainable development challenges. It affects the livelihoods of millions of people, threatening human well-being in drylands.[13] That risk, when considered relative to the foreseeable impacts of climate change, stands to grow significantly in the future, with estimates suggesting that as many as 50 million people will be in peril of physical displacement in the next ten years.[72]

This entry underscores a range of conceptual and practical issues influencing the design and implementation of interventions, with a special emphasis on conceptual frameworks and associated methods to monitor and evaluate impacts.

Lessons learned in the field highlight several issues threatening the success of prevention/reversal actions. The capacity to design and implement effective restoration actions and other countermeasures to desertification is often undermined by a lack of assessment of the outcomes of previous projects.

The assessment of actions is complex and requires conceptual tools such as human–environmental frameworks for integrated assessment and participatory approaches to foster social learning. These should become the basis for the development of multifunctional mitigation strategies and the formulation of interlinked policies to address desertification, climate change, and biodiversity. The development of participatory approaches in the assessment of interventions is critical to capacity building and knowledge exchange. Encouraging social learning and a true sense of ownership is essential for successful adaptive management.

Other aspects, lying beyond the scope of the present entry, are crucial to combating desertification.

Primarily, the assessment of intervention programs should involve the policy makers to promote the adoption of sustainable rural development policies and to counteract the socioeconomic and policy-driven dynamics of desertification.[73] As a second priority, future interventions should be increasingly oriented to income-generating actions to strengthen social and economic sustainability in concert with environmental sustainability.[74] Finally, it is important to keep in mind that practices and interventions can be considered as "good" or "best" only with reference to their suitability in relation to specific human–environmental contexts. In this regard, to develop strategies tuned to the changing land features, land evaluation techniques could be updated based on the integrated assessment principles, as suggested by the new "anthroscape" concept.[75]

Erosion

Dennis C. Flanagan

Introduction

Soil erosion is the detachment or breaking away of soil particles from a land surface by some erosive agent, most commonly water or wind, and subsequent transportation of the detached particles to another location. Usually, erosion occurs when a fluid (air or water) moves into and/or across a soil surface. Fluid and sediment particle impact forces, shear forces, and turbulence act to detach and lift soil into the fluid flow that then transports the particles away (Figure 1). The force of gravity moves detached soil particles downward, while cohesive forces between soil particles resist detachment and transport. Physical and chemical dispersion can disrupt cohesion and break soil aggregates into smaller and more easily transported particles. At some time and location away from the initial point of detachment, the sediment particles will eventually move back down to a state of rest on a soil surface, in a process known as deposition or sedimentation.

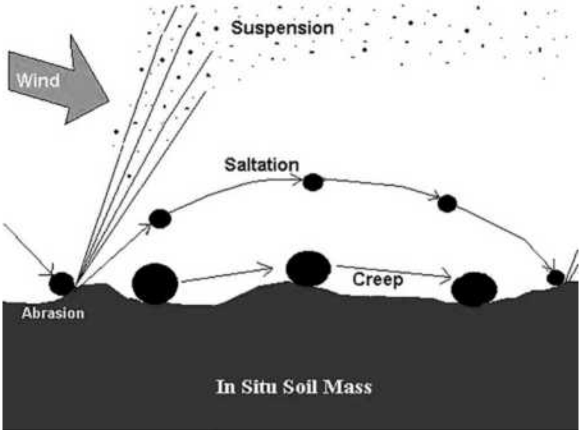

FIGURE 1 Soil erosion by wind, showing the three modes of movement (creep, saltation, and suspension).

Erosion by Wind

Erosion by wind occurs when wind speed exceeds a certain critical or threshold value. Soil particles can be detached and moved through suspension, saltation, or creep (Figure 1). Suspension usually lifts the smallest soil particles (clays, silts, organic matter) so high into the air mass that they are easily kept in motion and can travel for long distances. Soil particles that move by creep are larger sand grains and aggregates that stay in contact with the soil surface at almost all times—their motion is often through rolling and bouncing. Saltating soil particles are usually moderate in size and, once detached, move in trajectories up into the air and then back down to the soil surface. Saltating particles often cause further detachment through abrasion by striking the soil surface with sufficient momentum to dislodge additional soil particles from the in situ soil mass.

Erosion by Water

The most common types of soil erosion by water are sheet and rill erosion on upland areas, channel and gully erosion in small watersheds, and stream channel and bank erosion in larger catchments. Sheet erosion is caused by the action of raindrops (Figure 2) and shallow overland flows that remove a relatively uniform depth (or sheet) of soil. Because of the uniform nature of the soil loss, it is often difficult to detect and gauge the extent of damage caused by sheet erosion. On the other hand, rill erosion occurs in well-defined and visible flow concentrations or rills (Figure 3). Soil detachment in rills is large because of flow shear stress forces acting on the wetted perimeter of the rill channel (Figure 4). Once detached, larger sediment particles move as bedload, rolling and bouncing down slope with the flow, and are almost always in contact with the soil (or bed) surface. Smaller sediment particles (silts and clays) are much easier to transport and travel in the rill channels as suspended load. Rills are also the major pathways for transporting away sediment that is detached by sheet erosion (also known as interrill detachment).

By definition, rill channels are small enough to be obliterated by tillage and will not reform in exactly the same location. As one moves from smaller hillslopes to larger fields and watersheds, additional erosion processes come into play, because of the increasing amounts of runoff water. Gullies are incised erosion channels that are larger than rills and form in regions of large runoff flow concentration. Ephemeral gullies are a common type of erosion feature in many fields (Figure 5). They are small enough to be tilled over but will re-form in the same location owing to the convergent topography in small catchments. Runoff flows from large events can erode down through tilled soil layers, until a nonerodible layer is reached, and then the ephemeral gully channel will widen and soil detachment will decrease. Classical

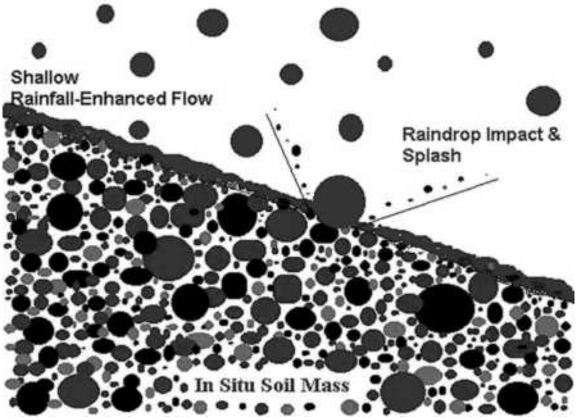

FIGURE 2 Soil detachment by raindrop impact and shallow flow transport.

FIGURE 3 Rill erosion, which is caused by concentration of flowing water, forms easily recognizable regions of detachment on a soil surface. (Courtesy M. Huhnke, Oklahoma State University.)

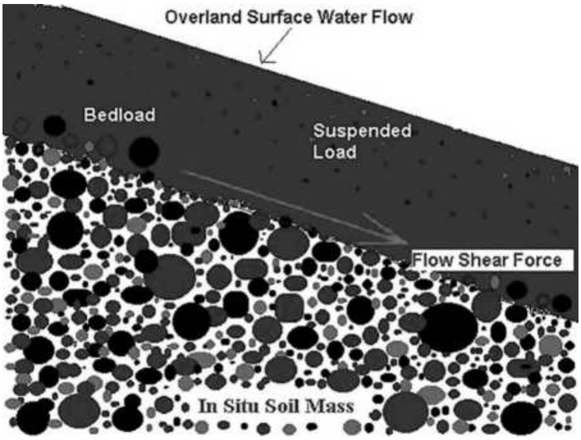

FIGURE 4 Soil detachment and transport in rills are largely because of flow shear forces.

gullies are larger erosion features that cannot normally be tilled across (Figure 6). The physical processes in classical gullies include other factors such as headcutting, seepage, sidewall sloughing, and clean-out of fallen sidewall materials.

As the size of watersheds increases further, and streams increase in size and become perennial (because of subsurface water flows from springs and aquifers), the erosion processes in play change as well. Stream and channel erosion at these larger scales can include scouring of the channel beds as well as the contributions from the channel banks. Areas in streams may be in states of degradation, in which active detachment is lowering the level of the channel bed, or they may be in states of aggradation, in which sediment deposition is raising the bed level.

Gravity-Induced Erosion

There are also less frequent but more extreme forms of gravity-induced erosion on steep slopes from saturated soils that can be exacerbated by events such as earthquakes. Large masses of land can slowly or rapidly slide down hills when the cohesive forces holding them in place fail (landcreep, landslide, debris flow, etc.).

FIGURE 5 Typical ephemeral gully located in a soybean field in Indiana.

FIGURE 6 Classical gullies in the Loess Plateau of China. Terrace farming is being used to stabilize some of the hillslopes.

These types of erosion events typically occur when large rainfall or snowmelt water depths saturate soil profiles and weaken their resistance to slip.

Erosion Assessment

Erosion is a serious problem within the United States and throughout the world. In 2015, the United States Department of Agriculture (USDA)-Natural Resources Conservation Service estimated that about 1.7 billion tons of soils are lost each year from nonfederal rural croplands because of sheet and rill erosion by water and erosion by wind.[1] Also, over 20% of cropland in the United States is eroding at excessive rates. These estimates are on the low side because erosion of other types (e.g., gully) and at other locations (urban lands, federal lands) were not included in this inventory. Throughout the world, FAO estimates that 16% of the total land area (21,960,000 km^2 of 134,907,000 km^2) is subject to significant risk of soil erosion.[2] In Asia, South America, and Africa, soil erosion rates are highest at an estimated average of 30–40 t/ha/yr, while in Europe and North America average rates are somewhat lower at about 17 tons/ha/yr.[3,4] A sustainable rate of soil loss (rate of soil loss is equal to rate of soil formation) is thought to be about 1 t/ha/yr.[3]

Erosion assessment can be a difficult task to perform in the field, and monitoring of soil lost and transported by wind or water can be expensive and prone to measurement errors. Gullies are easy to recognize, while soil lost to sheet and rill erosion is hard to gauge. Sheet and rill erosion may be occurring on hill slopes that are adjacent to a gully and may actually contribute more sediment to runoff water than the gully itself. Visual assessment of rates of wind erosion losses can be even more difficult to perform. Mathematical equations or sets of equations have been developed and used since the mid-1900s to estimate the rates of soil loss caused by wind ("Wind Erosion Equation"[5]) or water ("Universal Soil Loss Equation"[6,7]). More recently, computer models are being applied to simulate soil erosion processes and to estimate detachment, transport, and deposition of sediment.[8,9,10,11]

Erosion Impacts

Erosion has a range of impacts, both on-site and off-site. Soil loss removes fertile topsoil, organic matter, and nutrients, thus decreasing the tilth, water-holding capacity, and general productivity of a soil for on-site agricultural production. Regions of detachment can expand to dislodge and remove small crop seedlings, while regions of deposition can bury and kill small plants. In the case of wind erosion, the erosion process can damage fragile young seedlings through abrasion of plant tissue. When excessive detachment occurs, such as is the case with gully erosion, whole sections of fields may be destroyed or may become inaccessible to farmers and their equipment. Eroded sediment can cause a number of off-site problems, including deposition along windbreaks, ditches, and waterways. The deposited sediment may require costly dredging and removal operations. Nutrients and pesticides associated with sediments can also contaminate air and water bodies. Erosion by wind can cause massive dust storms that blind drivers and cause accidents, and sand particles can abrade and damage painted surfaces on buildings and vehicles. Some recent estimates are that the cost of combined on-site and off-site effects from soil erosion in the United States is as high as $44 billion per year.[3]

Erosion Control and Soil Conservation

Many nations have created government agencies or organizations to specifically deal with soil erosion problems and to interact with landowners to get conservation practices implemented on the landscape. In the United States, the Natural Resources Conservation Service assists in the implementation of soil conservation practices on agricultural lands, the Forest Service manages sediment delivery from forests and timber harvest roads, and the Bureau of Land Management manages soil loss on range and grazing lands. The Department of Defense is responsible for managing erosion and off-site sediment delivery from lands that it uses for military training activities. However, in some countries, efforts to address and minimize erosion problems are nonexistent or severely limited because of the poor economic conditions, failure to recognize the erosion threat, and/or the extreme magnitude of the soil erosion.

A variety of soil conservation methods are available that can be applied on a landscape to minimize erosion problems caused by wind or water. Wind erosion can be controlled through the use of windbreaks, crop residues, and tillage to induce significant surface roughness. Control procedures for erosion by water need to be determined, based upon the types of active erosion processes. For example, if sheet and rill erosion is a major problem, then some type of conservation tillage practice that leaves large amounts of crop residues intact on the soil surface may be appropriate. However, if the water erosion problem is because of the large amounts of surface runoff concentrating in a field and forming an ephemeral gully, then crop residues may not be adequate; instead, permanent vegetative cover in a grass waterway may be necessary, along with appropriate engineering structures (e.g., drop-box). Erosion prediction models can be used to assist in selecting and designing appropriate conservation practices.

Through the use of proper conservation planning and application of appropriate soil conservation methods, most erosion problems can be minimized or eliminated. This is critically important if the soil resource is to be preserved for continuous use in food and fiber production for current and future generations.

Conclusions

Erosion is a natural process of soil detachment and removal that can be greatly influenced through human activities (agriculture, construction, timber-harvesting, etc.). Use of proper erosion prediction technology and appropriate erosion control methodologies is critical if we are to sustain the soil resource for use by future generations.

Erosion by Water: Erosivity and Erodibility

Peter I.A. Kinnell

Introduction

Conceptually, rainfall erosivity is the capacity of rain to produce erosion, whereas soil erodibility is the susceptibility of the soil to be eroded. Historically, the terms erosivity and erodibility were originally associated with the *R* and *K* factors in the Universal Soil Loss Equation (USLE),

$$A = R\ K\ L\ S\ C\ P \tag{1}$$

where *A* is the long-term (e.g., 20 years) annual average soil loss per unit area from sheet and rill erosion, *R* is the rainfall (erosivity) factor defined as the average annual value of the product of the total storm kinetic energy (*E*) and the maximum 30-min intensity (I_{30}, twice the maximum amount of rain that falls in any 30-min period during a storm), *K* is the soil (erodibility) factor, *L* is the slope length factor, *S* is the slope gradient factor, *C* is the crop (vegetation) and crop management factor, and *P* is the conservation support practice factor.[1] Numerically, soil erodibility is the mass of soil eroded per unit of the erosive index. This means that numerical values of *K* can only be used when *R* is as it was originally defined as the average annual value of the product of *E* and I_{30}.

The USLE was designed to predict sheet and rill erosion from field-sized areas and only *R* and *K* have units. The *L*, *S*, *C*, and *P* factors each have values of 1.0 for the so-called "unit" plot, a bare fallow area 22.1 m long on a 9% slope with cultivation up and down the slope. Consequently, the soil loss for the "unit" plot (A_1) is given by

$$A_1 = R\ K \tag{2}$$

and, for any other situation,

$$A = A_1\ L\ S\ C\ P \tag{3}$$

Although, traditionally, K is calculated by dividing A_1 by R, K can be perceived as acting similarly to the regression coefficient in the direct relationship between event soil loss on the unit plot (A_{1e}) and EI_{30}. However, regression analysis of the relationships between storm soil losses on the unit plot and EI_{30} tends to produce regression coefficients that may differ appreciably from those calculated using the traditional method. Consequently, the traditional approach should always be used in determining K values from runoff and soil loss plot data.

To reduce the need to run long-term experiments to determine K values for soils where K is unknown, Wischmeier[2] developed a nomograph for determining K from soil properties for soils with less than 70% silt in the United States. Alternatively, K values in customary U.S. units for soils where the nomograph can be used may be obtained using

$$K = \left(2.1\ X_1^{1.14}10^{-4}\left(12 - X_2\right) + 3.25\left(X_3 - 2\right) + 2.5\left(X_4 - 3\right)\right)/100 \tag{4}$$

where X_1 is % silt multiplied by 100 – % clay, X_2 is % organic matter, X_3 is the soil structure code used in the U.S. soil classification, and X_4 is the profile permeability code. A number of other equations have been developed for soils at various geographic locations (e.g., El-Swaify,[3] Young and Mutchler,[4] Loch,[5] and Zhang et al.[6]), but Eq. (4) is frequently used outside the United States without being validated for the soils involved. Division of the right-hand side of Eq. (4) by 7.59 will yield K values in SI units of t h /MJ/mm.

The two-staged mathematical approach shown by Eqs. (2) and (3) results from the fact that the USLE is an empirically based model. It was developed in the 1960s and 1970s from more than 10,000 plot years of data. Mathematically, the Revised Universal Soil Loss Equation (RUSLE[7]) uses Eqs. (2) and (3) in the same way as the USLE, but changes were made to how some of the factors in the model are calculated. Originally, in the USLE, the events used to calculate R were restricted to those that produced more than 12.5 mm of rain or at least 6.25 mm of rain in 15 min. That rule was abandoned in the RUSLE when R values were calculated for the western part of the United States because it was argued that the rule had no appreciable effect on R values. Yu[8] noted that changing the threshold to zero increased the R factor by 5% in the tropical region of Australia. However, the abandonment of the rule in the RUSLE failed to recognize that that rule had been put in place as a means of discounting storms that tended to be nonerosive because they produced no runoff.

Variants of the USLE

Eq. (2) operates on the assumption that a direct linear relationship exists between event erosion (A_e) and EI_{30}. Although this assumption is appropriate at some geographic locations, it is not appropriate at others (Figure 1). Soil measured as a loss from the plots used to develop the USLE was discharged in runoff. When runoff occurs, the amount of soil discharged (Q_s) in the runoff can be considered to be the product of the amount of water discharged (Q_w) and the sediment concentration (c_s), the amount of soil per unit quantity of water,

$$Q_s = Q_w c \tag{5}$$

It follows from Eq. (5) that, in the USLE, the sediment concentration is directly proportional to EI_{30} divided by runoff amount. However, it has been observed[10] that the sediment concentration for an event at some geographic locations is correlated to the product of the kinetic energy per unit quantity of rain and I_{30} (Figure 2). This results in an event erosivity index (R_e) that is given by

$$R_e = Q_{Re} EI_{30} \tag{6}$$

where Q_{Re} is the runoff ratio (runoff amount divided by rainfall amount) for the event. This index is more effective in accounting for event soil losses at some locations where the EI_{30} index does not work

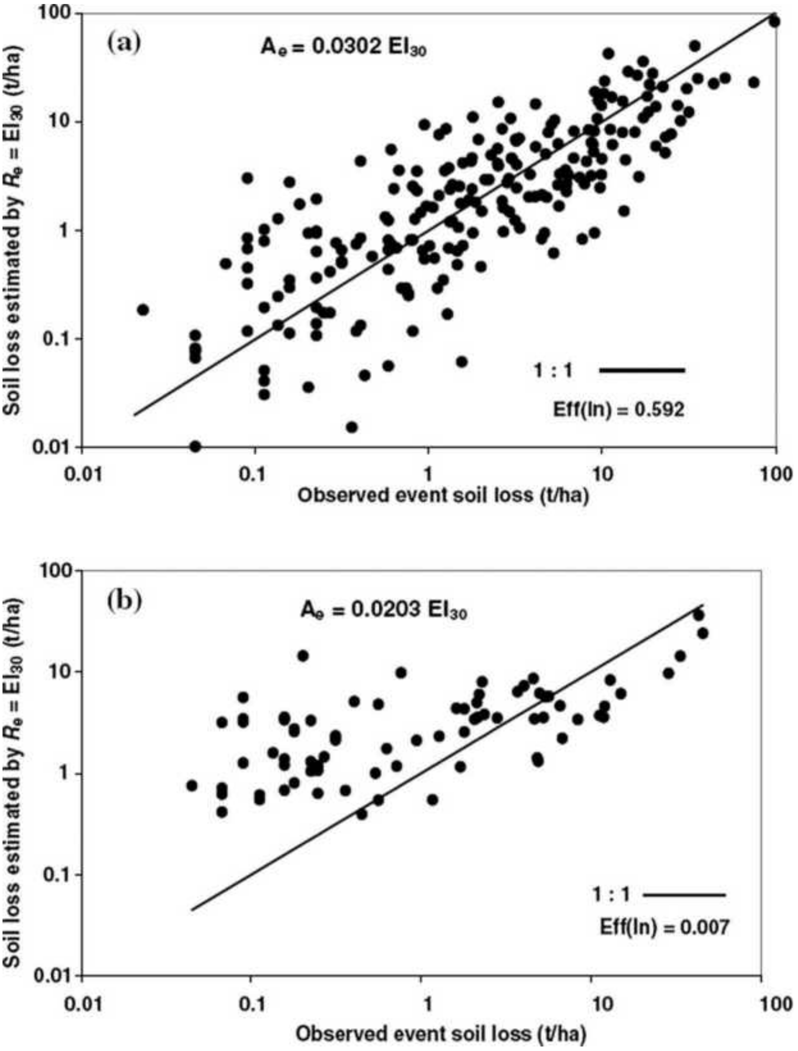

FIGURE 1 The relationships between event erosion (A_e) and EI_{30} obtained on bare fallow plots in the United States: (a) Plot 5 Experiment 3 at Holly Springs, Mississippi, and (b) Plot 5 Experiment 1 at Morris, Minnesota. Eff(ln) is the Nash–Sutcliffe[9] efficiency factor for logarithmic transforms of the data.

well (Figure 3). Because R_e is not equal to EI_{30}, USLE K factor values cannot be used in conjunction with Eq. (6). Soil erodibilities associated with Eq. (6) are calculated dividing A_1 by the average annual sum of the product of Q_{Re} and EI_{30}.

A number of other event erosivity indices have been proposed. Williams[11] proposed a modification of the USLE to predict event sediment yield (SY_e):

$$SY_e = 11.8\left(q_e q_p\right)^{0.56} K\ L\ S\ C_e\ P_e \tag{7}$$

where q_e is the volume of runoff (m^3) for the event; q_p is the peak flow rate (m^3/sec); K, L, and S are standard USLE factors; and C_e and P_e are event C and P factors, respectively. This model is commonly known as the Modified Universal Soil Loss Equation (MUSLE). It should be noted the value of 11.8 in

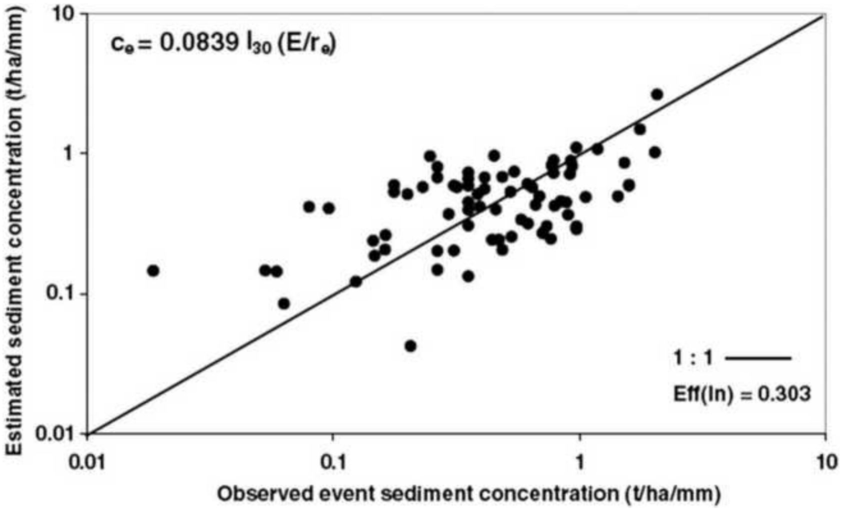

FIGURE 2 The relationship between event sediment concentration (c_e) and the product of I_{30} and the kinetic energy per unit quantity of rain (E/r_e) for Plot 5 Experiment 1 at Morris, Minnesota.

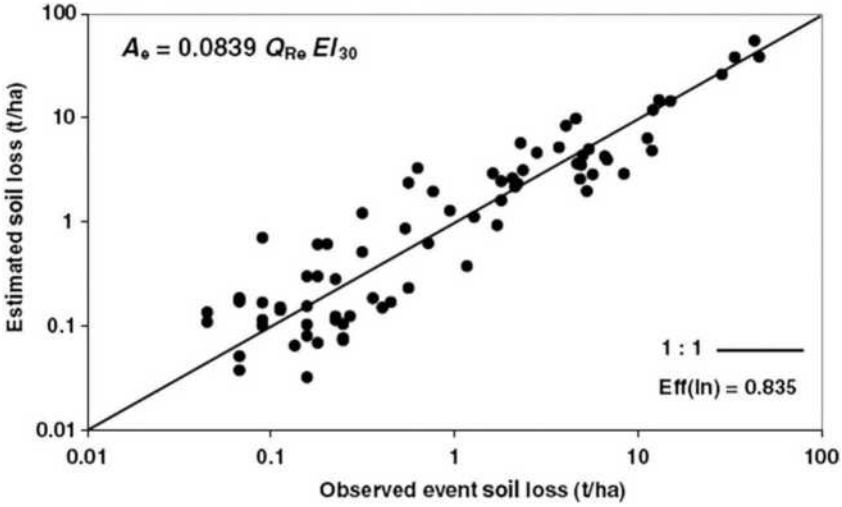

FIGURE 3 The relationship between event erosion and the product of event runoff ratio (Q_{Re}) and EI_{30} for Plot 5 Experiment 1 at Morris, Minnesota.

Eq. (7) was generated for the specific situation where Williams[11] obtained measured data. Consequently, the general applicability of this value is questionable. In Agricultural Policy/Experimental eXtender Model (APEX),[12]

$$\mathrm{SY_e} = X_e K\ L\ S\ C_e\ P_e[\mathrm{RKOF}] \tag{8}$$

X_e is selected from

$$X_e = EI_{30} \tag{9a}$$

$$X_e = 1.586\left(q_e q_{pe}\right)^{0.56} \mathrm{DA}^{0.12} \tag{9b}$$

$$X_{\mathrm{e}} = 0.65\ EI_{30} + 0.45\left(q_{\mathrm{e}}q_{\mathrm{pe}}\right)^{0.33} \tag{9c}$$

$$X_{\mathrm{e}} = 2.5\left(q_{\mathrm{e}}q_{\mathrm{pe}}\right)^{0.5} \tag{9d}$$

$$X_{\mathrm{e}} = 0.79\left(q_{\mathrm{e}}q_{\mathrm{pe}}\right)^{0.65}\ \mathrm{DA}^{0.009} \tag{9e}$$

$$X_{\mathrm{e}} = b_5 q_{\mathrm{e}}^{\ b6}\ q_{\mathrm{e}}^{\ b7}\ \mathrm{DA}^{b8} \tag{9f}$$

where DA is drainage area expressed in hectares, *b*6–*b*8 are user-selected coefficients,[12] and RKOF is the coarse fragment factor as defined by Simanton et al.[13] However, Eqs. (7) and (8) with Eqs. (9b–9f) all use USLE *K* factor values and not ones that are associated with the different erosivity indices used and so do not conform with the mathematical modeling rules upon which the USLE model is based. Consequently, the MUSLE and APEX models are not valid variations of the USLE. In addition, any model that uses event erosivity index values that are calculated using runoff from a vegetated area or any area that is not cultivated up and down the slope will violate the mathematical rules if it uses USLE *C* and *P* factor values.

Mathematical models like the USLE and its derivatives are largely designed to aid management decisions and operate at a level where spatial and temporal variations in the various forms of erosion (splash erosion, sheet erosion, rill erosion, interrill erosion) are not considered in any appreciable detail. However, rill erosion is driven by flow energy, while sheet and interrill erosion are associated more closely with rainfall kinetic energy. In order to better account for this, Onstad and Foster[14] used the equation

$$R_{\mathrm{e}} = 0.5EI_{30} + 0.5\alpha\left(q_{\mathrm{e}}q_{\mathrm{p}}\right)^{0.333} \tag{10}$$

Eq. (10) indicates that the sediment concentration for an event (c_{e}) in the data set considered by Onstad and Foster[14] is given by

$$c_{\mathrm{e}} = 0.5\left[EI_{30}/q_{\mathrm{e}}\right] + 0.5\left[\alpha\left(q_{\mathrm{p}}\right)^{0.333}/q_{\mathrm{e}}^{\ 0.666}\right] \tag{11}$$

The value of α in Eq. (10) was set so that the long-term average value of R_{e} produced by Eq. (10) was the same as the long-term average value produced when $R_{\mathrm{e}} = EI_{30}$. Given that *K* is, by definition, the amount of soil loss per unit of *R* when $R_{\mathrm{e}} = EI_{30}$, this enabled Eq. (10) to be used with USLE *K* values to predict soil loss from bare fallow areas. Although Williams et al.[15,16] indicated that Onstad and Foster[14] was the source of Eq. (9c), there is no provision in APEX to do the same and ensure that USLE *K* values can be used.

Bagarello et al.[17] observed that

$$R_{\mathrm{e}} = \left(Q_{\mathrm{Re}}EI_{30}\right)^{\beta} \tag{12}$$

with $\beta > 1.0$ applied to soil losses from a number of simultaneously operating plots of different length (λ) established at the experimental station of Sparacia, Sicily. Subsequent analysis [Bagarello et al.[18]] established that $\beta > 1.0$ appeared to be the result of an interaction between event runoff (Q_{e}) and slope length (λ) on sediment concentration so that

$$R_{\mathrm{e}} = Q_{\mathrm{Re}}EI_{30}Q_{\mathrm{e}}^{\ 0.0207\lambda} \tag{13}$$

when λ is in meters.

Arguably, from a physical viewpoint, since slope length and gradient influence the erosive stress, they can be considered to be factors that influence erosivity, but the USLE model is not designed to model the physical processes themselves. It is designed to predict rainfall erosion based on climate, soil, topography, crops, and management factors. Normally, in the USLE model, the effect of slope length on soil loss is expressed through the L factor, but in the case of Eq. (13), L would remain at 1.0 irrespective of variations in slope length. The positive effect of runoff on sediment concentration may have been associated with the fact that the data were collected on a 15% slope. Rainfall erosion on much lower slope gradients is not associated with as high an erosion stress from runoff as likely to have been the case at the Sparacia site. In fact, the RUSLE makes provision for the cushioning effect of water depth on the energy of raindrop impact on low slopes.

Because, as noted above, R_e is not equal to EI_{30}, USLE K factor values cannot be used in conjunction with Eqs. (12) and (13). Soil erodibilities associated with Eq. (12) are calculated dividing A_1 by the average annual sum of $(Q_{Re}\, EI_{30})^{\beta}$. β varies between geographic locations in Italy, and consequently, the units for the associated soil erodibilities vary geographically. That is inconsistent with the concept of erodibility in the USLE modeling system. However, Kinnell (2018) showed that Eq. (12) can be rewritten as

$$R_e = a_1 \left(Q_{Re} EI_{30}\right)^{\beta} \tag{X1}$$

where a_1 is the ratio of the average annual value of $(Q_{Re}\, EI_{30})$ to the average annual value of $(Q_{Re}\, EI_{30})^{\beta}$. a_1 and β are related mathematically to each other, a_1 being equal to 1.0 when β equals 1.0, less than 1.0 when β is greater than 1.0, and greater than 1.0 when β is less than 1.0. When Eq. (X1) is used, soil erodibilities determined by dividing A_1 by average annual value of $(Q_{Re}\, EI_{30})$ apply at all geographic locations irrespective of the value of β.

Rainfall Kinetic Energy

Data on storm rainfall kinetic energy are not measured at many geographic locations, and often, kinetic energy values are obtained indirectly. If data on storm rainfall intensities are available, then it is common for storm kinetic energies to be estimated from rainfall kinetic energy–intensity relationships. These relationships are based on raindrop-size data collected during rainfall events at a geographic location assumed to have rainfall characteristics that are consistent with those at the geographic location of interest. Various techniques have been employed to do this, and these have generated rainfall intensity–kinetic energy relationships which are often used at locations that lie outside the climatic zones where the measurements were originally made. In the USLE, the relationship recommended between the kinetic energy per unit quantity of rain (e) and rainfall intensity (I) for the United States is expressed by

$$\begin{gathered} e = 916 + 331 \log_{10} I, \\ \text{for } I < 3 \ \text{ in./h} \end{gathered} \tag{14a}$$

$$\begin{gathered} e = 1074, \\ \text{for } I \geq 3 \ \text{ in./h} \end{gathered} \tag{14b}$$

where e is in units of foot-tons per acre per inch and I is in inches per hour, following analysis of drop-size data collected by Law and Parsons.[19] In the RUSLE, Eq. (14) is replaced by

$$e = 1099\left(1 - 0.72 \exp\left[-1.27I\right]\right) \tag{15}$$

whose metric equivalent is

$$e_m = 0.29\left(1 - 0.72 \exp\left[0.05I_m\right]\right) \tag{16}$$

where e_m has units of megajoules per hectare per millimeter and I_m has units of millimeters per hour. Eqs. (15) and (16) use the mathematical form proposed by Kinnell.[20,21] Yu[8] observed that replacing

Eq. (14) by Eq. (15) reduced the R factor by about 10% in the tropical region of Australia. A number of other mathematical equations have been reviewed by van Dijk et al.[22] Some of these produce negative values of rainfall kinetic energy at low rainfall intensities. In RUSLE2 (USDA, 2013),

$$e_{\mathrm{m}} = 0.29\left(1 - 0.72\ \exp\left[0.08 I_{\mathrm{m}}\right]\right) \tag{X2}$$

Both Eq. (16) and Eq. (X2) produce response curves that increase non-linearly from low values at low intensities with e_{m} values remaining close to 0.29 MJ/ha/mm for intensities beyond 75–100 mm/h, but Eq. (X2) gives higher values of e_{m} below 75 mm/h. Eq. (X2) was adopted because it produced results that were more consistent with the USLE equation (Nearing et al., 2017). However, short-term values measured during rainstorms vary greatly about the values produced by Eq. (X2) or any other rainfall intensity-e_{m} relationship. Also, although Eqs. (15), (16), and (X2) were developed for use in the United States, they have been used in other parts of the world without validation. In reality, storm kinetic energies calculated from rainfall intensity–kinetic energy relationships are often not close to actual storm kinetic energies but are, in effect, numerical values that are biased toward high-intensity rainfall at the expense of low-intensity rainfall.

In many geographic locations, there is a lack of rainfall intensity data so that it is not possible to determine storm kinetic energies using rainfall kinetic energy–intensity relationships. Event or daily rainfall amounts are more commonly recorded. One approach that has been used in a number of geographic areas such as Canada,[23] Finland,[24,25] Italy,[26] and Australia[27] considers that EI_{30} is related to a power of event rainfall amount (X_{p}),

$$EI_{30} = a_1 X_{\mathrm{P}}^{b1} \tag{17}$$

where a_1 and b_1 are empirical constants. The value of a_1 may show seasonal variation.[25,28] Given that, in the context of the criteria associated with the USLE/RUSLE model, daily rainfall provides a reasonable proxy for storm rainfall amount[29]; Eq. (17) provides a practical approach to extending observed EI_{30} values to areas where appropriate rainfall intensity data are lacking.

Although determining R is a primary requirement for modeling soil loss using the USLE approach, temporal variations in erosivity during the year are required in order to account for the effects of crops and crop management on erosion. $C = 1$ when soil is bare, and $C = 0$ when vegetation completely protects the soil against erosion. Consequently, how erosivity and the protective effect of crops vary during the year are factors that are taken into account in determining C for various agricultural systems. In RUSLE2, a factor known as "erosivity density" is used (USDA, 2013). Erosivity density is EI_{30} divided by storm rainfall amount. While rainfall storm rainfall amounts are highly variable in time and space, erosivity densities are more readily mapped in time and space than EI_{30} itself. Because storm energy is highly influenced by the amount of rain energy that occurs when I_{30} is measured, storm erosivity densities tend to be highly influenced by variations in I_{30}.

More Process-Based Models

Although the USLE/RUSLE is the most widely used method of predicting soil losses from the land worldwide, rainfall erosion results from various forms of erosion (splash erosion, sheet erosion, rill erosion, interrill erosion) that are driven by different forces so that there is no absolute measure of either rainfall erosivity or soil erodibility. Consequently, more process-based models have been developed in order to predict the contributions of the various forms of erosion more directly. Often, the forms vary in a topographic sequence with splash erosion dominating erosion at the upper end of a slope and sheet erosion further down before areas of rill and interrill erosion. Particles detached at the top of the slope may be transported by a number of different transport mechanisms before being finally discharged from the eroding area. The Water Erosion Prediction Program in the United States generated the WEPP model, a more process-based model than the USLE/RUSLE designed to model the spatial contributions of rill and interrill erosion in agricultural landscapes.[30] Flow shear stress (τ) is used as the erosivity factor in rill erosion model,

$$D_r = k_r(\tau - \tau_c)(1 - q_{sr}/T_r) \tag{18}$$

where D_r is rill detachment, k_r is the rill erodibility factor, τ_c is the critical shear stress that has to be exceeded before detachment occurs, q_{sr} is the sediment load in the flow, and T_{cr} is the sediment load at the transport limit. For erosion to occur, particles must be plucked from within the soil surface where they are held by cohesion and interparticle friction. Detachment is the term used to refer to this process. For detachment in rills to occur, the flow must have shear stress that exceeds τ_c. Also, for erosion to occur, detached particles must be transported away from the site of detachment. Flows are known to have a limited capacity to transport soil material and that limit is represented by T_r in Eq. (18). Consequently, the term $1-q_{sr}/T_r$ causes $D_r = 0$ when the sediment load in the rill equals the transport limit. As a result, D_r may vary along the length of a rill. Interrill erosion contributes to q_{sr} so that rill erosion may be completely suppressed if the discharge of sediment from the interrill areas is high enough.

Originally, the erosivity factor in the WEPP interrill model was assumed to be the square of rainfall intensity (I) so that

$$D_i = k_i I^2 \tag{19}$$

where D_i is interrill detachment and k_i is the interrill soil erodibility factor. A series of rainfall simulation experiments[31] were undertaken to determine k_i values for soils in the United States. Subsequent analysis[32] of the data generated by these experiments established that it was more appropriate to use

$$D_i = k_{iq} q_i I \tag{20}$$

where q_i is the runoff rate from the interrill area and k_{iq} is the interrill erodibility factor. The k_i values determined using Eq. (19) cannot be used in Eq. (20).[32]

D_i is determined using data on the amounts of soil material discharged from interrill areas. The use of the term "detachment" in relation to D_i is not absolutely correct because the transport processes involved in moving soil material over interrill areas are not 100% efficient. Also, detachment varies with raindrop size and velocity but, in using Eq. (20), that effect is ignored. However, provision is made in WEPP to take account of differences in drop-size distribution associated with different rainfall simulators in experiments designed to determine values of k_{iq}.

Eqs. (18) and (20) provide the basic equations that enable WEPP to model the contributions of rill and interrill erosion to soil loss more directly than when the USLE/RUSLE model is used but, in WEPP, the spatial distribution of rill and interrill areas needs to be well defined. WEPP was originally designed to operate in situations where ridge tillage is used. With ridge tillage, interrill erosion is well defined as being on the ridge slopes and rill erosion as being in the furrows. In other situations, the distributions of rill and interrill areas are more difficult to specify. In rangelands, broad areas of surface water flow occur more commonly than rills so that splash and sheet erosion dominate. An alternative to the WEPP cropland interrill erosion model,

$$D_{SS} = k_{SS} I^{1.05} q_{SS}{}^{0.59} \tag{21}$$

where D_{ss} is the "detachment" associated with splash and sheet erosion, k_{ss} is the erodibility factor, and q_{ss} is the runoff rate from the associated eroding surface, has been developed for use in rangelands.[33]

EUROSEM is another erosion model that is more process based than the USLE/RUSLE. In EUROSEM, detachment by raindrop impact (D_r) is modeled using

$$D_{\mathrm{r}} = \frac{k_D}{\rho_{\mathrm{s}}} KE \exp(-zh) \tag{22}$$

where k_D is an index of detachability that is determined experimentally, ρ_{s} is particle density, KE is the rainfall kinetic energy of the raindrops impacting the ground, z is a factor that varies with soil texture, and h is the mean depth of the water layer on the soil surface. Detachment by flow is modeled using

$$D_{\mathrm{f}} = \beta w\ v_{\mathrm{s}}(C_{\mathrm{T}} - C) \tag{23}$$

where β is an index of detachability, w is flow width, v_{s} is particle settling velocity, C is the sediment concentration, and C_{t} is the sediment concentration at the transport capacity of the flow.

The coefficients used in Eq. (22) result from measurement of soil material transported by splash under ponded conditions in the experiments of Torri et al.[34] where increases in water depth were observed to reduce splash erosion. The effect of water depth on splash erosion results from (1) dissipation of raindrop energy in the water layer and (2) the effect of water depth on splash trajectories. Considering that splash does not transport 100% of the material detached by raindrops impacting water, Eq. (22) does not actually model detachment. Also, erosion by rain-impacted flows where sediment is transported by rolling, saltation, and suspension in the flow is the real focus of Eq. (22), and the effect of flow depth on erosion by rain-impacted flows is quite different from its effect on splash erosion.[35]

As a general rule, the values of soil erodibility factors have to be determined experimentally, although there are cases where they are predicted from soil properties. In areas where detachment results from raindrop impact, erodibility is affected by modification of the soil surface generated by the impacts. Raindrop impacts on surfaces not covered by water may break soil aggregates and generate surface crusts that affect soil erodibility. In areas where soil crusts occur, particles are held more tightly within the soil surface than in areas that are not crusted and this reduces detachment. With splash erosion, loose particles sit and wait on the soil surface between drop impacts. The transport efficiency of splash increases with slope gradient but, over time, a layer of loose particles builds up on the soil surface, and energy has to be expended in moving them before detachment can occur. Consequently, this layer provides a degree of protection against detachment. When raindrops impact a soil surface covered by water, the protection provided by loose particles sitting on the surface is in addition to that provided as the result of the dissipation of raindrop energy in the water layer.

Although splash erosion may dominate erosion for considerable periods during a rainfall event, rain-impacted flows are usually more important in moving soil material across the soil surface because the transport mechanisms in rain-impacted flows are much more efficient than splash transport. In rain-impacted flows, particles move across the soil surface by rolling, saltation, and complete suspension. Shallow low-velocity flows often do not have the capacity to cause particles to move by rolling and saltation by themselves, but rolling and saltation can be stimulated to occur when raindrops impact the soil surface through the flow. Under these circumstances, each rolling or saltation event is of limited duration and is associated with individual raindrop impacts. Figure 4 illustrates how raindrop and flow factors influence the detachment and transport processes associated with the erosion of fine particles, silt, and sand by rainfall. Particles moving by raindrop-induced rolling and saltation move across the surface at rates that depend on raindrop size, impact frequency, particle size, and density and the velocity of the flow. Consequently, depending on the rain and flow conditions, particles in rain-impacted flows travel across the surface at virtual velocities that vary from near zero to the velocity of the flow. In effect, particles are winnowed from the soil surface at various rates. Large gravel particles may not move at all and so, over time, soils that have high gravel contents may become highly resistant to erosion through the formation of erosion "pavements." Particles moving by raindrop-induced rolling and saltation sit on the soil surface between drop impacts and so provide a degree of protection against detachment as described in the case of splash erosion. As a result, soil resistance to erosion may vary considerably during a rainfall event. If H is the degree of protection provided by the loose material, then all the material

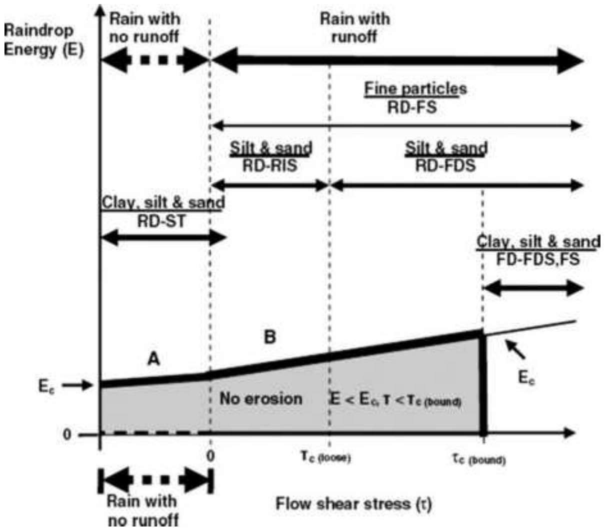

FIGURE 4 Schematic of how variations in raindrop kinetic energy and flow shear stress affect the detachment and transport of silt, sand, and fine particles during rainfall erosion. E_c is the critical raindrop kinetic energy required to cause raindrop detachment (RD). Its variation during rain with no runoff signifies changes in resistance to detachment caused by, for example, the development of a soil crust. Its variation with flow shear stress signifies the cushioning effect of increasing water depths. τ_c (bound) is the critical shear stress required to cause flow detachment (FD). τ_c (loose) is the critical shear stress required to cause flow-driven saltation (FDS). FS is continuous suspension in the flow. RIS is raindrop-induced saltation. ST is splash transport.

discharged from the soil surface comes from the layer of loose material when $H = 1.0$. Consequently, it follows from Eq. (20) that, for any given rainfall event,

$$D_{\mathrm{i}} = \left(k_{\mathrm{iq.U}}\left(1 - H\right) + Hk_{\mathrm{iq.P}}\right)q_{\mathrm{i}}I \tag{24}$$

where $k_{\mathrm{iq\cdot U}}$ is the interrill erodibility factor when no loose material exists on the surface and $k_{\mathrm{iq.P}}$ is the soil erodibility factor when loose material completely protects the soil surface from detachment. As noted earlier, detachment of soil particles from a cohesive surface varies with cohesion and interparticle friction so that factors such as the development of surface crusts can cause $k_{\mathrm{iq\cdot U}}$ to vary with time. The soil erodibility term in Eq. (24) is $k_{\mathrm{iq\cdot U}}(1\text{–H}) + H\, k_{\mathrm{iq.P}}$, and values of k_{iq} obtained in rainfall simulator experiments like those undertaken by Elliot et al.[31] lie between $k_{\mathrm{iq\cdot U}}$ and $k_{\mathrm{iq.P}}$. Where exactly they do lie is unknown because H is unknown.

Effect of Particle Travel Rates on Sediment Composition and Erodibility

As noted above, erodibilities have units of soil loss per unit of the erosivity index used in the model that is being considered in the analysis of the data. Factors such as cohesion, particle size, and aggregate stability have been observed to influence these erodibilities. Data on the physical and chemical nature of the soil involved may, in some cases, be used to predict erodibility, but often little attention is given to the composition of the sediment discharged in experiments undertaken to determine erodibility.

The composition of the soil transported from an eroding area by rain-impacted flow during an experiment tends to be finer than the original soil (e.g., Meyer et al.,[36] Miller and Baharuddin,[37] Palis,[38] and Parsons[39]), and particle travel rate is one of the factors influencing sediment composition. Fast-moving

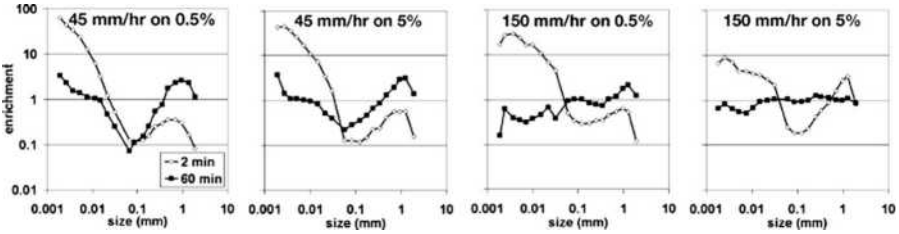

FIGURE 5 Enrichment factor curves for sediment discharged at 2 and 60 min when beds of sand were eroded by rain-impacted flows in experiments undertaken by Walker et al.[40] using 2.7 mm raindrops.
Source: Extracted from Figure 3 of Walker et al.[40]

particles detached at the top of an eroding area arrive at the downstream boundary well before slow-moving particles detached at the same place at the same time. Consequently, once sediment transport in rain-impacted flow starts, the fine material dominates the early discharge of sediment, but the composition of the sediment becomes coarser with time as more of the slower-moving particles reach the downstream boundary. If the particles are stable, then at the steady state, the composition of the sediment discharge must be the same both physically and chemically as the original soil. This is demonstrated by the results of laboratory experiments on erosion of sand by rain-impacted flows undertaken by Walker et al.[39] In these experiments, 3-m-long sloping beds of sand were eroded for 1 hour by rain-impacted flows generated by artificial rain at three rainfall intensities (45, 100, and 150 mm/h). The data shown in Figure 5 were generated by rain made up of a single drop size (2.7 mm) falling on rain generated flows over beds of sand with two different slope gradients (5% and 0.5%). The least erosive situation is the case where 45 mm/h rain fell when the slope gradient was 0.5%. The most erosive situation is the case where 150 mm/h rain fell when the gradient was 5%. The enrichment factor is the ratio of the proportion of the material in the sediment discharge to the proportion in the original material. In all cases, the discharge of sediment was dominated by fine material at 2 min and, in some cases, coarse material at 1 h (Figure 5). In the most erosive situation (150 mm/h rain falling on 5% slope), the sediment composition at 1 hour was close to the composition for the steady state, the composition that occurs when the

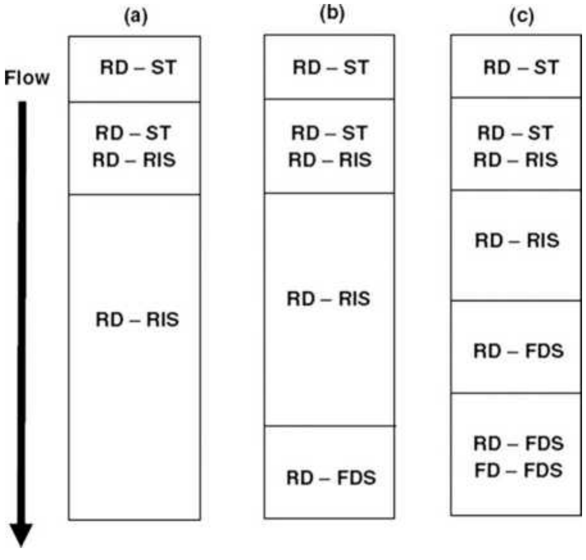

FIGURE 6 Schematic representation of how detachment and transport processes associated with rainfall erosion may vary spatially on planar inclined bare soil surfaces.

enrichment factor for all particle sizes equals 1.0. Sediment composition generated by the rain-impacted flows varies with the intensity of the rain, the slope gradient, slope length, and time because particles of different size and density travel at different rates. The differential rate of transport of particles in rain-impacted flows has consequences with respect to erodibility because the actual area contributing to the soil loss does not stabilize until the slowest-moving particles detached at the farthest point from the downslope boundary at the start of the rainfall event are discharged. This fact is seldom considered when experiments are undertaken to determine erodibility.

Eq. (24) is essentially targeted at situations where raindrop-induced saltation (RIS) controls sediment discharge in situations like that illustrated in Figure 6a. Particles of silt and sand may travel over the soil surface in more than one mode before being discharged. For example, as may be perceived from Figure 6b, they may leave the point of detachment traveling in splash (ST), then move further downslope by RIS, and finally by flow-driven saltation (FDS) as flow energy increases down the slope. Transitions between RIS and FDS may vary in time and space during a rainfall event and will depend on the intensity of the rain, the infiltration characteristics of the soil, the length of the slope, and the

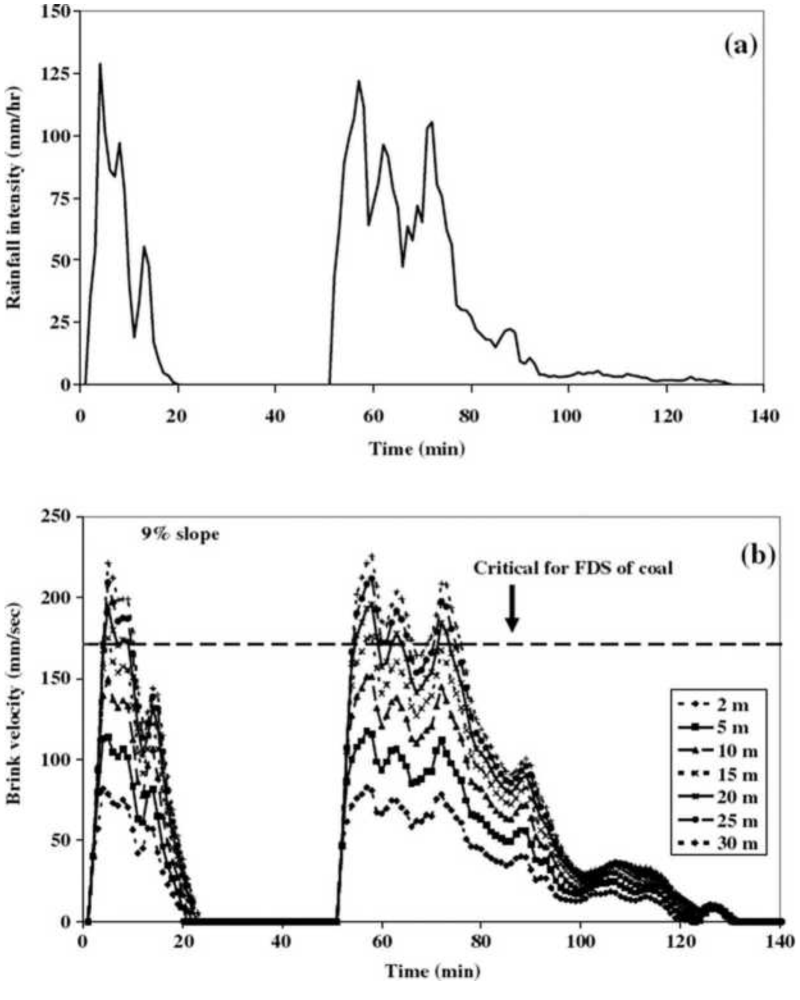

FIGURE 7 Brink (downstream boundary) flow velocities (b) for bare soil of various lengths inclined at 9% produced by the rainfall-runoff model described by Moore and Kinnell[41] and the rainfall intensities recorded during a rainfall event at the Ginninderra Experiment Station, Canberra, Australia (a).

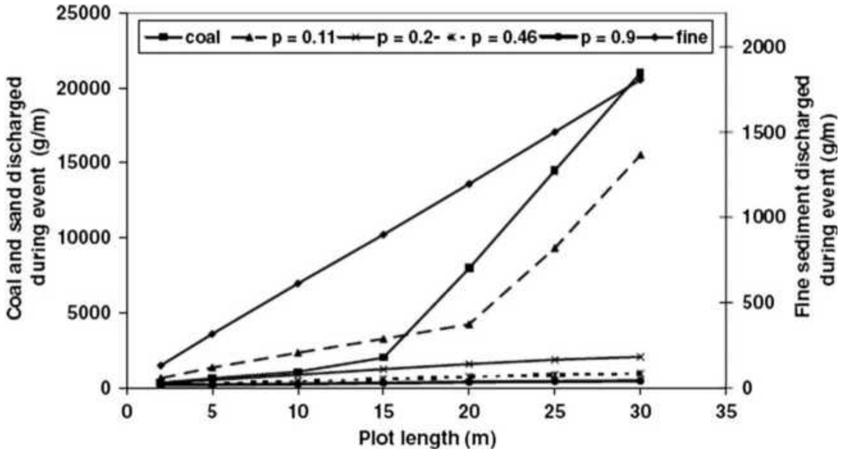

FIGURE 8 Amounts of coal, sand, and fine particles discharged for the rainfall and runoff conditions shown in Figure 7 when a mechanistic model of erosion by rain-impacted flow was used by Kinnell.[42]

slope gradient. The effect of the transition can have an appreciable effect on both soil loss and the composition of the sediment discharged. Figure 7b shows modeled flow velocities at the brink (discharge boundary) of planar bare soil surfaces of various length on a 9% slope resulting from the rainfall event shown in Figure 7a. Figure 8 shows the loss of materials of various size and density from those bare soil surfaces when a mechanistic model of erosion by rain-impacted flow was used by Kinnell.[42] For the surfaces up to 15 m in length, particles larger than 0.1 mm in size traveled over the whole length by RIS. Under these conditions, more of the 0.11 mm sand was lost during the event than the 0.46 mm coal. On the 20-m-long area, the 0.46 mm coal, which had been traveling slower than the 0.11 sand on shorter areas, traveled for a short period of time by FDS during the high-intensity bursts of rain, and, as a result, more of the 0.46 mm coal was lost than the 0.11 mm sand. On areas 25 m long and more, FDS also contributed to the discharge of the 0.11 mm sand, but the amount lost was always less than the amount of the 0.46 mm coal. Little regard is given to the effect of temporal and spatial changes in transport mechanism when experiments are undertaken to determine values for soil erodibility factors in sheet and interrill erosion areas even though these changes may have a major impact on the amount of soil lost from an area.

Conclusion

Although conceptually, rainfall erosivity is the capacity of rain to produce erosion, whereas soil erodibility is the susceptibility of the soil to be eroded, the factors controlling the erosive stress applied to the soil surface and the factors influencing the resistance of the soil to them vary in time and space in complex ways. In all existing predictive models of rainfall erosion, numerous simplifications and assumptions have to be made for practical reasons, and, as a result, these models do not have the capacity to deal with such complexity. Consequently, erosivity and erodibility values are specific to the model in which they are parameterized and to the scale that the model operates within.

Contents

SECTION I APC: Anthropogenic Chemicals and Activities

SECTION II COV: Comparative Overviews of Important Topics for Environmental Management

SECTION III CSS: Case Studies of Environmental Management

SECTION IV DIA: Diagnostic Tools: Monitoring, Ecological Modeling, Ecological Indicators, and Ecological Services

SECTION V ELE: Focuses on the Use of Legislation or Policy to Address Environmental Problems

SECTION VI ENT: Environmental Management Using Environmental Technologies

SECTION VII NEC: Natural Elements and Chemicals Found in Nature

SECTION VIII PRO: Basic Environmental Processes

Preface

Given the current state of the world as compiled in the massive Millennium Ecosystem Assessment Report, humans have changed ecosystems more rapidly and extensively during the past 50 years than in any other time in human history. These are unprecedented changes that need certain action. As a result, it is imperative that we have a good scientific understanding of how these systems function and good strategies on how to manage them.

In a very practical way, this multivolume *Environmental Management Handbook* provides a comprehensive reference to demonstrate the key processes and provisions for enhancing environmental management. The experience, evidence, methods, and models relevant for studying environmental management are presented here in six stand-alone thematic volumes, as follows:

VOLUME 1 – Managing Global Resources and Universal Processes
VOLUME 2 – Managing Biological and Ecological Systems
VOLUME 3 – Managing Soils and Terrestrial Systems
VOLUME 4 – Managing Water Resources and Hydrological Systems
VOLUME 5 – Managing Air Quality and Energy Systems
VOLUME 6 – Managing Human and Social Systems

In this manner, the handbook introduces in the first volume the general concepts and processes used in environmental management. The next four volumes deal with each of the four spheres of nature (biosphere, geosphere, hydrosphere, and atmosphere). The last volume ties the material together in its application to human and social systems. These are very important chapters for a wide spectrum of students and professionals to understand and implement environmental management. In particular, features include the following:

- The first handbook that demonstrates the key processes and provisions for enhancing environmental management.
- Addresses new and cutting-edge topics on ecosystem services, resilience, sustainability, food–energy–water nexus, socio-ecological systems, etc.
- Provides an excellent basic knowledge on environmental systems, explains how these systems function, and gives strategies on how to manage them.
- Written by an outstanding group of environmental experts.

Since the handbook covers such a wide range of materials from basic processes, to tools, technologies, case studies, and legislative actions, each handbook entry is further classified into the following categories:

APC: Anthropogenic chemicals: The chapters cover human-manufactured chemicals and their activities

COV: Indicates that the chapters give comparative overviews of important topics for environmental management

CSS: The chapters give a case study of a particular environmental management example
DIA: Means that the chapters are about diagnostic tools: monitoring, ecological modeling, ecological indicators, and ecological services
ELE: Focuses on the use of legislation or policy to address environmental problems
ENT: Addresses environmental management using environmental technologies
NEC: Natural elements and chemicals: The chapters cover basic elements and chemicals found in nature
PRO: The chapters cover basic environmental processes.

Volume 4, *Managing Water Resources and Hydrological Systems*, has extensive coverage in over 80 entries of water supply, water treatment, wetlands, lakes, and other natural water systems. New entries cover the evolution of water management, with application of optimization tools, and the innovative move toward integrating the energy and water nexus. Case studies include the Aral Sea, Chesapeake Bay, Baltic Sea, and Yellow River to name a few. Policy implications regarding wetland conservation, use of remote sensing and GIS, and agricultural water use are included.

Editors

Brian D. Fath is Professor in the Department of Biological Sciences at Towson University (Maryland, USA) and Senior Research Scholar at the International Institute for Applied Systems Analysis (Laxenburg, Austria). He has published over 180 research papers, reports, and book chapters on environmental systems modeling, specifically in the areas of network analysis, urban metabolism, and sustainability. He has co-authored the books *A New Ecology: Systems Perspective* (2020), *Foundations for Sustainability: A Coherent Framework of Life–Environment Relations* (2019), and *Flourishing within Limits to Growth: Following Nature's Way* (2015). He is also Editor-in-Chief for the journal *Ecological Modelling* and Co-Editor-in-Chief for *Current Research in Environmental Sustainability*. Dr. Fath was the 2016 recipient of the Prigogine Medal for outstanding work in systems ecology and twice a Fulbright Distinguished Chair (Parthenope University, Naples, Italy in 2012 and Masaryk University, Czech Republic in 2019). In addition, he has served as Secretary General of the International Society for Ecological Modelling, Co-Chair of the Ecosystem Dynamics Focus Research Group in the Community Surface Modeling Dynamics System, and member and past Chair of Baltimore County Commission on Environmental Quality.

Sven E. Jørgensen (1934–2016) was Professor of environmental chemistry at Copenhagen University. He received a doctorate of engineering in environmental technology and a doctorate of science in ecological modeling. He was an honorable doctor of science at Coimbra University (Portugal) and at Dar es Salaam (Tanzania). He was Editor-in-Chief of *Ecological Modelling* from the journal inception in 1975 until 2009. He was Editor-in-Chief for the *Encyclopedia of Environmental Management* (2013) and *Encyclopedia of Ecology* (2008). In 2004, Dr. Jørgensen was awarded the Stockholm Water Prize and the Prigogine Medal. He was awarded the Einstein Professorship by the Chinese Academy of Sciences in 2005. In 2007, he received the Pascal Medal and was elected a member of the European Academy of Sciences. He has published over 350 papers, and has edited or written over 70 books. Dr. Jørgensen gave popular and well-received lectures and courses in ecological modeling, ecosystem theory, and ecological engineering worldwide.

Aquatic Communities: Pesticide Impacts

David P. Kreutzweiser and
Paul K. Sibley

Introduction

A biotic community can be defined as an assemblage of plant or animal species utilizing common resources and cohabiting a specific area. Examples could include a fish community of a stream, an insect community of a forest pond, or a phytoplankton community of a lake. Interactions among species provide ecological linkages that connect food webs and energy pathways, and these interconnections provide a degree of stability, or balance, to the community. Community balance can be described as a state of dynamic equilibrium in which species and their population dynamics within a community remain relatively stable, subject to changes through natural adjustment processes. Toxic effects of pesticides can disrupt these processes and linkages and thereby cause community balance upsets. For example, this can occur when a pesticide has a direct impact on a certain species in a community and reduces its abundance while other unaffected species increase in abundance in response to the reduced competition for food resources or increased habitat availability. Some of the best examples of pesticide impacts on biological communities are found in freshwater studies. Freshwater aquatic communities are usually contained within distinct boundaries or systems, and this generates a high degree of connectivity among species, thereby increasing their susceptibility to pesticide-induced disturbances at the community level.

We examine traditional and developing methods for measuring pesticide impacts on freshwater communities, with emphasis on recent improvements in risk assessment approaches and analyses, and provide some examples for illustration. We then describe some advances in impact mitigation strategies and discuss some ongoing issues pertaining to understanding, assessing, and preventing pesticide impacts including probabilistic risk assessment (PRA), population and ecological modeling, and pesticide interactions with multiple stressors. The integration of improved risk assessment and mitigation approaches and technologies together with information generated from the numerous impact studies available will provide a sound scientific basis for decisions around the use and regulation of pesticides in and near water bodies.

Measuring Impacts on Aquatic Communities

Changes in aquatic communities can be measured directly in water bodies by a number of quantitative and qualitative sampling methods. Descriptions of those methods can be found in any up-to-date text or handbook (e.g., Hauer and Lamberti[1]). Measurements can be in terms of community structure (species composition) or community function (a measurable ecosystem process attributable to a biotic community that causes a change in condition) and can include both direct and indirect effects.[2,3] Community structure is a measure of biodiversity in its most general sense, that is, the number of species or other taxonomic units and their relative abundances. Some community functions are referred to as environmental or ecosystem services. Examples include organic matter breakdown and nutrient cycling that is largely mediated by microbial communities, or water uptake, filtration, and flood control mediated by shoreline plant communities.[4] Both community structure (biodiversity) and function (ecosystem services) are being increasingly valued by society and global economies,[5,6] and therefore sustaining healthy aquatic communities will be an important driver of pesticide impact mitigation efforts.

Detecting impacts of pesticides typically involves repeated sampling and a comparison of community attributes among contaminated and uncontaminated test units over time, or across a gradient of pesticide concentrations. The test units can range from petri dishes to natural ecosystems, with a trade-off between experimental control in small test units and environmental realism in field-level testing and whole ecosystems.[7] In an effort to incorporate both experimental control and environmental realism in pesticide impact testing, the use of microcosms or model ecosystems for measuring impacts on aquatic communities has increased over the past couple of decades.[8,9] Model ecosystems for community-level pesticide testing can be quite simple at lower-trophic levels such as with microbial communities (e.g., Widenfalk et al.[10]) but will necessarily be more complex for testing higher-order biological communities (e.g., Wojtaszek[11]). Regardless of the test units, an important consideration for measuring pesticide impacts will be an assessment of the duration of impact or rate of recovery. A rapid return to pre-pesticide or reference (nopesticide) community condition will reduce the long-term ecological consequences of the pesticide disturbance.[12]

Traditional measures of community-level impacts have focused on structure and have usually been expressed in terms of single-variable indices such as species richness, diversity, or abundance. These indices are useful descriptors of community structure but suffer from the fact that they reduce complex community data to a single summary metric and may miss subtle or ecologically important changes in species composition across sites or times. Over the last couple of decades, ecotoxicologists have increasingly turned to multivariate statistical techniques for analyzing community response data.[13] A variety of multivariate statistical techniques and software are available and are usually considered superior for the analysis of community data because they retain and incorporate the spatial and temporal multidimensional nature of biological communities.[14] This includes various ordination techniques that can provide graphical representation of spatiotemporal patterns in community structure in which points that lie close together in the ordination plot represent communities of similar composition (richness, abundance), while communities with dissimilar species composition are plotted further apart.

Figure 1 illustrates the use of an ordination plot generated by nonmetric multidimensional scaling for detecting differences among aquatic insect communities in four control and eight insecticide-treated streams. These data have been adjusted for illustrative purposes but are based on real invertebrate community responses to an insecticide in outdoor stream channels.[15] At both concentrations of the insecticide, the community structure of stream insects clearly shifted away from the natural community composition in control streams as depicted by the separation of treated streams (T1 and T2) from controls (C) in the ordination bi-plot. The plot also illustrates that the variability among treated streams (relative distance between points) was greater than that among control streams, that the low-concentration streams (T1) and high-concentration streams (T2) tended to separate along axis 1, and that the T2 streams were further removed from controls than the T1 streams, indicating a differential response by the insect communities to the two test concentrations. Canonical correspondence analysis

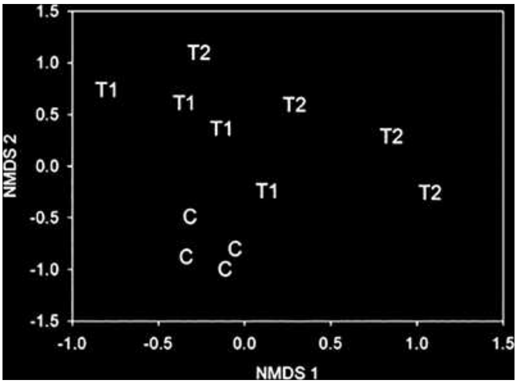

FIGURE 1 Ordination by nonmetric multidimensional scaling of aquatic insect communities in stream channels. Each point represents the community structure of control channels (C) and channels treated with a neem-based insecticide at a low (T1) and high (T2) concentration.

and redundancy analysis have also been commonly used to assess aquatic community responses to pesticide contamination.[16,17] A useful refinement of an ordination technique for detecting and interpreting pesticide impacts on aquatic communities is principal response curves (PRCs).[18] PRC is derived from redundancy analysis, and time-dependent responses in the treatments are expressed as deviations from the control or reference system allowing for clear visualization of pesticide effects.

Assessing Risk of Pesticide Impacts on Aquatic Communities

The likelihood or risk of harmful effects on aquatic communities from exposure to pesticides will depend on the exposure concentration, bioavailability, exposure duration, rate of uptake, inherent species sensitivities, community composition, and other community attributes. All of these must be measured, estimated, modeled, or predicted to derive an assessment of risk to aquatic communities for any given pesticide. Formalized risk assessment frameworks and guidelines for pesticides have been developed in the United States,[19] the European Union,[20] Canada,[21] and elsewhere and can be consulted for detailed information on the various components of a risk assessment. In brief, pesticide risk assessments typically include the following phases: 1) defining the problem by determining the pesticide use patterns and developing conceptual models and hypotheses around how it is expected to behave, the anticipated exposure regimes, the kinds of organisms that are likely to be at risk, the community or entity that is to be protected, and the level of protection that will be acceptable; 2) developing the measurement endpoints for assessing risk of harm by establishing which response measurements are relevant and applicable, and how the measurements will be made; 3) outlining the risk assessment process by specifying the kinds of data to be used and how they will be derived including simulation modeling, empirical laboratory, microcosm or field testing, their appropriate spatial and temporal scales, and their statistical analyses; 4) applying the risk assessment by running models or collecting data, completing analyses, summarizing outputs, and providing risk estimates; 5) conducting risk communication and management by answering questions posed in the problem formulation, suggesting risk mitigation strategies if necessary, and communicating those to appropriate users; and 6) conducting follow-up monitoring to evaluate the success of mitigation strategies and to implement adaptive management to address deficiencies if or when necessary.[22,23]

Traditionally, pesticide risk assessments have relied on standardized, single-species toxicity tests to predict effects on communities, the underlying assumption being that protecting the most sensitive species will protect whole communities. In this case, the selection and relevance of test species are critically important to a successful and meaningful risk assessment.[24] However, the accuracy and relevance of estimating the potential risk to aquatic communities can be greatly improved by consideration of specific species or community attributes. In particular, attribute information can improve the ecological relevance and predictive capabilities of conceptual models and the generation of hypotheses in the risk assessment process. Insofar as these attributes affect exposure, sensitivity, or both, they can increase or decrease risk beyond what could be determined from toxicity estimates or species sensitivity distributions alone.

Behavioral attributes can elevate the risk of pesticide effects on species by increasing the likelihood of intercepting the stressor. For example, young-of-the-year bluefish (*Pomatomus saltatrix*) typically feed in estuaries during their early life stages where agricultural runoff can elevate concentrations of pesticides in food items. This feeding behavior can result in bioaccumulation and in adverse effects such as reduced migration, overwinter survival, and recruitment success in fish communities.[25] Incorporating this kind of information into conceptual models and risk hypotheses will generate more realistic risk assessments. In addition, behavioral attributes themselves can be relevant measurement endpoints if the pesticide mode of action indicates risk of sublethal behavioral effects at expected concentrations. For example, some pesticides have been shown to impair the ability to capture prey in fish[26] and the ability to avoid predators in zooplankton.[27] These types of adverse effects can disrupt trophic linkages and reduce survival or reproduction, thus impacting community balance.

Inclusion of life history information into conceptual models and risk hypotheses can also refine and improve the risk assessment process. Life history strategies can influence a species susceptibility to a stressor through effects on a population's resilience or ability to recover from disturbance.[28] Different species exposed to the same pesticide and experiencing similar levels of effect in terms of population declines do not necessarily recover at the same rates when recovery is dependent on reproduction or dispersion. Populations of organisms with short regeneration times (e.g., several generations per year) and/or high dispersal capacity have higher likelihood of recovery from pesticide-induced population declines than those with longer regeneration periods and limited dispersal capacity. These differential life history strategies and their influences on community response and recovery from pesticide effects have been demonstrated empirically (e.g., van den Brink et al.[29] and Kreutzweiser et al.[30]) and through population modeling.[31] These community balance upsets could not have been predicted from screening-level toxicity data or from species sensitivity data; thus, inclusion of life history information in conceptual models can improve risk hypotheses and direct the assessment to focus on species at higher risk owing to specific life history strategies.

Life history attributes can also influence the risk of pesticide effects through differential life-stage sensitivity or susceptibility. Early life stages are often (but not exclusively) more sensitive to pesticides than later stages. An organism's life stage can also influence its susceptibility to a pesticide by increasing or decreasing the likelihood of intercepting the stressor. If a contaminant is present in the environment at effective concentrations during a period in which the particular life stage of a species is present, then the risk to that species is increased. For some amphibians, aquatic (larval) stages could be at higher risk of direct and indirect effects of pesticides than their terrestrial (adult) life stages when their larval stage coincides with pesticide contamination of water bodies.[32] Thus, while a species sensitivity and geographical distribution may indicate potential risk, the life-stage information coupled with pesticide use pattern, timing, or fate information may indicate little likelihood of exposure to the pesticide and the risk assessment can be adjusted accordingly.

Functional attributes may also be important for refining or improving pesticide risk assessments. Protection goals for populations and communities often include the safeguarding of critical biological processes or ecosystem function. Measuring ecosystem function integrates responses of component populations and can be a relevant measurement endpoint when species loss affects ecosystem function such as energy transfer and organic matter cycling.[33] However, most ecosystems are complex and it may not be clear which functional attributes are critical for sustaining ecological processes or the extent to which they can sustain changes in structural properties (e.g., population levels, diversity) without adversely affecting ecosystem function. Neither is it clear if functional endpoints are more or less sensitive than structural endpoints for detecting ecosystem disturbance. Some studies investigating the relationship between species diversity and ecosystem function have indicated that ecosystems can tolerate some species loss because of functional redundancy.[34] Functional redundancy is thought to occur when several species perform similar functions in ecosystems such that some may be eliminated with little or no effect on ecosystem processes. Others have suggested that redundant species are required to ensure ecosystem resilience to disturbance as a form of biological insurance, especially at large spatial scales.[35]

Given these discrepancies, measurement endpoints based on functional attributes are not typically used in pesticide risk assessments because it is generally accepted that protection of community structure will protect ecosystem function. However, when specific functional attributes can be identified and are known or suspected to be at risk from a pesticide, they can be included in the data requirements for a risk assessment. An example would be the risk of adverse effects on leaf litter decomposition (a critical ecosystem function in forest soils and water bodies) posed by a systemic insecticide for control of wood-boring insects in trees.[36] In that case, the protection goal was maintaining leaf litter decomposition, the community at risk was decomposer invertebrates feeding on leaves from insecticide-treated trees, and the selection of test species was directed to a specific functional group because of the unique route of exposure to decomposer organisms identified in the risk hypotheses.

Some Examples of Pesticide Impacts on Aquatic Communities

A few examples will serve to illustrate how pesticides can cause disruptions to aquatic communities. DeNoyelles et al.[37] reviewed studies into pesticide impacts on aquatic communities and reported that herbicides like atrazine, hexazinone, and copper sulfate were directly toxic to most species of phytoplankton (waterborne algae). After herbicide applications, reductions in phytoplankton caused secondary reductions in herbivorous zooplankton, resulting from a depleted food source for the zooplankton. They further showed that direct adverse effects on phytoplankton can also cause disruptions to the bacterial-based energy pathways by reducing carbon flow from phytoplankton to bacteria, and ultimately to grazing protozoans and zooplankton. Boyle et al.[38] found that applications of the insecticide diflubenzuron to small ponds reduced populations of several aquatic invertebrate species. This in turn resulted in indirect effects on algae (increased productivity because of release from grazing pressure by the invertebrates) and on juvenile fish populations (reduced production because of limited invertebrate prey availability). George et al.[39] used a novel approach to predict effects of pesticide mixtures on zooplankton communities and then tested the predictions in outdoor microcosms. Responses among zooplankton populations within the community differed, depending on the pesticide mixture, and those differences appeared to reflect the relative susceptibilities among specific taxa within groups. Cladocerans declined but were less sensitive than copepods to a chlorpyrifos-dominated mixture, while rotifers actually increased after application in response to release from competition or predation pressures.

Kreutzweiser et al.[40] applied a neem-based insecticide to forest pond enclosures and measured effects on zooplankton community structure, respiration, and food web stability. Significant concentration-dependent reductions in numbers of adult copepods were observed, but immature copepods and cladocerans were unaffected (Figure 2). There was no evidence of recovery of adult copepods within the sampling season. During the period of maximal impact (about 4 to 9 weeks after the applications), total plankton community respiration was significantly reduced, and this contributed to significant concentration-dependent increases in dissolved oxygen and decreases in specific conductance. The reductions in adult copepods resulted in negative effects on zooplankton food web stability through elimination of a trophic link and reduced interactions and connectance.

Van Wijngaarden et al.[41] evaluated the responses of aquatic communities in indoor microcosms to a suite of pesticides used for bulb crop protection. At pesticide concentrations equivalent to 5%

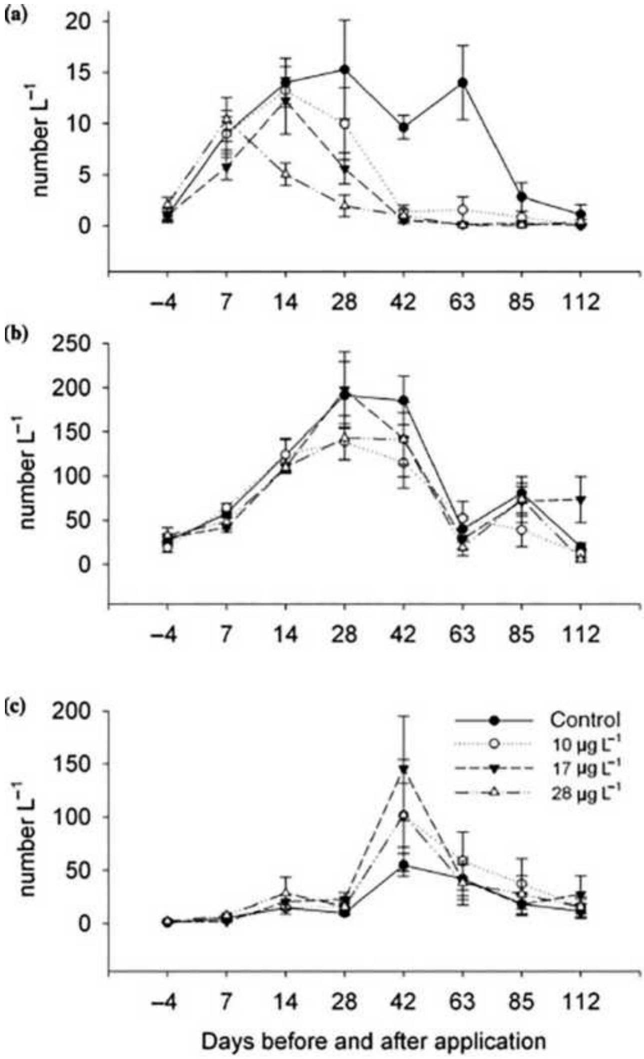

FIGURE 2 Mean abundance (±1 SE, n = 5) of (a) adult copepods, (b) immature copepods, and (c) cladocerans in natural pond microcosms (controls) and microcosms treated at three different rates of a neem-based insecticide
Source: Taken from Kreutzweiser et al.[40]

spray drift deposition, zooplankton taxa within communities showed significant changes relative to non-treated controls, reflecting taxon-specific sensitivities. Some copepods and rotifers in particular showed significant declines for at least 13 weeks, while many other rotifers and cladocerans were unaffected or increased weeks, while many other rotifers and cladocerans were unaffected or increased. Several macroinvertebrate taxa were negatively affected, and this contributed to significant declines in leaf litter decomposition among treated microcosms. The herbicide asulam was among the suite of pesticides, and it induced significant reduction of the macrophyte *Elodea nuttallii*. This in turn caused significant changes in water chemistry (decreases in dissolved oxygen and pH, increases in alkalinity and specific conductance) and increases in phytoplankton biomass from decreased competition for nutrients. Increased phytoplankton and reduced zooplankton predators combined to support higher abundance of less sensitive zooplankton taxa. The authors point out that most of these effects were not measurable at more realistic rates of spray drift deposition.

Relyea and Hoverman[42] investigated impacts of the insecticide malathion on aquatic communities in microcosms designed to mimic a simple aquatic food web that can be found in ponds and wetlands. The insecticide generally reduced zooplankton abundance, and these reductions stimulated increases in phytoplankton, decreases in periphyton (attached algae), and decreases in growth of frog tadpoles. While invertebrate predator survival was not affected, amphibian prey survival increased with insecticide concentration, apparently the result of insecticide-induced impairment of predation success by the invertebrates. Overall, the study demonstrated that realistic concentrations of an insecticide can interact with natural predators to induce large changes in aquatic community balance.

Reducing Risk of Pesticide Impacts on Aquatic Communities

For pesticides applied to crops and forests, exposure to aquatic communities can be minimized by the implementation of vegetated spray buffers or setbacks to intercept off-target spray drift and runoff.[43] Pesticide runoff can be further reduced by using formulations that are less prone to wash-off, leaching, and mobilization. Recent advances in spray drift reduction and improved spray guidance systems can also significantly reduce the off-target movement of pesticides to water bodies.[44] Examples include new technologies in map-based automated boom systems for row crops[45] and Geographical Information System (GIS)-based landscape analysis for predicting off-target pesticide movement.[46]

The risk of adverse effects on aquatic communities may also be decreased by intentional selection and use of pesticides that are inherently safer to the environment. This would include so-called reduced-risk pesticides that are bioactive compounds usually with unique modes of action and derived from microbial, plant, or other natural sources. These are generally thought to be less persistent and toxic to non-target organisms than conventional synthetic pesticides.[47] Examples include the bacteria-derived insecticide *Bt (Bacillus thuringiensis),* the plant-derived insecticide neem, and the microbe-derived herbicide phosphinothricin. However, Thompson and Kreutzweiser[48] caution that it cannot be assumed that this group of pesticides is inherently safer or more environmentally acceptable than synthetic counterparts and that full environmental risk evaluations must be conducted to ensure their environmental safety.

These types of technologies combined with the use of non-pesticide approaches to pest management form the basis of integrated pest management (IPM) strategies. IPM strategies are those in which the judicious use of pesticides is only one of several concurrent methods to control or manage losses from pest damage. This can include the use of natural enemies and parasites, biological control agents, insect growth regulators, confusion pheromones, sterile male releases, synchronizing with weather patterns known to diminish pest populations, and cultivation methods and crop varieties to improve conditions for natural enemies or degrade conditions for pest survival.[49] Increasing the use of IPM approaches can reduce reliance on pesticides and thus reduce the risk of pesticide impacts overall.

Recent Advances and Outstanding Issues

Pesticide risk assessments and risk reductions have recently been advanced in terms of ecological realism and effectiveness through some developing methods and techniques. Traditional risk assessments have estimated hazards from pesticides by comparing the expected environmental concentration (often predicted from worst-case scenarios) to the toxic threshold for the most sensitive test species. When the expected concentration is higher than the toxicity threshold, the pesticide is considered to have potential for environmental effects. These so-called hazard or risk quotient approaches are still widely used in pesticide risk assessment and regulation, but more recently, PRA and probabilistic hazard assessment (PHA) approaches are being adopted. In these approaches, pesticide exposure levels and the likelihood of toxic effects are estimated from probability distributions based on all reliable data available.[50] In PRA, exposure and effects distributions are developed from modeling or measurements in laboratory, microcosm, or field studies and used to improve the accuracy and relevance of the estimated likelihood

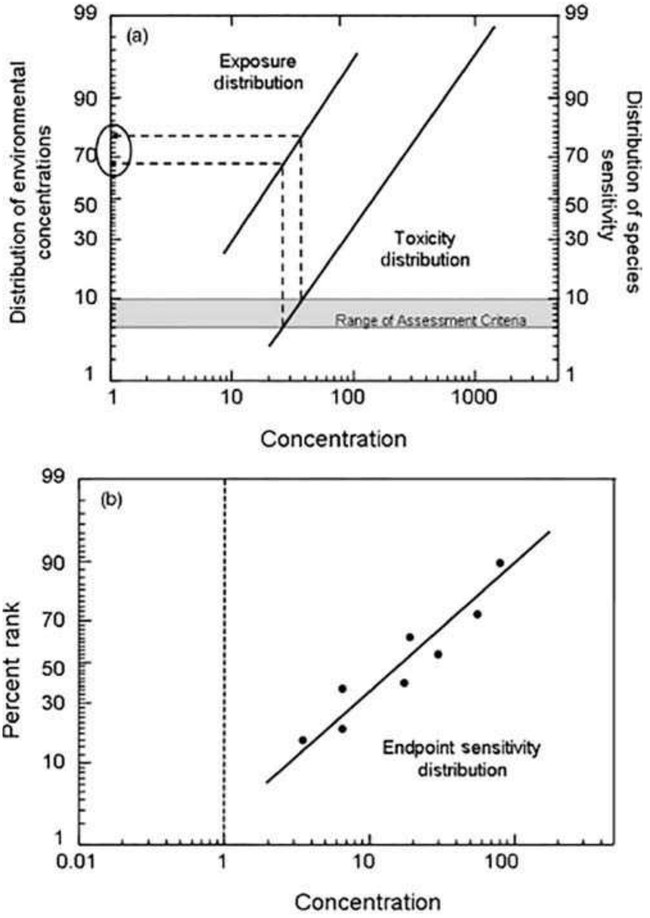

FIGURE 3 Schematic illustrating the principle of PRA (a) and PHA (b). PRA is based on a comparison of exposure and effects distributions using a predetermined criterion typically in the range of 5%-10% (shaded area and dashed lines in panel A) to determine the probability of exceeding the criterion (ellipse on y-axis); PHA is based on a comparison of an endpoint-derived sensitivity distribution within a test species to a threshold value such as a hazard quotient (dashed line in panel B).

of environmental effects compared to the traditional worst-case (hazard/risk quotient) approach (e.g., Solomon[51]). In PHA, a distribution approach is also used, except that the probability of hazard is estimated from distributions built on the relative sensitivity of interspecies endpoints rather than species sensitivity itself.[52] Figure 3 illustrates the principles of PRA (Figure 3a) and PHA (Figure 3b). Regardless of the approach, one important aspect of PRA that is ongoing is the development and use of uncertainty analysis to quantify variability and uncertainty in exposure and effects estimates. Characterizing and quantifying uncertainty will provide more meaningful risk assessments and improved decision making for minimizing potential risk of pesticide impacts in or near water.[53]

Efforts at incorporating population or ecological modeling into pesticide risk assessments have also improved their accuracy and relevance for predicting, and therefore mitigating, risk of harm to aquatic communities.[54] The use of ecological models to incorporate a suite of factors including lethal and sublethal effects and their influences on the risks to organisms, populations, or communities can provide useful insights into receptor/pesticide interactions and can thereby improve risk assessments and direct mitigation measures. Population models that account for differential demographics and population growth rates within communities have been shown to provide more accurate assessments of potential pesticide impacts on populations and communities than what conventional lethal concentration estimates can provide.[55] Ecological and population modeling combined with pesticide exposure modeling and case-based reasoning (drawing on past experience or information from similar chemical exposures) can provide further refinements and improve risk assessment for aquatic communities.[56] Another recent advancement in ecological modeling to predict pesticide effects is the use of trait-based information such as organism morphology, life history, physiology, and feeding ecology in risk assessments.[57] This approach includes some of the functional attributes and concepts described above in the section on "Assessing Risk of Pesticide Impacts on Aquatic Communities" and has the advantage of formally expressing communities as combinations of functional traits rather than as groups of species, thereby yielding a more meaningful description of community structure and function. Taken together, these modeling approaches that incorporate probability distributions, toxicological sensitivities, population dynamics, ecological information, and functional trait attributes can be integrated into improved risk assessments that will inform mitigation and prevention strategies for pesticide use.[58]

Two additional issues that present challenges to pesticide risk assessment and mitigation are pesticide mixtures and the combined or cumulative effects of multiple stressors on pesticide impacts. Pesticides frequently occur as mixtures in aquatic systems, particularly in agricultural regions, and methods to assess and/or predict pesticide mixture toxicity under laboratory conditions have been relatively well developed. However, there are still large uncertainties associated with the prediction of pesticide mixture toxicity, and additional studies are needed to evaluate the performance of mixture models when evaluating community-level endpoints and toxicity thresholds over long-term exposures.[59] Secondly, whereas most pesticide assessment data are derived from tests or experiments under controlled or semicontrolled environmental conditions, pesticides in natural environments may interact with a number of other natural or human-caused stressors that can substantially alter the likelihood and magnitude of pesticide impacts.[60] Other stressors could include overarching effects of climate change that can influence water temperature and quality; land use activities that result in chemical, sediment, and nutrient pollution of waterways; and biotic interactions with invasive species in aquatic communities. A number of studies have examined the combined effects of a pesticide with other stressors, but they have usually been single stressor effects tested at the single-species level. Examples of studies that examined combined effects include pesticide interactions with water temperature,[61] pH,[62] dissolved organic matter,[63] UV radiation,[64] predators,[65] competitors,[66] food availability,[67] elevated sediments,[68] and other chemical stressors.[69] However, potential multiple stressors and their interactions with pesticides can be myriad and testing or extrapolating to community-level impacts is onerous at best. Sorting out and mitigating pesticide impacts from among these multiple stressors continues to be a challenge, and the suggestion by Laskowski et al.[70] to include studies of toxicant interactions with a range of environmental conditions in risk assessments seems warranted.

Conclusions

Because of the high degree of connectivity among species in an aquatic community, pesticides pose a risk of harm to the community stability or balance. The community structure can be altered by direct effects, indirect effects, or both, and this can cause disruptions to the interactions and linkages among species and to their ecological function. This risk of harm will depend on exposure concentration, bioavailability, exposure duration, rate of uptake, species sensitivities, community composition, and other community attributes. Recent advances in pesticide risk assessment for aquatic communities have improved the ecological relevance and predictive capabilities for determining, and thus mitigating, potential harmful impacts. Pesticide impacts on aquatic communities can be minimized by the use of improved application technologies to reduce application rates and to decrease off-target movement to water bodies. Potential impacts can be further minimized through the selection and use of pesticides that are demonstrated to be inherently safer to the environment and through the application of IPM strategies. Given the preponderance of pesticide impact studies in freshwater aquatic ecosystems, the improved risk assessment frameworks and regulatory requirements for pesticide evaluations, and the recent advances in mitigation technologies, many decisions around the use of pesticides can be made on a sound scientific basis rather than on misinformed perceptions or politically driven agendas. Integrated, science-based pest management strategies including the prudent use of appropriate pesticides will contribute to ensuring the sustainability of aquatic communities in areas subjected to pest management programs.

Coastal Water: Pollution

Piotr Szefer

Introduction

The anthropogenic activity of man in coastal regions and even in areas located far inland is responsible for generating a huge amount of pollutants that are transported to marine ecosystems directly or by means of coastal watersheds, rivers, and precipitation from air.

Therefore, water pollution is a key global problem that has threatened marine organisms, including edible ones, and marine life in general.

There are two types of water pollutants, i.e., point source and nonpoint source.

The point source type is attributable to harmful contaminants released directly to the aquatic environment while nonpoint source delivers pollutants indirectly to the site of their approach.

The former one is a single, well-localized source, e.g., directly discharging sewage or industrial waste to the sea, whereas in the latter, the source of pollution is not well defined. Examples of such nonpoint source are agricultural runoff and windblown debris. Nonpoint sources are considered to be much more difficult to control and regulate as compared to point source pollutants.

The following are the classifications of other sources of pollution in coastal waters:

- Discharge of sewage and industrial waste
- Exploration and exploitation of the seabed
- Accidental pollution by oil and other pollutants from the land via air and other routes

Among these sources of pollutants dominate those connected with the discharge of municipal sewage and industrial wastes into coastal or estuarine regions, especially in the case of their inadequate treatment to remove persistent and harmful compounds. However, natural (and not anthropogenic) phenomena (e.g., volcanoes, storms, algae blooms, earthquakes, and geysers) could also be responsible for polluting aquatic systems. Their influence causes crucial changes in the ecological status of aquatic ecosystems.

The following are factors that determine the severity of pollutants:[1]

- Chemical structure
- Concentration
- Persistence

Independent on their sources in the water, pollutants may be classified as those for which the environment has some or little/no absorptive capacity. They are named “stock pollutants” (e.g., persistent synthetic chemicals, non-biodegradable plastics, and heavy metals).[2]

Most marine pollutants have land origin. They are often transported via rivers from agricultural sources and also via atmospheric trajectory. A lot of pollutants may be taken up by various compartments (biotic and abiotic) of aquatic environments; some of them could be biomagnified along the successive members of the food chain. A good example of having such ability to biomagnify is mercury. Such biomagnification could have negative effect on the quality of the water and hence on the health of the plants, animals, and humans whose lives depend on the quality of aquatic environments.

It should be emphasized that coastal areas are generally damaged from pollution, resulting in considerable impact on commercial coastal and marine fisheries. The pollution problem is very complex because of its interactions, interconnectedness, and uncertainty.[3–5] Pollutants, independent of their origin (e.g., air, water, land), enter the ocean, whether earlier or later.[3] Spatial distribution patterns of contamination concentrations exhibit a trend of their increase during transition from the south to the northern part of all oceans, i.e., to areas neighboring with both industrial centers and concentration of main pollution sources.[6]

The following are considered major pollutants:[6–11] fertilizers, pesticides, and agrochemicals; domestic and municipal wastes and sewage sludge; oil and ship pollution; trace elements; radionuclides; organic compounds; plastics; sediments; eutrophication and algal bloom; biological pollution; noise pollution; and light.

Heavy Metals and Metalloids

In contrast to organic pollutants, e.g., Polichlorinated Biphenyls (PCBs), heavy metals occur as natural elements of particular abiotic and biotic components of continental and aquatic ecosystems. They are present at a natural background level in rocks, soils, sediments, water, and biota. Human industrial and agricultural activities result in the elevation of this natural level to sometimes significantly higher values.

Typical metal concentrations are generally observed in open waters of marine ecosystems, although these remote regions can be affected by elevated levels of trace elements of anthropogenic or volcanic origin. For instance, the atmosphere affects the oceans and continental matter facilitating metal fluxes between these two compartments. Therefore, the atmosphere is a very important component as it makes it possible to transport metals that are natural in origin into distances far from their sources, e.g., from areas closest to forest fires as well as windblown dust, vegetation, and sea aerosols.[12,13] These sources are responsible for contributing metals to the lower troposphere, and therefore, their transport is associated to local and regional wind patterns, in contrast to specific sources such as volcano eruption, which can be responsible for injecting particulate metals not only into the troposphere but also into the stratosphere. In the latter case, particulate metals can be transported long distances under the appropriate circumstances.[13] Another example of long-distance transport of metals from their sources is dust carried from the Sahara Desert resulting in deposition of Fe, Mn, Al, and trace elements across the Mediterranean Sea, Atlantic Ocean, and Caribbean Sea.[13,14] Therefore, wind-driven dust transports particulate metals far offshore, in contrast to riverine flux carrying greater pole of mineral components from continental material to the coastal waters. These metals are promptly deposited to bottom sediments or taken up by biota, especially by phytoplankton in the surface waters, and transferred next to the food chain, recycles or settled to the bottom.[13]

The mass of metal of anthropogenic origin emitted to ecosystems is now equal to or greater than the mass introduced to the natural cycle on a global scale.[13] Some metals, e.g., Pb, Hg, and Cd, owing to their great toxicity, pose a high health risk; therefore, great attention has been paid to estimate their inputs to marine ecosystems, particularly to coastal waters. For instance, the largest masses of Pb are emitted to the atmosphere during processing of the metal (smelters) or from combustion-related sources like motor vehicles. Lead from motor vehicle exhaust was identified not only in the atmosphere but also in remote surface waters as well as in remote terrestrial areas. A ban on Pb usage in vehicle fuel has resulted in the effective reduction of metal inputs to the ecosystem since the 1970s. The decline in atmospheric Pb detected over a time scale of 10 years (from 1979 to 1989) because of the reduction of leaded gasoline in western European countries should be reflected in decreasing Pb levels in surficial water and biota. In fact, the temporal negative trend for cod in the Baltic Sea seems to support this argumentation.[15]

According to Mason et al.,[16] preindustrial fluxes and reservoirs of Hg pose one-third of its fluxes in the civilization era. It is suggested that modern emission of Hg to the atmosphere increased considerably, even 4 to 5 times, due to the human activities. The extremely elevated levels of Hg are frequently associated with Hg mining.

As has been reported, ca. 300 metric tons of dissolved Cd annually enter the oceans from rivers while ca. 400 to 700 metric tons of dissolved and particulate Cd are annually deposited to the oceans from the atmosphere.[17,18] It is estimated that human activities have contributed to increased Cd inputs to the ocean by 60% in the 1980s. It is also found that the higher proportion of land deposition of Cd is associated to the rapid removal of this metal from the atmosphere near inputs of air pollution. A substantial pole of Cd transported by rivers is deposited in estuaries and continental margins of oceans. It is found that increased concentrations of Cd occur locally, reflecting its mosaic contamination, especially near mining and industrial point sources—not managed.

A significant fraction of Zn entering the oceans is derived from atmospheric deposition.[18] Soils and sediments are main natural reservoirs of Zn. Zinc, like Cd, is not distributed evenly across the Earth's surface, since its increased concentrations occur locally in the vicinity of increased inputs, i.e., specific points of source inputs.

The concentrations of many trace elements, e.g., Pb, Cd, Hg, Cu, Zn, Se, and As in coastal and estuarine waters, especially in highly industrialized areas, are generally significantly greater than those in open oceanic waters.[13,18–20] The waters of harbors and marinas around the world contain variable concentrations of tributyltin (TBT),[13] but its extremely high levels may be characteristic for marinas in southwest England.[21]

Human industrial and agricultural activities affect inputs of several metals to reservoir/reservoirs and hence increase their concentrations, even sometimes very dramatically, above natural background levels. There are numerous examples of worldwide events leading to serious contamination of coastal waters by heavy metals and metalloids.[15] Therefore, relationships between man and ecosystem health have been explored, especially in relation to perturbed ecosystems. This includes the pollution status of coastal regions harmed by some catastrophes, large-scale pollution, environmental accidents and episodes, etc. High risk groups consume extremely high quantities of trace metals present in specific assortment of seafood or offal and it concerns seaside populations. Marine fish and shellfish may be the dominant dietary sources of Hg for local populations.[22–25] A notable example of aquatic pollution by a toxic metal is the Minamata incident, commencing in 1953 and resulting in fish, shellfish, and bird mortalities in waters of the partially landlocked Minamata Bay.[15] Dogs, pigs, and especially cats were also victims of this incident. By the end of 1974, 107 of 798 officially verified patients had died. According to Tomiyasu et al.,[26] the sediments from the Minamata Bay contained levels of Hg that highly exceeded its background level. Among other incidents resulting in the release of Hg compounds to the environment, the most significant ones happened in the 1960s and early 1970s in Sweden, Canada and the United States, northern Iraq, Guatemala, Pakistan, and Ghana.[27–31] MeHg in aquatic ecosystems, especially those that bioaccumulated in fish, is a major public health problem all over the world.[32] Its levels in the hair of fishermen represent the critical group for dietary exposure. For instance, the concentrations of Hg (total and MeHg) in the hair of fishermen from Kuwait were 2 times higher than the "normal" level according to the World Health Organization.[33] Biomass burning in tropical forests also seems to have contributed significantly to the Hg input to the atmosphere. Approximately 31% of the Hg concentrations were associated with the vegetation fire component.[34] It is postulated (based on long-range air mass trajectory analyses) that Hg occurs in the Amazon basin over two main routes: to the South Atlantic and to the Tropical Pacific, over the Andes.[34]

Global emission flux estimates exhibited that biomass burning could be major contributor of heavy metals and black carbon to the atmosphere.[15] It is estimated that savannah and tropical forest biomass burning could emit huge amounts of Cu, Zn, and black carbon to the atmosphere, corresponding to 2%, 3%, and 12%, respectively, of the global level of these elements.[35]

The toxic effects of TBT were first indicated towards the end of the 1970s in Arcachon Bay, France, as the "TBT problem."[36,37] The release of TBT (from antifouling paints) to the area resulted in shell abnormalities and reduced growth and settlement in oysters, *Crassostrea gigas,* cultured in the vicinity of marinas. In much polluted water, oyster production was severely affected by the absence of reproduction, resulting in a strong decline in the marketable value of the remaining stock.[37] Imposex, i.e., the development of male sexual characteristics in female marine mesogastropoda and neogastropoda caused by TBT pollution, is a widespread phenomenon concerning several coastal species and, more recently, offshore species as well.[23,38,39] Subsequent regulations in 1990 that prohibit the use of TBT-based antifoulants on vessels less than 25 m in length have been highly effective in reducing TBT levels in coastal waters. However, larger vessels have continued the release of TBT, and major harbors remained pollution hot spots.[40] The Organotin Antifouling Paint Control Act restricted in the United States the use of TBT paints to vessels greater than 25 m in length.[41] The voluntary stoppage of TBT production in January 2001 by major U.S. and European manufacturers resulted in the decline of its presence in marine biota, but TBT paint is still being used in most Asian countries. The International Maritime Organization (IMO) imposed an international ban for the use of organotin compounds in antifouling treatments on ships longer than 25 m. The target is to prohibit their application starting 2003 and to require the removal of TBT from ships' hulls by January 1, 2008.[41,42]

The extensive flooding, especially occurred in river area of former or operating metalliferous mining can be responsible for wide-spreading of heavy metals and metalloids far distance from pollution source. An example of such environmental events is the flooding of the Severn catchment (United Kingdom) in January 1998.[43]

Radionuclides

Physicochemical aspects and applications of radioactivity in the environment were extensively presented in a book by Valcovic.[8] There are numerous papers reporting on problems resulting from radionuclide pollution and their sources in different ecosystems.[15,44] One of the first low- level emissions of radioactivity took place in the Hanford reactors (Columbia River, Washington, United States), which released radionuclides (mainly ^{60}Co, ^{51}Cr, and ^{65}Zn) to its environs from 1940 to 1971.[28] The nuclear reactors in Cumbria (northwest England) have also been responsible for discharging quantities of radioisotopes, i.e., ^{144}Ce, ^{137}Cs, ^{95}Nb, ^{106}Ru, and ^{95}Zr, to the marine environment. Although these emissions have been diminished recently, discharges from nuclear power stations such as Sellafield (formerly named Windscale) could still be identified, even in distances far away from their source.[45,46] Significant quantities of artificial radionuclides (^{137}Cs, ^{134}Cs, ^{90}Sr, ^{99}Tc) have been transported to the North Atlantic and Arctic from Sellafield, together with measurable amounts of Pu and Am.[46–48] The nuclear reprocessing plant at La Hague in France emitted ^{137}Cs and $^{239+240}$Pu to the environment, although this plant mainly supplies ^{129}I and ^{125}Sb.[28,48,49] Besides the expected emission of radionuclides from nuclear and reprocessing facilities, significant quantities of radioisotopes contaminate aquatic and terrestrial environments from either nuclear weapons testing or nuclear reactor accidents.[15] For instance, the thermonuclear detonation that took place in 1954 at Bikini Atoll resulted in the contamination of a large area of the Marshall Islands. A number of atmospheric tests (520 in total) were mostly carried out in the Northern Hemisphere, including eight underwater tests, with a total yield of 542 Mt. Moreover, there have been a total of 1352 underground tests with a total yield of 90 Mt.[50]

A number of nuclear incidents were concernedly noted, including those affecting the crew of the Japanese fishing vessel "Fukuru Maru".[28] Plutonium released from the Kyshtym accident in the Urals has been much probably detected in deep basins of the Arctic Ocean.[51] In 1968, an aircraft from the U.S. Strategic Air Command crashed near the Thule Airbase in NW Greenland, releasing to the marine environment ca. 1 TBq $^{239+240}$Pu.[52] As a consequence, marine sediments as well as benthic organisms, i.e., bivalves, shrimps, and sea stars, have been contaminated by Pu, although their levels rapidly decreased.[53] A number of American and Russian nuclear submarines have been lost in the world's oceans. For instance, the Soviet Komsomolets submarine sank at a depth of 1700 m at Bear Island in the eastern part of the Norwegian Sea. The estimated radioactivity in the wreck was 2.8 PBq ^{90}Sr and 3 PBq ^{137}Cs.[54] Some nuclear powered satellites can incidentally be sources of radioactivity. They can burn up in the upper atmosphere, resulting in the contamination of the ocean. For instance, such an accident happened in 1964 when a SNAP-9A nuclear power generator containing 0.6 PBq ^{238}Pu aboard a U.S. satellite re-entered the atmosphere in the Southern Hemisphere. The estimated ^{238}Pu/$^{239+240}$Pu ratio in this region was higher than that in the ocean water from the Northern Hemisphere.[55,56]

Sea dumping was carried out since the late 1940s to mid-1960s mainly by the United States in the Atlantic Ocean and Pacific Ocean as well as by the United Kingdom in the Northeast Atlantic Ocean.[56] In 1967, an international operation was initiated by the former European Nuclear Energy Agency that contributed to the deposition of ca. 0.3 PBq solid waste at a depth of 5 km in the eastern Atlantic Ocean. Other international operations were continued until 1982 when ca. 0.7 PBq α activity, 42 PBq β activity, and 15 PBq tritium activity have been dumped in the North Atlantic.[57] It has been assessed that the radiological impact of the NEA (former European Nuclear Energy Agency) dumping activities resulted in some releases of Pu from the dumped waste.[15] This source would be responsible for only a part of the total body burden radioactivity in local benthic organisms, e.g., sea cucumbers; the remainder has been attributed to fallout.[58] According to Consortium for Risk Evaluation with Stakeholder Participation (CRESP) evaluation, the individual dose of a critical group consuming seafood such as molluscs from the Antarctic Ocean was estimated to be 0.1 μSv yr^{-1}, in effect labeling ^{239}Pu and ^{241}Am as critical radionuclides. The indefinite collective dose to the world's population coming from sea dumping was estimated at 40,000 manSv with predominance of ^{14}C and ^{239}Pu.[56,58]

U.S. weapons production facilities account for a large fraction of radiocaesium discharges during the 1950s.[15] A striking incident occurred at Chernobyl in the former USSR where an explosion of a reactor core of the nuclear plant took place in April 1986. The Baltic countries and a large part of central and western Europe have been contaminated principally by ^{131}I, ^{134}Cs, and ^{137}Cs.[28,59] It is found that a significant part of the activity fell over the European marginal seas from which the Baltic Sea was the most affected by contamination.[56,60] It has been mainly responsible for additional inflow of the radioactive contaminants to the Northeast Atlantic Ocean.[56] Due to the Chernobyl accident, significant levels of ^{137}Cs were also found in the Black Sea. The outflow from this Sea has been the major source of additional ^{137}Cs in the Mediterranean Sea.[56] In the summer of 1987, the Chernobyl-derived ^{137}Cs was also detected in surficial waters of the Greenland Sea, Norwegian Sea, and Barents Sea as well as in the west coast of Norway and the Faroe Islands. According to Aarkrog,[56] the total Chernobyl ^{137}Cs input to the world's oceans was relatively significantly smaller than that estimated for nuclear weapons fallout because of the tropospheric nature of this accident that has contaminated the surrounding European continental areas.[15]

After the 2011 Tōhoku earthquake and tsunami, the radiation effects from the Fukushima Daiichi nuclear disaster resulted in the release of radioactive isotopes from the crippled Fukushima Daiichi

Nuclear Power Plant. The total amount of ^{131}I and ^{137}Cs released into the atmosphere has been estimated to exceed 10% of the emissions from the Chernobyl disaster. Large amounts of radioactive isotopes have also been released into the Pacific Ocean.[61]

Organic Compounds

The high lipophilicity of many persistent organic pollutants (POPs) enhances their bioconcentration/biomagnification, resulting in potential health hazards on predators at higher trophic levels, including humans. These xenobiotics occur widely in coastal waters and oceans from the Arctic to the Antarctic and from intertidal to abyssal. It should be emphasized that most of these compounds exist at a very low concentration level, and hence, their threat to marine biota is still not well recognized. However, it is well known that exposure to extremely low levels of halogenated hydrocarbons, e.g., PCBs, Dichlorodiphenyltrichloroethane (DDT), and TBT, may disrupt the normal metabolism of sex hormones in fish, birds, and marine mammals. Moreover, sublethal effects of these organic chemicals over long-term exposure may result in serious damage to marine populations since some of these POPs may impair reproduction functions of organisms while others may show carcinogenic, mutagenic, or teratogenic activity.[6] Some of the effects of these compounds have been reported by Goldberg.[62] For instance, very low levels of TBT (as endocrine disruptor) cause a significant disruption in sex hormone metabolism, resulting in the malformation of oviducts and suppression of oogenesis in female whelks, e.g., *Nucella lapillus*.[63] As a consequence, sex imbalance leads to species decline if not species extinction in some field populations.[64] Butyltins may be responsible for mass mortality events of bottlenose dolphins in Florida through suppression of the immune system.[65] Trace environmental levels of other compounds like chlorinated hydrocarbons, organophosphates, and diethylstilbestrol may be responsible for significant endocrine disruption and reproductive failure in different groups of animals, i.e., marine invertebrates, fish, birds, reptiles, and mammals.[6] For instance, high levels of DDT, PCBs, and organochlorines in the Baltic Sea significantly reduced the hatching rates of the fish-eating whitetailed eagle *(Haliaeetus albicilla)* in the 1960s and the 1970s.[66] Another example of the toxic impact of POPs is organochlorine contamination in different cetacean species dependent upon their diet, sex, age, and behavior. Many of these compounds, as endocrine disruptors, reduce reproduction and/or suppress immune function. DDT and PCBs are known as compounds affecting steroid reproductive hormones and can increase mammalian vulnerability to bacterial and viral diseases. Jepson et al.[67] reported a statistically significant relationship between elevated PCB level and infectious disease mortality of harbor porpoises *(Phocoena phocoena).*

The assessment and monitoring of existing and emerging chemicals in the European marine and coastal environment have been overviewed based on numerous, most recent worldwide references.[5] From this report, the extensive range of chemicals that are capable of disrupting the endocrine systems of animals can be categorized into the following: environmental estrogens (e.g., bisphenol A, methoxychlor, octylphenol, and nonylphenol), environmental anti-estrogens (e.g., dioxin, endosulfan, and tamoxifen), environmental anti-androgens [e.g., dichlorodiphenyldichloroethylene (DDE), procymidone, and vinclozolin], chemicals that reduce steroid hormone levels (e.g., fenarimol and ketoconazole), chemicals that affect reproduction primarily through effects on the central nervous system (e.g., dithiocarbamate pesticides, and methanol), and chemicals with multiple mechanisms of endocrine action (e.g., phthalates and TBT). There is a high level of international concern regarding developmental and reproductive impacts on marine organisms from exposure to endocrine- disrupting chemicals. This is the case for "new" substances such as alkylphenols; there is also renewed interest for some "old" organochlorines such as DDT and its metabolites. Brominated flame retardants (BFRs), particularly the brominated diphenyl ethers (BDEs) and hexabromocyclododecane (HBCD), have been detected in the European marine environment. It has been reported that the input of BDEs into the Baltic Sea through atmospheric deposition now exceeds that of PCBs by almost a factor of 40. BDEs are found in fish from various geographic regions. This resulted from the long-range atmospheric transport and deposition of these substances.[5] HBCD was detected in liver and blubber samples from harbor seals and harbor porpoises from the Wadden Sea and the North Sea. It is found that environmental concentrations of these BFRs in Japan and South China increased significantly during the last decades. PBDE levels in marine mammals and sediments from Japan, after showing peak concentrations in the 1990s, appear to have leveled off in recent years. Furthermore, in recent years, HBCD concentrations in marine mammals from Japanese waters appear to exceed those of PBDEs, presumably reflecting the increasing use of HBCDs over PBDEs. Pentabromotoluene (PBT) and Decarbomodiphenyl (DBDPE), for example, have been found in Arctic samples remote from sources of contamination. It is an indication of their potential for long-range atmospheric transport, showing a tendency for accumulation in top predators. Polymeric BFRs may be a source of emerging brominated organic compounds to the environment. Medium- and short-chain chlorinated paraffins (SC- CPs) are ubiquitous in the environment and tend to behave in a similar way to POPs. They have been found in water as well as in fish and marine mammals.[5]

Perfluorinated compounds (PFCs), namely, perfluorooctane sulfonate (PFOS), have been detected in marine mammals.[5] They are globally distributed anthropogenic contaminants. PFCs, such as PFOS, have been industrially manufactured for more than 50 years and their production and use have increased considerably since the early 1980s. The main producer of PFOS voluntarily ceased its production in 2002. Furthermore, the large-scale use of PFOS has been restricted. PFOS has been used in many industrial applications such as fire-fighting foams and consumer applications such as surface coatings for carpets, furniture, and paper. PFCs are released into the environment during the production and use of products containing these compounds. About 350 polyfluorinated compounds of different chemical structures are known.[5] The most widely known are PFOS (C8F17SO3) and perfluorooctanoic acid (PFOA; C8F15O2), which are chemically stable and thus may be persistent (substance dependent). PFCs do not accumulate in lipid but instead accumulate in the liver, gallbladder, and blood, where they bind to proteins. PFCs have been detected worldwide, including the Arctic Ocean and Antarctic Ocean, in almost all matrices of the environment. High concentrations of PFCs have been found in marine mammals.[5] A screening project in Greenland and the Faroe Islands indicated high biomagnification of PFCs, with elevated concentrations in polar bear liver. A time trend study (1983–2003) showed increasing concentrations for all PFCs for ringed seals from East Greenland. In the United Kingdom, a study on stranded and by-catch harbor porpoise liver (1992 and 2003) found PFOS at up to 2420 pg kg^{-1} wet weight. There is a decreasing trend going from south to north.[5]

Antifouling paint booster biocides were recently introduced as alternatives to organotin compounds in antifouling products.[5] These replacement products are generally based on copper metal oxides and organic biocides. Commonly used biocides in today's antifouling paints are as follows: Irgarol 1051, diuron, Sea-Nine 211, dichlofluanid, chlorothalonil, zinc pyrithione, TCMS (2,3,3,6-tetra- chloro-4-methylsulfonyl) pyridine, TCMTB [2-(thiocyanomethylthio) benzothiazole], and zineb. It has been reported that the presence of these biocides in coastal environments around the world is a result of their increased use (notably in Australia, the Caribbean, Europe, Japan, Singapore, and the United States). For example, Irgarol 1051, the Irgarol 1051 degradation product GS26575, diuron, and three diuron degradation products [1-(3-chlorophenyl)-3,1-di- methylurea (CPDU), 1-(3,4-dichlorophenyl)-3-methylu- rea (DCPMU), and 1-(3,4-dichlorophenyl)urea (DCPU)] were all detected in marine surface waters and some sediments in the United Kingdom. Risk assessments indicate that the predicted levels of chlorothalonil, Sea-Nine 211, and dichlofluanid, in contrast to Irgarol 1051, in marinas represent a risk to marine invertebrates. Finally, non-eroding silicone-based coatings can effectively reduce fouling of ship hulls and are an alternative to biocidal and heavy- metal-based antifouling paints. Although polydimethylsiloxanes (PDMSs) are unable to bioaccumulate in marine organisms and their soluble fractions have low toxicity to marine biota, undissolved silicone oil films or droplets can cause physical–mechanical effects such as trapping and suffocation of organisms.[5]

Human and veterinary pharmaceuticals are designed to have a specific mode of action, affecting the activity of, e.g., an enzyme, ion channel, receptor, or transporter protein.[5] Clotrimazole, dextropropoxyphene, erythromycin, ibuprofen, propranolol, tamoxifen, and trimethoprim were detected in U.K. coastal waters and in U.K. estuaries. Concentrations of some pharmaceutical compounds are effectively reduced during their passage through a tertiary wastewater treatment works, while others are sufficiently persistent to end up in estuaries and coastal waters.[5] Compared with mammalian and freshwater organisms, there is a lack of experimental data on the impacts of pharmaceuticals in marine and estuarine species. However, there is experimental evidence that selected pharmaceuticals have the potential to cause sublethal effects in a variety of organisms. It has been concluded that antibiotic substances in marine ecosystems can pose a potential threat to bacterial diversity, nutrient recycling, and removal of other chemical pollutants. Although data on the occurrence of pharmaceuticals and antibiotics in the marine environment are becoming more available, the true extent of the potential risks posed by this group of contaminants cannot, at present, be assessed, mainly due the lack of effect data.[5]

Several studies showed that among personal care products (PCPs), synthetic musks (nitromusks, polycyclic musks, and macrocyclic musks) are widespread in marine and freshwater environments and bioaccumulate in fish and invertebrates.[5] There were identified products such as benzotriazole organic UV filters, namely, UV-320 [2-(3,5- di-i-butyl-2-hydroxyphenyl)benzotriazole], UV-326 [2-(3- i-butyl-2-hydroxy-5-ethylphenyl)-5-chlorobenzotriazole], UV-327 [2,4-di-*t*-butyl-6-(5-chloro-2*H*-benzotriazol-2-yl) phenol], and UV-328 [2-(2*H*-benzotriazol-2yl)-4,6-di-*t*- pentylphenol]. Their relatively high concentrations were found in marine organisms collected from waters of western Japan. There are indications that marine mammals and seabirds accumulate UV-326, UV-328, and UV-327. Benzotriazole UV filters were also detected in surface sediments from this area. The results suggest a significant bioaccumulation of UV filters through the marine food webs and a strong adsorption to sediments. Although a full risk assessment of some of these has been performed (e.g., musks), for most PCPs, there is little data on their occurrence and their effects in the marine environment.[5]

Biological Pollution

Eutrophication and Algal Bloom

Nutrient loadings in coastal waters cause direct responses such as changes in chlorophyll, primary production, macro- and microalgal biomass, sedimentation of organic matter, altered nutrient ratios, and harmful algal blooms. The indirect responses of nutrient loadings are responsible for changes in benthos biomass, benthos community structure, benthic macrophytes, habitat quality, water transparency, sediment organic matter, sediment biogeochemistry, dissolved oxygen, mortality of aquatic organisms, food web structure, etc. Moreover, increase in phytoplankton biomass and attributing decrease in transparency and light intensity limit growth of submerged vascular plants.[6,68] Generally speaking, eutrophication leads to major changes in qualitative and quantitative species composition, structure, and function of marine communities over large areas. As for phytoplankton communities, such changes are connected with an increase in biomass and productivity.[69] For instance, a general shift from diatoms to dinoflagellates, as well as dominance of small-size nanoplankton (microflagellates, coccoids), has been reported. Similar trends were observed in the case of zooplankton communities, indicating replacement of herbivorous copepods by small- size zooplankton.[70,71] Some examples of consequences of eutrophication have been reported based on worldwide references.[15] The harmful deoxygenation of water giving rise to fish kills was producing nutrient-derived large mats of macroalgae in the Peel-Harvey Estuary, Western Australia.[72] Similar events took place in the northern Adriatic Sea where diatom blooming in summer resulted in the production of mucilage, affecting tourism in northeastern Italy and reducing fish catch.[28,73,74] Insufficient water exchange and increasing production of organic matter during this century caused depletion of O_2 in all deep waters of the Baltic Proper.[15] It resulted in devastating consequences for marine biota, leading to the replacement of O_2 by H_2S in these bottom waters.[75] Although eutrophication generally leads to an increase in fish productivity, it can also cause negative environmental changes in fish populations. Fish such as cod and plaice are threatened by O_2 depletion in Baltic deep basins, causing decreasing fish catch in Koge Bay in the Sound.[75]

The blooms of blue-green algae as well as *Nodularia* produce a toxic peptide hepatoxin under particular conditions, which can pass through the food web, affecting top consumers, e.g., man. The toxin is responsible for the degeneration of liver cells, promoting tumors and causing death from hepatic hemorrhage.[75] Paralytic shell poisoning (PSP) and/or ciguatera has/have been identified predominantly in the subtropical and tropical zones such as Australia[76–80] and especially in other Indo-Pacific regions, e.g., India, Thailand, Indonesia, Philippines, and Papua New Guinea.[81,82] Principal toxic dinoflagellate species, i.e., *Pyrodinium bahamense* var. *compressa,* killed many fish and shellfish from these regions.[15] The consumption of seafood in the Indo-Pacific area posed considerable public health problems.[28] The significant PSP incidences also took place in temperate zones. For instance, in May 1968, a poisoning episode affected 78 persons inhabiting Britain after consumption of soft tissue of the blue mussel *Mytilus edulis.*[83] Another dinoflagellate-poisoning event again happened in northeast England in the summer of 1990, possibly attributed to a specific combination of elevated nutrient inputs from rivers and exceptionally warm weather conditions, which could be favorable for algae growing.[28]

It has been reported that anthropogenically derived atmospheric N deposition to the North Atlantic Ocean was strictly responsible for harmful algal bloom expansion.[84] This event concerned especially the Eastern Gulf of Mexico, U.S. Atlantic coastal waters, the North Sea, and the Baltic Sea.[84–95] Expanding blooms of the noxious dinoflagellate *Alexandrium tamarense* have been observed along the Northeast U.S. Atlantic coastline.[84,92] There are numerous examples of specific harmful algal bloom expansions in coastal and off-shore waters in case of significant atmospheric deposition of N, e.g., in the North Sea, Adriatic Sea, Western Mediterranean Sea, and Baltic Sea.[84,96] Great attention has been paid to toxic hypoxia- inducing dinoflagellate blooms in the North Sea and the Western Baltic.[84] In the summer of 1991, a very extensive bloom of *Nodularia spumigena* in the open Baltic Sea and along the southern and southeastern Swedish coasts was observed. Dogs' mortalities caused by toxic *Nodularia* blooms have been observed in Denmark, Gotland, and the Swedish coastal waters.[15] In other Baltic areas, horses, cows, sheep, pigs, cats, birds, and fish also suffered from this event. *Nodularia* blooms have caused human health problems such as stomach complaints, headaches, eczema, and eye inflammation.[75] In the Skagerrak and Kattegat, harmful algal bloom expansion of toxic algae species such as *Prorocentrum, Dinophysis, Dichtyocha, Prymnesium,* and *Chrysochromulina* has taken place.[88] The recent blooms mostly killed pelagic organisms and the phyto- and zoobenthic organisms.

Invasive Species

The impacts of introduction and invasion of species throughout the world have recently been identified. There are an increasing number of reports that document this phenomenon taking place in coastal, estuarine, and marine waters.[6] For instance, the Chinese mitten crab *(Eriocheir sinensis),* as invasive species, now inhabits coastal regions in northwestern Europe, and it has caused damage to flood defense walls by burrowing, affecting local community structure.

Worldwide fish species introduction is connected with various consequences.[97] It has been pointed out that many aquaculture species are recently genetically modified. Such modified populations are frequently released and mixed with the natural populations and are breeding with them. It causes biological pollution from a molecular level to community and ecosystem levels. An example of such events is the flooding in Central Europe that caused the release of hybrid and modified fish like sturgeon *(Acipenser* spp.) from aquaculture installations.[98] The local populations of fish are generally not resistant to the pathogenic organisms carried by the introduced species and vice versa. Therefore, deliberate genetic selection and breeding for a long time may have numerous consequences in the aquaculture unit itself as well as the loss of the natural stock for numerous species in a global scale.[6,98,99]

Fertilizers and Pesticides

Agricultural activity as an important pollution source has contributed to significant enrichment of nutrients (mainly ammonium ion and nitrates) in coastal marine waters. It is found[100] that wastes, manures, and sludges provide soils with significantly more hazardous substances as compared to fertilizers for achieving the equivalent plant nutrient content. The worldwide use of fertilizers, including organic fertilizers like manure, is huge. In the case of intensively monocultivated areas, a relatively small number of pesticides have been widely used in spite of their variety.[6]

The large mass of pesticide residues is accumulated in the environment since they are not rapidly degradable. The total global DDT production from the 1940s to 2004 was estimated as ca. 4.5 Mt.[101] Duursma and Marchand[102] estimated the world production of DDT to be ca. 2.8 Mt, of which 25% is assumed to be released to the ocean. According to Shahidul Islam and Tanaka,[6] the total emission of DDT through agricultural applications amounts to 1030 kt between 1947 and 2000. Organochlorine pesticides (OCPs) originating mostly in temperate and warmer areas of the world can be transported to coastal waters and even via atmospheric long-range transport and ocean currents to the Arctic. Owing to their bioaccumulative abilities (as lipophilic compounds) and biomagnification along the sequential trophic levels of the food chain, pesticides are classified as one of the most destructive agents for marine organisms. As a consequence, their very high levels can be observed among top predators, including man. Their toxic effects to marine organisms are often complex because they may be associated with the combination of exposure to pesticides and other POPs with environmental stresses such as eutrophication and pathogens.[6]

Sewage Effluents

Sewage effluents contain industrial, municipal, and domestic wastes; animal remains; etc. The huge amounts of these effluents generated in big cities are transported by drainage systems into rivers or other aquatic systems, e.g., coastal waters. It is estimated that the annual production of sewage amounts to ca. 1.8×10^8 m^3 for a population of 800,000. This load is equivalent to an annual release of 3.6×10^3 tons of organic matter.[6] Sewages pose significant effects on coastal marine ecosystems because they contain POPs (heavy metals/trace elements, organic pollutants) as well as viral, bacterial, and protozoan pathogens and organic substances subjected to bacterial decay. In case of such bacterial activity, the content of oxygen in water is reduced, resulting in the destruction of proteins and other nitrogenous compounds. Releasing hydrogen sulfide and ammonia exhibits toxic activity to marine biota, even at low levels. As for pathogens, domestic sewage released to coastal waters contains such harmful pathogens as *Salmonella* spp., *Escherichia coli, Streptococcus* sp., *Staphylococcus aureus*, *Pseudomonas aeruginosa*, the fungi *Candida*, and viruses such as enterovirus, hepatitis, poliomyelitis, influenza, and herpes.[6] Different bacteria and viruses can be transferred to some representatives of marine fauna, e.g., marine mammals.

Oils

The recently observed increase in tanker operations and oil use as well as marine tanker catastrophes has been responsible for the presence of excessively large amounts of oil spillage in coastal and marine ecosystems. It is estimated that ca. 2.7 million tons of oil pollution enter the ocean each year. The tanker accidents between 1967 and 2007 released ca. 4.5 million tons of oil to seawater. Notable examples of ecological catastrophes are the huge spill from a drilling platform in Gulf of Mexico (Mexico) in 1979 and the Deepwater Horizon drilling rig explosion in the Gulf of Mexico (United States) (April 20 to July 15, 2010), resulting in massive amounts of oil in the gulf. Another similar example took place during the Persian Gulf War in 1991, where ca. 2 million tons of oil was spilled, resulting to the death of many species of marine biota.[7,103,104] Therefore, oil pollution poses serious adverse effects on aquatic environment and marine organisms represented different trophic levels from primary producers to the top predators.[6]

Although aerial and flying birds (e.g., gulls, gannets) are not seriously exposed to oil toxicity, birds that spend most of their time in contact with oil on the water surface (e.g., ducks, auks, divers, penguins) are at greater risk of oil toxicity. According to Smith,[105] the annual release of hydrocarbon can range from 0.6 to 1 million tons. Coastal refineries can be an important source of oil pollution since millions of gallons of crude oil and its fractions are processed and stored there. During their operation, pollutants are continuously released by way of leakages, spills, etc.

Marine Debris and Plastics

Marine debris, especially plastics, is one of the most pervasive pollution problems. Nets, food wrappers, bottles, resin pellets, etc., have serious impacts on humans and marine biota. Medical and personal hygiene debris can enter coastal water through direct sewage outflows, posing a serious threat to human health and safety. Contact with water contaminated with these pollutants and pathogens (e.g., *E. coli*) can result in infectious hepatitis, diarrhea, bacillary dysentery, skin rashes, typhoid, and cholera.[106]

There are numerous reviews devoted to an important topic such as pollution by marine debris.[106–110] Entanglement in marine debris such as nets, fishing line, ropes, etc., can hamper an organism's mobility, prevent it from eating, inflict wounds, and cause suffocation or drowning. It was estimated that 136 marine species have been involved in entanglement incidents, including some species of seabirds, marine mammals, and sea turtles.[111] The decline in the population of the northern sea lion *(Eumetopias jubatus*), endangered Hawaiian monk seal (*Monachus schauinslandi*), and northern fur seal has been explained by entanglement of young specimens in lost or discarded nets and packing bands.[112] Abandoned fishing gear, e.g., fishing net, can contribute to catching and killing marine animals. This process called ghost fishing or ghost net can kill a huge number of commercial species.[108] An example of another serious pollution problem is ingestion of debris by marine animals. Plastic pellets and plastic shopping bags can be swallowed and lodged in animals' throats and digestive tracts, causing some animals to stop eating and slowly starve to death.[106] According to the U.S. Marine Mammal Commission,[111] ingestion incidents concerned 111 species of seabirds, 26 species of marine mammals, and 6 species of turtles. For instance, plastic cups were found in the gut of some species of fish from British coastal waters; the ingested cups were eventually responsible for their deaths.[112] Even Antarctic and sub-Antarctic seabirds, e.g., Wilson's storm-petrel *(Oceanites oceanicus)* and white-faced storm-petrel *(Pelagodroma marina),* are at risk for this ingestion hazard.[112–115] It is reported that the proportion of plastic debris among litter increases with distance from source because it is transported more easily as compared to a denser material like glass or metal and because it lasts longer than other low-density materials (paper). Floating plastic articles (material less dense than water, e.g., polyamide, polyterephthalate, polyvinyl chloride) pose a global problem because they can contaminate even the most remote islands.[107,116] Drift plastics can increase the range of some marine organisms or introduce unwanted and aggressive alien taxa species into an environment. It could be risky to littoral, intertidal zones, and the shoreline.[112,117] There is also potential danger to marine ecosystems from the accumulation of plastic debris (material more dense than water) on the seafloor. Such bottom accumulation of plastic can inhibit the gas exchange between overlying waters and the pore water. This process can result in hypoxia or anoxia in the benthic fauna, altering the makeup of life on the sea bottom.[6] Another threat is connected with potential entanglement and ingestion hazards for pelagic and benthic animals.[62,112,118] Plastic can adsorb and concentrate some pollutants in coastal waters, including PCBs, DDE, nonylphenyl, and phenanthrene. It has been reported that these sorbed POPs could subsequently be released if the plastics are ingested.[109,110] For instance, PCBs in tissues of great shearwaters *(Puffinus gravis)* were derived from ingested plastic debris.[119]

Noise Pollution

In recent years, the marine biota has been affected by noise pollution. Natural sources of underwater noise may be physical and biological in character. Physical sources include wind, waves, rainfall, thunder and lighting, earthquake-generated seismic energy, and the movement of ice. Biological sources include marine mammal vocalizations and sounds produced by fish and invertebrates.[120,121]

Anthropogenic sound sources can be grouped into six categories, namely, shipping, seismic surveying, sonars, explosions, industrial activity, and miscellaneous.[122] Vessel traffic significantly contributes to underwater noise, mainly at low frequencies. Commercial shipping vessels generate noise mainly in areas confined to ports, harbors, and shipping lanes.[122] In contrast to wide geographic distribution of shipping industry, the oil and gas industry activities have taken place along continental margins in specific worldwide areas. Such resources exploration activities have been typically observed in shallow waters less than 200 m in depth. Other activities, in spite of their geographically widespread range, are also confined to near-shore coastal regions, namely, pile driving, dredging, operation of land- and ocean-based wind power turbines, power plant operations, and typical harbor and shipyard activities.[120] Offshore wind turbines may have significantly contributed noise to the underwater ecosystem bearing in mind that the relatively recent growth in offshore wind development has increased. It has been suggested that marine mammals may be indirectly affected by noise from offshore wind turbines, e.g., prey fish avoiding the sound source as well as the masking of marine mammals' mating and communication calls. On the other hand, a number of mass stranding of marine mammals, especially whales, found on worldwide beaches may be associated with the use of concurrent military sonar.[120] Another example of noise pollution affecting marine animals is continued exposure to anthropogenic noise pressure in vital sea turtle habitats, resulting in potential impact on its behavior and ecology. Brown shrimp exposed to higher pressure levels of noise in experimental area exhibited increased aggression, higher mortality rates, and significant reduction in their food uptake, growth, and reproduction. Sound exhibits measurable damage to sensory cells in the ears of fish.[123]

Light Pollution

A remarkable recent interest concerns the introduction of light to the coastal zone and nearshore environment. It is estimated that at least 3351 cities in the coastal zones all over the world are illuminated. It is expected that artificial light will be continuously intensified not only by population growth but also by dramatically increasing the number of locations of high-intensity artificial light. According to the United Nations World Tourism Organization (UN- WTO), there were ca. 900 million international tourist arrivals all over the world.[9] Tourist visits to beaches cause light pollution along the coastline since tracking the movement of population over time by research using satellite imagery showed that wherever human population density increases, the use of artificial light at night also increases. Living organisms are mostly sensitive to changes in the quality and intensity of natural light in the ecosystem. For instance, for algae and seaweeds, photosynthetic activity is highly dependent on available light, i.e., different cycles in natural light intensity and quality.[9] Light pollution takes place when biota is exposed to artificial light, especially in coastal areas, resulting in damaging effects on marine species in seas. The behavior, reproduction, and survival of marine invertebrates, amphibians, fish, and birds have been influenced by artificial lights. Light pollution disrupts the migration patterns of nocturnal birds and can result in hatchling sea turtles to head inland, away from the sea, which could be eaten by predators or run over by cars.[124] Ecological effects of light pollution concern disruption of predator–prey relationship. For instance, artificial light disturbs natural vertical migrations of zooplankton in the water column in accordance with the day-night cycle when natural light helps to reduce their predation by fish and other animals.[125]

Conclusion

The anthropogenic activity of man in coastal regions and even in offshore areas is responsible for emission of a huge amount of pollutants that are transported to marine ecosystems directly or by means of coastal watersheds, rivers, and precipitation from air. A lot of pollutants may be taken up by various compartments, i.e., biotic and abiotic, of aquatic environments and some of them could be biomagnified along the successive members of the food chain. Therefore, water pollution could have a negative effect on the quality of the water and hence on the health of the plants, animals, and humans whose lives depend on the quality of aquatic environments. Coastal areas are generally damaged from pollution, resulting in considerable impact on commercial coastal and marine fisheries.

There are numerous examples of worldwide events leading to serious contamination of coastal waters by persistent pollutants. Therefore, these areas have been extensively explored, especially in relation to perturbed ecosystems by heavy metals, radionuclides, POPs, oils, etc.

Elevated levels of nutrients in coastal waters resulted in eutrophication and proliferation of toxic algal blooms. The recently observed increase in tanker operations and oil use as well as marine tanker catastrophes has been responsible for the presence of excessively large amounts of oil spillage in coastal and marine ecosystems. Marine debris, especially plastics, is one of the most pervasive pollution problems. Marine pollutants are generally present in increased concentrations in the enclosed seas and coastal areas than in the open seawaters. Spatial distribution patterns of contamination concentrations exhibit a trend of their increase during transition from the south to the northern part of all oceans, i.e., in areas neighboring with industrial centers and concentration of main pollution sources.

Groundwater: Mining Pollution

Jeff Skousen and
George Vance

Introduction

Mining activities can impact the quantity, quality, and usability of groundwater supplies. Underground mining for coal by longwall or room and pillar mining methods often interrupts and depletes groundwater, and can also alter its quality. Surface mining can enhance the introduction of surface water with dissolved solids into groundwater systems through fractures or other conduits. The type and nature of the mining activity, the disturbed geologic strata, and alteration of surface and subsurface materials will determine how groundwater supplies will be impacted. As waters contact and interact with disturbed geologic materials, constituents such as salts, metals, trace elements, and organic compounds become mobilized [1,2]. The dissolved substances can leach into deep aquifers and cause groundwater quality impacts [3]. In addition to concerns due to naturally occurring contaminants from disturbance activities, mining operations may also contribute to groundwater pollution from leaking underground storage tanks, improper disposal of lubricants and solvents, and contaminant spills. Blasting and hydraulic fracking activities can provide additional connection to surface water inputs, and underground injection of wastes can also occur during these operations [4].

In the United States, the Clean Water Act (CWA) and its subsequent amendments establish the authority for all water pollution control actions at the federal level [5] and regulate discharges into surface streams, wetlands, and oceans. Mining operations must acquire National Pollutant Discharge Elimination System (NPDES) permits for discharges to surface waters. Groundwater quality in the United States is regulated by the Safe Drinking Water Act (SDWA), which was originally enacted in 1974 and amended in 1996. The SDWA was passed to protect drinking water supplies by requiring discharges into groundwaters to meet the use standard or the ambient condition, whichever is of higher quality [6]. This is done by legislating maximum contaminant levels (MCLs) above which waters are considered unsafe for human consumption. The Office of Water within the Environmental Protection Agency provides guidance, specifies scientific methods and data collection requirements, and performs oversight for entities that supply drinking water including groundwater. Examples of some water contaminants with specified MCLs associated with mining activities are listed in Table 1 [7].

Because mining activities can result in poor-quality groundwaters, enforcement of regulations is needed to minimize and/or eliminate potential problems. The Surface Mining Control and Reclamation

TABLE 1 Selected Contaminants in Drinking Waters That May Be Influenced by Mining Activities [7]

Contaminant	MCL (mg/L)	MCLG
	Inorganics	
Arsenic	0.010	0
Cadmium	0.005	0.005
Chromium	0.1	0.1
Copper	LV	1.3
Cyanide	0.2	0.2
Fluoride	4.0	4.0
Lead	LV	0
Mercury	0.002	0.002
Nitrate (NO_3-N)	10	10
Selenium	0.05	0.05
Sulfate	500	500
	Radionuclides	
Radium	5 pCi/L	0
Uranium	30 ug/L	0
	Organics	
Benzene	0.005	0
Carbon tetrachloride	0.005	0
Pentachlorophenol	0.001	0
Toluene	1	1
Xylenes	10	10
	Microbiological	
Total coliforms	LV	0
Viruses	LV	0

MCL, Maximum contaminant levels permissible for a contaminant in water that is delivered to any user of a public water system; MCLG, Maximum contaminant level goals of a drinking water contaminant that is protective of adverse human health effects and which allows for an adequate margin of safety; LV, Lowest value that can be achieved using the best available technology.

Act (SMCRA) of 1977 identifies policies and practices for mining and reclamation to minimize water quality impacts [8]. SMCRA requires that specific actions be taken to protect the quantity and quality of both on- and off-site groundwaters. All mines are required to meet either state or federal groundwater guidelines, which are generally related to priority pollutant standards described in the CWA and SDWA.

Groundwater Resources

Groundwater resources are the world's third largest source of water behind oceans (97%) and glaciers (2%), and represent 0.6% of the earth's water content [9]. Approximately 53% of the US population uses groundwater as a drinking water source, but this percentage increases to almost 97% for rural households. In areas of low rainfall, weathering and translocation of dissolved constituents are relatively slow compared to high rainfall areas. For example, only 12% of precipitation will recharge underground water supplies in a dry coal mining area like Gillette, Wyoming, while almost 47% of precipitation was available for recharge in coal mining areas of Tennessee [10]. Transport of contaminants from surface

TABLE 2 Important Hydrogeological Characteristics of a Site That Determine Groundwater Quantity and Quality

Geological
Type of water-bearing unit or aquifer (rock type, overburden).
Thickness and areal extent of water-bearing units and aquifers.
Type of porosity (primary, such as intergranular pore space, or secondary, such as bedrock discontinuities, e.g., fracture or solution cavities).
Presence or absence of impermeable units or confining layers.
Depths to water tables; thickness of vadose zone.
Permeability and connectivity to other voids or conduits.
Hydraulic
Hydraulic properties of water-bearing unit or aquifer (hydraulic conductivity, transmissivity, storability, permeability, dispersivity).
Pressure conditions (confined, unconfined, leaky confined).
Groundwater flow directions (hydraulic gradients, both horizontal and vertical), volumes (specific discharge), rate (average linear velocity).
Recharge and discharge areas.
Groundwater or surface water interactions; areas of groundwater discharge to surface water or vice versa.
Seasonal variations of groundwater conditions.
Groundwater Use
Existing or potential underground sources of drinking water.
Existing or near-site use of groundwater.

and subsurface environments to groundwaters is generally accelerated as the amount of percolating water increases.

Infiltrating water moves through the vadose zone (unsaturated region) into groundwater zones (saturated region). The upper boundary of the groundwater system (e.g., water table) fluctuates depending on the amount of water received or removed from the groundwater zone. Groundwater movement is a function of hydraulic gradients and hydraulic conductivities, which represent the combined forces with which water moves as a function of gravitational, osmotic, and pressure forces and the permeability of geologic strata. Groundwater moves faster in coarse-textured materials and where hydraulic gradients are high. Aquifers are groundwater systems that have sufficient porosity and permeability to supply enough water for specific purposes. For an aquifer to be useful, it must be able to store, transmit, and yield sufficient amounts of good-quality water. Important hydrogeological characteristics of a site that determine groundwater quantity and quality are listed in Table 2.

Groundwater Contaminants

Several types of substances affect groundwater quality [1,11]. Water contaminants include inorganic, organic, and biological materials. Some have a direct impact on water quality, while others indirectly cause physical, chemical, or biological changes that make the water unsuitable for its designated use. Substances that degrade groundwaters include nutrients, salts, heavy metals, trace elements, and organic chemicals, as well as contaminants such as radionuclides, carcinogens, pathogens, and petroleum wastes (Table 3, [12]). Several types of organic chemicals entering groundwaters are less dense than water and tend to move to and along the surface of the water table. Changes can also occur in groundwaters due to temperature fluctuations and odors. Some groundwaters near coal seams contain natural organic substances (such as dissolved methane gas) and synthetic organic chemicals. Methane gas can be extracted from coal beds where underground and surface mining operations are projected,

TABLE 3 Different Classes of Groundwater Pollutants and Their Causes [12]

Water Pollutant Class	Contributions
Inorganic chemicals	Toxic metals and acidic substances from mining operations and various industrial wastes
Organic chemicals	Petroleum products, pesticides, and materials from organic wastes industrial operations
Infectious agents	Bacteria and viruses
Radioactive substances	Waste materials from mining and processing of radioactive substances or from improper disposal of radioactive isotopes

and this extraction can alter methane gas concentrations in groundwaters [10]. Organic contamination may also result from leaking gas tanks, oil spills, or runoff from equipment-serving areas. In these cases, the source of the contamination must be identified and removed. Gasoline, diesel, or oil-soaked areas should be immediately excavated and disposed of by approved methods.

The chemistry of groundwaters and potential levels of naturally occurring contaminants are related to (1) groundwater hydrologic conditions, (2) mineralogy of the mined and locally impacted geological materials, (3) mining operations (e.g., extent of disturbed materials and its exposure to atmospheric conditions), and (4) time. Movement of metal contaminants in groundwaters varies depending on the chemical of concern. Solubility considerations include metals such as cobalt, copper, nickel, and zinc being more mobile than silver and lead, and gold and tin being even less mobile [1]. As conditions such as pH, redox, and ionic strength change over time, dissolved constituents in groundwaters may decrease due to adsorption, precipitation, and chemical speciation reactions and transformations.

Acid mine drainage (AMD) is the most prevalent groundwater quality concern at inactive and abandoned surface and underground mine sites. If geologic strata containing reduced S minerals (e.g., pyrite (FeS_2)) are exposed to weathering conditions, such as when pyritic overburden materials are brought to the surface during mining activities and then reburied, high concentrations of sulfuric acid (H_2SO_4) can develop and form acid waters with pH levels below 2 [2]. Neutralization of some or all of the acidity produced during the oxidation of reduced S compounds can occur when carbonate minerals in proximity to the acid-producing materials dissolve [3]. Neutralization can also occur when silicate minerals dissolve, but sometimes high levels of potentially toxic metals such as Al, Cu, Cd, Fe, Mn, Ni, Pb, and Zn may be released. For example, mining of coal in the Toms Run area of northwestern Pennsylvania resulted in groundwater contamination by AMD containing high concentrations of Fe and sulfate (SO_4) that leached into the underlying aquifer through joints, fractures, and abandoned oil and gas wells.

The Gwennap Mining District in the United Kingdom contained numerous mines that operated over several centuries to extract various mineral resources. One of these mines, the Wheal Jane metal mine in Cornwall, extracted ores that included cassiterite (Sn-containing mineral), chalcopyrite (Cu), pyrite (Fe), wolframite (tungsten, W), arsenopyrite (arsenic, As), in addition to smaller deposits of Ag, galena (Pb), and other minerals. After closure in the early 1990s, extensive voids remaining in the Wheal Jane mine that contained oxidized and weathered minerals were flooded. Initial groundwater quality was poor with a pH of 2.9 and a total metal concentration of 5000 mg/L, which contained elevated levels of Fe, Zn, Cu, and Cd. Water quality worsened with depth, and at 180 m, the groundwater had a pH of 2.5 and a metal concentration of 7000 mg/L. Treatment of discharge waters originating from the mine involves an expensive process that will continue long term to preserve environmental quality in surface and groundwaters in the region. A similar situation occurred when a Zn mine in southwestern France was closed. In this case after flooding, discharge mine waters had a solution pH near neutral, but the water still contained high concentrations of Zn, Cd, Mn, Fe, and SO_4.

Within the Coeur D' Alene District of Idaho at the Bunker Hill Superfund site, groundwater samples were found to contain high concentrations of Zn, Pb, and Cd [13]. The contamination originated from the leaching of old mine tailings deposited on a sand and gravel aquifer. When settling ponds were constructed to catch the runoff from the tailings, water from the ponds infiltrated into the aquifer and caused an increase in metal concentration in the local groundwater system [14].

Gold mining operations have used cyanide as a leaching agent to solubilize Au from ores, which often contain arsenopyrite (As, Fe, and S) and pyrite [1]. Unfortunately, cyanide, in addition to being toxic on its own, is a powerful nonselective solvent that solubilizes numerous substances that can be environmental contaminants. These ore waste materials are often stored in tailing ponds and, depending on the local geology and climate, the cyanide present in the tailings can exist as free cyanide (CN^-, HCN); inorganic compounds containing cyanide (NaCN, $HgCN_2$); metal-cyanide complexes with Cu, Fe, Ni, and Zn; and/or the compound CNS. Because cyanide species are mobile and persistent under certain conditions, a large potential exists for trace element and cyanide migration into groundwaters. For example, a tailings dam failure resulted in cyanide contamination of groundwater at a gold mining operation in British Columbia, Canada [1].

Arsenic and uranium (U) contamination has resulted from extensive mining and smelting of ores containing various metals (Ag, Au, Co, Ni, Pb, and Zn) and/or nonmetals (As, P, and U). Arsenic-contaminated groundwaters have been a source of surface recharge and drinking water supplies. At one site, a nearby river had As levels 7 and 13 times greater than the recommended national and local drinking water standards, respectively [1]. Arsenic is known as a carcinogen and has been the contributing cause of death to humans in several parts of the world that rely on As-contaminated drinking water [11]. Waters from dewatering a U mine in New Mexico had elevated levels of U and radium (Ra) activities as well as high concentrations of dissolved Mo and Se, which were detected in stream water 140 km downstream from the mine.

Groundwater Analysis

Both the remediation and prevention of groundwater contamination by nutrients, salts, heavy metals, trace elements, organic chemicals (natural and synthetic), pathogens, and other contaminants require the evaluation of the composition and concentration of these constituents either *in situ* or in groundwater samples [2,10]. Monitoring may require the analysis of physical properties, inorganic and organic chemical compositions, and/or microorganisms according to well-established protocols for sampling, storage, and analysis [15]. For example, if groundwater will be used for human or animal consumption, the most appropriate tests would be nitrate-nitrogen (NO_3-N), trace metals, pathogens, and organic chemicals. Several common constituents measured in groundwaters are listed in Table 4. However, other tests can be conducted on waters including tests for hardness, electrical conductivity (EC), chlorine, radioactivity, water toxicity, and odors [16].

Recommendations based on interpretation of the groundwater test results should be related to the ultimate use of the water [2]. The interpretation and recommendation processes may be as simple as determining that a drinking water well exceeds the established MCLs for NO_3-N and recommending the

TABLE 4 Groundwater Quality Parameters and Constituents Measured in Some Testing Programs [16]

well should not be used as a drinking water source or that a purification system be installed. However, interpretations of most groundwater analyses can be quite complicated and require additional information for proper interpretation. If a contaminant exceeds an acceptable concentration, all potential sources contributing to the pollution and pathways by which the contaminant moves must be identified. In many cases, multiple groundwater contaminants are present at different concentrations. Because the interpretation of water analyses is a complex process, recommendations should be based on a complete evaluation of the water's physical, chemical, and biological properties. Integrating water analyses into predictive models that can assess the effects of mining activities on water quality is needed in the long term to determine the most effective means to preserve and restore water quality.

Strategies for Remediating Contaminated Groundwaters

Mine sites that have been contaminated generally contain mixtures of inorganic and/or organic constituents, so it is important to understand these multi-component systems in order to develop remediation strategies. Therefore, a proper remediation program must consider identification, assessment, and correction of the problem [17,18]. Identification of a potential problem site requires that the past history of the area and activities that took place are known, or when a water analysis indicates a site has been contaminated. Assessment addresses questions such as (1) what is the problem, (2) where and to what extent is the problem, and (3) who and what is affected by the problem. Afterward, a remediation action plan must be developed that will address the specific problems identified. A remediation action program may require that substrata materials (e.g., backfill) and groundwater be treated.

If remedial action is considered necessary, then three general options are available: (1) containment, (2) *in situ* treatment, or (3) pump-and-treat method (Figure 1). The method(s) used for the containment of contaminants are beneficial for restricting contaminant transport and dispersal. Of the remediation techniques, *in situ* treatment measures are the most appealing because they generally do less surface damage, require a minimal amount of facilities, reduce the potential for human exposure to contaminants, and when effective, reduce or remove the contaminant so that the groundwater can be utilized again [18]. *In situ* remediation can be achieved by physical, chemical, and/or biological techniques. Biological *in situ* techniques used for groundwater bioremediation can either rely on the indigenous (native) microorganisms to degrade organic contaminants or on amending the groundwater environment with specialized microorganisms (bioaugmentation). The pump-and-treat method, however, is one of the more commonly used processes for remediating contaminated groundwaters [17]. With the pump-and-treat methods, the contaminated waters are pumped to the surface where one of the

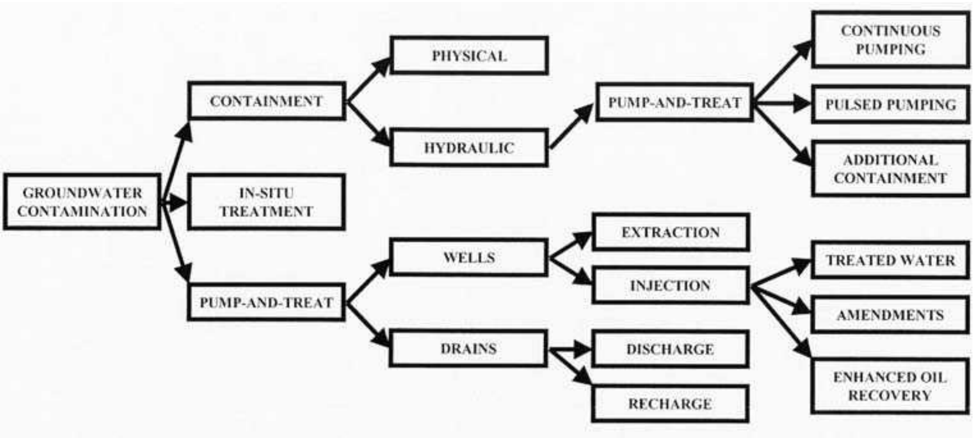

FIGURE 1 Remedial options to consider if cleanup of contaminated groundwater is deemed necessary.

many treatment processes can be utilized. A major consideration in the pump-and-treat technology is the placement of wells, which is dependent on the contaminant and site characteristics (see Table 2). Extraction wells are used to pump the contaminated water to the surface where it can be treated and re-injected or discharged. Injection wells can be used to re-inject the treated water, water containing nutrients and other substances that increase the chances for chemical alteration or microbial degradation of the contaminants, or materials for enhanced oil recovery.

Treatment techniques can be grouped into three categories, namely, physical, chemical, and biological methods [2,18].

Physical methods include several techniques. Adsorption methods physically adsorb or trap contaminants on various types of resins. Separation treatments include physically separating contaminants by forcing water through semipermeable membranes (e.g., reverse osmosis). Flotation, or density separation, is commonly used to separate low-density organic chemicals from groundwaters. Air and steam stripping can remove volatile organic chemicals. Isolation utilizes barriers placed above, below, or around sites to restrict movement of the contaminant. Containment systems should have a permeability of 10^{-7} cm/s or less.

Chemical methods are also numerous. Chemical treatment involves addition of chemical agent(s) in an injection system to neutralize, immobilize, and/or chemically modify contaminants. Extraction (leaching) of contaminants uses one of the several different aqueous extracting agents such as an acid, base, detergent, or organic solvent miscible in water. Oxidation and reduction of groundwater contaminants are commonly done using air, oxygen, ozone, chlorine, hypochlorite, and hydrogen peroxide. Ionic and nonionic exchange resins can adsorb contaminants, thus reducing their leaching potential.

Biological methods for contaminant remediation are less extensive than physical and chemical techniques. Land treatment is an effective method for treating groundwaters by applying the contaminated waters to lands using surface, overland flow, or subsurface irrigation. Activated sludge and aerated surface impoundments are used to precipitate or degrade contaminants present in water and include both aerobic and anaerobic processes. Biodegradation is one of the several biological-mediated processes that transform contaminants, and it utilizes vegetation and microorganisms.

Groundwater: Nitrogen Fertilizer Contamination

Lloyd B. Owens and
Douglas L. Karlen

Introduction

Groundwater is widely used for domestic and public water supplies, particularly in rural areas.[1] When it resurfaces, groundwater also becomes surface water that ultimately flows through streams and lakes to the oceans. Generally, groundwater is quite pure unless it contains natural contaminants such as high iron, sulfur, or possibly an intrusion of saltwater if the aquifer is located close to an ocean or estuary. Such contaminants usually result from the geological formations through which the groundwater source is flowing or residing in. Another groundwater contaminant, nitrate-nitrogen (NO_3-N), can originate naturally but is most often associated with areas where human intervention and the management practices being used have significantly increased the amount of NO_3-N that is available for leaching as water moves through soil and the underlying geology into groundwater aquifers.

Why is NO_3-N in groundwater a problem? When water with high nitrate (NO_3) concentrations is consumed by humans, it can cause several adverse health problems. One of the most common is known as “blue baby syndrome” or methemoglobinemia, an illness that arises when an infant’s blood is unable to carry enough oxygen to body cells and tissue. Consumption of high-NO_3 water has also been associated with increased levels of nitrosamine and some types of cancer. High levels of NO_3-N in streams, lakes, and oceans can stimulate excess growth of plants and bacteria, which upon death and decay subsequently deplete much of the oxygen in water. This causes fish kills and “dead zones,” such as the hypoxic area in the Gulf of Mexico.

Elevated levels of NO_3-N in groundwater have been reported in many parts of the world.[2,3] Although this can occur naturally, leaching of N fertilizer is often a major factor responsible for high NO_3-N concentrations in groundwater. This occurs because nitrogen (N) is an essential plant nutrient, and to achieve optimum crop yields, the amount of N that becomes available through natural cycling must be supplemented with additional N from either inorganic (i.e., fertilizer) or organic (i.e., manure or legume) sources. When the total amount of N provided through natural and supplemental sources exceeds that removed by harvested portions of the crop, excess N can accumulate in the soil profile and become available for leaching into subsurface drainage lines or directly into groundwater aquifers. The challenge of providing adequate plant-available N without creating an excess that is available for leaching has been studied for decades in attempts to determine the economically optimum N level (EON). Such studies have been conducted not only for agronomic crops (e.g., maize, wheat, cotton, and rice) but also for turf grasses and containerized horticultural crops, which usually receive frequent and high N fertilizer rates. Despite these efforts to identify EON rates, there are some situations when there will still be a positive yield response to N fertilizer at rates exceeding the amount of N that the plants will utilize. When this occurs, excess NO_3-N accumulates in the soil profile and becomes available for leaching, thus resulting in NO_3-N concentrations that exceed the maximum contaminant levels (MCLs) for drinking water (i.e., 10 mg L^{-1}). Many approaches can be used to reduce the NO_3 leaching potential. This includes reducing overall N fertilizer inputs; applying N in split applications, coinciding with the time when plants can use the N most efficiently; using slow-release N fertilizers; and growing cover crops to capture part of the residual N accumulating in the soil profile before it can be leached to the groundwater. This entry focuses on groundwater and how it is impacted by NO_3-N leaching. Several factors contributing to leaching are addressed and supported by accompanying references, but space does not permit this to be a comprehensive literature review. Our primary emphasis is given to alternate management practices for row crops, grasslands/turf, and containerized horticultural crops that can be used to reduce potential N loss to groundwater resources.

Why N in Groundwater Is a Problem

Human Health Impacts

Groundwater is a major source of water for human consumption. When contaminated, the N is usually in the form of NO_3, which can pose major human health concerns at high levels, especially for infants. The link between high NO_3 in polluted water and serious blood changes in infants was first reported in 1945. From 1947 to 1950, 139 cases of methemoglobinemia were reported, including 14 deaths in Minnesota alone. In response to this documented threat to human health, a MCL standard has been set stating that NO_3 in excess of 45 mg L^{-1} (10 mg L^{-1} NO_3-N) is considered hazardous to human health.[4]

Even though the number of reported cases of methemoglobinemia has greatly decreased, recent studies indicate possible adverse impacts on human health at NO_3 levels below MCL.[5–7] Occurrences of bladder and ovarian cancer[8] and non-Hodgkin's lymphoma[9] have been linked to people with long-term exposure to public water supplies with NO_3-N concentrations of 2 to 4 mg L^{-1}.

Environmental Impacts

As part of the hydrologic cycle, a portion of what is classified as groundwater, especially shallow groundwater, resurfaces to feed streams, rivers, reservoirs, and eventually, estuaries and oceans. Nutrients and pollutants in the groundwater are thus transported in surface waters as well. A major challenge associated with groundwater contamination is that its flow is generally very slow. It can take years or decades for water to move through an aquifer from recharge areas to discharge areas and for land management changes/chemical applications to be reflected in "downstream" groundwater quality.[1,10,11] Green et al.[12] concluded that current fertilizer management practices in the United States will likely affect regional groundwater quality for decades to centuries.

Over the past 40 years, there has been an eightfold increase in the use of synthetic N fertilizers.[13] This has led to increased NO_3-N contamination in both groundwater and surface water bodies.[2,14,15] High NO_3-N levels can cause excess plant and bacterial growth in aquatic systems. Subsequently, the decay of this organic matter can deplete much of the oxygen in the water, causing fish kills and dead zones to appear. Phosphorus receives much of the attention with regard to eutrophication in fresh waters because it often is the limiting nutrient, but as water systems become more brackish, N often becomes the limiting factor.[16] Well-known examples of this situation include hypoxia in the Gulf of Mexico,[17] Danish coastal waters,[18] the western Indian continental shelf,[19] and the Changjiang Estuary in the East China Sea.[20] Hypoxia occurs when the concentration of dissolved oxygen is less than 2 mg L^{-1}. Nitrogen contributions to the Gulf of Mexico, and other large bodies of water, come from multiple sources, including surface runoff, subsurface drainage, and resurfacing of groundwater. There are several sources of N, e.g., fertilizer, animal manures, septic tanks, atmospheric deposition, land application of treated wastewater and biosolids, and mineralization of organic matter that can contribute to NO_3-N contamination. For example, in a 960 km^2 basin in Florida, it was estimated that fertilizer applied to cropland, lawns, and pine stands contributed 51% of the annual N load to groundwater in the basin.[21]

Agricultural Practices Contributing to Groundwater NO_3

Row Crops

High levels of NO_3-N in subsurface drainage from row crops, especially corn (*Zea mays* L.), are well documented. Nitrate-nitrogen concentrations in tile drainage from silt loam soils in Iowa that were fertilized for either continuous corn or corn grown in rotation with soybean [*Glycine max* (L.) Merr.] were reported to exceed 10 mg L^{-1} more than two decades ago.[22–24] Similar findings have been reported for clay loam soil in Minnesota,[25–27] silty clay loam in Illinois,[28] silt loam in Indiana,[29] silt loam and silty clay loam in Ohio,[30] and clay over silty clay loam and fine sand over clay in Ontario, Canada.[31] Analyses of subsurface water collected with monolith lysimeters[32,33] and ceramic porous-cup samplers[34,35] are in agreement with these findings.

Nitrate-nitrogen concentrations in tile drainage have been studied frequently because of the widespread use of artificial drainage throughout the U.S. Corn and Soybean Belt and the relative ease of collecting water samples. The majority of NO_3-N moves in the subsurface water during the late autumn, winter, and early spring recharge period[28,29,32] in this region. There are several factors influencing the amount of N exported via tile drainage, including timing, rate, source, and area receiving N fertilization.[28] Variable weather patterns, especially rainfall amounts, have a major influence on the amount of drainage that occurs. Increasing subsurface drain spacing can decrease NO_3-N losses,[25,29] although the NO_3-N concentration in the drainage water may change very little.[29] Furthermore, even though the increased spacing may reduce NO_3-N losses through the drainage water, it probably increases NO_3-N losses in seepage below the drains. Model simulation studies show that reducing N fertilization rates will have much greater impact for reducing NO_3-N losses than changing tile drain spacing or depth.[25]

There are many management factors contributing to the leaching loss of NO_3-N. Nitrogen is an essential plant nutrient that exhibits easily recognizable visual symptoms (e.g., yellow or light green plants, slow growth and development, decreased yield) when plant-available supplies are low. Also, until recently, N fertilizer was relatively inexpensive, and therefore, to reduce the risk of encountering a deficiency, it was often applied at rates in excess of crop need to ensure that inadequate N would not limit crop yield. Another factor is the difficulty in synchronizing N application with crop need because of the narrow window of time that producers may have if weather conditions are not optimum. As a result, it has been shown conclusively that there is a direct relationship between NO_3-N loss by leaching and N application rates that exceed crop needs.[34,36,37] Soil NO_3-N in excess of current plant needs can result from overapplication of N fertilizer or manure or from not accurately accounting for residual N from previous years, mineralization of organic N, or decomposition of legume crops. The latter is especially true following a dry year because if water limits crop growth, the plant will not utilize as much N as when a "normal" amount of water is available.[27] When this occurs, there is an increased amount of residual N to begin the next cropping season. Nitrogen management is therefore very difficult, and even when EON practices are used, it is not unusual to find NO_3-N concentrations in subsurface water that exceed the 10 mg L^{-1} MCL standard for drinking water.[34–36] This leads to the conclusion that optimum corn production will likely result in elevated NO_3-N concentrations in groundwater.[36] Stated in another manner, to achieve NO_3-N concentrations in groundwater that are less than the MCL, N fertilizer rates will need to be below the level associated with normal crop production recommendations.[37]

Nitrogen fertilizer management is also difficult within irrigated production systems, as evidenced by high NO_3-N concentrations found in subsurface water beneath sprinkler-irrigated crops in Spain[38] and Nebraska.[39] High NO_3-N concentrations also occurred in North Dakota[40] with sprinkler-irrigated corn and intermittent soybean and potato (*Solanum tuberosum* L.). The different crops did not directly affect NO_3-N concentrations. The most important factor leading to increased NO_3-N moving through the root zone and into groundwater was the amount of fall residual NO_3-N in the soil profile. Flood-irrigated wheat in Arizona[41] also produced high NO_3-N concentrations in groundwater, and even with best management practices (BMPs) for flood irrigation, NO_3-N concentrations in groundwater in excess of the MCL can be expected.

Animal manures are generally land applied for both disposal and their fertilizer nutrient value. This is especially true for organic production systems. High rates of manure application can result in high groundwater NO_3-N concentrations,[42,43] but even at low rates, manure management can be very difficult. For example, when liquid swine manure was applied at rates to meet the N requirements for either continuous corn or the corn phase of a corn/soybean rotation in Iowa, NO_3-N concentrations in tile flow from manure and urea ammonium NO_3 treatments consistently exceeded the MCL for drinking water. Furthermore, NO_3-N concentrations from the manure treatment exceeded those from the fertilizer treatments.[42] In another Iowa study, swine manure applications to both corn and soybean in a corn/soybean rotation were compared with application to only the corn phase of the rotation.[44] Average flow-weighted NO_3-N concentrations and leaching losses to subsurface drainage water were more than 50% greater when manure was applied to both corn and soybean. This response was credited to greater total N application when manure was applied every year compared with every other year. The studies also identified some of the challenges associated with using manure as a nutrient source. These include variability in manure composition and the importance of knowing the composition at the time of application.[43] Because of these factors, knowing the quantity of manure-applied N is much more difficult than for mineral fertilizer. Therefore, manure is often applied at a target rate to meet crop P requirements, with additional N subsequently being applied using another source.

Although leaching of NO_3-N dominates N loss to surface and groundwater, movement of dissolved organic N (DON) has also been recognized for more than 100 years.[45] Numerous studies have shown that DON leaching from forest ecosystems can be substantial, but DON leaching from agricultural soil has received little attention. Significant amounts of DON leaching were reported for agricultural soils in England,[46] and for cropped soils in Germany, DON leaching accounted for 6–21% of the total N flux.[47] In Ohio, DON accounted for 32–37% of the total N leaching from corn/soybean rotations,[48] with the primary source of DON in agricultural soils being crop residues and soil organic matter.[45] Just as for mineral N dynamics,[46] several factors, including leaching, mineralization, immobilization, and plant uptake, also affect DON leaching.

Grasslands/Turf

Because of the animal component, NO_3-N leaching in grazed grassland is very complex,[49,50] and even on highly fertilized pastures, much of the N loss has been attributed to excreta.[51,52] Considerable NO_3-N leaching can occur from the feces and urine in a management-intensive grazing system[53] and can result in a greater impact on water quality than moderate N fertilization.[54] A New Zealand study showed that when subsurface drainage occurred immediately following intensive grazing, drainage water had higher total N concentrations as a result of total organic N and NH_4-N from direct drainage or preferential flow of cattle urine.[55] However, those elevated concentrations were short lived and contributed a relatively small amount to the total N loss. Studies in England,[56,57] the Netherlands,[58] and the eastern United States[59,60] have shown that NO_3-N concentrations in subsurface water are often greater than the MCL when >100 kg N ha^{-1} was applied annually to grazed grasslands. In grazed bahiagrass (*Paspalum notatum* Fluegge) pastures in Florida that were fertilized with 76.5 kg N ha^{-1} (the recommended rate), NO_3-N leaching was not harmful to water quality.[61] Other processes, including accumulation of fertilizer N during drought or release of N from decaying plant material following tillage or chemically killing the sod in preparation for reseeding, may affect N leaching from pastures more than the loss from small areas affected by urine.[51] Once again, management is the key as demonstrated by a field experiment in the Netherlands showing that cattle slurry can replace some or most of the mineral N fertilizer for cut grassland on wet sandy soils without increasing NO_3-N leaching if the slurry is applied during the growing season and at rates that do not exceed crop uptake.[62] This was not the case on dry sandy soil, perhaps because denitrification in the wet soil minimized the amount of N available for leaching. Nevertheless, long-term leaching risk may increase as soil organic N increases unless mineral N applications are decreased accordingly.[61] In some nongrazed systems, NO_3-N leaching from highly fertilized systems has been reported to be very low, e.g., 29 kg N ha^{-1} lost from ryegrass (*Latium perenne* L.) receiving 420 kg N ha^{-1}.[63]

Fertilized turf, whether for home lawns or golf courses, is another N source with potential environmental issues. Annual applications up to 244 kg N ha^{-1} to turfgrass on sandy loam soils in Rhode Island did not appear to pose a threat to drinking water aquifers,[64] but overwatering did increase N loadings to bays and estuaries in coastal areas. A literature review by the Horsley Witten Group[65] concluded that a 20% loading rate to groundwater was an adequate estimate for modeling N leaching in the Cape Cod, Massachusetts, area. The excess N movement was most prevalent with late-summer N applications. Several studies have shown that late-fall applications of N fertilizer to turf result in higher N leaching rates during the late fall and winter.[66–69] Some late-season (October through December) N fertilization recommendations are for the purpose of maintaining/improving turf color, but increased N leaching from such applications indicated they should be managed to achieve acceptable water quality and not to maximize turf color.[67,70] Slow-release formulations of N fertilizer have also shown great reductions in the rate of N leaching.[66,69] The differences were even greater during a high-precipitation year than during a low-or normal-precipitation year,[69] especially with high autumn precipitation.[68] Irrigation management is critical, as evidenced by studies showing that increasing irrigation from 70% to 140% replacement of daily pan evaporation increased N leaching by almost 400%[71] and that flushing porous golf greens with high rates of irrigation can leach elevated rates of N.[72] Grass species is an important factor influencing N leaching, with less occurring beneath grasses with greater aboveground biomass and deeper root systems, e.g., bentgrass species (*Agrostis* spp.). High-quality grass could also reduce fertilizer N leaching under sand-based putting greens.[73]

Turfgrass is most vulnerable for NO_3-N leaching during establishment. Even though this period represents a small period of the average turf's life,[65] the soil disturbance, limited root biomass and N uptake, and tendency of turf managers to overfertilize during this period cause the NO_3-N leaching losses to exceed the MCL.[74,75] A mature turf may have actual N requirements below recommended levels. Research in Michigan on a 10-year-old Kentucky bluegrass (*Poa pratensis* L.) compared annual applications of 245 kg N ha^{-1} (49 kg N ha^{-1} per application) and 98 kg N ha^{-1} (24.5 kg N ha^{-1} application).[76] With resultant NO_3-N leachate concentrations often greater than 20 mg L^{-1} and below 5 mg L^{-1}, respectively, the conclusion was that applying high rates of water-soluble N to mature turfgrass should be avoided to minimize the potential for NO_3-N leaching. Returning clippings to the turfgrass ecosystem reduced the N fertilizer requirement by 25–60%, with the reduction increasing as the time after establishment increased from 10 to more than 50 years.[77]

Grass sod has the capacity to use large amounts of N, with 85–90% of fertilizer N being retained in the turf-soil ecosystem.[78] Roots and thatch can represent a large N pool that becomes available for mineralization and subsequent leaching if disturbed.[79] Reseeding and sod establishment within 2 mo of "turfdeath" can stabilize this N pool.[78] High rates of NO_3-N leaching can occur at very high N fertilizer rates, e.g., 450 kg N ha^{-1} per year. Although most NO_3-N leaching occurred during autumn and winter, it was the accumulation of all N fertilizer applications and not just the autumn application[68] that determined the actual loss. Excess soil NO_3 in the fall is the driving force that causes leaching, regardless of N source or time of application. Therefore, high rates of N application to turf should be avoided in the fall because it can result in high NO_3-N leaching rates. A significant portion of the N leached can be in the organic form.[71] A survey of several golf courses across the United States indicated that NO_3-N concentrations above the MCL occurred in only 4% of the samples,[80] with most of these being attributed to prior agricultural land use. Pollution of groundwater by NO3-N leaching from N-fertilized turf should be minimal with good management, which includes consideration of soil texture, N source, rate and timing, and irrigation/rainfall.[81]

Containerized Horticultural Crops

Although the acreage for containerized horticultural crops is small compared with row crops or grasslands, the production intensity is great, and "hot spots" of potential NO_3-N leaching can develop. Assuming 80,000 pots ha^{-1} for a typical foliage plant nursery and using a soluble granular fertilizer, over 650 kg N ha^{-1} could be lost annually through leaching.[82] During a 10-week greenhouse study of potted flowers, average NO_3-N in the leachate ranged from 250 mg NL^{-1} to 450 mg NL^{-1}.[83] Irrigation and fertilization are critical management components of this intensive industry. Trickle irrigation has been shown to move less water and leach less N than overhead irrigation,[84] but precipitation could nullify this difference.[85] Increasing the irrigation rate, e.g., from 1 to 2 cm day^{-1}, increased the amount of water lost and N leached[86] even though N concentrations were decreased. The use of controlled-release fertilizers (CRFs) is one practice that can significantly reduce leaching losses.[82,87] Even with the use of CRF, NO_3-N concentrations can be high in leachate[88]; if the use of CRF is combined with large irrigation volumes, NO_3-N can move into the soil profile beneath containers.[89] Water management is crucial, as illustrated by one experiment that compared a low leaching fraction (0.0 to 0.2 of the irrigation water) with a high leaching fraction (0.4 to 0.6). The lower leaching fraction reduced irrigation volume, effluent volume, and NO_3-N in the effluent by 44%, 63%, and 66%, respectively.[90] However, these gains in efficiency resulted in a 10% loss in total plant growth (shoots and roots). Thus, establishing an acceptable balance among the level of plant growth, water and nutrient use efficiencies, and the potential environmental impacts becomes a management decision. Although beyond the scope of this entry, vegetable crops also have a high N demand but low apparent N recovery, as illustrated by sweet peppers,[91] which can leave large amounts of N in the soil and residues at harvest.

Practices That Can Mitigate NO_3 Leaching from Agriculture

Nitrate contamination of groundwater is not caused by any single factor, because non-agricultural and agricultural practices contribute to the problem. Fertilizer management decisions (i.e., rates, formulations, timing, etc.) are an agricultural contributing factor, but so are tillage, crop selection, soil organic matter levels, and drainage.[92] Temperature and precipitation patterns also combine with these factors. Likewise, various strategies and approaches are needed to reduce NO_3-N loss to groundwater. This includes using appropriate N fertilizer rates, proper timing, soil testing and plant monitoring, nitrification inhibitors, cover crops, diversified crop rotations, and reduced tillage[92] as well as various combinations of these and other management practices.

Testing, Timing, Rates of Application, and Nitrification Inhibitors

Preplant N tests or pre-side-dress N tests[93] can assess soil N levels from cover crops and help provide adequate N credits for legume or fertilizer carryover from prior crops. For example, in Iowa, use of the late-spring NO_3 test reduced fertilizer N application[94] and resulted in up to a 30% decrease in NO_3-N in discharge waters compared with using traditional fall application. Testing plant tissue for N concentration can determine in-season crop N status and be used to guide supplemental N fertilizer applications. Calibrated chlorophyll meter readings have been correlated to plant N status[95–97] and used to increase N fertilizer efficiency and reduce leaching.[96] Splitting N applications also has the potential to reduce the total application rate and to apply the fertilizer N when it is needed by the crop. However, one disadvantage of applying N fertilizer after initial crop growth is that weather conditions may create a very small window of opportunity for side-dress N applications.

Nitrification inhibitors used with ammoniacal N sources can slow the rate of oxidation to NO_3-N and thus decrease the amount of NO_3-N available for leaching,[98] especially with fall N applications. In a Minnesota study, NO_3-N losses in subsurface drainage from a corn/soybean rotation were reduced 14% by spring N application compared with late-fall anhydrous ammonia application and 10% by late-fall N application using the nitrification inhibitor nitrapyrin.[99] The use of nitrapyrin with spring-applied N showed no further reduction of N losses. However, even with these improved practices, it may be necessary to reduce the N fertilization rate to below the EON level to achieve NO_3-N concentrations in groundwater that are below the MCL[37] for drinking water.

Winter Cover Crops, Diversified Crop Rotations, and Reduced Tillage

Winter cover crops have been shown to be an effective strategy for reducing NO_3-N leaching.[100–103] A variety of crops including annual grasses, cereals, and legumes have been used as cover crops with varying degrees of success—often depending upon the specific soil and climatic pattern of cropping sequence being used. Winter rye (*Secale cereale* L.) is the most common cover crop used to reduce NO_3-N leaching following corn or corn-soybean rotations in the United States.[100,101,104–106] Winter cover crops have also significantly reduced NO_3-N leaching for broccoli (*Brassica oleracea* L.) crops[107] and potato (*S. tuberosum* L.)–based rotations[108] in the United States. For potato, spring wheat (*Triticum aestivum* L.), sugar beet (*Beta vulgaris* L.), and oat (*Avena sativa* L.) rotation in the Netherlands, adding cover crops helped to decrease NO_3- N concentrations in leachate to near or below the European Union standard (11.3 mg L^{-1}).[109] Care needs to be exercised with long-term cover crops because if they are disturbed, some of the accumulated N may become mineralized and actually increase NO_3-N leaching.[110] Even in short-term situations, the efficacy of cover crops to reduce NO_3-N leaching is relatively low when considering the entire crop succession, and N saved by the cover crop generally does not increase N utilization by the next crop.[111] Deep-rooted cover crops may help capture N leached to deeper soil layers,[112] and rapid establishment of a deeprooting system is one factor influencing the efficacy of cover crops for reducing NO_3-N leaching.[113] Although sometimes cover crops are considered to be a BMP for reducing NO_3-N leaching,[114] this is not always true. For example, on the Delmarva Peninsula in the mid-Atlantic United States, a rye winter cover crop following corn did not reduce NO_3-N leaching, presumably because the existing corn crop did not allow the rye to be seeded early enough in the autumn. Similarly, owing to the restricted time for cover crop growth in a Wisconsin study, winter rye did not utilize significant amounts of fertilizer N from the previous crop residues or soil.[115] However, in temperate regions with mild winters that favor long growing seasons and winter N mineralization, cover crops have been demonstrated as a valuable tool to reduce NO_3-N leaching.[116]

Diversifying cropping systems to include perennial crops is another strategy that will probably reduce NO_3-N leaching.[117] Compared with annual crops, perennials have an extended period of growth and therefore greater N utilization. However, having an adequate market for satisfactory economic return on such crops can be problematic. Fortunately, the emerging biofuel industry provides a potential market that may make such cropping systems more profitable.

Reduced tillage is a BMP for reducing soil erosion, but it is not usually an option for N management. Tillage promotes N mineralization from soil organic matter, which decreases soil quality and makes more N available for oxidation and subsequent leaching. Although water movement through the soil profile tends to be greater with no-till than conventional or limited tillage, NO_3-N concentrations are usually lower with no-till. Therefore, the amount of NO_3-N leaching can be either similar or less with no-till.[118] Overall, differences are small, and it is often concluded that tillage has less impact on NO_3-N leaching than factors such as crop rotation.[92,117,119]

Use of Alternate Grassland/Turf Management

Demonstrated management options to reduce NO3-N leaching from grasslands include using grass–legume mixtures instead of highly fertilized grass[52,120]; ensuring total N input does not exceed 100 kg ha^{-1}[59,60]; coordinating fertilizer application rate and timing with other N sources (e.g., manure applications); avoiding excessive N application rates[121]; using irrigation, especially during dry periods, to encourage N uptake[52]; and integrating forage cutting and grazing for optimum management throughout the year. Concentrations of NO_3-N in groundwater associated with high-fertility, high-stocking-density grazing systems can also be reduced by continuous grazing or haying if external N inputs are reduced or eliminated.[122]

In areas where NO_3-N contamination from turf is a concern, late-summer N fertilizer applications should be reduced, and the amount of irrigation water should be limited.[64] Other management practices for reducing N leaching from turf include using slow-release fertilizers,[66,69] avoiding excess irrigation, and using grass species with greater aboveground biomass and deeper root systems.[73] Because the vulnerability for leaching during turf establishment, irrigation and fertilizer rates should be limited until the turf root system is well developed. Throughout the midwestern United States, excess soil NO_3-N in the fall is the driving force responsible for NO_3-N leaching. Therefore, using any or all of the management practices mentioned above should help avoid this buildup and thus help reduce NO_3-N leaching.

Conclusions

High NO_3-N concentrations in drinking water can pose human health problems, and when found in surface water bodies, they can create many environmental problems. Several factors have contributed to high groundwater NO_3-N concentrations, including the increased use of relatively inexpensive N fertilizer to minimize the yield risk associated with encountering nutrient deficiencies. The unintended consequence is that when N is applied at rates exceeding levels to which crops respond, the potential for excess N to accumulate in the soil and leach is increased. Thus, EON rates may often produce NO_3-N levels in groundwater that exceed MCLs. This has been measured with grain crops, grasslands, and turf, which receive high rates of fertilizer N, and nursery container crops.

There are several management practices that can help reduce excess N application. These include splitting applications of N so that it is most available when plants need it; using preplant, pre-sidedress, and plant tissue N tests to determine appropriate rates of application; applying slow-release fertilizer sources so that the N is available as plants need it instead of all at once; improving timeliness of irrigation to help plants take up N during drought periods and to avoid excess irrigation, which will reduce leaching; avoiding late-season fertilizer applications, especially common for turf; and using cover crops to capture excess N that remains in the soil profile after growth of the crop so that NO_3-N leaching is reduced.

Research challenges to improve N management and reduce NO_3-N leaching are multidisciplinary. Although *precision agriculture* is a term generally applied to using soil tests, yield results, and Geographic Information system (GIS) mapping to match fertilizer rates with yield responses in a field, it also has the potential to reduce NO_3-N leaching by encouraging the use of variable N rates instead of a constant rate for an entire field. Traditionally, the sole focus for agriculture has been on crop yield, but to simultaneously address groundwater quality, effects of climate change, and other emerging factors, interactions with other crops must also be included. Collectively, these practices can improve overall N use efficiency and have both economic and environmental benefits.

Groundwater: Pesticide Contamination

Roy F. Spalding

Introduction

Trace concentrations of most of the commonly used pesticides have been confirmed in groundwaters of the United States. Since groundwater is the source of 53% of the potable water, the more toxic pesticides and their transformation products are a concern from the standpoint of human health. Others are a risk to the environment in areas where contaminated groundwater enters surface water. Through toxicological testing, the USEPA has established Maximum Contaminant Levels (MCLs) or lifetime Health Advisory Levels (HALs) for several pesticides (Table 1).

The EPA also has a separate list of unregulated compounds, including newly registered pesticides and their transformation products, such as acetochlor and alachlor ESA, that are presently being evaluated or being considered for toxicological evaluation. Based on the results of the EPAs National Pesticide Assessment,[2] 10.4% of 94,600 community systems contained detectable concentrations of at least one pesticide. Evaluation of these results led to an estimated 0.6% of rural domestic wells containing one or more pesticides above the MCL.

Pesticide Use

In the United States about 80% of pesticide usage is in agriculture. The remainder is used by industry, homeowners, and gardeners. About 500 million pounds of herbicide, 180 million pounds of insecticide, and 70 million pounds of fungicide were applied for agricultural purposes in 1993.[3] Several maps of the United States delineate usage patterns of several pesticides.[4] The majority of the triazine and amide herbicides are applied to fields in the north central corn belt states of Michigan, Wisconsin, Minnesota, Nebraska, Iowa, Illinois, Indiana, and Ohio. Commonly used organophosphorus insecticides are more heavily applied to fields in California and along the southeastern seaboard than in the northern corn belt. Carbamate and thiocarbamate pesticides are heavily used in potato growing areas of northern

TABLE 1 U.S. Maximum Contaminant Levels for Drinking Water

Organic Chemical Name	MCL (mg/L)	Organic Chemical Name	MCL (mg/L)	Organic Chemical Name	MCL (mg/L)
2,4,5-TP (Silvex)	0.05	Chlordane	0.002	Heptachlor	0.0004
2,4-D	0.07	Dalapon	0.2	Heptachlor Epoxide	0.0002
Alachlor	0.002	Dinoseb	0.007	Lindane	0.0002
Aldicarb	0.007	Diquat	0.02	Methoxychlor	0.04
Aldicarb sulfone	0.007	Endothall	0.1	Oxamyl (Vydate)	0.2
Aldicarb sulfoxide	0.004	Endrin	0.002	Picloram	0.5
Atrazine	0.003	Ethylene dibromide	0.00005	Simazine	0.004
Carbofuran	0.04	Glyphosate	0.7	Toxaphene	0.003
Carbon tetrachloride	0.005				

Source: U.S. Environmental Protection Agency.[1]

Maine, Idaho, the Delmarva Peninsula, and vegetable fields of California and the southeastern coastal states. Fungicide use is concentrated in high humidity and irrigated areas of the coastal states and to some extent along the Great Lakes and Mississippi River Valley. The fumigants carbon tetrachloride and ethylene dibromide (EDB) were used heavily in the past at grain storage elevators throughout the Midwest and elsewhere in the United States.

Associated Pesticide Behavior in Soils and Water

Although pesticide use is a dominant factor in groundwater contamination, leaching variability among pesticides exhibiting similar behaviors is striking and explains why several heavily used pesticides seldom if ever are detected in groundwater. In general, pesticides within a class have similar chemical characteristics upon which soil leaching predictions can be made based on persistence, solubility, and mobility. Pesticide class relationships with soils and water transport described in the following text are detailed in Weber.[5] Individual frequencies of groundwater pesticide detection, in parenthesis next to commonly used products, are calculated from the Pesticide Groundwater Data Base (PGWDB)[4] and the National Water Quality Assessment (NAWQA) database.[6] High frequencies of detection identify those pesticides with a disposition to leach.

Insecticides

Chlorinated hydrocarbons are one of the oldest chemical classes of insecticides. Some of the best-known compounds include aldrin, dieldrin, DDE, DDT, endrin, and toxaphene. Although banned since the 1960s, their extremely persistent nature precludes their detection in very trace quantities in groundwater of the upper Midwest. On the other hand, heavily used organophosphates like malathion, methylparathion, disulfoton, and others have been extensively surveyed during several groundwater monitoring studies and have not been detected. The organophosphate insecticides, parathion (not reported (NR), <1), % occurrence from PGWDB, % occurrence from NAQWA data. terbufos (<1, <1), fonofos (<1, <1), and chlorpyrifos (<1, <1), which are heavily used on corn and sorghum, were also seldom detected. Diazinon (1.1, 1.3), the common garden insecticide, is occasionally detected in groundwater. Generally, the organic phosphates are rapid degraders and are strongly retained on soils.

For the most part, carbamates and thiocarbamates are very sparingly soluble and exhibit low to moderate soil retention; however, a small number have high solubility and low soil retention. Most carbamates are characterized as having short longevities. Generally, pesticides in this group having half-lives of 30 days or more have the potential to leach. The thiocarbamates butylate (<1, <1) and

EPTC (2.6, <1) are extensively used in agriculture and have relatively short half-lives. Aldicarb (<1, <1) and carbofuran (14.7, <1) are at the high end for solubility and longevity in their class. Their metabolites have been frequently detected beneath high use crops, such as potatoes in the potato growing regions of the United States.

The pyrethroid insecticides have low solubilities, short half-lives, and high soil retentions that make them unlikely to leach. Yet, permethrin (<1, <1) is occasionally detected in very trace quantities in groundwater.

Fungicides and Fumigants

Fungicides are non-volatile organometallic compounds with low aqueous solubility that inhibit growth of actinomycetes and many fungi. The best-known fungicides zineb (not detected (ND), NR) and captan are zinc-based, and maneb (ND, NR) is manganese-based. Some, like bordeaux, are copper sulfate-based. Although their detection frequency is very low, fungicides have not been analyzed in many surveys.

Fumigants are very volatile halogenated compounds that generally are knifed below the soil surface. These compounds have high aqueous solubility and very low soil retention. The fumigants EDB and 1,3-dichloropropene have been frequently detected in the subsurface and in groundwater in high-use regions, such as California.[7] Ethylene dibromide and carbon tetrachloride were also used in grain storage facilities during the 1950s and 1960s. Spills, leaks, and improper handling resulted in 400 reported groundwater contamination sites in Kansas and Nebraska.

Herbicides

There are at least eight major chemical classes of herbicides. These include: quaternary N, basic, acidic, carboxylic acid, hydroxy and aminosulfonyl, amide and anilide, dinitroaniline, and phenylurea herbicides.[5] Several herbicide classes have similar behaviors with respect to soil and water.

Both quaternary N and dinitroaniline herbicides are very highly retained by soils and are not expected to be detected in groundwater. However, paraquat, pendimethalin, and trifluralin have been reported several times in groundwater. Their presence indicates that transport is dependent on factors not directly related to compound longevity, solubility, and mobility. Vertical transport by preferential flow through macropores is a commonly accepted mechanism used to explain these detections. In some instances, compounds have been described as preferentially transported attached to colloidal material.

Carboxylic, hydroxy, and aminosulfonyl acids, and thiocarbamate herbicides have very low to low soil retention and very short to moderate longevity. Thus, the more heavily used and persistent pesticides in these groups are the ones most generally detected in groundwater. They include the acids, dicamba (2.0, NR), picloram (2.5, <1), bromacil (1.8, 1.0), and dinoseb (1.4, <1).

Phenylurea herbicides have low to high soil retentions and short to moderate longevity. Linuron (16.7, <1) and diuron (<1, 1.9) are the most frequently detected in groundwater and both have moderately long half-lives ranging from 60 to 90 days.

Amide and anilide herbicides have low soil retention and short to moderate longevity. Several amide herbicides and their transformation products have been detected in groundwater. The commonly used amides in the Midwestern corn belt, namely alachlor (1.7, 2.7), metolachlor (<1, 12), propachlor (1.2, <1), and acetochlor (NR, <1), are the most frequent offenders because they are relatively persistent.

As suggested by the name, basic herbicides behave as bases. The group contains several subclasses including aniline, formamidine, imidazole, pyrimidine, thiadiazole, triazines, and triazole. Basic herbicides have low to high soil retention and very short to moderate longevity. Again, it is generally the most persistent and heavily used pesticides that are more frequently found in groundwater. The most frequently detected compounds in the group are the triazines, namely atrazine (5.6, 30), metribuzin (4.2, 1.9), cyanazine (2.0, 1.4), simazine (2.0, 14.8), and prometon (2.1, 11.6).

Groundwater Contamination

It stands to reason that there are generally good associations between pesticide use and their detection in groundwater. Since groundwater flows very slowly at rates normally ranging from 0.1 ft/day to 3 ft/day, pesticide sources are generally very near the monitored well. Thus, high frequencies of triazine and acetamide detections are reported in the states of the northern corn belt. More fungicides and fumigants were detected in warm humid states of California and Florida where vegetable and fruit crops dominate the landscape. In an analysis of the 20 NAWQAs for pesticides, frequencies of pesticide detection in groundwater were significantly related to the estimated amount of agricultural use within a 1km radius of the sampled site.[6] They also emphasized that pesticides were detected beneath both agricultural (60.4%) and urban areas (48.5%). Discontinued used pesticides have been detected numerous times in shallow aquifers.

In general, families of pesticides have similar chemical characteristics from which predictions have been made as to the product's potential for contamination of groundwater; however, differences in the leaching behavior of pesticides exhibiting similar chemistry can be appreciable and is the reason several heavily used pesticides are seldom, if ever, detected in groundwater.

Management of Point Sources of Groundwater Contamination

Important steps are being taken to reduce water quality pollution by pesticides occurring from spills and back siphoning events (point sources). Since it is easier to resolve point than non-point sources, laws have been enacted to eliminate contamination of surface water bodies, which may be in hydraulic contact with groundwater, from used pesticide containers and rinseate from chemical wash downs. Check valves are mandatory when pesticides are mixed and/or diluted and prevent backflow to groundwater. Soils at and adjacent to agrichemical supply facilities have been surveyed in several states and found to be highly contaminated with pesticide residues. The herbicides, atrazine, alachlor, metolachlor, cyanazine, and metribuzin are the worst offenders from the standpoint of pesticide mass in the soils at sites in Wisconsin and Illinois.[4] Many of these sites and those in other states are now involved in soil cleanups, which are designed to protect underlying groundwater from further pollution.

Management of Non-Point Sources of Groundwater Contamination

Normal farm chemical applications of pesticides are generally considered potential non-point sources of groundwater contamination because they are dispersed over large areas ranging from fields to watersheds. Management strategies are in place to reduce leaching of field applied chemicals.[8] These strategies vary from regulatory restrictions to outright bans on application in areas deemed more vulnerable to leaching. Integrated pest management, fostered by the office of pesticide management at the USEPA, is designed to reduce chemical applications. The practice of banding applications has reduced amounts applied. Both target more efficient pesticides and genetically engineered plants sensitive only to specific herbicidal action have been and are being developed. These new pesticides and pesticide-plant combinations require less chemical than in the past, and the altered plants allow for pest control with more environmentally sensitive chemicals. The USEPA has announced a plan to reduce the mass of applied chemicals from commonly used triazines and amides that are frequently detected in groundwater.

Irrigation Management

Irrigation practices can influence pesticide leaching. Atrazine was vertically transported deeper and faster when using flood rather than sprinkler irrigation.[19] Sprinkler systems allow for much more uniform and efficient water management practices than furrow irrigation, and recent studies have shown that they reduce chemical leaching.[10] In the Nebraska's Platte Valley[11] and in the Walnut Creek watershed in Iowa,[12] peak herbicide concentrations were strongly related to rapid flushing beneath drainage areas where surface water ponds during heavy rainfall events on the cropped fields. Application of excess irrigation water also was reported to increase herbicide leaching.[9,11]

Future Research

More research is necessary to evaluate the health risks of transformation products from heavily used pesticides that are frequently detected in groundwater. Research needs to focus on precision application of pesticides to specific field problem areas as a potential mechanism to reduce chemical application.

There is a need to evaluate the environmental cost/benefit of safer product replacements used in conjunction with genetically altered crops. As new products are registered to replace more persistent and mobile pesticides, long-term fate studies, including the monitoring of the transformation product impact, on groundwater quality are necessary.

Lakes and Reservoirs: Pollution

Subhankar
Karmakar and
O.M. Musthafa

Introduction

Surface water is one of the most important natural resources in the world. It has been explicitly established that water of good quality is a fundamental element to sustainable socioeconomic development. It is the habitat for a large number of species and is a crucial component for metabolic activities of plants and animals. Aquatic ecosystems are endangered on a worldwide scale by a multitude of pollutants as well as damaging land-use or water-management practices. Some problems have been present for a long time but have only recently reached a critical level, while the rest are recently emerging. Oxygen balance in the aquatic systems is severely affected by organic pollution, which often results in severe pathogenic contamination. Enrichment of aquatic systems with nutrients from various origins, predominantly domestic sewage, agricultural runoff, and agro-industrial effluents, results in enhanced eutrophication, of which lakes and reservoirs are affected the most.

Lakes and reservoirs are the major resources of fresh surface water. They are larger and deeper than ponds and are not part of the ocean. Lakes and reservoirs are major resources as these hold about 90% of the world's fresh surface water and are the key freshwater resources for agriculture, fisheries, domestic, industrial, recreational, landscape entertainment, and energy production. Natural lakes are bodies of water, created by volcanic, tectonic, or glacial activity, whereas reservoirs are artificial impoundments. A lake is a relatively large lentic freshwater or saltwater body, which is localized in a basin surrounded by land. Natural lakes are generally found in mountainous areas, rift zones, and areas with ongoing glaciations. In some parts of the world, there are many lakes formed due to chaotic drainage patterns left over from the last ice age. They are the habitats of a variety of flora and fauna, making them a source of fish and a destination for migratory birds to reproduce or rest. A reservoir, which is known as an artificial lake, is constructed for the benefit of man's water needs, sometimes for one particular purpose, but more recently for multiple purposes. Reservoirs are different from lakes in many ways. They have usually larger drainage basins than lakes, and many are located in watersheds with extensive agricultural activities.

Direct contamination of surface waters with metals in discharges from mining, smelting, and industrial manufacturing is a long-lasting phenomenon. The emission of airborne pollutants has now reached such proportions that long-range atmospheric transport causes contamination, not only in the vicinity of industrial regions but also in more remote areas. Similarly, precipitation of acid rain occurs, when moisture in the atmosphere combines with gases such as sulfur dioxide, which are produced when fossil fuels are burnt. This may cause significant acidification of surface waters, especially lakes and reservoirs. Contamination of water by synthetic organic micropollutants and emerging contaminants results either from direct discharge into the surface waters through runoff or after transport through the atmosphere.

This entry briefly presents classification of lakes and reservoirs based on the flow of water in and out of the system and their utility, respectively, followed by the problems associated with lakes and reservoirs causing deterioration of water quality. A discussion on monitoring of water quality and various protective and restorative measures is also made through a literature survey, which may be useful to future research aspirants and water resource professionals in identifying economically and environmentally sustainable lake and reservoir management strategy.

Classification of Lakes and Reservoirs

All lakes are temporary over geologic time scales, as they will slowly fill in with sediments or spill out of the basin.[1] Water enters into lakes from a variety of sources such as seepage through groundwater storage, runoff from watershed, direct precipitation into the lake, and other surface waters bodies (like streams or rivers). Water may drain out from lakes through deep percolation to join groundwater table or through surface water flow and evaporation. Natural lakes can be classified into four major types based on how water enters and exits the lake. Water may enter into the lake through one source or multiple sources. The water quality of a lake and its biodiversity are significantly influenced by the type of lake. Depending upon the way of entrance and exit of water, lakes can be classified into four categories as shown in Figure 1.

Seepage lakes do not have a distinct inlet or an outlet, and occasionally overflow. The major sources of water are direct precipitation, surface runoff from the immediate drainage area, and seepage through groundwater storage, as seepage lakes are landlocked water bodies. Since seepage lakes are sensitive to groundwater levels and local rainfall patterns, water levels may fluctuate seasonally. These lakes may have a less diverse fishery as the direct source of water is not a flowing water body or stream. Seepage lakes also have a smaller drainage area, which may help to account for lower nutrient levels. *Spring lakes* have no distinct inlet, but do have an outlet. The major source of water for spring lakes is groundwater flowing into the bottom of the lake from inside and outside the immediate surface drainage area. *Groundwater drained lakes* have no inlet, but similar to spring lakes, these may have an uninterruptedly flowing outlet. Drained lakes are not groundwater fed and their principal sources of water are precipitation and direct drainage from the surrounding land. The water levels in drained lakes fluctuate frequently depending on the supply of water. Under severe conditions, the outlets from drained lakes may become intermittent. *Drainage lakes* have both an inlet and an outlet where the main water source is stream drainage. These lakes support fish populations that are not necessarily identical to the streams connected to them. Drainage lakes mostly have higher nutrient levels than natural seepage or spring lakes.[2] Depending on the utility, reservoirs can be classified into four classes as shown in Figure 2.

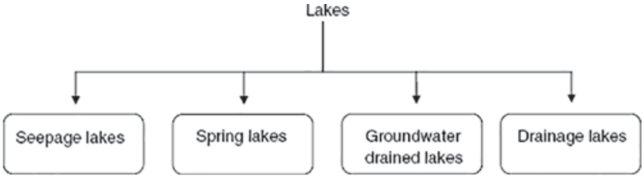

FIGURE 1 Classification of lakes.

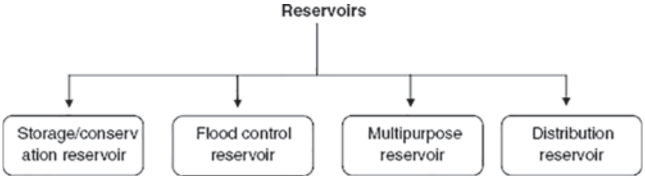

FIGURE 2 Classification of reservoirs.

Storage/conservation reservoirs retain excess water supplies during peak flows and release water gradually during low flows as and when needed. A *flood control reservoir* stores a portion of the flood flows so that it can minimize the flood peaks in the areas to be protected downstream. A *multipurpose reservoir* is meant for serving multiple purposes such as water supply, flood and soil erosion control, hydroelectric power generation, recreation, irrigation, etc. A *distribution reservoir* is connected with a network of primary water supply and is used to supply water to the end users according to fluctuations in demand over a short time period and serves as local storage in the case of emergency. Such reservoirs, thus, support the water treatment plants to work at a uniform rate and can store water when there is less demand and, thus, supply water during high-demand periods. Water quality in both lakes and reservoirs is influenced by many factors such as water body type, ecosystem characteristics, land use and land cover, and human activities.[3]

Freshwater/Saline Lakes

Most lakes hold freshwater, but some, particularly those where water cannot discharge via a river, can be salty. As a matter of fact, some lakes such as the Great Salt Lakes are saltier than the oceans. Lakes whose salinity content is more than 3 g/L are considered as saline lakes. They are prevalent and present on all regions, including Antarctica(e.g., Caspian Sea, Dead Sea, etc.). Though the inland saline water constitutes around 45% of the total inland water, a few deep lakes (mainly the Caspian Sea) occupy a significant volume of these saline waters. Salinity has a great influence on the freezing point of water, amount of dissolved oxygen, etc.[4]

Trophic Status

Lakes can be classified based on their trophic state as “eutrophic,” “mesotrophic,” and “oligotrophic.” The word “trophic” means nutrition or growth. A eutrophic lake is characterized by the presence of a high concentration of plant nutrients and associated excess plant growth. On the other hand, an oligotrophic lake is characterized by low nutrient concentrations and low plant growth. Mesotrophic lakes fall in between these two. The major factors that regulate the trophic status of a lake are as follows: 1) rate of nutrient supply; 2) climatic condition (sunlight, temperature, precipitation, lake basin turnover time, etc.), and 3) morphometry/shape of lake basin (mean and maximum depth, volume and surface area, watershed-to-lake surface area ratio, etc.).[5]

Problems Associated with Lakes and Reservoirs

Although more than three-fourths of the earth is occupied with water, only less than 0.3% (including surface water and groundwater) is available for human consumption.[6] The total area of the lakes on earth amounts to approximately 2.5×10^6 km^2 or 1.8% of the continental area, containing 1.2×10^5 km^3 of water. The 253 largest lakes (larger than 500 km^2) of the planet contain an estimated 78% of the world's unfrozen fresh surface water and thus represent an essential global life support system.[7] Though the amount of water in lakes and reservoirs is very small, because of its rapid renewal, these habitats are the primary sustainable supplier of freshwater for most regions. Since freshwater on the earth is scarce, sincere efforts are required for the conservation of existing water resources to ensure the availability of sufficiently good quality water. The surface water resources are more susceptible to pollution as compared to the groundwater resources due to the ease of access of pollutants and contaminants in the former.[8,9]

Most of the lakes and reservoirs around the world face environmental stress, and the appropriate functioning of various vital ecosystems is in danger. Due to the explosion in human population, supplementary demand-related damage is forced on lakes and reservoirs. Water levels become lower as a result of higher consumption by households and industries; a growing number of human population results in shrinking and altering their water resources; inappropriate use of the land, particularly hills and mountains, results in increased sedimentation on their basins. Ultimately, pollution from agricultural lands and from domestic and industrial sources may produce eutrophication, resulting in undesirable effects such as the presence of toxic algae, reduction of oxygen, and generation of foul odor. The proliferation of contaminants within lake and reservoir systems can deteriorate water quality significantly. In many regions, lake ecosystems have already degraded and restoration to desirable water quality needs enormous effort and high cost. Following the present status, none can predict for how long these resources can serve as renewable sources of pure surface water for domestic, industrial, and agricultural uses, or as sources of protein-rich food.[10] Lakes and reservoirs have a more vulnerable and complex ecosystem than rivers as they do not have a self purifying ability and, hence, readily accumulate pollutants. Because of their importance, their beauty, their religious and cultural significance, and their relative susceptibility to degradation, lakes and reservoirs require more concerted attention than is paid generally to river systems.[11] The next few paragraphs elaborate the major pollution problems of lakes and reservoirs.

Eutrophication

It can be defined as the process of enrichment of waters with plant nutrients that causes raw water quality loads, such as high primary production, low oxygen concentrations, and increased concentrations of hydrogen sulfide, carbon dioxide, dissolved iron, and manganese in the hypolimnion.[12] It is considered as one of the serious negative effects faced by the lentic water bodies such as lakes, ponds, and reservoirs and is one of the major water quality problems worldwide[13] and the most serious challenge for water management professionals in densely populated areas.[14] Water from eutrophic reservoirs may have meager taste, odor, and color, and some have high concentrations of naturally occurring organic compounds that may form trihalomethanes, which are carcinogenic and mutagenic and other by-products of disinfection.[15,16]

Seasonal pattern is prominently influenced by the availability of solar insolation and nutrients. Usually, the shallower the lake, the less the check of internal nutrient recycling by thermal stratification and light availability by critical depth as compared to mixing depth. During summer wind events, the lakes that are having an Osgood Index (OI)[17] less than 7 will show a strong tendency for mixing, as a result of which, nutrients from sediments/hypolimnion undergo recycling and enter into the photic zone. Such events entrain nutrients and cause summer blooms.[18] Thus, in highly dynamic lakes, the pattern of phytoplankton abundance/species composition differs with wind events.

Toxic Materials

It includes mainly heavy metals, toxin-producing microphytes, and pesticides from agricultural land. Toxic substances may enter water bodies directly as land runoff from urban streets and mining areas or as agricultural runoff including forestry drainage, discharge of inadequately treated sewage, and industrial effluents, and through deposition of airborne pollutants. Toxic substances can also be created in drinking water when chemicals from treatment plants interact with organic molecules in the raw water to form carcinogenic compounds such as trihalomethanes. A range of heavy metals such as mercury, arsenic, lead, and cadmium; chlorinated substances such as dichlorodiphenyltrichloroethane (DDT), dichlorodiphenyldichloroethylene (DDE), and polychlorinated biphenyls (PCBs); organic substances such as polyaromatic hydrocarbons (PAHs); Dieldrin; etc., create toxic conditions.

A large diversity of organic pollutants poses a serious threat to aquatic ecosystems. PCBs and 3,4-benzpyrene were confirmed as jeopardizing Lake Constance.[19] However, pesticide is the major group of contaminants in the top layers of sediments. The recognition of DDT as being harmful to human and animals served as the eye opener to serious consequences of various pesticides. PCBs are also considered as persistent organic pollutants and, thus, have huge potential hazards. The main sources of pesticides in lakes and reservoirs are 1) agriculture and forestry; 2) actions against aquatic weeds (e.g., water fern *Salvinia molesta, Eichhornia crassipes*); 3) actions against parasites and waterborne diseases (e.g., malaria and schistosomiasis); and 4) regulation of fish populations with rotenone (an active ingredient of derris, which is used as a fish poison for centuries). Atrazine, which is used for the protection of corn from weeds, is demonstrated as detrimental to human, and hence, it has recently been proscribed in many countries. Likewise, lindane, a persistent organochlorine insecticide, is toxic to fish in concentrations as low as 1 ppm. Pesticides are applied for curbing undesirable weeds such as water fern *Salvinia* sp. and *Azolla* sp., water hyacinth *E. crassipes,* water lettuce *Pistia stratiotes,* etc. Application of the pesticides should only be considered in cases where mechanical and biological approaches fail.[19]

Sedimentation

Sedimentation of lakes is a common phenomenon; in general, it takes place very slowly. Any process in a lake watershed that disturbs the soil can significantly hasten this process. Most of these activities are anthropogenic and comprised farming on fragile soils and on steep slopes, surface mining, and construction activities. Suspended sediment and sedimentation have many degrading effects on lakes and shoreline ecosystems. Peripheral wetlands can be completely covered by silt, eradicating their value as nutrient sinks, wave absorbers, nursery areas for fishers, and habitat. As silt settles in a lake, spawning areas are covered and lake volume is reduced, and this causes degradation in fishery production. As a result of reduced storage capacity, both the volume and extent of flooding can increase. In the case of hydroelectric amenities, generating capacity may reduce significantly. The increase in shoal areas as a result of sedimentation can enhance increased macrophyte growth and can interfere with recreational activities such as boating and fishing. Soil loss and suspended silt also contribute to eutrophication and lake contamination since the silt generally includes attached nutrients, herbicides, pesticides, and other chemicals. This increases water treatment costs and maintenance problems of water treatment plants.

Acidification

Atmospheric pollution by sulfur dioxide and nitrous oxides is the major cause of acidification in aquatic systems, through precipitation (dry or wet deposition) and, to a larger extent, through leaching from affected land. Other sources of acid deposits include industrial effluents and mining wastes.

Fish Depletion

Fish provides a substantial portion of animal protein consumed by humans. In tropical developing countries, 60% of the people depend on fish and 40% or more of total protein intake comes from fish.[20] The majority of the world's landed fish catch (87%) comes from marine areas. New developments in watersheds, such as dams and reservoirs to control the annual distribution of water, frequently cause large losses in floodplain fertility and species diversity. Floodplains are needed by many species of fish for reproduction and for refuge. The natural seasonal flooding and drying are signals used by some river-dwelling animals to begin to reproduce or migrate. Proper timing of water level drawdowns in upstream reservoirs is therefore important, especially to enhance spawning of certain species.

Stratification

Stratification is a significant feature influencing water quality in reasonably stagnant, deep waters, such as lakes and reservoirs, which occurs mainly because of the difference in temperature, leading to a variation in density. Occasionally, it can be due to the difference in solute concentrations. Water quality in various layers of stratified water body is subjected to different influences. Solar insolation will be more in the upper layer while the lower layer is physically detached from the atmosphere and may be in touch with decaying sediments that exert an oxygen demand. Because of these varying influences, the lower layer will usually have a reduced oxygen concentration relative to the upper layer. The anoxic condition thus produced will enhance the diffusion of constituents from sediments and form various compounds such as ammonia, nitrate, phosphate, sulfide, silicate, iron, and manganese.

During summer and spring, the surface layer of the water body in temperate regions becomes warmer and hence less dense. A resistance to vertical mixing is formed, because of the existence of warm water over cold water. The top warmer surface layer is known as the epilimnion and the colder water stuck underneath is the hypolimnion. There is a shallow zone called metalimnion or the thermocline, in between epilimnion and hypolimnion, where the temperature changes from warmer epilimnion to colder hypolimnion. Normally, wind-and surface-current-induced mixing is limited to epilimnion, while hypolimnion remains stagnant. The density difference between two layers (viz., epilimnion and hypolimnion) is diminished gradually when the weather becomes cooler. This will enhance the wind-induced vertical mixing between these two layers, which will result in the phenomenon known as "overturn," which can occur quite rapidly. The frequency of overturn and mixing governs predominantly on climate (temperature, solar insolation, and wind) and the characteristics of the lake and its surroundings (depth and exposure to wind). Lakes may be classified according to the frequency of overturn as follows:

- Monomictic: once a year—temperate lakes that do not freeze
- Dimictic: twice a year—temperate lakes that do freeze.
- Polymictic: several times a year—shallow, temperate, or tropical lakes
- Amictic: no mixing—arctic or high-altitude lakes with permanent ice cover, and underground lakes
- Oligomictic: Poor mixing—deep tropical lakes
- Meromictic: incomplete mixing—mainly oligomictic lakes but sometimes deep monomictic and dimictic lakes Because of the action of crosswind and the flow of water, thermal stratification is not seen in lakes, which have depths less than 10 m. In shallow tropical lakes, complete mixing occurs several times a year, whereas in very deep lakes, stratification may continue all over the year, even in tropical and equatorial regions. This stable stratification results in "meromixis."

In the case of tropical lakes, as a result of moderately constant solar insolation, seasonal changes in water temperature are small. The annual water temperature range is only 2–3°C at the surface and even less at depths greater than 30 m.[21] Winds and precipitation, both play a vital role in mixing. Because of the large difference in rainfall between wet and dry seasons, large variation in water level is seen in some tropical lakes. Such variations have a prominent influence on dilution and nutrient supply, which, in turn, affect algal blooms, zooplankton reproduction, and fish spawning. Wind speeds are usually greater during the dry season and evaporation rates are at their highest. The subsequent heat losses, combined with the turbulence caused by wind action, stimulate the process of mixing.

As far as recreation is concerned, reservoirs are as important as natural lakes but have surplus scopes for flood control, hydropower generation, and water supply. Although both lakes and reservoirs are subjected to silt, organic, and nutrient loadings, reservoirs usually having hefty watersheds and peculiar morphometric conformations are subjected to more water quality problems. Even though lakes and reservoirs have biotic and abiotic processes in common and similar habitats, they have some significant differences. They differ in their geologic history and setting, basin morphology, and hydrologic factors.[22,23]

Non-point source of water pollution generated by expanding agricultural production is considered as a major environmental threat to some lakes. Many chemicals in common agricultural use have a strong affinity for fine soil particles. When the latter erode, these chemicals are carried with them into surface waters. The soil itself is a problem when it accumulates in great quantity in lakes. Lake Pittsfield lost nearly a quarter of its volume to sedimentation in only 24 years. Transport and deposition of eroded materials as well as substances dissolved in runoff and attached to soil particles lead to negative impacts on agricultural land and the Three Gorges Reservoir including water quality decline,[24,25] which are generally thought to be caused by land use changes of converting forest resources to agriculture in watersheds. Conversion of cropland with a slope greater than 10° into forestland meets the reduction goal.[26]

Over recent decades, the water quality of lakes and reservoirs has been deteriorating rapidly due to external and internal pollution including that from the sediment, and the eutrophication phenomenon has become a more serious global threat. Some researchers suggest applying a plan of sediment dredging to this water body. After dredging, however, a vast amount of sediment would become solid pollutants containing high concentrations of heavy metals (mainly Hg and Cd), which would certainly cause secondary pollution. This pollution should not be ignored, and a further research is therefore needed on the elaborate restoration scheme for these precious drinking-water sources.[27] Major pollution issues of lakes and reservoirs with few representative past studies are tabulated in Table 1.

TABLE 1 Major Pollution Issues of Lakes and Reservoirs

Sl. No.	Pollution Issue	Effects	Representative Case Studies
1	Eutrophication	High primary production, low oxygen concentrations and increased concentrations of hydrogen sulfide, carbon dioxide, dissolved iron, and manganese in the hypolimnion	West Twin Lake, Ohio[28]
2	Sedimentation	Volume will be decreased, macrophytes growth may be enhanced	Lake Superior at Superior Harbor, Wisconsin[29]
3	Acidification	Adverse effects on the most sensitive aquatic species	Many Scandinavian lakes[11]
4	Toxic substances and heavy metal contamination	Bioaccumulation of these toxicants poses health hazards to all members of the food chain including humans	Lake Nainital, India[30]
5	Fish depletion	As the fishery plays a vital role in the supply of animal protein, its depletion affects the food security and economy of a significant portion of humans	Lake Victoria, Uganda[11]

Sources of Lakes and Reservoir Pollution

Lakes and reservoirs tend to collect not only sediments but also most of the pollutants that are washed into them, and thus they function, in part, as environmental sinks. Eroded soil dissolves in the water and fills in lake bottoms—this activity has significantly degraded lake ecosystems across the world. The sources of pollution can be mainly classified into two: 1) point sources and 2) non-point sources. A point source of pollution is a single identifiable localized source of air, water, thermal, noise, or light pollution.[31] In earlier days, control of "point source" nutrients and toxic contaminants was the principal focus of exertions for the protection and restoration of lakes and reservoirs, but nowadays, the substantial contaminant and nutrient sources to lakes and reservoirs are "non-point" type such as agricultural runoff, erosion from urban or deforested areas, surface mining, or atmospheric depositions. Most lake water is rich in nutrients that support growth of many aquatic macrophytes and algal blooms. Besides, water is contaminated with metals like chromium (Cr), copper (Cu), iron (Fe), manganese (Mn), nickel (Ni), lead (Pb), and zinc (Zn). High concentrations of these metals are also found in sediments, but it is found that the level of metal concentrations of lake varies considerably in different seasons.

In earlier days, we believed that lakes and reservoirs were enriched with nutrients and organic matter from "point" sources such as industrial discharges and wastewater treatment plant outfalls. However, for many lakes, non-point or diffuse nutrient loading, both internal and external, is found to be momentous. These non-point sources are challenging to assess and regulate,[32] and water quality in many lakes has remained deteriorated following diversion or treatment of point sources.

The main pollutants that enter through non-point sources are various forms of phosphorus and nitrogen such as total phosphorus, phosphate phosphorus, nitrate nitrogen, nitrite nitrogen, ammoniacal nitrogen, organic nitrogen, chlorine, sodium, calcium, and suspended solids. The exports of all constituents occur mostly during rainfall-or snowmelt-generated runoff events during the spring runoff period. It has been shown that one of the major reasons for the enrichment of lakes is the conversion of previously cropped land into agricultural production while conversion to forests has very little impact on enrichment.

The runoff of nutrients from old fields depends on the nutrient status of the soils and soil water. This nutrient status reflects the soil type, fertilizer and cropping practices prior to abandonment, number of years since abandonment, and the succeeding vegetation present at any particular point. Soil data identify the reservoir of nutrients available for runoff, provide a means to relate runoff to nutrient content of that particular soil, and provide the data necessary for design of management schemes to prevent release of nutrients. Farm lands that have been abandoned for 15 to 20 years are not major non-point sources of pollution.

Water Quality Monitoring

Water quality monitoring refers to the acquisition of quantitative and representative information on the physical, chemical, and biological characteristics of a water body over time and space.[33] It is a complex task, comprising all the activities to extract information with respect to the aquatic system. A variety of contaminants, in addition to a multitude of imprudent water quality management practices and destructive land uses, are currently threatening aquatic systems on a worldwide scale. In addition, it has been shown that water of good quality is a critical component for sustainable socioeconomic development.[34] The impact and behavior of contaminants in an aquatic ecosystem are complex and may involve adsorption-desorption, precipitation-solubilization, filtration, biological uptake, excretion, and sedimentation-suspension. Besides natural processes affecting water quality, there are also anthropogenic impacts, such as man-induced point and non-point sources, xenobiotic, and alteration of water quality due to unwise water use and river engineering projects (e.g., irrigation, damming, etc.).[35]

The degradation of water resources has increased the need for determining the ambient status of water quality, in order to provide an indication of changes induced by anthropogenic activities. To understand the process dynamics of a watershed, a well-designed water quality monitoring network identifies water quality problems while establishing baseline values for short-and long-term trend analysis. The need to evaluate observed water quality conditions and their suitability for the intended uses reflects a need for cost-effective and logistically practical water quality monitoring network design methods.

Types of Monitoring

Lake Sampling

It characterizes the water quality of the lake to identify status and trends. Two main types of lake monitoring are water-column sampling and near-shore (shallow water) sampling. Water-column sampling tries to quantify the overall response of the lake to contamination. The lake's trophic status, as designated by phosphorus, turbidity, chlorophyll-a, and dissolved oxygen, is of particular concern. Some invasive species, such as spiny water flea, can also be identified by water-column sampling. During seasons when the lake is stratified, the water-column sample should be sampled in both the epilimnion (the warm upper layer) and hypolimnion (lower layer of cold water).

Near-shore refers to the depth at which rooted plants can grow. Sampling can be adequately done at the end of a dock. Sampling for pathogens and pathogen indicators is important because of contact recreation such as swimming. Near-shore monitoring allows study of the lake bottom including sediment sampling for heavy metals, macroinvertebrates, and attached or rooted invasives such as zebra mussels and Eurasian watermilfoil.

Tributary Mass Load Sampling

It determines the tributary mass loads of water contaminants entering the lake. A significant portion of the lake's water pollution is brought by the tributaries flowing into it. Determination of tributary mass loads is particularly important for management of the lake's phosphorus and sediment problems.

Tributary Water Quality Sampling

It characterizes the water quality of tributaries to identify status and trends. Tributaries may be threatened by contaminants or stresses that affect the stream health but are not significantly detrimental to the lake. The tributaries are valued for recreation and aesthetics, drinking water, irrigation, and wildlife habitat and deserve protection.

Biological Integrity Sampling

It characterizes the long-term ecological health of the lake and tributaries. Ecological sampling is useful for detecting the effects of impairments that are not present at the time of sampling, for evaluating habitat health and for determining the biological integrity of surface waters. Ecological sampling may include bioassessments of fish and benthic macroinvertebrate communities, periphyton, and single-species monitoring (trout, salmon, and freshwater mussels are often used). Biological indices, a composite of different indicators, can be developed.

Citizen Monitoring

It encourages citizen participation in the measurement of watershed quality. To the extent that people care about the watershed's lands and waters, the watershed will be protected and enhanced for generations to come. One way to encourage such stewardship is through involvement of students and other citizens in water quality monitoring. Monitoring conducted by citizen volunteers increases public awareness and knowledge about water quality and its protection.

The design of efficient water quality monitoring network is essential for effective water management. To date, many water quality monitoring networks for surface freshwaters have been rather arbitrarily designed without a consistent or logical design strategy. Moreover, design practices in recent years indicate a need for cost-effective and logistically adaptable network design approaches.[36] Furthermore, the monitoring in a water quality management program is recognized as a statistical approach, so that both the assessment and the design problems can be addressed via a statistical method. In this view, the statistical methods have been found very efficient for redesigning and assessment of water quality monitoring networks (WQM).

The International Organization for Standardization (ISO) defines water quality monitoring as: "the programmed process of sampling, measurement and subsequent recording or signaling, or both, of various water characteristics, often with the aim of assessing conformity to specified objectives." This general definition can be differentiated into three types of monitoring activities that distinguish between long-term, short-term, and continuous monitoring programs:

- Long-term observation and standardized measurement of the aquatic environment for defining the water quality status and prediction of the trend are known as monitoring.
- Intensive programs for the measurement and observation of status of the aquatic environment for a specific purpose are known as surveys. These are of limited duration.
- Continuous measurement and observation of the aquatic environment for the management of the quality of the water and other operational activities are known as surveillance.

The constituents that decide the quality of the water are transported by water from the watershed. Therefore, we have to construct a perfect water budget, as it plays a key role in identifying a lake's (reservoir's) problem. By conducting a reconnaissance survey of water from the watershed, main tributaries can be selected. Since high flows are the chief segment of the water budget and huge volume influxes are followed by high concentration, continuous gauge recording is recommended for the determination of flow in major tributaries. From a successive record of inflow and outflow in the main tributaries, an annual water budget is constructed so that estimated inflows equal outflows with a correction for lake storage.

The water budget is formulated as:[37]

$$\mathrm{SF_i + GW + DP + WW = SF_o + EVP + EXF + WS + \Delta STOR}$$

where $\mathrm{SF_i}$ and $\mathrm{SF_o}$ are stream flow in and out, respectively; GW is groundwater in (includes deep and subsurface seepage); DP is direct precipitation on the lake surface; WW is wastewater, if any; EVP is evaporation; EXF is exfiltration; WS is removal for water supply, if any; and ASTOR is the change in lake volume.

Protective and Restorative Measures

Removal or treatment of direct input of wastewater, stormwater, or both constitutes the primary step in the restoration of water quality of eutrophic lakes and reservoirs, as these sources frequently contain comparatively high concentrations of phosphorus and nitrogen. For the realization of any long-term benefits from in-lake treatments, such external loadings should be reduced. In some cases, reduction of external loading is adequate to restore the water body (e.g., Lake Washington[38,39]), but in others, where internal loading of nutrients is significant, in-lake treatments may be indispensable to accomplish lake quality improvement (e.g., Lake Trummen[40]).

Advanced wastewater treatment (AWT) and diversions are two most commonly used techniques for the reduction of external inputs. In diversion, the treated sewage or industrial wastewater is carried away from the degraded water body to waters that are having high assimilative capacity, by the installation of interceptor lines. AWT involves the reduction of phosphorus concentration in wastewater effluent by using chemicals such as alum (aluminum sulfate), lime (calcium hydroxide), or ferric chloride. Stormwater runoff is the next dominant source of external enrichment. Even though the P concentration in stormwater is very low (2%–10%), and solubility is less than that of sewage effluent, such non-point sources can denote momentous contributions. P retention in wet detention basins and wetlands, rapid filtration through soil, and P removal in predetention basins are the principal P removal methods applied for runoff water. If internal loading of P is anticipated to hinder the recovery following primary treatments such as diversion or AWT, then supplementary in-lake treatments may be justified to accelerate reclamation. Lakes and reservoirs lose volume due to siltation. Sediment removal, together with land management and construction of device to trap silt, is an example of their restoration and protection. Some management approaches are institutional arrangement, formation and operation of lake association, sports fishery management, etc.

Eutrophication can be controlled if the phosphorus (P) concentrations in the water body are lowered to a level that will limit the growth of the algae. This can be achieved by diversion of external input, dilution, flushing, or a combination of these approaches. Where there is substantial loading reduction, comparatively augmented rate of algal flushing, and negligible recycling from sediment, in-lake phosphorus concentration can be reduced significantly and trophic state can be improved rapidly. Lake Washington is a good example for this approach.[40,41] However, for many lakes, internal phosphorus release sustained the lake's enriched trophic state and reinforced the state of continued eutrophication, in spite of the removal of a noteworthy fraction of external loading by diversion.[42,43] In those lakes, following nutrient diversion, supplementary in-lake treatment may be necessary, to avoid an extended eutrophic state.

Other methods are dilution and flushing, which are used interchangeably. Dilution involves the reduction in the concentration of the nutrients and a washout of algal cells, whereas flushing comprises only the latter. Where there is a high nutrient load, water should be diverted if possible for the low dilution rate to be most effective. This plan provides for a reduction in biomass primarily through nutrient limitation. If only moderate to high nutrient water is available, flushing may work well if the loss rate of cells is sufficiently great relative to the growth rate. Flushing rate on the order of 10%–15% per day will afford some control through washout. We can opt for the technique such as "phosphorus inactivation," which involves, usually, the application of salts of aluminum, such as aluminum sulfate (alum), sodium aluminate, etc., to precipitate phosphate as aluminum phosphate and thus to bind a significant fraction of P. Aluminum hydroxide floc, which is formed during this process, enhances the settling of the precipitate and it will continue to sorb and retain P in their molecular lattices.

Nutrient reduction mainly consists of processes such as source reduction in the watershed, issuance of fertilizer guidelines, setting up of shoreland buffer strips, and restriction of motorboats. *Biological control* involves processes such as use of bacteria for algae control, use of algae-eating fishes, biomanipulation, aquascaping, and bioscaping. *Lake aeration* comprises conventional aeration, solar powered aeration, wind-powered aeration, fountain aeration, and hypolimnetic aeration. *Addition of chemicals* includes use of barley straw, alum, buffered alum for sediment treatments, calcium compounds, liquid dyes, chlorine, and algicide[44] (Figure 3). Copper is an efficient algicide. Copper sulfate application, the typical treatment for algal problems for many decades, is often effective for short-term solution to a current algae problem, predominantly in water supply reservoirs. However, there is substantial

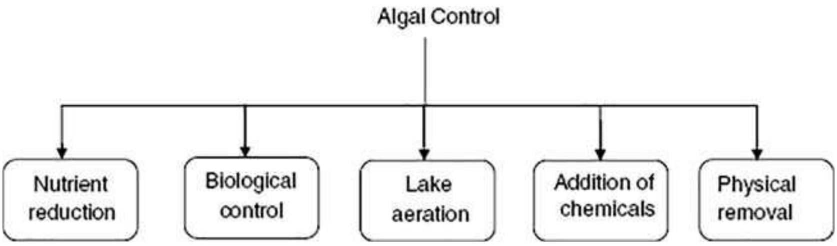

FIGURE 3 Major algal control measures.

TABLE 2 Major Restoration Measures for the Lakes and Reservoirs

Sl. No.	Restoration Measure	Advantage(s)	Drawback(s)
1	Diversion	Reduce the overall nutrient loading to the system	Presence of another water body (having high assimilative capacity) is required in the near vicinity
2	Advanced wastewater treatment	Control eutrophication by limiting nutrient concentration with suitable chemicals	Accumulation of chemicals in the system and high cost
3	Dilution and flushing	Control eutrophication by limiting the P concentration	Cannot accommodate high nutrient loading
4	Application of appropriate algicide (such as copper sulfate)	Control eutrophication by curbing algal growth	Its effects are found to be temporary, higher cost, there are major negative impacts to non-target organisms, and significant copper contamination of sediments can be possible
5	Sediment removal (dredging)	Sediment removal, together with land management can restore the lake, affected by siltation	High cost and, in some cases, may cause environmental damage

confirmation against the prolonged usage of this chemical. Its effects are found to be temporary, cost can be higher, there are major negative impacts to non-target organisms, and significant copper contamination of sediments can be possible. We can go for long-term and permanent options such as control of external and internal nutrient loading for the effective management of algal bloom. For a better water quality, and if the P is not estimated to reach an algal limiting level, an in-lake treatment for the control sediment should be established soon after external controls are in place.

Macrophytes includes all macroscopic aquatic flora, comprising macroalgae such as the stoneworts *Chara* and *Nitella*, aquatic liverworts, mosses, ferns, and flowering vascular plants. Aquatic plant management aims to curb annoyance species, to exploit the favorable features of plants in water bodies, and to reorganize plant communities. Its principal objective is the establishment of stable, diverse, aquatic plant communities comprising high percentages of desirable species. An exhaustive understanding of macrophytes biology is the foundation for evolving innovative management tactics. Continued research and development will advance our understanding of the relationship of aquatic plants to overall lake and reservoir quality and our capability to manage aquatic plant communities to preserve or improve that quality.[36,37] Table 2 shows major restoration measures for the lakes and reservoirs.

Eutrophication Model Framework

Phosphorus-loading models are often employed for the evaluation of eutrophication problems in lakes and reservoirs. In these models, phosphorus loading is linked to the average total phosphorus concentration in the lake water and to other indicators of water quality that are associated to algal bloom, such as chlorophyll and transparency. Physical and hydrologic features influence the response of the lake to phosphorus loading and thus these models take in to account various characteristics such as lake volume, average depth, flushing rate, etc. The underlying principles behind the eutrophication model are as follows: 1) phosphorus acts as the limiting nutrient for algal growth; 2) any change in the amount of phosphorus discharged into a lake over an annual or seasonal period will alter the average concentration of P in lakes and hence the extent of algal bloom; and 3) the capacity of the lake to adjust with the P loading, without causing algal blooms increases with the volume, depth, and the flushing rate of the lake. Models recapitulate these relationships in mathematical forms, based upon observed water quality responses of large numbers of lakes and reservoirs. Eutrophication models are pitched for the prediction of average status of water quality over a season or a year. Averaging is mainly done over three dimensions: 1) depth; 2) sampling stations; and 1) season.[45]

Conventions for the Protection of Lakes and Reservoirs

Lakes and Wetlands—Ramsar Convention, Iran, February 2, 1971

The Ramsar Convention (The Convention on Wetlands of International Importance) is an international treaty for the conservation and sustainable utilization of wetlands. The convention was developed and implemented by participating countries at a meeting in Ramsar, hosted by the Iranian Department of Environment, and came into force on December 21, 1975. The Ramsar List of Wetlands of International Importance presently comprises 1950 sites (known as Ramsar Sites) covering around 1,900,000 km^2 up from 1021 sites in 2000. The nation with the highest number of sites is the United Kingdom at 168; the nation with the greatest area of listed wetlands is Canada, with more than 130,000 km^2. Presently, there are 161 contracting parties, up from 119 in 1999 and from 21 initial signatory nations in 1971. Signatories meet every 3 years as the Conference of the Contracting Parties (COP); the first was held in Cagliari, Italy, in 1981. There is a standing committee, a scientific review panel, and a secretariat. The headquarters is located in Gland, Switzerland, shared with the International Union for Conservation of Nature (IUCN).[46]

UNECE Water Convention, Helsinki, March 17, 1992

The Convention on the Protection and Use of Transboundary Watercourses and International Lakes (Water Convention) is intended to strengthen national measures for the protection and ecologically sound management of transboundary surface waters and groundwater. The Parties to this convention are obliged to prevent, control, and reduce transboundary impact; use transboundary waters in a reasonable and equitable way; and ensure their sustainable management. Parties bordering the same transboundary waters shall cooperate by entering into specific agreements and establishing joint bodies. The Convention includes provisions on monitoring, research and development, consultations, warning and alarm systems, mutual assistance, and exchange of information, as well as access to information by the public.

Protocol on Water and Health, London, June 17, 1999

The Protocol on Water and Health aims to protect human health and well-being by better water management, including the protection of water ecosystems, and by preventing, controlling, and reducing water-related diseases. It is the first international agreement of its kind adopted specifically to attain an adequate supply of safe drinking water and adequate sanitation for everyone and effectively protect water used as a source of drinking water. Parties to the Protocol commit to set targets in relation to the entire water cycle.[47]

Conclusion

Many of the lakes and reservoirs are situated in developing countries or industrializing countries that only now identify the devastating economic and social impact that pollution, overfishing, and habitat degradation are having on their water resources. Once these natural systems are severely polluted, they often cannot be restored completely; they can at best only be improved to a level where they can meet basic functions, and society must bear the increased costs and risks to human health.

The reviewed case studies in this entry and elsewhere illustrate that contaminated lakes and reservoirs can be restored, at least partially. The entry presented a number of examples where this process has been undertaken effectively. From an economic and environmental point of view, it appears wise to prevent the occurrence or exacerbation of problems, rather than going for radical and expensive restorative actions. Ample evaluations of water resources should be conducted to understand the state of lakes and reservoirs, so that we can provide the essential means for the establishment of imperative water resource management goals and objectives.

All-inclusive watershed management programs that comprise significant water quality objectives precise to the hydraulic characteristics of lakes and reservoirs should be prepared. The differences between temperate and tropical lake situations need to be highlighted. During the formulation of management strategies, all exertion should be made to avert the discharge of toxic substances to lakes and reservoirs. Introduction of exotic and invasive species should be banned, unless there has been ample environmental assessment.

We should incorporate the "precautionary" approach and the "polluter pays" principle in the management of lakes and reservoirs, which can benefit from various economic tools and ample financial policies. Primary action areas for protection and restoration of lakes and reservoirs involve watershed assessment, watershed control measures, and best management practices, which comprise management of pollution from agriculture, silviculture, mining, industrial pollution, urban runoff, and other pollutant sources, predominantly for nutrients and persistent toxic pollutants. Management programs for lakes and reservoirs should be comprehensive in scope and watershed-wide in nature. If necessary, joint governance institutions, such as joint commissions, composed of high-level government officials, should be established to improve management of transboundary lake and reservoir basins. The formulation of legal instruments, treaties, and a hierarchy for making the decision are essential for the advancement of the water resources management. It is clear that the world's lake reservoirs are threatened. In many cases, lake degradation is so advanced that populations depending on them are in great danger. The scope, magnitude, and dimension of the problem demand an international cooperation as well as national exertions.

A logical and consistent design methodology that allows more efficient and effective data collection and, hence, more useful information extraction should be developed. Such an approach not only permits better water pollution control recommendations and better allocation of financial resources but also, ultimately, a better understanding of the ecosystems. To appreciate the challenges of designing water quality networks, it is crucial to clearly define objectives and identify statistically acceptable assumptions. Assumptions are an inherent part of the monitoring network design process, mainly due to the stochastic influences on water quality variables in the aquatic environment. The number and type of simplifying assumptions made or allowed are dependent upon network objectives. Furthermore, assumptions in monitoring network design should be made relative to water quality hydrologic principles, applicable statistics, information utilization, and budget constraints.

Mines: Acidic Drainage Water

Wendy B. Gagliano
and Jerry M. Bigham

Introduction

What Is Acid Mine Drainage?

Acid mine drainage refers to metal-rich sulfuric acid solutions released from mine tunnels, open pits, and waste rock piles (Table 1). Similar solutions are produced by the drainage of some coastal wetlands, resulting in the formation of acid sulfate soils. Acid mine drainage typically yields pH values ranging from 2 to 4; however, extreme sites such as Iron Mountain, California, have produced pH values as low as −3.6.[1] Neutral to alkaline mine drainage is also common in areas where the surrounding geologic units contain carbonate rocks to buffer acidity (Table 1).

Why Is Acid Mine Drainage a Problem?

Landscapes exposed to acid mine drainage do not support vegetation and are susceptible to erosion. When acid mine drainage enters natural waterways, changes in pH and the formation of voluminous

TABLE 1 Summary of Mine Drainage Chemistry from 101 Bituminous Coal Mine Sites in Pennsylvania

	Range	Median	Mean
pH	2.7–7.3	5.2	3.6
Fe (mg/L)	0.16–512.0	43.0	58.9
Al (mg/L)	0.01–108.0	1.3	9.8
Mn (mg/L)	0.12–74.0	2.2	6.2
SO4 (mg/L)	120–2000	580.0	711.2

Unpublished data from C. Cravolta, III, 2001. USGS, Lemoyne, PA.

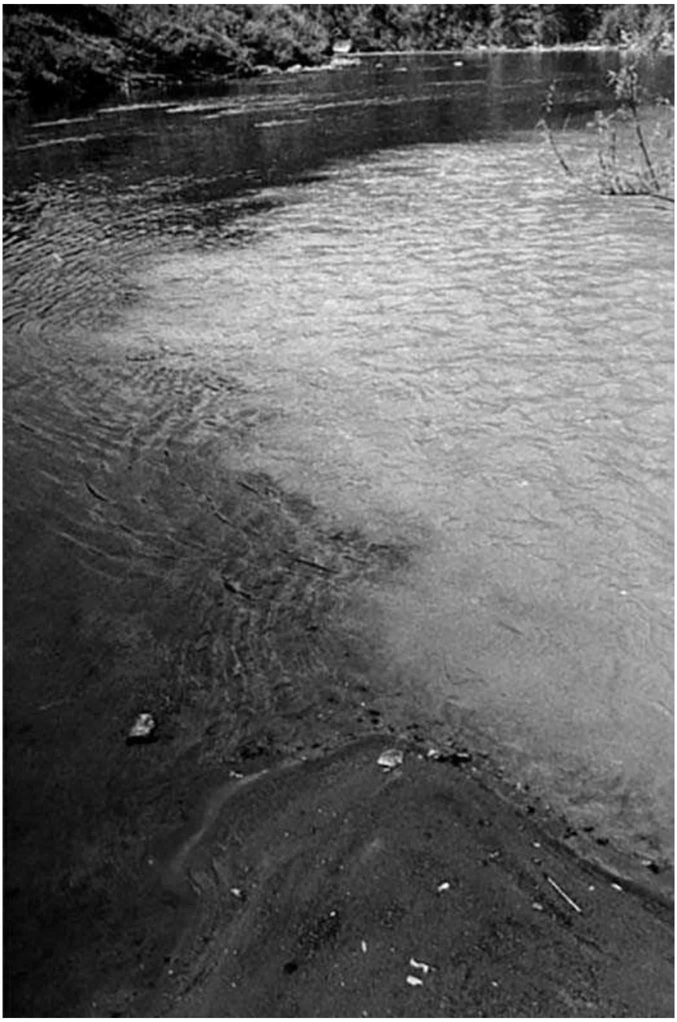

FIGURE 1

precipitates of metal hydroxides can devastate fish populations and other aquatic life (Figure 1). The corrosion of engineered structures such as bridges is also greatly accelerated. There may be as many as 500,000 inactive or abandoned mines in the United States, with mine drainage severely impacting approximately 19,300 km of streams and more than 72,000 ha of lakes and reservoirs.[2,3] Once initiated, mine drainage may persist for decades, making it a challenging problem to solve.

What Causes Acid Mine Drainage?

Mine drainage results from the oxidation of sulfide minerals such as pyrite (cubic FeS_2), marcasite (orthorhombic FeS_2), pyrrhotite ($Fe_{1-X}S$), chalcopyrite ($CuFeS_2$), and arsenopyrite ($FeAsS$). These minerals are commonly found in coal and ore deposits and are stable until exposed to oxygen and water. Their oxidation causes the release of metals and the production of sulfuric acid. This process can occur as a form of natural mineral weathering but is exacerbated by mining because of the sudden, large-scale exposure of unweathered rock to atmospheric conditions.

Mine Drainage Chemistry

Mine drainage is a complex biogeochemical process involving oxidation-reduction, hydrolysis, precipitation, and dissolution reactions as well as microbial catalysis.[1] The entire sequence is commonly represented by Reaction 1, which describes the overall oxidation of pyrite by oxygen in the presence of water to form iron hydroxide [$Fe(OH)_3$] and sulfuric acid.

$$FeS_{2(s)} + 3\frac{3}{4}O_{2(g)} + 3\frac{1}{2}H_2O_{(l)} \rightarrow Fe(OH)_{3(s)} + 2H_2SO_{4(aq)} \tag{1}$$

The actual oxidation process is considerably more complicated.

Pyrite and related sulfide minerals contain both Fe and S in reduced oxidation states. When exposed to oxygen and water, the sulfur moiety is oxidized first, releasing Fe^{2+} and sulfuric acid to solution (Reaction 2). The rate of oxidation is dependent on environmental factors like temperature, pH, Eh, and relative humidity, as well as mineral surface area and microbial catalysis.

$$FeS_{2(s)} + 3\frac{1}{2}O_{2(g)} + H_2O_{(l)} \rightarrow Fe^{2+}_{(aq)} + 2SO^{2-}_{4(aq)} + 2H^{+}_{(aq)} \tag{2}$$

Reaction 2 is most important in the initial stages of mine drainage generation and can be either strictly abiotic or mediated by contact with sulfur-oxidizing bacteria.[4] The Fe^{2+} released by pyrite decomposition is rapidly oxidized by oxygen at $pH > 3$ as per Reaction 3.

$$Fe^{2+}_{(aq)} + \frac{1}{4}O_{2(aq)} + H^{+}_{(aq)} \rightarrow Fe^{3+}_{(aq)} + \frac{1}{2}H_2O_{(l)} \tag{3}$$

If acidity generated by Reaction 2 exceeds the buffering capacity of the system, the pH eventually decreases. Below pH 3, Fe^{3+} solubility increases and a second mechanism of pyrite oxidation becomes important[5] (Reaction 4).

$$FeS_{1(2)} + 14Fe^{3}_{(aq)} + 8H_2O_{(l)} \rightarrow 15Fe^{2+}_{(aq)} + 2SO^{2-}_{4(aq)} + 16H^{+}_{(aq)} \tag{4}$$

In this case, pyrite is oxidized by Fe^{3+} resulting in the generation of even greater acidity than when oxygen is the primary oxidant. Pyrite decomposition is thus controlled by the rate at which Fe^{2+} is converted to Fe^{3+} at low pH.[6] At $pH < 3$, Fe^{2+} oxidation is very slow unless it is catalyzed by populations of iron-oxidizing bacteria like *Acidithiobacillus ferrooxidans* or *Leptospirillum ferrooxidans.* These acidophilic bacteria oxidize Fe^{2+} as a means of generating energy to fix carbon. In doing so, they supply soluble Fe^{3+} at a rate equal to or slightly greater than the rate of pyrite oxidation by Fe^{3+}.[5] Pyrite oxidation then regenerates Fe^{2+} (Reaction 4), creating a cyclic situation that leads to vigorous acidification of mine drainage water.

Mine Drainage Mineralogy

The hydrolysis of Fe^{3+} causes the precipitation of various iron minerals—generally represented as ($Fe[OH]_3$)—that are often the most obvious indicators of mine drainage contamination (Reaction 5).

$$Fe^{3+}_{(aq)} + 3H_2O_{(l)} \rightarrow Fe(OH)_{3(s)} + 3H^{+}_{(aq)} \tag{5}$$

These precipitates are yellow-to-red-to-brown in color and have long been referred to by North American miners as "yellow boy." The actual mineralogy of the precipitates is determined by solution parameters like pH, sulfate, and metal concentration and can vary both spatially and temporally. Some of the most common mine drainage minerals are goethite (α-FeOOH), ferrihydrite ($Fe_5HO_8.4H_2O$), schwertmannite ($Fe_8O_8[OH]_6SO_4$), and jarosite ($[H,K,Na]\ Fe_3[OH]_6[SO_4]_2$).[7]

Goethite is a crystalline oxyhydroxide that occurs over a wide pH range, is relatively stable, and may represent a final transformation product of other mine drainage minerals.[8] Ferrihydrite is a poorly crystalline ferric oxide that forms in higher pH (>6.5) environments. Schwertmannite is commonly found in drainage waters with pH ranging from 2.8 to 4.5, and with moderate to high sulfate contents. It may be the dominant phase controlling major and minor element activities in most acid mine drainage. Jarosite group minerals form in more extreme environments with $pH < 3$, very high sulfate concentrations, and in the presence of appropriate cations like Na and K.

Mine Drainage Microbiology

The most studied bacterial species in mine drainage systems belong to the genus *Acidithiobacillus* (formerly *Thiobacillus*)[9] Species like *Acidithiobacillus thiooxidans* and *A. ferrooxidans* are important to sulfur and iron oxidation in acid drainage; however, many other microorganisms may also be involved.[10] Bacteria have been found in close association with pyrite grains and may play a direct role in mineral oxidation, but they most likely function indirectly through oxidation of dissolved Fe^{2+} as described previously. In low pH systems (<3), *A. ferrooxidans* can increase the rate of iron oxidation as much as five orders of magnitude relative to strictly abiotic rates.[6]

Iron-oxidizing bacteria are chemolithotrophic, meaning they oxidize inorganic compounds, like Fe^{2+}, to generate energy and use CO_2 as a source of carbon. Iron oxidation, however, is a very low energy yielding process. It has been estimated that the oxidation of 90.1 mol of Fe^{2+} is required to assimilate 1 mol of C into biomass.[11] Thus, large amounts of Fe^{2+} must be oxidized to achieve even modest growth.

In addition to mediating iron oxidation, bacteria may play an additional role in mineral formation. Bacteria in mine drainage systems have been shown to be partially encrusted with mineral precipitates.[12] Bacterial cell walls provide reactive sites for the sorption of metal cations, which can accumulate and subsequently develop into precipitates, using the bacterial surface (living or dead) as a template.[13,14]

Environmental Impacts of Mine Drainage

Mine drainage is primarily released from open mine shafts or from mine spoil left exposed to the atmosphere. The drainage produced can have devastating effects on the surrounding ecosystem. Chemical precipitates can obstruct water flow, dramatically increase turbidity, and ruin stream aesthetics. Dissolved metals and acidity can also affect plant and aquatic animal populations.

Besides iron, Al is the most common dissolved metal in acid mine drainage. The primary source of Al is the acid dissolution of aluminosilicates found in soil, spoils, tailings deposits, and gangue material.[7] At high concentrations, Al can be toxic to plants, and colloidal aluminum precipitates can irritate the gills of fish, causing suffocation. Aluminum occurs as a dissolved species at low pH but rapidly hydrolyzes at about pH 5 to form felsöbanyáite $[Al_4(SO_4)(OH)_{10}\ 4H_2O]$ or gibbsite $[Al(OH)_3]$.[7,15] Aluminum precipitates are white in color but are readily masked by associated iron compounds.

Elevated levels of trace elements like As, Cu, Ni, Pb, and Zn may be released during the oxidation of sulfide minerals. These elements can play a role in mineralization processes by forming coprecipitates[16,17] but occur primarily as sorbed species.[18] Mine drainage precipitates can retain both anions and cations, depending on pH. While coprecipitation and sorption function to immobilize trace elements by removing them from solution, this effect may not be permanent. Dissolution of precipitates and shifts in pH can result in the release of sorbed species, providing a latent source of pollution.[19]

Dealing with Mine Drainage

Successful control of mine drainage usually involves elements of both prevention and treatment.

Prevention

Prevention techniques include sealing mine shafts, burying or submerging spoil piles, and adding bactericides to limit the function of iron-oxidizing bacteria. These techniques often have limited success. Sealing of mines is extremely difficult due to fractures and the permeability of surrounding rocks. Covering spoil with soil material can decrease the degree of sulfide oxidation by limiting exposure to oxygen, but establishment of a vegetative cover is necessary to prevent erosion from re-exposing the spoil. Inhibition of iron-oxidizing bacteria with bactericides can decrease sulfide oxidation and reduce metal mobility; however, reapplication is necessary and adequate distribution to all affected areas is difficult. In addition, target bacteria may develop resistance, and beneficial bacteria may be harmed.[20]

Treatment

Solution pH usually underestimates the total acidity of mine drainage. Total acidity is the sum of "proton acidity" and "mineral acidity" generated upon oxidation and hydrolysis of metals like Fe^{2+}, Fe^{3+}, Mn, and Al^{3+}.[21] The traditional approach to treatment of acid mine drainage involves neutralization of total acidity by the addition of alkaline agents like caustic soda (NaOH) or hydrated lime [$Ca(OH)_2$]. This method is effective in neutralizing acidity and precipitating dissolved metals; however, it requires continuous oversight and produces large amounts of waste sludge that require disposal. Newer remediation strategies focus on low-cost, sustainable methods for treatment of drainage waters. For example, limestone drains coupled with settling ponds or compost wetlands have shown some promise as passive remediation technologies.[22] In these systems, drainage is channeled through either oxic or anoxic limestone substrates to neutralize active acidity. Dissolved metals are then allowed to hydrolyze and precipitate in ponds or wetland cells. A major difficulty is the loss of reactive surface by armoring of limestone particles with precipitates of Fe and Al that eventually obstruct flow.

Compost wetlands are designed to stimulate the development of anaerobic microbial populations, particularly sulfate- reducing bacteria. The bacteria use the compost as an organic substrate and remove sulfate from solution, either by converting it to H_2S, which is lost to the atmosphere, or by forming insoluble iron sulfides (Reactions 6 and 7).

$$2CH_3CHOHCOO^-_{(aq)} + SO^{2-}_{4(aq)} \rightarrow 2CH_3COO^-_{(aq)} + 2HCO^-_{3(aq)} + H_2S_{(g)} \tag{6}$$

$$H_2S_{(s)} + Fe^{2+}_{(aq)} \rightarrow FeS_{(s)} + 2H^+_{(aq)} \tag{7}$$

Bicarbonate is formed as a by-product of sulfate reduction and functions to buffer acidity. These systems have also shown limited success in the field. The sulfate removal rates are usually low (<10%), and pH often remains unchanged or decreases within the wetland.[23]

Rivers and Lakes: Acidification

Agniezka Gałuszka
and Zdzistaw M.
Migaszewski

Introduction

Acidification of rivers and lakes was one of the major environmental issues in the second half of the 20th century. As a consequence of the release of large amounts of acidifying gases (SO_2 and NO_x) to the atmosphere, mostly from coal burning and vehicle exhausts, the pH of precipitation dropped below 5.6. Acid deposition was responsible for lowering of the pH of surface waters and soils, and in many regions of the world, it resulted in forest decline and fish kills.

This entry presents the problem of acidification of rivers and lakes caused by natural and anthropogenic factors that contribute to decrease in the pH of freshwaters. In the first section, a definition of acidification and characteristics of processes causing acidification are provided with a brief description of the metrics used for acidification measurements. Historical perspectives of the problem are also briefly described. In a subsequent section, natural and anthropogenic acidification of rivers and lakes is discussed in more detail. The final part of the entry summarizes the consequences of freshwater acidification and the attempts made to solve this issue.

What Is Acidification, and How Is It Measured?

The most frequently used parameter that characterizes the acidity or alkalinity of natural waters is the pH. It is defined as a negative logarithm of hydrogen (hydronium) ion activity. Typical pH values in lakes and rivers are in the 6–9 range. The term “acidification” is usually used for freshwater with a pH of about 5.0 (and alkalinity below 0).[1] Some authors suggest that the pH threshold for acidified water should be 5.65 because this value characterizes pure water in equilibrium with atmospheric CO_2.[2] Two types of acidification of lakes and rivers can be distinguished: 1) chronic or long term in case acidifying factor is permanent (on a decade– century timescale), for example, related to bedrock or soil characteristics; and 2) episodic or short term (on an hour– day timescale), when acidifying factor is temporal, for example, acidic metal-rich effluent, snowmelt runoff, heavy rainfalls etc.

Acidification of surface waters begins when the concentration of hydrogen ions exceeds base ions present in water. The bases are produced during hydrolysis of carbonate minerals (mostly calcite) that occur in rocks and soils. The difference between the sum of the cations of strong bases and the sum of the anions of strong acids is termed acid-neutralizing capacity (ANC). This parameter is widely used in modeling of freshwater acidification and in assessment of freshwater sensitivity to acidification (critical load concept). Its components include both strong (OH^-) and weak bases (e.g., carbonate species, aluminohydroxides, organic acids). Alkalinity expresses the ability of water to neutralize acids. It is often understood as a synonym of ANC only measured in filtered water samples, whereas ANC is measured in unfiltered samples.[3] The buffering capacity of natural waters is mostly governed by a bicarbonate buffering system. Gaseous CO_2, which is a product of weathering of carbonate rocks or decay of organic remains, dissolves in water and produces carbonic acid, which subsequently dissociates to form H^+, HCO_3^-, and CO_3^{2-} ions. These reactions remain in equilibrium:

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow HCO_3^- + H^+ \leftrightarrow CO_3^{2-} + 2H^+$$

Bicarbonate and carbonate ions are capable of removing H^+ from water, causing the reactions to shift to the left. The bicarbonate buffering system results in a relatively constant pH and is mainly responsible for the alkalinity of natural waters. Thus, the influence of acidifying compounds on freshwater pH is more complex and it depends on ANC of the catchment area. The concept of "critical load" was introduced to find catchments that are the most vulnerable to acidification. Critical loads, defined as "an ecological threshold or intolerance to the accumulation of a pollutant in an ecosystem,"[4] can be estimated precisely on the basis of deposition rates of acidifying compounds and freshwater chemistry (empirical approach). The critical loads for lakes is a pH of 6.0 and an ANC of 0.02 meq/L.[5] Waters that have low alkalinity values (in the range of 0–10 mg/L $CaCO_3$) are highly sensitive to acidification.[6]

Alternatively, information about local geologic makeup, soil, and the land use of a study area may be employed to assess the sensitivity of freshwater to acidification.[7] The response of diatom assemblages to acid deposition and calcium levels in waters can also be used to calculate critical loads.[8] The difference between deposition of acidifying compounds and critical load values is termed the exceedance of critical load, and its values are crucial in assessment of potential acidification of freshwaters in a given area.

Paleoenvironmental data and fly-ash particle analysis in dated sediment cores are applied to the study of the history of surface water acidification and allow one to address the question regarding the origin of acidification (anthropogenic or natural). Paleolimnological pH reconstruction is based on the assumption that diatom and chrysophyte microfossils in dated sediment core intervals reflect the pH of water at a time when these organisms thrived in it. Based on the diatom techniques, it is possible 1) to evaluate models of acidification; 2) to determine critical loads of acidity; 3) to study the extent of episodic acidification; and 4) eventually to monitor lakes and rivers that are recovering from acidification.[9] The results of paleolimnological studies have indicated that the pH of some lakes located in northern Europe, eastern Canada, and northeastern United States have dropped by 0.5–1.5 from the early 1800s to recent times.[10]

Historical Perspectives

Acid deposition has been studied since the onset of the industrial revolution when Robert Smith, a creator of the term "acid rain", published the first results of his study on the rainwater chemistry in Manchester, U.K.[10] Surprisingly, it took more than 100 years to recognize the influence of acid deposition on freshwater acidification.[11,12] Although the first studies on acid deposition were carried out in Europe, the impact of precipitation chemistry on freshwater ecosystems was originally identified in North America in the late fifties by Gorham.[11] In 1968, Svante Odén showed the relationship between sulfur emissions in continental Europe and sulfate deposition affecting acidification of lakes in Scandinavia.[12]

Fleisher and others[13] have distinguished three periods of research regarding acidification of the environment: 1) an inventory period (during the 1960s and 1970s); 2) a period of mechanism studies (late 1970s and 1980s); and 3) a synthesizing period (1990s). This sequence of scientific interests has been supplemented by Herrmann[14] who suggested that a consequence of detailed knowledge on this issue should trigger a period of implementation.

Lake and river acidification became one of the major environmental issues in the 1970s and 1980s, when most of the reports from regional monitoring surveys were published. Freshwater acidification was most intensively studied in Europe (the U.K. and Scandinavian countries including Norway, Sweden, and Finland) and North America (Canada and United States).

During the 1980s, the concept of critical load was applied to quantify ecosystem vulnerability to acidification. This approach was also widely used in an assessment of freshwater sensitivity to acidification, mostly in Europe, North America, and Asia.[6] Recent research activities are focused on the recovery of lakes and rivers from long term acidification in most susceptible to acidification areas throughout the world, with some constraints to their future.[15–17] Attention is also being given to the emerging acidification of freshwaters in developing countries that experience rapid industrialization (Asia, Africa, Latin America).[18,19]

Sources of Freshwater Acidification

Factors influencing freshwater acidification may be natural (Figure 1) or anthropogenic (Figure 2) in origin. The lowest pH values are recorded in inland waters influenced by natural sources of acidifying compounds, especially of geologic origin. However, it should be stressed that natural acidification is commonly overlapped or enhanced by anthropogenic influences. Hence, separating natural acidity from anthropogenic freshwater acidification due to their different effects on biota is reasonable.[20] An important difference between anthropogenic and natural acidification is that the former one is reversible, as shown by many studies conducted after decreasing SO_2 and NO_x emissions.[21]

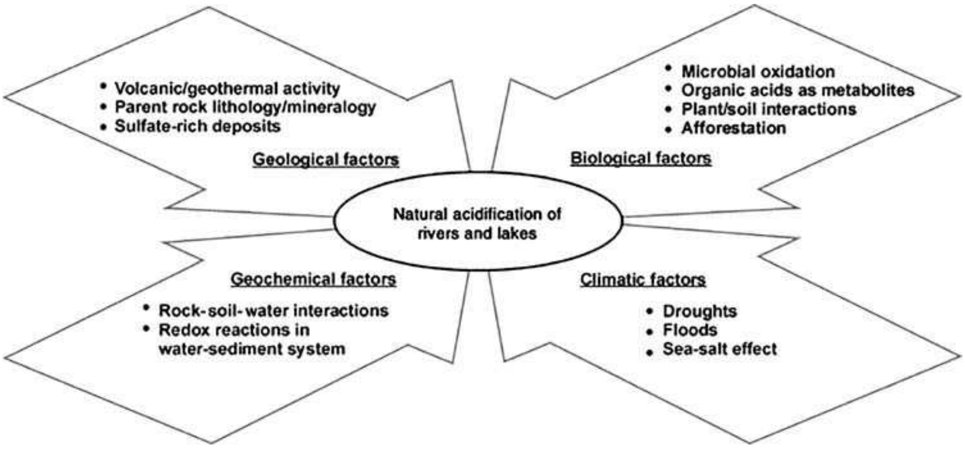

FIGURE 1 The most important natural factors influencing freshwater acidification.

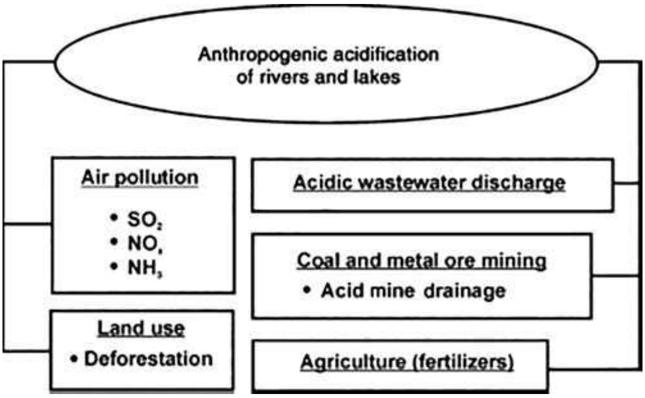

FIGURE 2 The most important anthropogenic factors influencing freshwater acidification.

Natural Sources of Freshwater Acidification

Geological Factors

Acidification of lakes and rivers as a consequence of natural processes in the environment is highly dependent on geologic factors, such as the presence of volcanic and geothermal activity and lithology/mineralogy of parent rocks. The volcanic/postvolcanic processes are responsible for formation of the world's mostly acidified surface waters; for example, the pH of caldera lake Kawah Ijen in western Java, Indonesia, is <0.3,[22] whereas the Banyupahit river, which originates from this lake, exhibits a pH in the range of about 0.7 to 3.3. Another example is the Kuril Islands (currently Russia) where many lakes and rivers are influenced by volcanic/postvolcanic activity. The main constituents of exhalations are sulfuric and hydrochloric acids. For example, the pH of Lake Usoriko (Japan) varies from 3.4 to 3.8.[23]

The extremely low pH values of inland waters are also caused by oxidation of pyrite and iron-bearing sulfide minerals (e.g., chalcopyrite, pyrrhotite, and marcasite). The mechanism of this process is natural and is known as "acid rock drainage" (ARD). It should be emphasized that ARD formation rate is usually accelerated by mining activities, and this process is called "acid mine drainage" (AMD), which will be further discussed in the next section. A series of reactions accompany the weathering of pyrite. Pyrite can undergo oxidation by two natural oxidants: 1) oxygen and 2) the even more effective ferric iron (Fe^{3+}), according to simplified reactions[24]:

$$FeS_2\left(\text{pyrite}\right) + 3.5O_2 + H_2O \rightarrow Fe^{2+} + 2SO_4^{2-} + 2H^+ \tag{1}$$

$$FeS_2 + 14Fe^{3+} + 8H_2O \rightarrow 15Fe^{2+} + 2SO_4^{2-} + 16H^+ \tag{2}$$

The first reaction is assisted by acidophilous bacterium species *Acidithiobacillus ferrooxidans*. In case of the second reaction, Fe^{3+} rapidly oxidizes pyrite in abiotic and anaerobic conditions. These two reactions (1 and 2) bring about a substantial drop in pH and an increase in concentrations of ferrous (Fe^{2+}) and sulfate ions in water. Subsequently, the Fe^{2+} undergoes oxidation and the dissolved Fe^{3+} supports the second reaction or may hydrolyze and ferric hydroxide precipitates according to the following simplified reactions:

$$Fe^{2+} + 1/4O_2 + H^+ \rightarrow Fe^{3+} + 1/2H_2O$$

$$Fe^{3+} + 3H_2O \rightarrow Fe\left(OH\right)_3 \downarrow 3H^+$$

This acidity has further been generated by complex processes of transformation of iron oxyhydroxysulfates and oxyhydroxides into goethite (α-FeOOH).

Although geologic processes lead to the formation of extremely low pH waters, their detrimental influence on the environment is usually restricted to relatively small areas. Besides, these factors occur in the environment for a long time, creating a unique ecological niche for acid tolerant organisms. Table 1 presents examples of surface inland waters acidified mostly by geological factors.

Geochemical Factors

Rock–Soil–Water Interactions The pH and concentrations of metals in surface waters are largely controlled by the chemistry and mineralogy of bedrock and soils. In areas where bedrock consists of igneous and metamorphic rocks (granites, gneisses, porphyries) or silicoclastic rocks, soils have a low buffering capacity, resulting in a naturally low pH of lakes and rivers. The slow weathering of rocks contributes particularly to increasing freshwater acidification. This process can be accelerated by construction activities or land melioration. The extent of exposure of mineralized rock formations to weathering at the surface, the amount of scattered sulfide minerals, and the presence or absence of buffering carbonate rocks or gangue minerals are decisive factors that affect the range of acidification of surface waters. Other geochemical factors having an influence on acidification are acidic metalliferous springs, whose waters have interacted with mineralized rock formations, and unmined mineral deposits.

Other soil properties can affect the pH of surface waters, mostly through ion-exchange reactions and their influence on water buffering capacity. Lakes and rivers located in areas with natural acidic soils are more susceptible to acidification.

Acid sulfate soils are soils abundant in pyrite and other sulfide minerals. These soils, formed under waterlogged conditions, when exposed to the air (e.g., by draining, excavation, cultivation), undergo chemical reactions that are responsible for sulfuric acid generation and subsequent acidification.

TABLE 1 Examples of Surface Inland Waters Acidified Mostly by Geological Factors

Name	Type	pH	Country	Reference
		Influence of volcanic/geothermal activity		
Kawah Ijen	Lake	<0.3	Indonesia	[22]
Banyupahit	River	0.7–3.3		
Usoriko	Lake	3.4–3.8	Japan	[23]

Lesnaya	River	4.8		
		Influence of bedrock lithology/mineralogy or acid rock drainage		
Woods Lake	Lake	4.4–5.9	United States (Adirondack Mts)	[30]
Lake Härkälampi	Lake	3.8–7.3	Finland	[31]
Langedalstjenn	Lake	4.4	Norway	[32]
Isiurqutuuq	Lake	4.5	Canada	[33]
Snake River	River	3.0	United States, Colorado	[34]
Rio Tinto	River	<3.0	Spain	[35]

Pyrite-rich soils that are not exposed to weathering pose no hazard to the environment and are called "potential acid sulfate soils" or cat-clays.

Most of the acid sulfate soils formed during the last 10,000 years following the postglacial sea level rise and the eustatic uplift of landmass. The acid sulfate soils occur mostly in lowland coastal regions (Australia, southeastern Asia, Finland), but they may also be associated with other environmental compartments favoring pyrite formation and oxidation, such as freshwater wetlands or, as mentioned above, areas with sulfide-scattered rock formations. It is estimated that acidic sulfate soils encompass an area of about 20 million ha globally.[36] The impact of acidic sulfate soils on freshwaters is highlighted by leaching of oxidation products into streams and lakes. The increased acidity of both soils and waters intensifies the mobility of many elements creating potentially toxic environments for living organisms.

Although acidic sulfate soils influence surface water acidification, there are also other soil types that may contribute to this process. Red soils developed on silicate rocks in Okinawa Island, Japan,[37] are one example. Their pH is low (4.5–5.5) and surface waters in the red-soil-dominated areas exhibit a pH within the range of 4.9–5.8.

Redox Reactions in Water–Sediment Systems

Freshwater pH can be changed by redox processes in sediments. During oxidation reactions, H^+ ions are produced, which decreases the pH of water. Nitrogen and sulfur (as inorganic and organic species) and iron are the most important elements in sediment/water redox processes. The changes in their oxidation state are usually microbially mediated. The effective acid production capacity (APC_{eff}) is a measure of acidification caused by oxidation reactions in sediment suspension. It is defined as

$$APC_{eff} = V/W.\left(\left[H^+\right]_e - \left[H^+\right]_O\right)$$

where V is the suspension volume, W is the solid mass, and $[H^+]_{e,o}$ is the H^+ concentration before and after oxidation.[38] The oxidation reactions that are responsible for acid generation in aquatic systems include 1) oxidation of sulfur from hydrogen sulfide, atomic sulfur, metal sulfides, and organic compounds (R-SH); 2) oxidation of pyrite (FeS_2) and Fe^{2+} ions; and 3) oxidation of N from NH_4^+, NO^-_2 (nitrification), and organic species (R-NH_2) (ammonification).

Several important buffer reactions occur in sediments, which can consume excess hydrogen ions and contribute to an increased ANC. These reactions involve $CaCO_3$, Al_2O_3, and Fe_2O_3:

$$CaCO_3 + 2H^+ \rightarrow Ca^{2+} + H_2O + CO_2 \tag{5}$$

$$Al_2O_3 + 6H^+ \rightarrow 2Al^{3+} + 3H_2O \tag{6}$$

$$Fe_2O_3 + 6H^+ \rightarrow 2Fe^{3+} + 3H_2O \tag{7}$$

Table 2 presents examples of surface inland waters acidified mostly by geochemical factors.

Biological Factors

Metabolic processes of living organisms also can contribute to the lowering of surface water pH. This drop in the pH values may be caused by numerous oxidation reactions that are mediated by microorganisms and produce H^+ as described in the previous sections.

As suggested by Rosenqvist as early as 1978,[44] expansion of coniferous forests brought about a decrease in the pH of surface waters in Norway. Afforestation of acid sensitive areas may result in freshwater acidification due to the following factors: 1) increased evapotranspiration; 2) intensive uptake of

TABLE 2 Examples of Surface Inland Waters Acidified Mostly by Geochemical Factors

Name	Type	pH	Country	Reference
Cudgen Lake	Lake	2.5	Australia	[39]

cations during the tree-stand growth; 3) increased filtering of gases and aerosols in the canopy and a subsequent increase of dry deposition; and 4) influx of organic acids from litter fall decay.[45] Acidifying effects of afforestation depends on the tree-stand maturity. After reaching a state of equilibrium between the standing and dead biomass, the forest-induced acidity decreases due to the lower uptake of cations from the soil by mature trees.[46]

Organic acids produced by living organisms are also responsible for acidification of freshwater. It has been estimated that organic acids may change the pH of lake waters having ANC values within the range of 0–50 μeq/L by 0.5–2.5 pH units.[47] On the other hand, organic acids prevent surface waters from further acidification due to their role as buffering substances for acids originating from acid deposition. Dissociation of humic and fulvic acids increases H^+ concentrations in waters leading to their pH decrease. The typical pH of lakes affected by organic acids generated by *Sphagnum* mosses is 3.3–4.5.[1] Table 3 presents examples of surface inland waters acidified mostly by biological factors.

Climatic Factors

The influence of climatic factors on freshwater acidification is mostly related to precipitation and temperature variations. Several processes are involved with acidification brought about by seasonal climatic changes. Water table lowering during long drought periods accelerates oxidation reactions and accompanying production of H^+ ions, especially in wetlands.[55] Water table rising during floods causes intensive water flow through surface soil horizons, which are usually more acidic as a result of higher organic acid concentrations and higher susceptibility to anthropogenic acidification in relation to underlying horizons. During winter, the ice-covered lake waters accumulate CO2 originating from respiration, organic decay, and rock weathering. Due to this process, the pH of waters in epilimnion

TABLE 3 Examples of Surface Inland Waters Acidified Mostly by Biological Factors

Name	Type	pH	Country	Reference
Valkea-Kotinen	Lake	5.0–5.4	Finland	[48]

Liepsalas	Lake	4.1–4.3		
Murmasts	Lake	3.7–3.9	Latvia	[54]
Pieslaistes	Lake	4.0–4.2		

is decreased. Precipitation waters are ionically deficient and have a very low ANC. Therefore, their discharges to surface waters during spring snowmelt floods or heavy storms bring about an episodic decrease in the pH of surface waters.

Occasional acidification of lakes and rivers in coastal areas is caused by deposition of marine aerosol salts during high wind periods, changing cation-exchange equilibria in soil. Cations present in seawater (Na^+ and Mg^{2+}) undergo cation-exchange reactions with hydrogen and aluminum ions, which are released from soil to water. This phenomenon is termed "sea-salt effect."[45]

Winds that carry $CaCO_3$-rich. dusts may increase ANC and pH of surface waters by mitigating the effect of freshwater acidification, as was reported for the influx of Saharan dust to southern Alps.[56] Table 4 presents examples of surface inland waters acidified mostly by climatic factors.

Anthropogenic Acidification of Rivers and Lakes

Air Pollution with Acidifying Compounds

Serious attention to the problem of freshwater acidification was given when it became clear that there was an influence of air pollutants on the formation of acid precipitation and subsequent changes in the pH of surface waters and soils. Atmospheric deposition of acidifying compounds from anthropogenic sources has greatly contributed to the river and lake acidification. Sulfur dioxide and nitrogen oxides undergo chemical transformations in the air, producing sulfuric and nitric acids, which are then deposited on the land surface, lowering the pH of surface waters. Oxidation of SO_2 may undergo gas-phase or aqueous-phase reactions, and the sulfuric acid produced may occur as liquid aerosols, or it may dissolve in clouds or rainwater. It is noteworthy that only a small fraction of acid precipitation is deposited directly in rivers and lakes; freshwaters are mostly impacted by surface runoff.

Most of the studies on the influence of acid deposition on acidification of soils and waters have been focused on SO_2 emissions derived from fossil fuel combustion and smelting of sulfide minerals, as well as on NO_x released from fossil fuel combustion and vehicle exhausts.[67] Before reduction of SO_2 emissions, acid precipitation was mostly attributed to sulfuric acid. Since the 1990s, nitrogen compounds have been regarded as a major contributor to lowering of the precipitation pH.[68] Hydrochloric acid also causes a decrease in the precipitation pH, although to a much lesser extent than sulfur and nitrogen oxides. Anthropogenic emissions of NH_3, derived mostly from livestock farming and agriculture, neutralize acids that occur in the atmosphere. However, after deposition, $NH4^+$ ions affect freshwater pH through nitrification reactions that produce H^+ ions and via uptake of NH_4^+ ions, which in turn

TABLE 4 Examples of Surface Inland Waters Acidified Mostly by Climatic Factors

Name	Type	pH	Country	Reference
		Induced by drought or flood		
Swan Lake	Lake	4.5	Canada	[57]
White pine Lake	Lake	4.1– 5.7	Canada	[58]
Hermanninlampi	Lake	4.0	Finland	[59]

Espedal	River	4.6	Norway	[65]
Allt a'Mharcaidh	Stream	<5.5	U.K.	[66]

release H^+ to soil solution. The acidification caused by strong acids contained in precipitation occurs immediately, whereas the acidification brought about by NH_3/NH_4^+ deposition is delayed in time. It is interesting to note that the acidification of ecosystems from NH_3 emissions may be equal to that from SO_2 emissions or even greater than that from NO_x emissions.[69]

Acid Mine Drainage

Acidification of freshwaters can be triggered by weathering of pyrite and other iron-bearing sulfide minerals in metal and coal mining areas. This process is termed acid mine drainage (AMD). Mine waste piles, mineral ponds, underground mines, and lignite open pits can potentially form acidic and/or metal-rich effluents that can enter local streams and rivers, which in turn may eventually reach various inland water bodies. The mechanism of acid formation resulting from pyrite oxidation was previously described in the subsection "Geological Factors."

AMD was responsible for serious environmental disasters in many areas throughout the world where metal ores or coals were mined.[70] The acid mine waters lead to lowering of the pH combined with the increase of sulfates and toxic element levels in surface water and groundwater. The most acidified waters in the world, originating from abandoned metal ore mines, were found in the Iron Mountain mining area in Shasta County, northern California.[71] In this area, several mines extracted pyrite (for sulfuric acid production) and Ag, Au, Cu, Fe, and Zn sulfide ores from the 1860s to 1962. The abandoned mines contain approximately 600,000 m^3 of strongly acidic water having a pH of about 1 and concentrations of Zn, Cu, and Cd in the range of several grams per liter. Prior to remediation, extremely high loads of dissolved Cd, Cu, and Zn (about 300 tons/yr) were discharged to the Sacramento River. Several massive fish kills were recorded as a consequence of high runoff episodes. Subsequent to the closure of the mines, more than 20 such events have occurred, with the most severe one in 1967, when at least 47,000 trout were killed during a single week.[72] Table 5 presents examples of surface inland waters acidified mostly by anthropogenic factors.

Other Sources

Aside from the natural and anthropogenic factors that were described in the previous subsections, there are also numerous sources of surface water acidification that are manifested by small-scale pH variations or are related to very specific cases.

Acidic wastewaters are also generated by metal processing industries, electroplating, oil refineries, and other chemical industries. Some wastewaters are not acidic, but eventually will become so after they undergo microbially mediated transformations (e.g., brewery wastewaters rich in organic carbon). The knowledge of wastewater properties enables us to control and avoid their detrimental influence on the environment with the help of the proper treatment technology.

Land use is sometimes responsible for acidification of surface waters. One of the examples is deforestation, which causes increased sensitivity of lakes and streams to acidification due to the removal of

cations with harvested biomass and intensification of nitrification of soils.[2] The increased acidity of lakes and rivers may also occur in agricultural lands, where acidification may come from fertilizers.

There are some additional natural factors contributing to surface water acidification, which need mentioning. Acidification of lakes depends on the watershed location because headwater lakes are more susceptible to acidification than downstream ones. Lakes located in the headwaters have a lower ANC.[82] Large amounts of sulfur dioxide released during natural fires in exposed lignite beds in Smoking Hills (Canada) caused acidification from deposition of sulfuric acid that was produced in the atmosphere.[83]

Environmental Problems Caused by Acidification of Lakes and Rivers

Inland water acidification has serious consequences for living organisms and ecosystem functioning. The direct influence of low pH on aquatic biota includes 1) the loss of species, especially fish (below pH 4.5), zooplankton, phytoplankton, benthic invertebrates, and periphyton; and 2) decreased or inhibited reproduction of fish and amphibians.[84]

Biological response to acidification may be rapid (a short-term effect) or delayed in time (a long-term effect).[85] Rapid response is caused by episodic events that result in a sudden decrease in the water pH, such as spring floods, heavy storms, or discharge of acidic wastewaters. The long-term effects on aquatic biota are highlighted mostly by changes in the ecosystem structure, with some reductions in species diversity and disappearance of acidsensitive species and dominance of acid-tolerant ones. The reduced biodiversity of freshwater systems in turn has an influence on the balance in biogeochemical cycles[86] and causes adverse changes in food chains. Acidification of lakes and rivers affects geochemical processes, including 1) higher mobility of most metals (e.g., Al, Pb, Zn, Mg, Cd); 2) increased methylmercury production; and 3) decreased phosphorus availability.

Aluminum mobilization from soil minerals to waters is responsible for increased fish mortality. The lethal aluminum toxicity to aquatic animals is most often recorded when acidic water mixes with alkaline water and $Al(OH)_3$ precipitates on the gills and filtering apparatus.[87] Some authors regard the release of free aluminum ions, which represent a bioavailable form for aquatic biota, as the most detrimental effect of freshwater acidification.[2]

Although methylmercury production is reduced at a low pH, synthesis of dimethylmercury by base-catalyzed disproportionation contributes to conversion of dimethyl mercury to monomethyl mercury by acid hydrolysis:

$$(CH_3)_2\,Hg + H^+ \rightarrow CH_3Hg^+ + CH_4 \uparrow \tag{8}$$

As a consequence of this reaction, an easily available and very toxic form of mercury is released to acidified surface waters.[86]

Bioavailability of phosphorus in acidified surface waters is diminished, as this element is adsorbed on aluminum oxides and hydroxides and may be irreversibly retained in sediments.[88] Acidic freshwaters decrease bioavailability of essential elements, such as calcium and magnesium.[89]

The response of aquatic biota to natural and anthropogenic acidification is believed to be different.[90] The mechanism of this difference is not well understood and can be explained by biogeographical histories of the region or the long-term evolutional adaptation to natural acidification sources.[90,91]

Solutions to the Problem of Freshwater Acidification

The problem of freshwater acidification has stimulated actions to minimize its consequences, mostly through legislation and various international initiatives that allowed reduction of the levels of acidifying air pollutants. An important tool for rehabilitation of acidified waters has been offered by technology.

Every effort undertaken to reduce the risk of freshwater acidification, apart from its character, has been driven by progress in scientific research as well as by international cooperation.

Environmental Legislation

Environmental legislation, both on national and international scales, has led to substantial reduction of SO_2 and NO_x emissions in Europe and North America in recent decades and has ameliorated the effect of acid precipitation on acidification of rivers and lakes. One of the most important documents concerning the control of acidifying compounds is The Convention on Long-Range Transboundary Air Pollution (LRTAP) under the auspices of the United Nations Economic Commission for Europe.[92] This Convention has been extended by four Protocols that control emission of acidifying compounds: 1) the 1999 Protocol to Abate Acidification, Eutrophication, and Ground-Level Ozone, supplemented with the revised guidance document on ammonia; 2) the 1994 Protocol on Further Reduction of Sulphur Emissions; 3) the 1988 Protocol Pertaining to the Control of Nitrogen Oxides or Their Transboundary Fluxes; and 4) the 1985 Protocol on the Reduction of Sulphur Emissions or their Transboundary Fluxes by at least 30%. One of the initiatives directly regarding acidification of lakes and rivers is The International Cooperative Programme on Assessment and Monitoring of Acidification of Rivers and Lakes (ICP Waters), which is the action of The Working Group on Effects within LRTAP Convention. The ICP Waters initiative collects data that are essential for monitoring the effects of acid precipitation on surface waters from 18 European countries, United States, and Canada.

For European Union member states, the emission standards of SO_2 and NO_x from specific sources are regulated by adequate directives, for example, emission limit values for new plants and industrial facilities from the Large Combustion Plant Directive (88/609/EEC) or the Directives 98/70/EC and 1999/32/EC that establish the limits on the sulfur content of gas oil for stationary and mobile sources and for heavy fuel oil.[93] In Europe, present emissions of SO_2 are less than half of the 1980s levels and emissions of NOx have been reduced by about 20%.[21]

In the United States, reductions in SO_2 and NO_x emission are regulated by the Amendment to the Clean Air Act, Title IV: Acid Deposition Control, also known as the Acid Rain Program, which was implemented in 1990. This document imposed reductions in SO_2 and NO_x emissions from fossil fuel power plants. The emissions of SO_2 from power generating plants in the United States were reduced from 17.3 million tons in 1980 to 11.2 million tons in 2000 and those of NO_x from 6.0 to 5.1 million tons, respectively.[94]

Technology

Both environmental technology and engineering help to reduce the emissions of acidifying gases from industrial sources and facilitate the proper management of acidified freshwaters. The practice, which is most commonly used for rehabilitation of acidified lakes and rivers, is liming. Its purpose is to restore the water to its preacidification state, which is often reconstructed with paleolimnological techniques. Limestone powder can be dispersed on the whole surface of the lake or, alternatively, can be dosed onto the ice cover. It is suggested that liming of lakes and inlet streams should be done with terrestrial liming, which ameliorates the effect of reacidification of the littoral zone during the ice cover and the snowmelt events.[95] Liming was extensively applied in Scandinavian countries; for example, in Sweden, it was used for about 8000 lakes and 12,000 km of surface waters to achieve the following restoration goals: $pH>6$ and $ANC>100$ meq/L.[96] Although liming is very popular, there are some limitations in its application; for example, Wällstedt and Borg,[97] in their study on remobilization of metals from limed and nonlimed lake sediments, have shown that there is a risk of potential toxicity of Al, Cd, Mn, and Zn in lakes that have been limed. Moreover, some toxic anionic metalloids (especially arsenic), which are more mobile at a higher pH, may be released from the sediment to the water column in case of alkalization by lime.

The Swedish Forest Agency has recommended that wood ash (received from timber waste combusted for energy production) should be used to mitigate acidification and to supplement nutrient removal.[98] In this method, the wood ash is added to the soil cover. Treatment of acidified waters is also possible with the use of ecotechnologies, such as constructed wetlands or controlled eutrophication.[99] The employment of these methods has many advantages. They are cost-effective, they are based on natural processes, and they can be applied to reduce acidification originating from non-point pollution sources (e.g., AMD).

Conclusion

Lake and river acidification has been probably one of the most often discussed environmental issues in recent decades. Although natural acidic freshwaters occur throughout the world, the human-induced changes in water pH have aroused international concern, especially in countries where anthropogenic emissions of SO_2, NO_2, and NH_3 caused a substantial decrease in the freshwater pH due to their low ANC (Scandinavian countries, eastern Canada, northeastern United States). Acidic lakes and rivers have jeopardized aquatic biota, not only due to the low acid tolerance of living organisms but also because of the geochemical changes that have led to increased geo and bioavailability of toxic metals (Al, Zn, Mn, Pb, Hg, Cd) and reduction in the amount of bioavailable essential elements (Ca, Mg, P). The long-term international interest in the problem of acidification resulted in better understanding of the acidification processes and mechanisms and in well-established knowledge of the methods of monitoring and remediation and proper management of acidified rivers and lakes. As a result of international efforts in the abatement of SO_2 and NO_x emissions from industrial sources, many lakes and streams have already recovered from anthropogenic acidification. Both environmental legislation and technology have contributed to substantial improvement of the quality of surface inland waters. The lessons learned from almost 50 years of studies on acidification and its mitigation have shown that environmental pollution is a global problem, which can only be solved with cooperation of governments, scientists, and societies. Whether these lessons will protect us from similar problems in the future is an open question. Many authors claim that acidification will soon develop in rapidly developing countries of Asia, Africa, and Latin America. The experience gained from remediation of acidified lakes and rivers in the northern hemisphere may thus become invaluable for the global sustainable future.

Rivers: Pollution

Bogdan Skwarzec

Introduction

More than 97% of all water on Earth is salty, and most of the remaining 3% is frozen in the polar ice caps. The atmosphere, rivers, lakes, and underground stores hold less than 1% of all freshwater and this tiny amount has to provide the freshwater needed to support the earth's population. Most of the water for human consumption originates from riverine system. The quantity of this water is very important for human life because the concentration of chemical and biological pollutants in many rivers is high.[1,2] The big rivers of Asia are the most polluted rivers in the world. They contain three times as many bacteria from human waste as the global average and 20 times more lead than rivers in industrialized countries. Water from half of the tested sections of China's and Indian's seven major rivers was found to be undrinkable because of pollution.[3–7] Almost 40% of America's rivers are too polluted for fishing, swimming, or aquatic life. The Mississippi River—which drains nearly 40% of the continental United States, including its central farmlands—carries an estimated 1.5 million metric tons of nitrogen pollution into the Gulf of Mexico each year. The resulting hypoxic coastal dead zone in the Gulf each summer is about the size of Massachusetts.[8–12] Also, other major rivers in the world (Amazon, Niger, big Russian rivers, and Australian rivers) are polluted by trace elements and heavy metals.[13–18] The King River is Australia's most polluted river, suffering from a severe acidic condition related to mining operations.[19,20] In European Union countries, rivers are polluted with sewage or fertilizer. The Sarno is the most polluted river in Europe, featuring a nasty mix of sewage, untreated agricultural waste, industrial waste, and chemicals.[21]

Apart from anthropogenic pollutants, continental material from land is also transported to the marine ecosystem through rivers. The total flux of dissolved and suspended matter transported by rivers is estimated to be 20×10^{15} g yr^{-1}, i.e., 15.5×10^{15} and 4.5×10^{15} g yr^{-1} for solid and dissolved loads, respectively.[1] The total load of pollutants in the river ecosystems varies among several regions and depends on the population density, location of industry centers, and the abundance as well as intensity of the exploitation of natural resources. The anthropogenic sources of riverine pollutants are mainly industrial wastewater, leakage from products in use and those removed from service, natural degradation of pro-products, as well as pollution from different types of land use, e.g., fertilizing and mining.[22] Most freshwater pollution is caused by the addition of organic material, which is mainly sewage but can be food waste or farm effluent. Bacteria, viruses, or parasites cause diseases such as cholera, typhoid, schistosomiasis, dysentery, and other diarrheal diseases. Moreover, other microorganisms feed on organic matter and large populations quickly develop, using up much of the oxygen dissolved in the water.[23–27]

Normally, oxygen is present in high quantities, but even a small drop in the level can have a harmful effect on the river animals. Animals can be listed according to their ability to tolerate low levels of oxygen. In the following species of animals are listed in the order of the least tolerant to the most tolerant to low oxygen levels: stone-fly nymphs, mayfly nymphs, freshwater shrimps, freshwater hog lice, blood worms, tubifex worms, and rat-tailed maggots.[23]

Sources of River Pollution

The general important sources of water pollution that work together to reduce the overall river water quality are acid rain and industrial and agricultural discharge liquid waste products. Rain, as it falls through the air or drains from urban areas and farmland, absorbs contaminants. Serious incidents resulting from spillages or discharges of toxic chemicals are pollution events that make the news.[1]

Acid Rain

Rain, when falling through polluted air, absorbs some pollutants. The main pollutant gases are sulfur dioxide (SO_2) and nitrogen oxides (N_xO_y), which are formed when fuels are burned. They react with rainwater to form sulfuric and nitric acids. On reaching the ground, the acid liquid produces a number of effects. It can release harmful substances such as aluminum and heavy metals from the soil. These substances are normally present in an inert, harmless state; however, in acid conditions, they can turn into compounds that are poisonous to plant and animal life. When washed into lakes and streams, aluminum can kill small water creatures and fish. Particularly at risk is the dipper, a river bird that actually walks underwater to catch its insect food. If acid rain kills the insects, then the dippers will disappear in turn.[28,29]

Industrial Pollution

Factories use water from rivers to power or cool down machinery. Dirty water containing chemicals flows back in the river. Water used for cooling is warmer than the river itself. Raising the temperature of the water lowers the level of dissolved oxygen and upsets the balance of life in the water. Many industrial wastes discharged into river water are mixtures of chemicals that are difficult to treat. Some industrial wastes are so toxic that they are strictly controlled, making them an expensive problem to deal with. Some companies try to cut the costs of safely dealing with waste by illegally dumping chemicals at times and in places where they think they will not be caught.[30–32] Chemical waste products from industrial processes are sometimes accidentally discharged into rivers. Examples of such pollutants include cyanide and toxic heavy metals (zinc, lead, copper, cadmium, and mercury) as well as oil. These substances may enter the water in such high concentrations that fish and other animals are killed immediately. Sometimes, the pollutants enter a food chain and accumulate until they reach toxic levels, eventually killing birds, fish, and mammals.[1,33,34]

Agricultural Pollution

Farmers use fertilizers and pesticides to enhance crop growth. However, these fertilizers and pesticides can be washed through the soil by rain, to end up in rivers. If large amounts of fertilizers or farm waste drain into a river, the concentration of nitrate and phosphate in the water increases considerably.[35] Algae use these substances to grow and multiply rapidly, turning the water green. This massive growth of algae, called eutrophication, leads to pollution. When the algae die, they are broken down by the action of bacteria, which quickly multiply, using up all the oxygen in the water, leading to the death of many animals. Also, when organic farm wastes such as silage or liquid manure (slurry) escape into rivers, the amount of oxygen in the water is reduced.[36,37] Nitrate pollution problems occur when too much chemical fertilizer is applied to the land. The excess runs off and can find its way into drinking water sources, or can trickle into rivers and lakes. Some experts believe that high levels of nitrate in drinking water may pose a threat to health. A European directive states that drinking water should not contain more than 50 mg of nitrates per liter of water. In rivers, streams, ponds, and lakes, too much nitrate can create a “pea soup” effect. The water becomes clogged with fast-growing plant life such as algae and weeds.[36–39]

Radionuclides

Radionuclides and radioactive waste are stored in riverine water ponds next to nuclear power stations. Nuclear atmospheric weapons tests and the Chernobyl accident were sources of many artificial radionuclides in oceans.[40–44] The river runoff of radioactive substances is an important source of marine radionuclide pollution, especially for closed seas, estuaries, and coastal zones. For example, the annual runoff of radiocesium, radiostrontium, polonium, uranium, and plutonium is an important source of radionuclides in southern Baltic Sea. The total runoff of these radionuclides from rivers to the southern Baltic Sea was calculated to consist of about 3.3 TBq of ^{90}Sr, 5.2 TBq of ^{137}Cs, 0.7 TBq of ^{210}Po, 4.5 TBq of $^{234+238}$U, and 1.3 GBq of $^{239+240}$Pu.[45]

Removal of Pollutants in River Waters

Many types of pollution are discharged into rivers, and purification processes remove them at different speeds. Some heavy metals, for example, are removed relatively quickly because suspended clay and

organic particles have a slight electric charge and adsorb the metal atoms. When the clay or organic particles settle out of the water, they take the metal atoms with them. Unfortunately, some pollutants are very persistent in the water and can accumulate downstream, causing great hazard.[1] Suspended solids in a moving body of water will settle out at various points or be carried within longer distances, depending on their size and the rate of the flow. The higher the amount of suspended solids is, the cloudier or more turbid the water becomes. Suspended matter can affect the amount of light entering the water, thus restricting the amount of photosynthesis that can occur, which consequently can limit the growth of plants. Small particles settling out in large amounts on the bottom of a water body can prevent some organisms from living there as well as prevent green plants from photosynthesizing.[19,21]

Conclusions

Rivers are contaminated by many natural and anthropogenic industrial pollutants. A lot of these pollutants are highly toxic to river organisms and to humans. The most important toxic chemicals in the seas are organic compounds (PCBs, DDT, PAHs, pesticides, furans, dioxins, phenol, oil), heavy metals, and radionuclides. Chemical and biological pollutants flow from big areas of river catchments to the seas and oceans. This runoff of toxic substances through river water is very dangerous, especially for coastal and estuarine zones and closed small seas. Figure 1 presents 10 of the most polluted areas and bodies of water in the world.[46]

Sea: Pollution

Bogdan Skwarzec

Introduction

Pollution is the release of harmful environmental contaminants, or the substances so released. Generally, the process needs to result from human activity to be regarded as pollution. Even relatively benign products of human activity are liable to be regarded as pollution, if they precipitate negative effects later on. The different forms of pollution are as follows: air pollution, water pollution, soil contamination, radioactive contamination, noise pollution, light pollution, and thermal pollution. Chemical pollutants can be natural substances (organic and mineral matter), or synthetic degradable or non-degradable substances (plastics, pesticides). They can be toxic or not with varying endurance. For example, in humans, polychlorinated biphenyls (PCBs) play a part in causing breast, lung, liver, and colon cancers. It can cause retardations in neurological development and growth. Persistent organic pollutants, drugs and their metabolites, and brominated organic compounds are concentrated in soft tissue of marine organisms and other filters, and they can develop typhoid, hepatitis, and other illnesses if they are ingested.[1–3]

Marine pollution occurs when harmful effects, or potentially harmful effects, can result from the entry into the ocean system of chemical, industrial, agricultural, and residential wastes, as well as invasive organisms. Marine pollution is, in the majority of cases, of land and atmospheric origin. Catastrophic accidents (shipping, platform) are also an important factor of marine pollution. Generally, sea pollutants are classified as having chemical and biological origin; however, toxic chemical substances are dominant. The most important chemical substances belong to the next group: trace and heavy toxic metals, metalo-organic compounds (tributyltin, TBT), nutrients, acid gases, radionuclides (especially artificial), radioactive waste, military toxic substances, and organic toxic substances (oil, pesticides, dioxins, furans, phenols, halogeno-organic compounds—especially DDT, PCBs, polychlorinated terphenyls [PCT], and their metabolites, as well as aromatic hydrocarbons polycyclic aromatic hydrocarbon, [PAHs]). Toxins can accumulate in the tissues of many species of aquatic life in a process called bioaccumulation.[1–3]

Many potentially toxic chemicals adhere to tiny particles that are taken up by marine organisms (plankton and benthos animals), most of which are either deposit or filter feeders (bivalvia). In this way, by bioconcentration of dissolved species, the toxins are concentrated upward within ocean food chains. When pesticides are incorporated into the marine ecosystem, they quickly become absorbed into marine food webs. Once in the food webs, these pesticides can cause mutations, as well as diseases, which can be harmful to humans as well as the entire food web. Toxic metals, metalloids, and radionuclides can also be introduced into marine food webs. These can cause a change to tissue matter, biochemistry, behavior, reproduction, and suppress growth in marine life. In addition, many animal feeds have a high fish meal or fish hydrolysate content. In this way, marine toxins can be transferred to land animals, and appear later in meat and dairy products. Pollution in marine environment is often classified as point source or non-point source pollution. Point source pollution occurs when there is a single, identifiable, and localized source of the pollution. An example is a direct discharge of sewage and industrial waste into the ocean. Pollution such as this occurs particularly in developing nations. Non-point source pollution occurs when the pollution comes from ill-defined and diffuse sources.[4,5]

Sources of Marine Pollution

There are many different ways to categorize and examine the inputs of pollution into our marine ecosystems. In principle, there are three main types of inputs of pollution into the ocean: direct discharge of waste into the oceans, runoff into the waters due to rain, and pollutants that are released from the atmosphere.[1,6]

Land and River Runoffs

Between 75% and 80% of marine pollution is caused by land, particularly agriculture, and 30% of this is from the atmosphere; however, around 12% of the pollution is caused by marine transport.[7] In South America, 98% of domestic wastewater ends up, untreated, in the sea. The countries along the Mediterranean Sea throw 50 million tons waste into it every year, and the Chinese throw 60 million tons of waste into the Yellow Sea daily.[8,9] Also, closed marine basins, such as the Baltic, Caspian, and Black Seas, are polluted every year with many million tons of chemical waste. Baltic fauna is practically decimated on half of the central Baltic's seabed as an effect of land-based pollution, especially nitrogenous.[1] In the Caspian Sea, 140 million tons of pollutants are poured every year in the northern part, especially that of the Volga delta. Also, the Black Sea is polluted by the Dniestr, Dniepr, Danube, and Don rivers. For eutrophication reason, 80% drop in fishing yield, only 6 species of fish can still be fished out of the 26 that could previously be commonly marked in this basin.[3] One important common path of entry by land and atmosphere contaminants to the sea are rivers.[9] The evaporation of water from oceans exceeds precipitation. The balance is restored by rain over the continents entering rivers and then being returned to the sea. Pollutants enter rivers and the sea directly from urban sewerage and industrial waste discharges, sometimes in the form of hazardous and toxic wastes (inorganic, radioactive, and organic). Most of the pollution is simply soil, which ends up in rivers flowing to the sea. More than 80% of all marine pollution comes from land-based activities, and many pollutants are deposited in estuarine and coastal waters. Here, the pollutants enter marine food chains, building up their concentrations until they reach toxic levels. It often takes human casualties to alert us to pollution and such was the case in Minamata Bay in Japan, when 649 people died from eating fish and shellfish contaminated with mercury and 3500 people had mercury poisoning. A factory was discharging waste containing mercury in low concentration into the sea and, as this pollutant passed through food chains, it became more concentrated in the tissues of marine organisms until it reached toxic levels.[10]

Surface water runoff contains pollutants from farming. Also, urban runoff and runoff from the construction of roads, buildings, ports, channels, and harbors can carry soil and particles laden with carbon, nitrogen, phosphorus, and minerals. This nutrient-rich water can lead to fleshy algae and phytoplankton thriving in coastal areas, known as algal blooms, which have the potential to create hypoxic conditions by using all available oxygen. Polluted runoff from roads and highways can be a significant source of water pollution in coastal areas.[11]

Oil and Ship Pollution

About 2.7 million tons of oil pollution enters our oceans each year. Of this, less than 10% is from natural seepage of oil from the ocean floor and sedimentary rock erosion. The remaining 90% comes from human activities. Offshore drilling, as a result of accident spills and other operations, accounts for only 2%. Spills from large tankers, which are reported worldwide, account for just over 5%.[3] Air pollution from cars and industry accounts for just over 13% of the total, as the hundreds of tons of hydrocarbons land in our oceans from particle fallout aided by rains, which washed the particles from air. Almost 4 times the amount of oil that comes from spills from large tankers spills, 19% is regularly released into the ocean from routine maintenance, which includes discharge as well as other ship operations. Oil is perhaps the most publicly recognized toxic pollutant. Tanker accidents between 1967 and 2007 spilled to the oceans nearly 4.5 million tons of oil. Now, from May 2010, the next million tons of oil has been delivered to the Gulf of Mexico, as a result of platform crash (BP accident). The biggest spill ever recorded took place during the 1979 drilling platform in the Gulf of Mexico as well as the 1991 Persian Gulf War, when about 2 million tons of oil was spilled. The effect of oil pollution on wildlife can be terrible. Many marine organisms (fishes, invertebrates, mammals, and birds) died.[3]

Ships can pollute waterways and oceans in many ways. Oil spills can have devastating effects. While being toxic to marine life, PAHs, the components in crude oil, are very difficult to clean up and last for years in the sediment and marine environment.[1,2] Discharge of cargo residues from bulk carriers can pollute ports, waterways, and oceans. In many instances, vessels intentionally discharge illegal waste despite foreign and domestic regulations prohibiting such actions. It has been estimated that container ships lose over 10,000 containers at sea each year (usually during storms). Ships also create noise pollution that disturbs natural wildlife, and water from ballast tanks can spread harmful algae and other invasive species. Also, ballast water taken up at sea and released in port is a major source of unwanted exotic marine life. The invasive marine species, native to the Black, Caspian, and Azov Seas, were transported to other basins (Baltic Sea, Great Lakes) via ballast water from a transoceanic vessel. Invasive species can take over once occupied areas, facilitate the spread of new diseases, introduce new genetic material, alter underwater seascapes, and jeopardize the ability of native species to obtain food.[12] Some strong toxic metalo-organic substances, especially TBT, are a source of marine pollution, as a result of commercial shipping.[13–16]

Atmospheric Pollution

Another important pathway of pollution occurs through the atmosphere.[17–21] Wind-blown dust and debris, including plastic bags, are blown seaward from landfills and other areas. Dust from the Sahara, moving around the southern periphery of the subtropical ridge, moves into the Caribbean and Florida during the warm season as the ridge builds and moves northward through the subtropical Atlantic. Dust can also be attributed to a global transport from the Gobi and Taklamakan deserts across Korea, Japan, and the Northern Pacific to the Hawaiian Islands.[22] Since 1970, dust outbreaks have worsened due to periods of drought in Africa. There is a large variability in dust transport to the Caribbean and Florida from year to year; however, the flux is greater during positive phases of the North Atlantic Oscillation.[23] Atmospheric particles containing chemical pollutants can be transported over thousands of kilometers, and airborne particles with heavy metals and radionuclides originating from anthropogenic sources can be detected even in remote areas.[24–26] The trace and heavy metals produced and emitted in Europe or North America are transported by air and deposited in the North Atlantic environment.[27,28] Also, organic toxic substances (especially pesticides) used in agriculture by farmers in warm regions (Africa and South Asia) are sublimated to air and transported to Arctic Ocean and accumulated in fish and mammals.[29]

Deep Sea Mining

Deep sea mining is a relatively new mineral retrieval process that takes place on the ocean floor; however, the complete consequences of full-scale mining operations are still unknown. Ocean mining sites are located usually around large areas of polymetallic nodules or active and extinct hydrothermal vents at about 1400–3700 m below the ocean's surface.[30] The vents create sulfide deposits, which contain precious metals such as silver, gold, copper, manganese, cobalt, and zinc.[31,32] The deposits are mined using either hydraulic pumps or bucket systems that take ore to the surface to be processed. As with all mining operations, deep sea mining raises questions about environmental damage to the surrounding areas. The removal of parts of the seafloor will result in disturbances to the benthic layer, increased toxicity of the water column, and sediment plumes from tailings. Removing parts of the seafloor disturbs the habitat of benthic organisms, possibly depending on the type of mining and location, causing permanent disturbances.[33] Among the deep sea mining products, sediment plumes could have the greatest impact. Plumes are caused when the tailings from mining (usually fine particles) are dumped back into the ocean, creating a cloud of particles floating in the water. Two types of plumes occur: near-bottom plumes and surface plumes.[30] Near-bottom plumes occur when the tailings are pumped back down to the mining site. The floating particles increase the turbidity, or cloudiness, of the water, clogging filter-feeding apparatuses used by benthic organisms. Surface plumes cause a more serious problem. Depending on the size of the particles and water currents, the plumes could spread over vast areas. The plumes could affect zooplankton and light penetration, in turn affecting the food web of the area.[30,34]

Acidification and Acid Rains

The ocean waters absorb carbon dioxide (CO_2), sulfur dioxide (SO_2) and trioxide (SO_3), and nitrogen oxides (N_xO_y) from the atmosphere. Because the atmospheric concentrations of these gaseous oxides are increasing, the oceans are becoming more acidic.[35] The potential consequences of ocean acidification are not fully understood; however, there are concerns that structures made of calcium carbonate may become vulnerable to dissolution, affecting corals and the ability of shellfish to form shells.[36,37] Oceans and coastal ecosystems play an important role in the global carbon cycle and have removed about 25% of the carbon dioxide emitted by human activities between 2000 and 2007. Rising ocean temperatures and ocean acidification means that the capacity of the ocean carbon sink will gradually become weaker. Also, the methane clathrate reservoirs, containing large amounts of the greenhouse gas methane, under sediments on the ocean floors, can potentially release the methane when oceanic water becomes warm. In 2004, the global inventory of ocean methane clathrates was estimated to occupy between 1 and 5 million cubic kilometers. This estimate corresponds to 500–2500 gigatonnes carbon (Gt C), and can be compared with the 5000 Gt C estimated for all other fossil fuel reserves.[38]

Radioactive Waste

Radionuclide and radioactive wastes are stored in marine water ponds next to nuclear power stations (electricity nuclear power and nuclear reprocessing factory) until it is considered safe for disposal. The waste is released directly into the sea about some kilometers from the coast. The ocean depth is used to dump high-level nuclear waste.[39,40] The liquid waste is sealed in glass, a process called vitrification, and stored steel canisters contain concrete. These containers are dumped in the sediment on the ocean floor. Also, nuclear atmospheric weapons test and the Chernobyl accident were sources of many artificial radionuclides in oceans.[24] Natural radionuclides in the environment can also be enhanced owing to human activity: industry, coal power, phosphate fertilizers in agriculture, and domestic and industrial sewage.[39] Moreover, coal mining is a source of huge amounts of waste containing large quantities of natural radionuclides, especially polonium, thorium, and uranium. During ashing of coal in power plants, some natural radionuclides are emitted to the atmosphere as a gas and radioactive dust, whereas the others stay as concentrated ash.[41,42] Also during production of phosphate fertilizers, about 10% of the initial of ^{226}Ra, 20% of uranium, and about 85% of ^{210}Po is found in the phosphogypsum waste.[43] Phosphogypsum wastes are often located near coasts of seas and enhance the concentration of soil groundwater and river water. For this reason, the surroundings of phosphogypsum waste are strongly polluted by natural radionuclides.[44,45] The runoff of radioactive substances are important sources of marine radionuclides pollution, especially for closed seas. For example, the total runoff of natural and artificial radionuclides from rivers to the southern Baltic Sea was calculated to comprise about 3.3 TBq of ^{90}Sr, 5.2 TBq of ^{137}Cs, 0.7 TBq of ^{210}Po, 4.5 TBq of $^{234+238}$U, and 1.3 GBq of $^{239+240}$Pu.[46] In turn, some basins of the North Sea (Irish Sea and French Channel) are strongly contaminated with artificial radionuclides (especially, radiocesium and plutonium) emitted from European nuclear reprocessing facilities in Sellafield and Cap de la Hague.[40] Radionuclides in the marine environment are strongly accumulated by biota, and the values of bioaccumulation factor for some radioactive elements (polonium, plutonium, americium) in sea algae, benthic animals, and fish are more than 5000.[47] Transuranic elements belong to the group of pollutants caused by human activity and are important from the radiological point of view owing to their high radiotoxicity, long physical lifetime, high chemical reactivity, and long residence in biological systems in the marine environment.[48]

Eutrophication

Eutrophication is an increase in chemical nutrients, typically compounds containing nitrogen or phosphorus, in an ecosystem. It can result in an increase in the ecosystem's primary productivity (excessive plant growth and decay), and further effects, including lack of oxygen and severe reductions in water quality and in fish and other animal populations.[11] The biggest culprits are rivers that empty into the ocean, and along with it many chemicals used as fertilizers in agriculture as well as waste from livestock and humans. An excess of oxygen-depleting chemicals in the water can lead to hypoxia and the creation of a dead zone.[49–51] Estuaries tend to be naturally eutrophic because land-derived nutrients are concentrated where runoff enters the marine environment in a confined channel. The World Resources Institute has identified 375 hypoxic coastal zones around the world, concentrated in coastal areas in Western Europe, the eastern and southern coasts of the United States, and East Asia, particularly in Japan. In the ocean, there are frequent red tide algae blooms that kill fish and marine mammals and cause respiratory problems in humans and some domestic animals when the blooms reach close to shore.[52–54] In addition to land runoff, atmospheric anthropogenic nitrogen can enter the open ocean. A study in 2008 found that this could account for around one-third of the ocean's external (non-recycled) nitrogen supply and up to 3% of the annual new marine biological production. It has been suggested that accumulating reactive nitrogen in the environment may have consequences as serious as putting carbon dioxide in the atmosphere.[54]

Plastic Debris

Marine debris is mainly discarded human rubbish that floats on, or is suspended in the ocean. Eighty percent of marine debris is plastic—a component that has been rapidly accumulating since the end of World War II. The mass of plastic in the oceans may be as high as 100 million metric tons. Discarded plastic bags, six-pack rings, and other forms of plastic wastes that finish up in the ocean constitute dangers to wildlife and fisheries. Aquatic life can be threatened through entanglement, suffocation, and ingestion. Fishing nets, usually made of plastic, can be left or lost in the ocean by fishermen. Known as ghost nets, they entangle fish, dolphins, sea turtles, sharks, dugongs, crocodiles, seabirds, crabs, and other creatures, restricting movement, causing starvation, laceration and infection, and, in those that need to return to the surface to breathe, suffocation. Many animals that live on or in the sea consume flotsam by mistake, as it often looks similar to their natural prey. Plastic debris, when bulky or tangled, is difficult to pass, and may become permanently lodged in the digestive tracts of these animals, blocking the passage of food and causing death through starvation or infection.[55] Plastics accumulate because they do not biodegrade in the way many other substances do. They will photodegrade on exposure to the sun, but they do so properly only under dry conditions, and water inhibits this process. In marine environments, photodegraded plastic disintegrates into ever smaller pieces while remaining polymers, even down to the molecular level. When floating plastic particles photodegrade down to zooplankton sizes, jellyfish attempt to consume them, and in this way the plastic enters the ocean food chain. Many of these long-lasting pieces end up in the stomachs of marine birds and animals, including sea turtles and black-footed albatross.[56,57] Plastic debris tends to accumulate at the center of ocean gyres. In particular, the Great Pacific Garbage Patch has a very high level of plastic particulate suspended in the upper water column. In samples taken in 1999, the mass of plastic exceeded that of zooplankton (the dominant animal life in the area) by a factor of 6.[57] Midway Atoll, in common with all the Hawaiian Islands, receives substantial amounts of debris from the garbage patch. When it comes to 90% plastic, this debris accumulates on the beaches of Midway where it becomes a hazard to the bird population of the island. Midway Atoll is home to two-thirds (1.5 million) of the global population of Laysan Albatross. Nearly all of these albatrosses have plastic in their digestive system and one-third of their chicks die.[58] Some plastic additives are known to disrupt the endocrine system when consumed; others can suppress the immune system or decrease reproductive rates. Floating debris can also absorb persistent organic pollutants from seawater, including PCBs, DDT, and PAHs.[58] Aside from toxic effects, when ingested, some of these are mistaken by the animal brain for estradiol, causing hormone disruption in the affected wildlife.[59]

Noise Pollution

Marine life can be susceptible to noise or sound pollution from sources such as passing ships, oil exploration seismic surveys, and naval low-frequency active sonar. Sound travels more rapidly and over larger distances in the sea than in the atmosphere. Marine animals, such as cetaceans, often have weak eyesight, and live in a world largely defined by acoustic information. This applies also to many deeper sea fish, which live in a world of darkness. Between 1950 and 1975, ambient noise in the ocean increased by about 10 dB (i.e., a tenfold increase).[3] Noise also makes species communicate louder, which is called the Lombard vocal response. Whale songs are longer when submarine detectors are on. If creatures do not "speak" loud enough, their voice can be masked by anthropogenic sounds. These unheard voices might be warnings, finding of prey, or preparations of net bubbling. When one species begins to speak louder, it will mask other species' voices, causing the whole ecosystem to eventually speak louder. Undersea noise pollution is like the death of a thousand cuts. Each sound in itself may not be a matter of critical concern, but taken altogether, the noise from shipping, seismic surveys, and military activity is creating a totally different environment than that existed even 50 years ago. That high level of noise is bound to have a hard, sweeping impact on life in the sea.[3,60]

Conclusions

The seas and oceans are contaminated with many natural and anthropogenic industrial pollutants. A lot of them are strongly toxic to the organisms and to humans. Apart from plastic, a very particular problem are toxins in the marine environment that do not disintegrate rapidly enough. The most important toxins in the seas are organic compounds (PCBs, DDT, PAHs, pesticides, furans, dioxins, phenol, oil), heavy metals, and radioactive waste. Heavy metals (especially, mercury, lead, nickel, and cadmium) are toxic (in the oxidized form, as ions) or poisonous at low concentrations. These toxins can accumulate in the tissues of many aquatic species. In particular, accumulation of toxins in benthic animals and fish in contaminated estuarine areas and closed seas is very dangerous, due to the high position of these organisms in the food chain and the strong toxicity of the chemicals. Moreover, surface runoff of pesticides to the marine environment can genetically alter the gender of snails and fish species, transforming male into female fish. Finally, the marine environment is an important part of the natural environment consisting of people and human activities, which in the last century have been responsible for production and deposition of many toxins in the oceans and seas.

COV: Comparative Overviews of Important Topics for Environmental Management

11

Rain Water: Harvesting

K.F. Andrew Lo

Introduction

Among the various alternative technologies to augment water resources, rainwater harvesting is a simple, decentralized solution and imposes insignificant impact on the environment. It is an important water source in many areas with significant rainfall but lacking any kind of conventional, centralized supply system. It is also a good option in areas where good-quality fresh surface water or groundwater is lacking. Rainwater harvesting systems have been used since ancient times and evidence of roof catchment systems dates back to early Roman times. In the Negev Desert in Israel, in Libya and Egypt, in Mexico, and in the Andes Range in South America as well as in the Arizona Desert in North America, stone dams and tanks were built to divert and store rainwater for irrigation purposes.

Advantages of Rainwater Harvesting

Rainwater harvesting systems can provide water at, or near, the point where water is needed or used. The systems can be both owner-operated and utility-operated, and owner-managed and utility-managed. Rainwater collected using existing structures (rooftops, parking lots, playgrounds, parks, ponds, and flood plains) has few negative environmental impacts compared with other water resources development technologies.[1] Rainwater is relatively clean and the quality is usually acceptable for many purposes with little or even no treatment. The physical and chemical properties of rainwater are usually superior to sources of groundwater that may have been subject to contamination.

Other advantages of rainwater harvesting include the following:

1. Rainwater harvesting can coexist with, and provide a good supplement to, other water sources and utility systems, thus relieving pressure on other water sources.
2. Rainwater harvesting provides a water supply buffer for use in times of emergency or breakdown of public water supply systems, particularly during natural disasters.

3. Rainwater harvesting can reduce storm drainage load and flooding in cities.
4. The owners who operate and manage the rainwater catchment system are more willing to exercise water conservation.
5. Rainwater harvesting technologies are flexible and can be built to meet almost any requirements.

Types of Rainwater Harvesting Systems

Collection systems can vary from simple households to large catchment systems. The categorization of rainwater harvesting systems depends on factors such as the size and nature of the catchment areas and whether the systems are in urban or rural settings.[2]

Simple Rooftop Collection Systems

The main components of a simple rooftop collection system are the cistern itself, the piping that leads to the cistern, and the appurtenances within the cistern (Figure 1). The materials and the degree of sophistication of the whole system largely depend on the initial capital investment. Some cost-effective systems involve cisterns made with ferrocement. In some cases, the harvested rainwater may be filtered or disinfected.

Large Systems for Educational Institutions, Stadiums, Airports, and Other Facilities

When the systems are larger, the overall system can become more complicated (e.g., rainwater collection from roofs and grounds of institutions, storage in underground reservoirs, and treatment and use for non-potable applications) (Figure 2).

Rooftop Collection Systems for High-Rise Buildings in Urbanized Areas

In high-rise buildings, roofs can be designed for catchment purposes and the collected roof water can be kept in separate cisterns on the roofs for non-potable uses.

Land Surface Catchments

Ground catchment techniques (Figure 3) provide more opportunity for collecting water from a larger surface area. By retaining small creek and stream flows in small storage surfaces or underground reservoirs,

FIGURE 1 A simple roof catchment system (illustrated by Chia-Ming Lin).

FIGURE 2 An indoor storage system in a monastery in China (photographed by K. F. Andrew Lo).

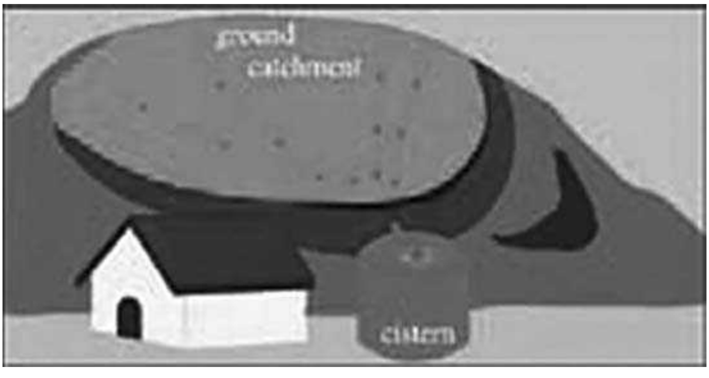

FIGURE 3 A land catchment system (illustrated by Chia-Ming Lin).

can meet water demands during dry periods. However, there is a possibility of high seepage loss to the ground. The marginal quality of the water collected is suitable for use mainly in agriculture.

Collection of Stormwater in Urbanized Catchment

The surface runoff collected in stormwater ponds/reservoirs from urban areas is subject to a wide variety of contaminants. Keeping these catchments clean is of primary importance; hence the cost of water pollution control can be considerable.

Design and Maintenance of Rainwater Harvesting Systems

Typically, a rainwater harvesting system consists of three basic elements: the collection system, the conveyance system, and the storage system.

Catchment Surface

The effective catchment area and the material used in constructing the catchment surface influence collection efficiency and water quality. Materials commonly used for roof catchment are corrugated aluminum and galvanized iron, concrete, fiberglass shingles, tiles, and slates. Mud is used primarily in rural areas. Bamboo roofs are least suitable because of possible health hazards. The catchment surface materials must be non-toxic and must not contain substances that impair water quality. Roofs with metallic paint or other coatings are not recommended because they may impart tastes or color to the collected water. Catchment surfaces and collection devices should be cleaned regularly to remove dust, leaves, and bird droppings to minimize bacterial contamination and to maintain the quality of collected water. Roofs should also be free from overhanging trees because birds and animals in the trees may defecate on the roofs.

When land surfaces are used as catchment areas, various techniques are available to increase runoff capacity: 1) clearing or altering vegetation cover; 2) increasing the land slope with artificial ground cover; and 3) reducing soil permeability by soil compaction. Specially constructed ground surfaces (concrete, paving stones, or some kind of liner) or paved runways can also be used to collect and convey rainwater to storage tanks or reservoirs. Care is required to avoid land surface damage and contamination by people and animals. If required, these surfaces should be fenced to prevent people and animal entry. Large cracks in the paved catchment because of soil movement, earthquakes, or prolonged exposure should be repaired immediately. Maintenance, typically consisting of the removal of dirt, leaves, and other accumulated materials, should take place annually before the start of the major rainfall season.

Conveyance Systems

Conveyance systems are required to transfer the rainwater collected on catchment surfaces to storage tanks. This is usually accomplished by making connections to one or more downpipes connected to collection devices. The pipes used for conveying rainwater, wherever possible, should be made of plastic, polyvinyl chloride (PVC), or other inert substance because the pH of rainwater can be acidic and may cause corrosion and mobilization of metals in metal pipes.

When it first starts to rain, dirt and debris from catchment surfaces and collection devices will be washed into the conveyance systems. Relatively clean water will only be available sometime later in the storm. The first part of each rainfall should be diverted from the storage tank. There are several possible options for selectively collecting clean water for the storage tanks. The common method is a sediment trap, which prevents debris entry into the tank. Installing a first-flush (or foul-flush) device is also useful to divert the initial batch of rainwater away from the tank.[3]

Rainwater pipes must be permanently marked in such a way that there is no risk of confusing them with drinking water pipes. Gutters and downpipes need to be periodically inspected and carefully cleaned. A good time to inspect gutters and downpipes is while it is raining, so that leaks can be easily detected.

Storage Tanks

Various types of rainwater storage facilities can be found in practice. Storage tanks should be constructed of inert material. Reinforced concrete, fiberglass, polyethylene, and stainless steel are suitable materials. Ferrocement tanks and jars made of mortar or earthen materials are commonly used. As an alternative, interconnected tanks made of pottery or polyethylene may be suitable. They are easy to clean. Bamboo-reinforced tanks are less successful because they may become infested with termites, bacteria, and fungi.

Precautions are required to prevent the entry of contaminants into storage tanks. The main sources of external contamination are pollution from debris, bird and animal droppings, and insects. A solid and secure cover is required to avoid breeding of mosquitoes, to prevent insects and rodents from entering the tank, and to keep out sunlight to prevent algae growth inside the tank.[4] A coarse inlet filter is also desirable for excluding coarse debris, dirt, leaves, and other solid materials.

All tanks need cleaning and their designs should allow for thorough scrubbing of the inner walls and floors. A sloped bottom and the provision of a pump and a drain are useful for collection and discharge of settled grit and sediment. Chlorination of the cisterns or storage tanks is necessary if the water is to be used for drinking and domestic uses. Cracks in the storage tanks can create major problems and should be repaired immediately.

The extraction system (taps/faucets, pumps) must not contaminate the stored water. Taps/faucets should be installed at least 10 cm above the base of the tank because this allows any debris entering the tank to settle on the bottom.[5] If it remains undisturbed, it will not affect the quality of the water. The handle of taps might be detachable to avoid misuse by children. Periodic maintenance should also be carried out on pumps used to lift water.

Conclusion

In the future, water scarcity in both developing and developed countries is inevitable.[6] The challenge of meeting the water demand can be largely met by appropriate understanding, study, and application of rainwater harvesting. Rainwater harvesting is about to come of age.[7] It has an appropriate image about it that meshes well with the gentler ideas of the late 20th century. Because the technique makes use of an untapped resource—precipitation that would otherwise be evaporated before it had a chance to play a useful role in feeding the human population—it looks like getting something for nothing. Making use of such a resource has certain poetry to it, particularly in a field where the resource itself can never be increased or decreased; unlike food, water cannot be grown to order, even given the right soil and the right fertilizer. But, like food, water can be harvested more efficiently. Doing so is a major priority for the 21st century.

Water Harvesting

Gary W. Frasier

Introduction

Water is one of the critical elements to support life. Without water, life as we know it cannot exist. Without water, plants will die. Humans and animals will die without drinking water. Yet, the planet we call earth has more area covered with water than landmass. From space, the planet looks blue from the water in the seas and the clouds. Even with all this water, there are many places on the land, classified as arid and semiarid land, where there is not enough drinking water for man and animals to live or plants to grow. In many of these arid and semiarid places, sufficient water can be obtained for drinking-water supplies and growing of plants by a process called water harvesting. In technical terms, water harvesting is defined as "the process of collecting and storing precipitation (rain or snow) for beneficial use from an area that has been treated or modified to increase precipitation runoff."[1]

With the modern advent of water transfers via canals and deep wells for supplying water for homes and irrigation of crops, there is a tendency to consider water harvesting as a "new" water supply technique. In actuality, water harvesting is an ancient practice that has been dated back to the Edom Mountain areas of Southern Jordan 9000 years ago.[2] There is evidence that water harvesting systems were used 3000 to 4000 years ago in various places of what we now call the Middle East. Some of these early systems were located in areas having less than 200 mm annual precipitation.[3] Water harvesting systems are currently being used for water supply in various places around the world such as Israel, Egypt, Jordan, Mexico, Australia, and the United States.

General Description

There are two general classifications of water harvesting systems. One group is used for providing drinking-water supplies for human and animal consumption. The other group is used to provide water for the growing of plants (runoff farming). All water harvesting systems have two major components: an area where the precipitation is collected (catchment area) and some means for storing the collected water.

The water collection area can be any surface that has been modified to increase precipitation runoff. They can include rock outcroppings with diversion facilities at the lower edge to direct the runoff water to a central point; smoothed compacted soil, chemically treated soil surfaces; soil covered with membranes of rubber, wood, or metal; and building rooftops. The water storage facility can be a tank, pond, or cistern with an impermeable lining or, in the case of runoff farming, the soil around the plants.

Water Harvesting for Livestock Drinking Water

Providing animal, domestic, and wildlife drinking water supplies is one of the newer applications of water harvesting (past 20–30 years). The catchment area can be a hillslope, an area covered or treated to reduce water infiltration and increase surface water runoff, or even roofs of buildings. The catchment area can be modified via various techniques, frequently separated into 3 general categories: 1) topography modification; 2) soil modification; and 3) impermeable coverings or membranes. Topography modification consists of land smoothing and clearing and frequently yields 20%–35% runoff efficiency. Some typical soil modification treatments used are sodium salts mixed in the top 6–12 cm of soil and compacted with runoff yields of 50%–80%. Water repellents and paraffin wax applied to the soil surface will yield 60%–95% runoff. Asphalts or bitumen sprayed on the soil surface provide 50%–80% runoff. More expensive catchment treatments consist of various impermeable coverings. They consist of gravel-covered sheeting (75%–95% runoff); asphalt membranes (85%–95% runoff); and concrete, sheet metal, and artificial rubber sheeting (60%–95% runoff).[4,5]

Storage of the collected water is a key component of any water harvesting system, but it is also one of the most expensive components. Unlined pits or ponds are usually not suitable unless seepage losses can be stopped. There are many types, shapes, and sizes of wooden, metal, concrete, or reinforced plastic storage containers that can be used. Also, in most arid and semiarid areas where the precipitation events are erratic, it is necessary to provide some means of controlling evaporative losses from the stored-water facility. Evaporation control on sloping-sided pits or ponds is difficult because the water surface area changes with depth.[5]

Water Harvesting for Domestic Use

Most of the techniques used for water harvesting for livestock and wildlife drinking supplies can be used to provide water for domestic uses. One technique that is used in several places in the world today is the collection of water from the roofs of buildings.[6] A relatively small roof area can provide significant quantities of water if collected and stored. One millimeter of precipitation will yield 1 L of water. This technique is very effective in areas where there are frequent precipitation events but little or no surface water, because of highly permeable soils or groundwater that has high concentrations of undesirable minerals. A simple wooden or metal tank or concrete cistern stores the collected water.

Water Harvesting for Growing of Crops

One form of water harvesting used for growing crops is termed runoff farming. Runoff farming maximizes the effect of limited precipitation by collecting surface runoff from a large area and applying it to a smaller cropped area. The collected water can be applied directly to the crop area during the precipitation event, referred to as floodwater farming,[3] or stored and applied later by some form of irrigation system.[7] A modified version is termed microcatchment farming, where a small runoff area is situated directly upslope of the growing area. This technique has been used for tree crops such as pistachio, olive, and almond.[3]

Other Considerations

Water harvesting should not be considered as a cheap or inexpensive means of water supply. It can supply water in areas where other water sources are unattainable or unsuitable. Water harvesting is not a new means of water supply or source but is receiving renewed interest in many places in the world.

It became a water source of interest with the work of Evenari and his colleagues[8] in the early 1960s reconstructing ancient water harvesting systems in the Negev Desert of Israel. Following this work, several research organizations around the world conducted extensive studies, primarily exploring various low-cost means of treating the soil to reduce infiltration and increase precipitation runoff. Much of this effort has currently been completed. Many water harvesting systems are being used around the world, most notably in arid and semiarid, underdeveloped areas where there is plentiful labor. At the same time, there are many places where the systems have failed. One of the most common reasons for failure is the lack of adequate maintenance of the collection area and the water storage facility. When properly designed and maintained, a water harvesting system can last for decades.

Groundwater: Saltwater Intrusion

Alexander
H.-D. Cheng

Introduction

Human beings have a tendency to live near coastal areas. About 23% of the world's population lives within 100 km of the coast. This figure is likely to increase to 50% in the next 25 years. In the United States, 54% of all Americans now live in 772 coastal counties adjacent to the Atlantic and Pacific Oceans, the Gulf of Mexico, and the Great Lakes. By the year 2025, nearly 75% of all Americans are expected to live in coastal counties.

Coastal aquifers serve as major sources for freshwater supply in many countries around the world, especially in arid and semiarid zones. Many coastal areas are also heavily urbanized, a fact that makes the need for freshwater even more acute. Coastal aquifers are highly sensitive to disturbances. Inappropriate management of a coastal aquifer can lead to its destruction as a source for freshwater much earlier than aquifers that are not connected to the sea. The reason is the threat of seawater intrusion into freshwater aquifers.

The origin of saltwater intrusion into freshwater aquifers can come from natural sources such as seawater and deep formation brines or from anthropogenic sources such as deicing salt, agricultural return flow, and leachate from landfills. The most frequent occurrences are found in coastal regions where overexploitation of groundwater has caused the encroachment of seawater into freshwater aquifers. Once an aquifer is invaded, a part of the salt will adsorb onto the solid surface, making it difficult to reverse the process and restore the aquifer. The slow movement of groundwater also makes the remediation time long. Salinity in water poses a health hazard for humans and livestock, damages crops, and corrodes pipes and boilers in industrial uses. Hence, the invasion of saltwater into a freshwater aquifer means the loss of that aquifer for water sources.

Saltwater Intrusion Problems around the World

Serious saltwater intrusion problems exist in many parts of the world. In the following, we shall review some of the more prominently reported cases.

United States

In the United States, the potential for saltwater intrusion was recognized as early as 1824 in New Jersey and 1854 on Long Island, New York.[1] In modern times, serious problems of saltwater intrusion into aquifers are found in the Miami, Long Island, Hawaii, and Los Angeles areas.

Seawater intrusion into aquifers is a problem throughout coastal Florida. Particularly, in the Miami area, a network of drainage canals was constructed from 1909 through the 1930s. The resulting drainage lowered water levels about 2 m in the Everglades. This drainage, combined with coastal pumping, caused seawater to advance progressively into the Biscayne aquifer.[2] The intrusion front has reached several kilometers inland.[3] The South Florida Water Management District is one of the regional water management agencies in the state that has the regulatory power to issue or deny a well construction permit, to require the installation of monitoring wells, and to impose restrictions on groundwater extraction during drought periods based on seawater intrusion considerations.

In Los Angeles County, California, severe groundwater overdraft from the early 1900s to the late 1950s caused water levels to drop below sea level, allowing saltwater to intrude into the potable aquifers, rendering coastal wells out of service. In an effort to halt the intrusion, groundwater management agencies took three major steps from the mid-1950s to mid-1960s, including the following: 1) construction of freshwater injection wells along the coast to prevent the saltwater intrusion; 2) limiting the amount of groundwater that could be pumped annually; and 3) creation of the Water Replenishment District of Southern California to purchase artificial replenishment water to make up the annual and accumulated overdrafts.[5]

For the Oahu Island of Hawaii, fresh groundwater exists as a lens floating on top of saltwater. In the predevelopment time (pre-1880), the freshwater lens in the Pearl Harbor area was estimated to be 400 m to 500 m thick.[6] In 1990, measured salinity profiles showed the freshwater lens to be only 200 m to 300 m thick.[7] Thus, the 100 years of development has caused the freshwater lens to reduce to half its thickness.

The Netherlands

The Netherlands is located on river deltas, with much of its territory below sea level, reclaimed from the sea. The low- lying lands, known as polders, are particularly susceptible to the invasion of seawater. To keep out the brackish water, year-round recharge of aquifers using reclaimed water is needed.[8]

A great concern for the Netherlands is the threat of sea level rise, as a result of the global warming trend. The rise of sea level can inundate land and push the saltwater-freshwater equilibrium point further inland. It will also increase the hydraulic pressure of seepage flow for the low-lying areas. Possible countermeasures have been investigated.[9]

Israel and Palestinian Territories

Due to the semiarid climate, Israel and Palestinian territories (Gaza Strip and West Bank) are critically dependent on groundwater for water supply. In fact, the sandstone Quaternary aquifer that underlies coastal Israel and the Gaza Strip is being “mined,” and the Mediterranean Sea intrudes along a saltwater front.[10,11] The water demands have been so much that the strategy is no longer to push the saltwater front outward to sea. The management goal is to allow the aquifer to be contaminated and to intercept the largest possible percentage of freshwater outflow to sea.

Mexico

The aquifer in northwestern Yucatan contains a freshwater lens that floats above a denser saline water wedge. It has been shown that at certain locations, the penetration of saline water can be more than 100 km inland.[12] The aquifer, which is unconfined except for a narrow band along the coast, is the sole freshwater source in northwestern Yucatan. Development of industry and agriculture and other land use changes pose a potential threat to the quantity and quality of freshwater resources in the Yucatan Peninsula.[13]

Italy

In the 1920s, Venice went through an Industrial Revolution. During this time period, water was constantly being pumped from the underlying aquifer. The lowering of the piezometric head has caused not only land subsidence but also the contamination of aquifer by saline water. Geophysical investigations have shown that the saline water may extend inshore up to 20 km from the Adriatic Sea coastline. The saltwater plume is observed from the near ground surface down to 100 m.[14,15] The combined effect of sea level rise and land subsidence can further enhance the saltwater contamination and the related soil salinization, with serious environmental and socioeconomic impacts.

Other Parts of the World

Saltwater intrusion problems are also found in the Nile Delta of Egypt,[16] Cap Bon of Tunisia,[17] China,[18] Cyprus,[19] Morocco,[20] and many other parts of the world.

Mechanisms of Saltwater Intrusion

Figure 1 gives a simplified view of seawater intrusion into an unconfined aquifer. We observe that saltwater is heavier and hence tends to stay underneath the freshwater. The freshwater, however, has a hydraulic gradient with head decreasing from inland toward the sea, thus driving a freshwater flow to the sea. This outflow momentum counteracts the density-driven seawater. Without it, seawater will continue to move inland until the entire aquifer below sea level is occupied by the heavier saltwater. However, since such a hydraulic gradient always exists due to the precipitation recharge inland, an equilibrium position of saltwater and freshwater will be established, schematically shown as the interface in Figure 1.

Ghyben-Herzberg Relation

The earliest and the simplest explanation of the saltwater intrusion mechanism was provided by Du Cummun,[21] Badon-Ghyben,[22] and Herzberg,[23] commonly known as the Ghyben-Herzberg relation. By making the following assumptions—1) a sharp interface exists, separating saltwater from freshwater; 2) the freshwater flow lines are approximately horizontal; and 3) there is no flow in the saltwater zone—a simple relation between the freshwater free surface elevation, h_f, and the interface location below the sea level, η, can be developed as (see Figure 1)

$$\eta = \frac{\rho_f}{\rho_s - \rho_f} h_f \approx 40 h_f \tag{1}$$

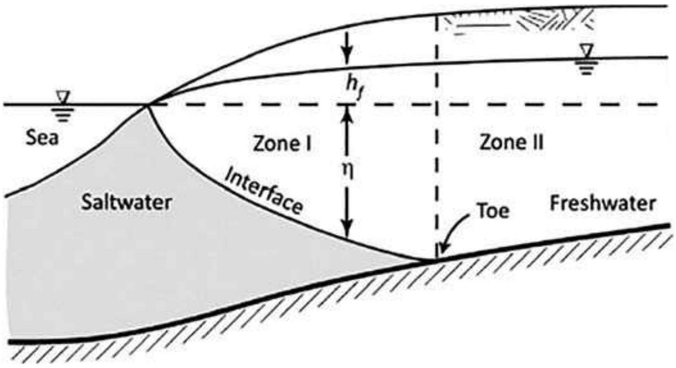

FIGURE 1 Seawater intrusion into an unconfined aquifer.

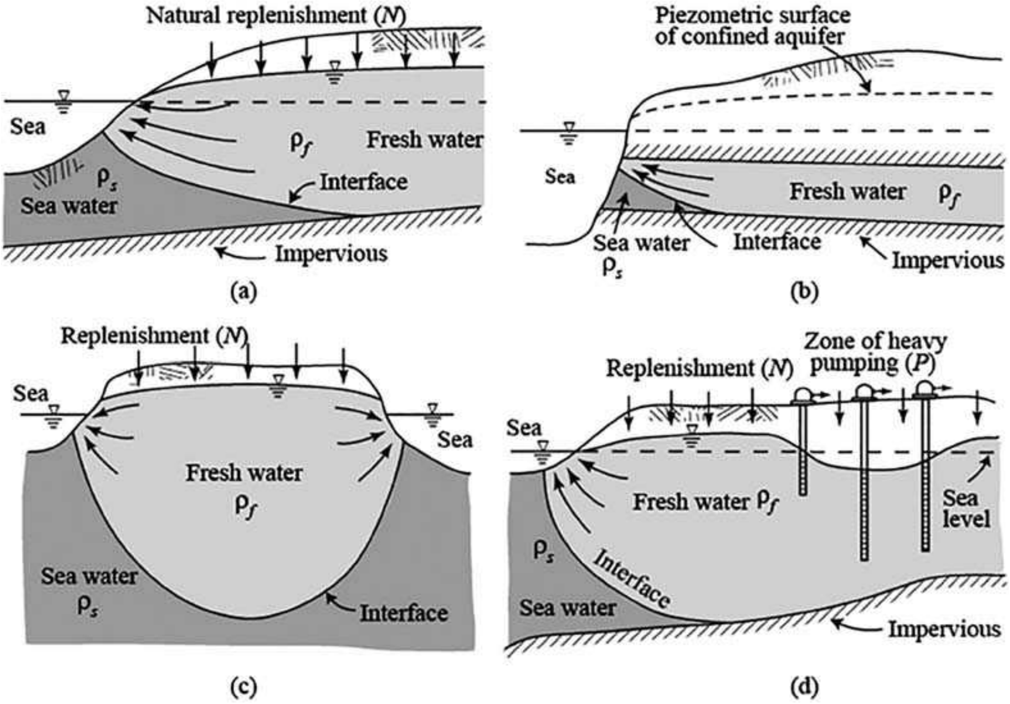

FIGURE 2 Typical vertical cross sections of seawater intrusion in coastal aquifers: (a) unconfined aquifer with replenishment; (b) confined aquifer; (c) freshwater lens on an island; (d) unconfined aquifer with pumping.

where ρ_f is freshwater density (1 g/cm^3) and ρ_s is saltwater density (approximately 1.025 g/cm^3). This is known as the

What the above relation says is that for every meter of freshwater head above sea level, the interface is pushed down 40 m below sea level. When the interface touches the bottom of an aquifer, a toe for the seawater wedge is located (Figure 1). Landward from the toe (zone 2), only freshwater exists; seaward from the toe (zone 1), saltwater and freshwater coexist.

Figure 2 presents some typical cross sections with interfaces in coastal aquifers under natural conditions (a–c) and with pumping (d). Like all figures that describe aquifers, these figures are highly distorted, with vertical scale much more magnified.

Up-Coning

This 40:1 ratio mentioned above based on the Ghyben–Herzberg relation may sound like good news for repelling saltwater by freshwater head. However, if pumping activity is increased in the coastal zone, as often is the case due to increasing population and economic activities, the reduced freshwater head will allow saltwater to move a large distance landward. Also, if a pumping well is situated above the interface in the saltwater-freshwater coexisting zone, the drawdown of a water table or piezometric head will cause the interface to rise up steeply to meet the well. This phenomenon is known as up-coning. Once the saltwater reaches the well, the well is generally considered to be lost.

For a pumping well situated at a distance d above an undisturbed interface (Figure 3), a formula that predicts the maximum allowable discharge, $Q_{\max}$, before the saltwater entering the well is given by[24,25]

$$Q_{\max} < 0.6\pi \Delta s K d^2 \approx 0.047 K d^2 \tag{2}$$

where K is the hydraulic conductivity, and $\Delta s = (\rho_s - \rho_f)/\rho_f \approx 0.25$. Take, for example, $K = 100$ m^1/day; then a well with its screened section situated 10 m above the interface can pump up to 470 m^2/day. On the other hand, if the distance d is reduced to 5 m, then the pumping rate is restricted to 117 m^3/day.

In Figure 4, we demonstrate a few saltwater intrusion scenarios with a well pumping above the interface. Figure 4a shows a confined aquifer with a well pumping at a relatively small rate. In this case, a freshwater capture zone is formed similar to a capture zone in the entirely freshwater region. Below the well, although there is an up-coning, the well is pumping freshwater.

In Figure 4b, the pumping rate is increased but not large enough to cause the interface to reach the well. At the cross section where the well is located, the (three-dimensional) capture zone touches the interface. Near the interface, there exists mixing of saltwater and freshwater due to hydrodynamic dispersion. Thus, trace salt content may be observed in the well. Figure 4c shows a similar situation as Figure 4b but for an unconfined aquifer.

Figure 4d gives a two-dimensional situation. A two dimensional pumping situation can be created either by a gallery (collector) well, that is, a perforated pipeline parallel to the coastline, or by a number of wells along the coast and close to each other, such that their influence zone overlaps. In this case, as long as the discharge per unit length of the gallery well does not exceed the freshwater outflow per unit length of coastline, the excess freshwater must flow underneath the well; hence, the interface cannot reach the well. In this way, the well can pump nearly as much as the entire freshwater outflow, not

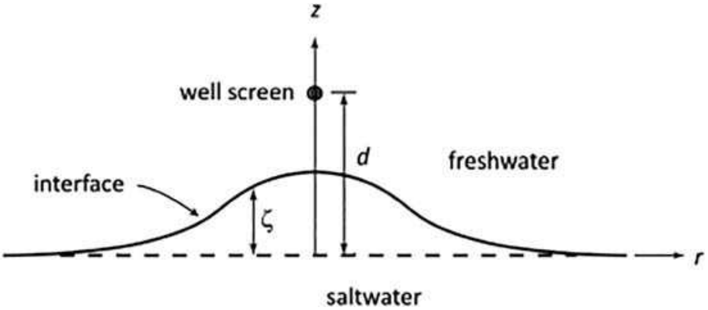

FIGURE 3 Interface up-coning below a pumping well.

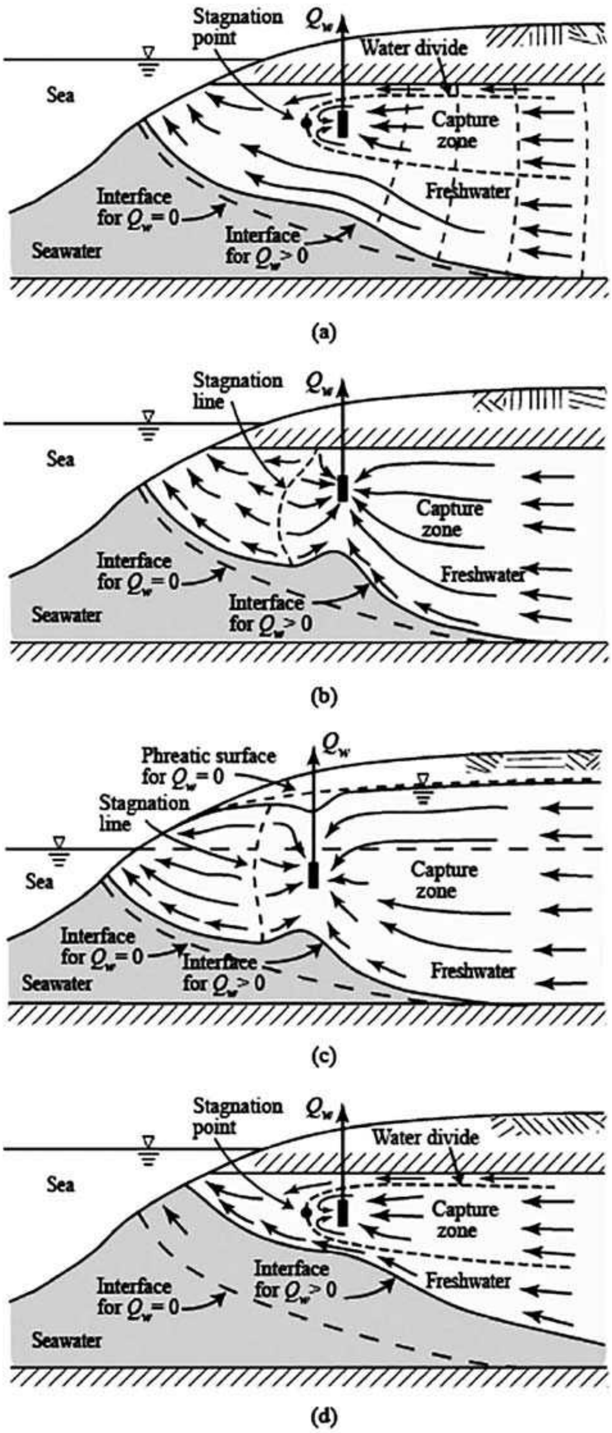

FIGURE 4 Up-coning, freshwater flow directions and capture zone in the vicinity of a well pumping above interface: (a) confined aquifer, smaller discharge; (b) confined aquifer, larger discharge; (c) unconfined aquifer; and (d) two-dimensional flow (with gallery well).
Source: Bear and Cheng.[26]

wasting any available freshwater. This type of skimming well that distributes the pumping rate over a line or over an area to avoid concentrated local up-coning beneath a point well has been practiced in Israel,[27] Palestinian territories,[28] and Pakistan.[29,30]

Transition Zone

In the above figures, saltwater and freshwater are shown to be separated by a sharp interface. This is a simplification of the actual situation, as saltwater and freshwater are miscible liquids. Actually, they constitute a single liquid phase—water—with different concentrations of total dissolved solid (TDS), such as salt. Often, the term "interface" is used for the iso-density surface that is midway between freshwater and seawater.

For the sake of simplicity, we shall continue to refer to two liquids—freshwater and seawater. The passage from the portion of the aquifer that is occupied by one liquid to the other takes the form of a transition zone, rather than a sharp interface. Depending on the extent of seawater intrusion and certain aquifer properties, this transition zone may be rather wide or narrow. The width of the transition zone is dictated by three phenomena:

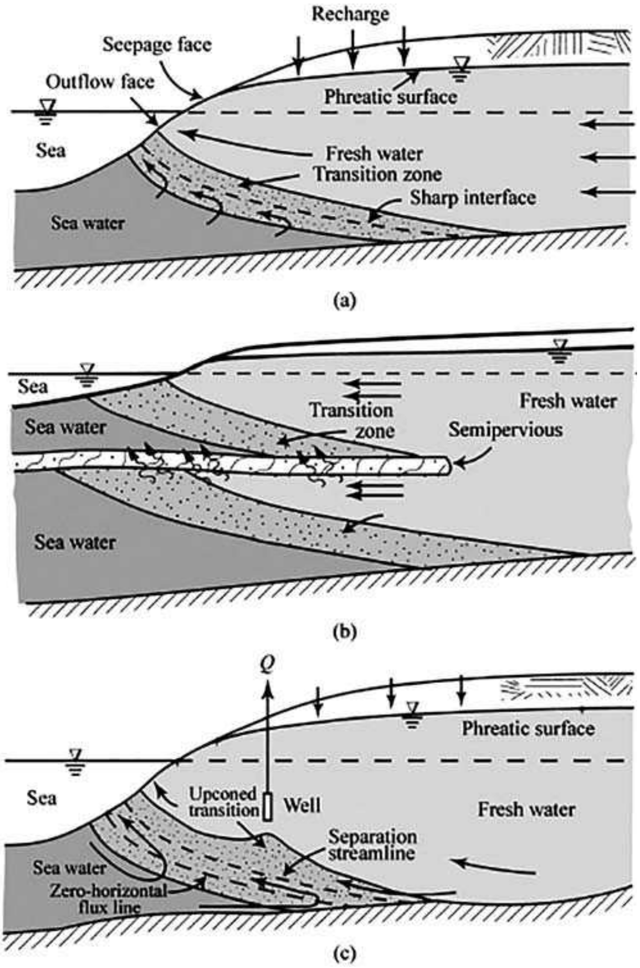

FIGURE 5 Transition zones between saltwater and freshwater regions: (a) an unconfined aquifer; (b) two aquifers separated by a semipervious layer; and (c) with a pumping well above interface.

- Hydrodynamic dispersion (dispersion and molecular diffusion)
- Advection of water—fresh and mixed—toward the sea (or, under certain conditions, landward)
- Recirculation of seawater and mixed water

Figure 5 demonstrates a few scenarios of transition zones between the saltwater and freshwater region. In Figure 5a, we observe that we can approximate a sharp interface location as the 50% relative concentration line. Figure 5b depicts a multilayer situation, where there are two transition zones. As the partition layer is semipervious, saltwater and freshwater exchange can also take place by leakage through the semipervious layer. Figure 5c shows the case with a pumping well above the interface, creating an up- coning situation.

Monitoring and Exploration of Saltwater Intrusion

Geological Investigation

A direct way of detecting saltwater intrusion is by the geological technique of drilling monitoring wells. In aquifers where a thick saltwater-freshwater transition zone exists, it is of interest to monitor the continuous change in salt concentration across the transition zone. Monitoring such information requires taking water samples at different depths. This can be achieved by the use of packers that seal sections of the well, selectively, such that each section has its own screen. Water samples taken from different sections are not mixed with each other. Obviously, such an operation is tedious, and the data obtained are limited to the well's location and to the elevation of the screened portions of the well. In order to cover a large area, a large number of wells need to be drilled, and the associated costs are usually high. The data obtained, however, are the most direct and, probably, the most accurate. Data obtained by this method are often used to calibrate data obtained by indirect methods, such as geophysical methods.

One way to reduce the effort and cost of monitoring is to utilize the Ghyben-Herzberg relation to interpret the interface location. In this case, monitoring wells need only to reach the phreatic surface, and water sampling for salt concentration is not necessary. With the Ghyben-Herzberg relation, it is possible to map the saltwater-freshwater interface using the following steps in a field investigation:

1. A network of shallow wells is deployed to observe the water table height, to give the freshwater head h_f above mean sea level.
2. The water table surface can be created using an interpolation procedure, such as kriging, expressed as $h_f(x,y)$.
3. The interface depth h(x,y) below mean sea level is represented by the same function $hf(x,y)$, except that it is amplified by a factor of 40, as indicated by Eq. 1.
4. The location of aquifer bottom $b(x,y)$ is interpolated from geological coring or map.
5. The intersection of the two surfaces h(x, y) and $b(x,y)$ is sought, which represents the toe location of the saltwater wedge.

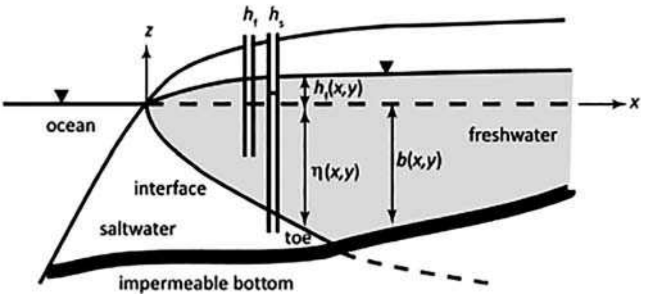

FIGURE 6 Locating saltwater toe by Ghyben–Herzberg relation.

This procedure is illustrated in Figure 6 using a vertical cross section. The above procedure is applicable for confined as well as unconfined aquifers.

The Ghyben–Herzberg relation, Eq. 1, contains the assumption that the saltwater is static. A better approximation for locating the interface that does not contain this assumption is given by[31]

$$\eta = \frac{\rho_f}{\rho_s - \rho_f} h_f - \frac{\rho_s}{\rho_s - \rho_f} h_s \tag{3}$$

The above relation states that if we can measure at the same location both the freshwater head h_f and the saltwater head h_s, as illustrated in Figure 6, then the interface location can be better determined.

Geophysical Investigation

Geophysical methods make use of physical properties, such as the velocity of seismic waves, electrical conductivity, electromagnetic permeability, thermal conductivity, etc., of the geomaterials, such as the soil, and the water occupying the void space, with the latter varying with the concentration of dissolved matter. The typical advantages of the geophysical methods are the following:

- Measurements are taken at ground surface, although some techniques also utilize existing or specially drilled boreholes.
- Sometimes, measurements can be conducted airborne by aircraft. Usually, this means less time consumed and lower cost.
- Measurements cover a large surface area, thus making the methods more suitable for field-scale investigations.

The disadvantage of the surface-based geophysical methods, however, is that they are indirect, measuring some analogous quantities, thus often requiring calibration from direct measurements. The optimal solution to this problem is to conduct an integrated survey that combines results from geophysical techniques with data obtained from direct water sampling.

Several geophysical methods that can be used for detecting the presence of saline water in geological formations are briefly discussed below, based on Stewart:[32]

- Direct current (DC) resistivity. The method is based on the increase in electrical conductivity with increasing pore water salinity. The principal advantages of the method are its simplicity and the relatively low cost of the required equipment. In the DC method, an electrical current is introduced into the ground through electrodes driven into the soil. The resulting electrical potential (voltage) is measured between the two electrodes. The measured resistance represents the integrated resistivity over the electrically heterogeneous soil. In the more advanced equipment, multiconductor cables connect a large number of electrodes along a profile. A receiver then cycles sequentially through the electrodes, producing a series of closely spaced soundings along the profile. A computer program then performs 2-D or 3-D resistivity inversions on the field data. The inversion, however, is not unique and is dependent on the assumed "model," e.g., the number of soil layers and their thickness. This technique may not be robust enough to accurately determine a continuously varying salt concentration in a transition zone. In the case of a sharp interface, however, there is a distinct change in electrical conductivity across such interface; hence, the interface location can, generally, be determined quite accurately.[33]
- Frequency-domain electromagnetic methods (FDEMs). The FDEM involves the generation of an electromagnetic field, which induces current in the soil, which in turn causes the subsurface to create a magnetic field. By measuring this secondary magnetic field, various subsurface properties and features can be deduced. The currents in the soil, termed eddy currents, are induced by time-varying magnetic fields produced by a frequency- controlled AC (alternating current) in a transmitter coil. The transmitted electromagnetic field is called the primary field. The induced

eddy currents in the soil produce a secondary field, which is usually 90° out of phase with the primary one. The ratio of the out-of-phase component of the secondary field to the in-phase component of the primary one is an indication of the terrain's conductivity. The depth of investigation by the FDEM is primarily a function of the frequency of the primary field, with lower frequencies having greater penetration.

- Airborne electromagnetic methods. The FDEM creates eddy currents through electromagnetic induction, so that, actually, no contact with the ground is required. This means that a frequency EM system can be flown by fixed-wing aircraft or by helicopters. The typical airborne system uses several receiver-transmitter coil pairs at varying frequencies. These coil pairs are placed in a "bird," which is towed behind the aircraft at elevations of 25–50 m above ground surface. The depth of investigation is determined by the transmitter's frequencies. Common frequencies range from 200 to 56,000 Hz, yielding penetration depths from tens of meters to less than one meter, respectively. The output, as an apparent resistivity map for each frequency, is produced by an inverse method. Interpretation is normally qualitative and typically needs to be calibrated with ground surface data. The airborne method is generally applied to surveys of large areas; it has been successfully applied to the detection of saltwater intrusion in freshwater aquifers and to the exploration of freshwater lenses in saltwater environments.
- Time-domain electromagnetic methods (TDEMs). The TDEM (transient) employs a transmitter that drives an AC through a square loop of insulated electrical cable laid on the ground. The current consists of equal periods of time on and time off, with base frequencies that range from 3 to 75 Hz, producing an electromagnetic field. Similar to the FDEM, the electrical current generates a primary, time-varying electromagnetic field, which in turn creates a secondary electromagnetic field. Time-domain electromagnetic method soundings can be used to detect saltwater at depths of 5 m to several hundred meters below land surface. The TDEM has several significant advantages over DC soundings, notably depths of investigation up to twice the transmitter coil dimension and the ability to sound through a conductive, near-surface unit, such as a clay confining layer. Time-domain electromagnetic method equipment, however, is more expensive and complicated to use than DC equipment, and the interpretation of TDEM data requires sophisticated interpretation software.

Other geophysical investigation techniques that have been employed for the detection of saline water in the subsurface include the ground penetrating radar, the loop-loop electromagnetic method, the very-low-frequency electromagnetic method, and various borehole geophysical methods. More details can be found in Stewart.[32]

Geochemical Investigation

As a part of exploration of freshwater contaminated by intruding saline water, it is important to identify the origin of the latter. In coastal aquifers, seawater encroachment inland is the most common reason for the increase in salinity; however, other sources or processes can contribute to groundwater salinity. Custodio[34] lists a number of salinity sources that can contaminate freshwater supply, which are not directly related to seawater encroachment. These include entrapped fossil seawater; sea-spray accumulation; evaporite rock dissolution; displacement of old saline groundwater from underlying or adjacent aquifers or aquitards through natural or man-imposed advection or by thermal convection; leaking aquitards through fault systems; and anthropogenic pollution from various sources, including sewage effluents, industrial effluents, mine water, road-deicing salts, effluents from water softening or deionization plants, and agriculture return flows.

In general, seawater has a uniform chemistry due to the long residence time of the major constituents. Its main features are[35] predominance of Cl^- and Na^+, with a molar ratio of 0.86; an excess of Cl^- over the alkali ions (Na and K); and Mg greatly in excess of Ca^{2+} (Mg/Ca = 4.5–5.2). In contrast, continental fresh groundwater is characterized by a highly variable chemical composition, although the predominant anions are HCO_3^- , SO_3^{-4} and Cl^-. If not anthropogenetically polluted, the fundamental cations are Ca^{2+} and Mg^{2+} and, to a lesser extent, the alkali ions, Na^+ and K^+. In most cases, Ca^{2+} predominates over Mg^{2+}. Seawater solutes are specifically characterized by $Mg > SO_4 + HCO_3$, whereas meteoric waters (dilute or saline), even if dominated by resolution of marine salts, reflect Na > Cl. In contrast, sedimentary basin fluids can carry significant Ca and perhaps K excess over $SO_4 + HCO_3$, due to diagenetic carbonate or silicate reactions.

Geochemists generally use the following criteria to define the signature and to distinguish the sources of salinization:[35]

- Salinity: In coastal aquifers, a time series of steadily increasing chloride concentrations can indicate the early evolution of a salinity breakthrough from seawater, due to the overexploitation of groundwater and reduction of the piezometric head.
- Cl/Br ratios: The Cl/Br ratio can be used as a reliable tracer, as both Cl and Br usually behave conservatively, except in the presence of very high amounts of organic matter. Seawater (Cl/Br weight ratio = 297) is distinguished from relics of evaporated seawater (hypersaline brine Cl/Br <297), evaporite-dissolution products (over 1000), and anthropogenic sources like sewage effluents (Cl/Br ratios up to 800) or agriculture return flows (low Cl/Br ratios).
- Na/Cl ratios: Na/Cl ratios of saltwater intrusion are usually lower than the marine values (i.e., <0.86 molar ratio). On the other hand, high (>1) Na/Cl ratios typically characterize anthropogenic sources, like domestic waste waters. Thus, low Na/Cl ratios, combined with other geochemical parameters, can foretell the arrival of saltwater intrusion, even at relatively low chloride concentrations, during early stages of salinization.
- Ca/Mg, $Ca/(HCO_3 + SO_4)$ ratios: One of the most conspicuous features of saltwater intrusion is the enrichment of Ca over its concentration in seawater. High Ca/Mg and $Ca/(HCO_3 + SO_4)$ ratios (>1) are further indicators of the intrusion of seawater.
- O and H isotopes: The stable O and H isotopes can be used to describe the mixing process between saline water and freshwater. Fresh groundwater is generally depleted in both ^{18}O and ^2H (deuterium) relative to seawater. Mixing of freshwater and seawater should result in a linear correlation. Different sources with high salinity (e.g., agriculture return flows, sewage effluents) would result in different slopes due to evaporation processes that would change the isotopic composition.
- Boron isotopes: One of the processes that modify the chemistry of seawater intrusion is the adsorption of potassium, boron, and lithium onto clay minerals in the host aquifer. These elements are relatively depleted in saline water associated with seawater intrusion. Hence, the boron isotopic composition of groundwater can be used as a tool to discern the salinization sources, in particular, to distinguish seawater from anthropogenic contamination, such as domestic waste water.

As a conclusion of this section, we observe that many of the techniques discussed above for the exploration of an environment intruded by saline water are of a qualitative nature. Hence, in island or coastal regions, an exploration program usually requires the conjunctive and integrated use of two or more complementary geophysical, geological, and geochemical methods. Using several methods can increase the confidence level of the interpretation of observed data. The collected data can be used to validate the numerical model constructed for the simulation of seawater intrusion for management purposes.

Mathematical Modeling

The use of field surveys, such as geophysical and geochemical studies, can reveal the present state of saltwater intrusion and perhaps some insight into its history. However, it cannot make predictions into the future and, particularly, cannot be used for scenario building and impact assessment based on different levels of anthropogenic activities. Mathematical models are needed for these purposes.

The Ghyben–Herzberg relation is a highly simplified model. More rigorously, the dynamic movement of groundwater flow and the solute transport of salt need to be considered. Generally speaking, there does not exist a sharp division between saltwater and freshwater zones, as implied in Figure 1. The salt concentration continuously changes from that of seawater to that of freshwater. A solute transport model including advection and dispersion is needed for the modeling. In addition, the salt at higher concentration is an active solute, because it can affect the density of water and can drive the flow. Hence a density- dependent solute transport model should be used. There are occasions, however, when the predominant change of concentration from saltwater to freshwater takes place within a narrow region called the transition zone. In that case, a simplified model using the sharp interface assumption can be attempted. Furthermore, if the aquifer modeled is of regional scale, then the flow variables are often averaged in the depth direction to reduce the three-dimensional problems to two-dimensional ones.

While these different models are discussed in more detail in Bear[36] and Bear and Cheng,[26] in the following, only the governing equations for the density-dependent solute transport model are presented.

First, rather than using a piezometric head h associated with a variable density p, we shall define a reference piezometric head h', associated with the (constant) freshwater density ρ *f*, as[37]

$$h'(x,y,z,t)=z+\frac{p}{\rho_f g} \tag{4}$$

In the above, p is pressure, z is the elevation above datum, and g is gravity acceleration. Next, we define the mass fraction (mass of dissolved salt, or TDS, per unit mass of fluid) as

$$\omega=\frac{c}{\rho} \tag{5}$$

where c is the concentration of salt in fluid (mass of dissolved salt per unit volume of fluid). The normalized salt mass fraction is defined as

$$\mathrm{C}=\frac{\omega-\omega_f}{\omega_{s-}\omega_f};\ 0\le C\le 1.0 \tag{6}$$

where ω, ω_s, ω_f, are respectively the salt mass fraction in mixed (salt- and fresh-) water, unmixed seawater, and unmixed freshwater.

Constitutive Equations

Constitutive equations express the relationship between the fluid density and viscosity with the pressure and the salt mass fraction. For fluid density, we ignore the pressure effect and present only the linearized constitutive equations here:

$$\rho=\rho_f\,(1+\beta_c C) \tag{7}$$

where β_c is a density difference factor defined as

$$\beta_c=\beta''_\omega\left(\omega_s-\omega_f\right) \tag{8}$$

and β''_ω is a coefficient expressing the effect of the change in salt mass fraction on the fluid density (at constant pressure), given by

$$\beta''_\omega=\frac{1}{-\rho_f}\frac{d\rho}{d\omega}. \tag{9}$$

The constitutive equation for the fluid dynamic viscosity can be expressed as[38]

$$\mu = \mu_0 \left(1 + 1.85\omega - 4.1\omega^2 + 44.5\omega^2\right) \tag{10}$$

in which the reference viscosity μ_o corresponds to viscosity at $\omega = 0$.

Darcy's Law

Darcy's law can be written in terms of h' and C as

$$\mathrm{q}\frac{\mathrm{K}_f}{\mu_r} = \left(\nabla h' + \beta_c C \nabla z\right) \tag{11}$$

where $\mu_r = \mu/\mu_o$ is the relative viscosity,

$$\mathrm{K}_f \frac{\rho_f \mathrm{gk}}{\mu_f} \tag{12}$$

is the hydraulic conductivity with respect to the reference density and viscosity (of freshwater), and k is the intrinsic permeability.

Mass Balance Equation for Water

The mass balance of water can be expressed in terms of h' and C as

$$\mathrm{S}_o \frac{\partial h'}{\partial t} + \phi\beta_c \frac{\rho}{\rho_f}\frac{\partial C}{\partial t} = \nabla \cdot \left[\frac{1+\beta_c C}{\mu}\mathbf{K}_f \cdot \left(\nabla h' + \beta_c C \nabla_z\right) + \phi\beta_c \mathbf{D} \cdot \nabla C\right]$$

$$+ \frac{\rho_R}{\rho_f} Q_R - \left(1 + \beta_c C\right)\mathrm{Q}_p \tag{13}$$

where S_o is the aquifer's specific storativity; ϕ is porosity; $\mathbf{D}$ is the coefficient of mechanical dispersion, a second- rank tensor; Q_R and Q_P are, respectively, rate of injection (recharge) and withdrawal (pumping) of water from the aquifer; and ρ_R is the density of the recharged water.

Mass Balance Equation for Dissolved Salt

The mass balance of TDS can be expressed as

$$\frac{\partial \phi\rho C}{\partial t} = -\nabla \cdot \left(\rho C \mathbf{q} - \phi\rho \mathbf{D}_h \cdot \nabla C\right) + \rho_R C_R Q_R - \rho C \mathrm{Q}_P \tag{14}$$

where $\mathrm{D}_h = \mathrm{D} + \mathrm{D}^*$ is the coefficient of hydrodynamic dispersion, D^* is the coefficient of molecular diffusion, and C_R is the salt mass fraction of recharged water.

Well-Posed Initial and Boundary Value Problem

Eq. 11, Darcy's law, predicts the specific discharge q, which can be used to eliminate that quantity in Eqs. 13 and 14. The equations of state given in the Constitutive Equations subsection tie the properties, such as density and viscosity, to the normalized salt mass fraction C. Hence, the two mass balance equations, Eqs. 13 and 14, contain two unknowns, h' and C. Given a domain, together with a set of well-posed initial and boundary conditions (see Bear[36] or Bear and Cheng[26] for a full description of initial and boundary conditions under various physical conditions), the system can be solved for these two unknowns.

Computer Models

With the exception of some simple geometries of saltwater intrusion, for which analytical solutions are available,[39] numerical solutions are needed for practical applications. Two of the most widely used computer codes are the SHARP[40,41] for sharp interface model and the SUTRA[42,43] for the density-dependent solute transport model; both are developed by the U.S. Geological Survey (USGS). However, like many complex engineering problems, there is no single code that can be most versatile, efficient, accurate, and stable at the same time, thus dominating the rest of the codes. Depending on the availability and reliability of input data, and the limited resources dedicated to modeling, different computer codes have been developed to offer a wide range of choices. A few of these codes are listed below. A comprehensive survey can be found in Sorek and Pinder[44] and Bear and Cheng.[26]

- SHARP (a quasi-three-dimensional, numerical finite difference method that simulates freshwater and saltwater flow separated by a sharp interface in layered coastal aquifer systems)[40,41] is an implicit finite-difference code that simulates layered aquifers with Dupuit assumption.
- MOCDENSE (a two-constituent solute transport model for groundwater with variable density)[45] and MOCDENSE3D[46] are, respectively, the two-dimensional and three-dimensional rendition of MOC (computer model of two-dimensional solute transport and dispersion in groundwater)[47] and MOC3D (three dimensional method-of-characteristics groundwater flow and transport model) [48] to allow for variable- density modeling.
- SUTRA (model for 2D or 3D saturated-unsaturated, variable-density groundwater flow, with solute or energy transport)[42,43] is a Galerkin finite-element code that solves groundwater flow and transport problems under saturated and unsaturated conditions.
- SEAWAT (computer program for simulation of three dimensional variable-density groundwater flow)[49] is a USGS code that combines MODFLOW[50] and MT3DMS[51] into a single computer program for the purpose of simulating saltwater intrusion. It is a finite- difference, Eulerian-Lagrangian code, in contrast to SUTRA, which is a finite-element code.
- CODESA-3D (coupled variable-density and saturation 3D model)[52] is0 a finite-element code, similar to SUTRA.
- FEMWATER (three-dimensional finite-element model of water flow through saturated-unsaturated media).[53] The code is available from the U.S. Environmental Protection Agency.

Combating Saltwater Intrusion

One of the most effective ways of combating saltwater intrusion is to regulate pumping activities. Generally speaking, the amount of groundwater extraction should not exceed that of natural replenishment. Optimization of pumping patterns to maximize the yield and minimize the extent of intrusion is a high-priority management issue. Recharge of natural surface water or reclaimed wastewater into aquifers can increase the freshwater outflow rate to push back saltwater wedge. A recharge near the coast can build a local freshwater mound that forms a barrier to protect the water table depression inland. Extraction of saltwater in an invaded saltwater wedge can also protect the freshwater behind, if a proper way can be found to dispose of the extracted saltwater. A similar method involving pumping simultaneously in the upper freshwater zone and the lower saltwater zone to prevent up-coning, known as double pumping, has been attempted. Using collector wells (horizontal wells) to skim the thin layer of freshwater floating on top of the saltwater wedge has been effectively used in water-poor countries such as Israel. Land reclamation has the added effect of pushing saltwater to the sea. Finally, in places where large freshwater springs flowing to the sea can be identified, physical barriers, such as solid walls or slurry curtains, can be used to intercept freshwater.

Planning and Management

Groundwater resource planning and management in coastal areas is similar to the traditional water resource planning in inland areas but with the additional complication of saltwater intrusion to eventually render portions of the coastal aquifer unusable as a source of drinking water. The recommended planning elements for managing coastal aquifers include the following:[54]

1. Collect and analyze existing data: Data like piezometric head, chlorine concentration, aquifer transmissivity, formation thickness, well location, screen depth, etc., need to be collected.
2. Develop an integrated database: The data need to be organized and integrated, typically using geographic information system software.
3. Identify saltwater intrusion problem and hypothesize intrusion scenarios, such as horizontally from the sea or vertically from the bottom brackish water.
4. Develop a groundwater simulation model using one of the above-mentioned computer codes and collected data.
5. Perform field studies for model validation: The collected existing data are likely to be insufficient, and the computer simulations are likely to be unreliable, lacking field validation. Hence, field studies are needed to fill the information gap. The geological, geophysical, and geochemical methods reviewed above can be used to conduct field studies.
6. Set planning objective: Once the extent and the time scale of the threat are understood, planning objectives, such as reducing pumping, increasing recharge, etc., should be set by consulting with the stakeholders.
7. Identify solutions and actions: One or more of the saltwater intrusion combating strategies can be recommended.
8. Evaluate management alternatives: Water resource management involves complex tradeoffs. The alternative actions need to be evaluated and selected using a multicriteria decision-making process.

Irrigation Systems: Water Conservation

Pai Wu, Javier
Barragan, and
Vince Bralts

Introduction

With the increasing consequence of limited water resources and the increasing need for environmental protection, drip irrigation will play an even more important role in the future. Drip irrigation systems can be used for many different types of agricultural crops, including fruit trees, vegetables, pastures, specialty crops such as sugarcane, ornamentals, golf course grasses, and high economic value crops grown in greenhouses. An understanding of drip irrigation systems, irrigation scheduling, crop response, and economic ramifications will encourage greater use of drip irrigation in future agricultural production.

Uniformity of Water Application and Design Considerations

The desired uniformity of water application and the specific crops to be grown guides the creation of drip irrigation systems. There are two types of drip irrigation uniformity: system uniformity and spatial uniformity in the field. The consistency of system distribution of water into the field describes the system uniformity. The spatial uniformity is the regularity of water distribution considering overlapping emitter flow and translocation of water in the soil. For drip irrigation systems designed for trees with large spacing, the system uniformity is equal to the water application uniformity in the field. For high-density plantings, the emitter spacing should be designed considering overlapped wetting patterns and the spatial uniformity in the field. The uniformity of a drip irrigation system depends primarily on the hydraulic design, but must also consider the manufacturer's variation, temperature effects, and potential emitter plugging. The effect of water temperature is generally negligible when using turbulent flow emitters. A combination of proper filtration and turbulent emitters can control emitter plugging. When grouping a number of emitters together as a unit, such as those designed to irrigate an individual plant's root system, the uniformity of water application with respect to the plant will improve.

Many expressions have been used to describe uniformity. The system uniformity, or emitter flow uniformity, can be expressed as the range or variation of water distribution in the field. This term was initially used for hydraulic design of drip irrigation systems given that the minimum and maximum emitter flows could be calculated and determined.[1] When more emitter flows are used or more samples are required for determining variation or spatial uniformity in the field, the Christiansen uniformity coefficient (UCC)[2] and coefficient of variation (CV), which is the ratio of standard deviation and the mean, are used. Each of the uniformity expressions are highly correlated with one other.

Hydraulic Design of Drip Irrigation Systems

Once selection of the type of drip irrigation emitter is complete, the hydraulic design can be made to achieve the expected uniformity of irrigation application.

The hydraulic design of a drip irrigation system involves designing both the submain and lateral lines. Early research in drip irrigation hydraulic design concentrated mainly on the single lateral line approach,[1,3,4] but in 1985 Bralts and Segerlind developed a method to design a submain unit. The hydraulic design is based on the energy relations in the drip tubing, the friction drop, and energy changes due to slopes in the field. Direct calculations of water pressures along a lateral line or in a submain unit are made by using an energy gradient line approach.[1] All emitter flows along a lateral line and in a submain can be determined based on their corresponding water pressures. Once the emitter flows are determined, the emitter flow variation, q_{var} is expressed by

$$q_{\mathrm{var}} = \frac{q_{\max} - q_{\min}}{q_{\max}} \tag{1}$$

where $q_{\max}$ is the maximum emitter flow and $q_{\min}$ is the minimum emitter flow. Based on these data, other uniformity parameters such as UCC and CV can also be determined. There is a strong correlation between any two of the three uniformity parameters in the hydraulic design of drip irrigation systems, thus any one of the uniformity parameters can be used as a design criterion. This correlation also justifies using the simple emitter flow variation q_{var} for hydraulic design. The emitter flow variation q_{var} is converted to the CV when it is combined with the manufacturer's variation of emitter flow.

The total emitter flow variation caused by both hydraulic and manufacturer's variation can be expressed by[5]

$$\mathrm{CV_{HM}} = \sqrt{\mathrm{CV_H^2}} + \mathrm{CV_M^2} \tag{2}$$

where $\mathrm{CV_{HM}}$ is the coefficient of variation of emitter flows caused by both hydraulic and manufacturer's variation; $\mathrm{CV_H}$ and $\mathrm{CV_M}$ are the coefficients of variation of emitter flows caused by hydraulic design and manufacturer's variation, respectively.

The design criterion for emitter flow variation q_{var} for drip irrigation design is arbitrarily set as 10.0%–20.0%, which is equivalent to a CV, from 0.033 to 0.076, or 3.0%–8.0%. Based on the research of last 30 years, the manufacturer's variation of turbulent emitters is maintained only in a range 3.0%–5.0%, expressed by CV. When this variation is combined with emitter flow variation caused by hydraulic design with a range 3.0%–8.0% in CV, the total variation determined by the equation above will be limited to a CV of less than 10.0%. This variation illustrates that the drip irrigation systems are designed to achieve high uniformity and irrigation application efficiency.

Economic return can also be the basis of design criteria for drip irrigation. A new set of design criteria for drip irrigation was developed,[6] based on achieving an expected economic return with various water resources and environmental considerations (Table 1).

TABLE 1 Design Criteria for Uniformity of Drip Irrigation System Design

Design Consideration	CV (%)	UCC (%)
Water is abundant and no environmental	30–20	75–85
pollution problems	20–10	80–90
Water is abundant but with environmental protection considerations	25–15	80–90
Limited water resources but with no environmental pollution problems	15–5	85–95
Considerations for both water conservation and environmental protection		

Drip Irrigation for Optimal Return, Water Conservation, and Environmental Protection

When the uniformity of a drip irrigation system is designed with a UCC of 70.0%, 30.0% or less in CV, the irrigation application is expressed as a straight-line distribution,[7,8] as shown in Figure 1. This figure was plotted using percent of area (PA) against a relative irrigation depth, *X*, which is the ratio of required irrigation depth to mean irrigation application. The straight-line distribution in the dimensionless plot can be specified by a minimum value, *a*, a maximum value, $(a+b)$, in the *X*-scale and a slope *b*, where *b* specifies the uniformity of water application.[9]

When a drip irrigation system is designed with fixed uniformity, it is possible to determine the sloped straight line with known value of *a* and *b*. A value (*X*) can then be selected between value *a* and $(a+b)$ and plotted (Figure 1). The triangle formed above the horizontal line (*X*) results in an irrigation deficit and yield reduction. The triangle below the horizontal line results in over-irrigation and deep seepage.

An important irrigation scheduling parameter, the relative irrigation depth, (*X*) indicates how much irrigation water is applied. The effectiveness of drip irrigation is shown not only by the high uniformity of the drip irrigation system, but also by the irrigation requirement and the strategy of irrigation scheduling. As illustrated in Figure 1, the irrigation scheduling parameter (*X*) affects the areas of overirrigation and water deficit conditions in the field and is directly related to the economic return. Practically

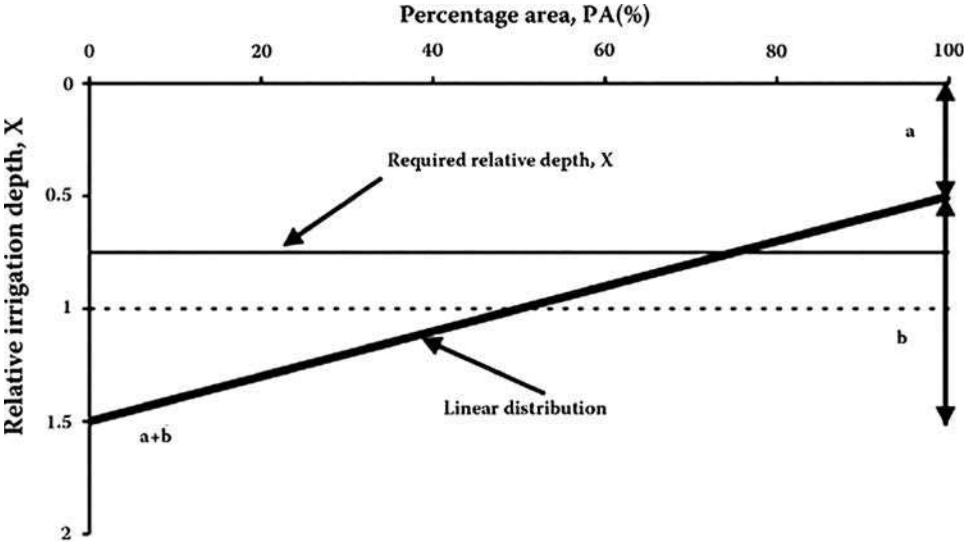

FIGURE 1 A linear water application model for drip irrigation.

speaking, the X parameter is selected in a range from a to $(a+b)$, as shown in Figure 1. Three typical irrigation schedules can be expressed by X and are as follows:

$X=a$	This schedule is a conventional irrigation schedule, which is based on the minimum emitter or minimum water application. The field is fully irrigated and whole field is over-irrigated except the point of minimum irrigation application.
$X=X_0$	For an optimal return there is a value of X for the irrigation scheduling parameter between a and (a+b).
$X=(a+b)$	This irrigation schedule is based on the maximum emitter flow or maximum irrigation application. The whole field is under deficit condition except the point of maximum water application. There is no deep percolation.

An optimal irrigation schedule for maximum economic return was determined[9] based on cost of water, price of the yield, and damage such as environmental pollution and groundwater contamination caused by over irrigation. Different irrigation strategies require different amounts of water application. Water conservation and environmental protection are realized by comparing any two of the irrigation strategies.[10]

Conclusion

Drip irrigation is an irrigation method that can distribute irrigation water uniformly and directly into the root zone of crops. It is one of the most efficient irrigation methods and can be designed and scheduled to meet the water requirement of crop and produce maximum yield in the field.

When the drip irrigation system is designed with high uniformity, the slope b of the straight line of water application function (Figure 1) can be controlled to achieve the desired variation. In this case the conventional irrigation schedule, $X=a$, optimal irrigation schedule, X_0, which is a location between a and $(a+b)$, and the irrigation schedule for environmental protection, $X=a+b$, are in close proximity. This closeness shows that the drip irrigation system can achieve optimal economic return, water conservation, and environmental protection.

Irrigation: Erosion

David L. Bjorneberg

Introduction

Irrigation is vital to food production in the world. However, irrigation-induced soil erosion reduces productivity of irrigated land and can cause off-site water quality problems. Surface irrigation utilizes the soil to distribute water through the field. Water flowing over soil inherently detaches and transports sediment. Sprinkler and drip irrigation distribute water through fields in pipes, eliminating erosion from water distribution, but erosion can still occur if water is applied faster than it can infiltrate into the soil. This entry will briefly discuss the importance of irrigation to global food production and then discuss the important factors affecting soil erosion for surface-and sprinkler-irrigated land. Much of the information will focus on the United States, with international information included when possible.

Importance of Irrigation

Irrigated agriculture contributes a disproportionate amount to global food production. The most cited statistics indicate that irrigated cropland produces about one-third of the world's crop production on only 16% of the cropland that is irrigated.[1] In the United States, farms with all cropland irrigated account for only 8% of the total cropland and about half of the total irrigated land.[2] These farms produce 33% of the market value of crops and 12% of the market value of livestock. Over half of the crop value (55%) is produced on farms with some irrigated land, and these farms account for only 26% of the total cropland in the United States.[3] In some areas, irrigation provides essentially all of the water necessary for crop growth. In other areas, irrigation provides only a small portion of the total crop water requirement but reduces the potential for water stress during critical periods.

While irrigation is critical to global food production, applying water to soil can cause erosion. This is especially true with surface irrigation, where the soil conveys and distributes water through a field by gravity. Sprinkler irrigation and microirrigation use pipes to distribute water through the field. Surface irrigation is generally thought to cause more erosion than sprinkler irrigation; however, erosion can occur any time water flows over soil. Water can be applied with sprinkler irrigation so no runoff occurs, and therefore, no erosion will occur. However, there are situations, especially with moving irrigation systems like center pivots, where water is applied faster than it can infiltrate into the soil, resulting in ponding and, possibly, runoff.

Unique Aspects of Irrigation Erosion

The factors affecting soil erosion from irrigation are the same as rainfall. Water detaches and transports sediment in both situations. However, there are some unique differences in how the factors occur with irrigation.[4] For example, rainfall occurs relatively uniformly over an entire field, whereas irrigation is seldom applied to an entire field at the same time. Irrigation is a controlled procedure where water is applied to a specific field, or portion of a field, at a specific time. This can affect the hydrology of the erosion processes on surface- and sprinkler-irrigated fields. A center pivot, for example, is essentially a moving storm that covers only 1%–2% of the field at any given time. This results in unique runoff conditions where water can do the following: 1) flow parallel to the lateral under similar conditions as rainfall; 2) flow from wet soil onto dry soil if the lateral is moving downhill; or 3) flow onto wet soil if the lateral is moving uphill.

In surface irrigation, water flow rate decreases with distance during surface irrigation as water infiltrates. Furrow flow rates also increase with time as infiltration rate decreases (Figure 1). This creates a condition where sediment can be detached on the upper end of the field and deposited on the lower end. Trout[4] documented erosion rates on the upper end of a field that were 6 to 20 times greater than the field-average erosion rates. Figure 2 shows eroded furrows on the upper end of a field after one furrow irrigation. During rainfall, raindrops wet the soil surface and detach soil particles. As runoff begins, rills form in wet soil. In contrast, irrigation furrows are formed prior to irrigation, and water flows onto initially dry soil. Furrows with initially dry soil have greater soil erosion than furrows that were prewet immediately before furrow irrigation.[5] Irrigation water flowing in furrows is not exposed to falling raindrops that can increase sediment detachment and decrease deposition.

The quality of irrigation water can vary dramatically among water sources, or even within an irrigation tract if drainage water is reused. Conversely, electrolyte concentration of rainfall is quite consistent. Electrolyte concentration in irrigation water affects erosion for both surface and sprinkler irrigation. Furrow-irrigation erosion was greater on a silt loam when irrigation water had low electrical conductivity (EC$=$0.7 dS m^{-1}) and high sodium adsorption ratio (SAR$=$9.1) compared with low EC (0.5 dS m^{-1}) and low SAR (0.9), high EC (2.1 dS m^{-1}) and low SAR (0.5), and high EC (1.7 dS m^{-1}) and high SAR (9.3).[6] Soil erosion was also greater with low-EC water in laboratory and field rainfall simulation studies.[7,8] Lower electrolyte concentrations in water cause greater dispersion of soil particles, which tends to reduce infiltration and increase soil loss.[9]

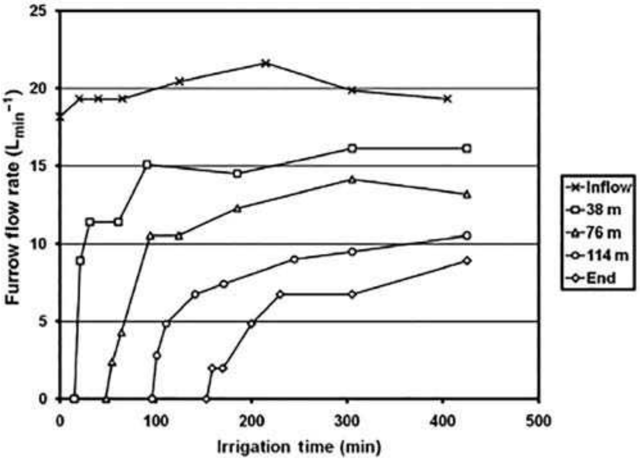

FIGURE 1 Furrow flow rate with time at five points in a 150 m–long furrow.

FIGURE 2 Eroded furrows on the upper end of a furrow-irrigated field in Idaho with approximately 1% slope.

Surface-Irrigation Erosion

Surface irrigation continues to be the most common method of irrigation in the world. The four countries with the most irrigated land are India (60.8 Mha), China (57.8 Mha), United States (22.4 Mha), and Pakistan (19.6 Mha).[10] These four countries account for 58% of the irrigated area in the world. All other countries have less than 10 Mha of irrigated land.[10] According to the country fact sheets on the Food and Agriculture Organization's Aquastat Web site,[11] surface irrigation is used on 97% of the irrigated land in India, 94% in China, 44% in the United States, and 100% in Pakistan.

Koluvek et al.[12] provided a good overview of soil erosion from irrigation in the United States. Unfortunately, this information has not been updated, and similar information is not readily available from other countries, so it is difficult to track erosion trends on irrigated lands. Some early studies documented erosion rates as great as 145 Mg ha^{-1} in 1 h[13] and 40 Mg ha^{-1} in 30 min.[14] While these rates represent extreme conditions that can occur, not typical season-long soil loss rates, these studies indicate the potential severity of the problem. One study measured annual soil losses of 1 to 141 Mg ha^{-1} from 33 fields with silt loam soils.[15] The greatest soil loss occurred on a sugar beet (*Beta vulgaris* L.) field with 4% slope. The authors noted that erosion increased sharply when field slope was greater than 1%. Close-growing crops like alfalfa *(Medicago sativa* L.) or wheat (*Triticum aestivum* L.) on fields with 1% slope had annual soil loss of less than 1 Mg ha^{-1}. A recent study in the same area documented that average soil loss from an 80,000 ha irrigated watershed decreased from 450 kg ha^{-1} in 1970 to less than 50 kg ha^{-1} in 2005.[16] This watershed was approximately 90% furrow irrigated in 1970 and 60% furrow irrigated in 2005. Another study measured daily sediment loads of 0.4 kg ha^{-1} in a watershed with no furrow irrigation compared to 19 kg ha^{-1} in a watershed with 58% of the cropland furrow irrigated.[17] Irrigation method explained 67% of the variation in soil loss measured in April and May in these nine watersheds.

The main factors affecting surface-irrigation erosion are soil type, field slope and flow rate. Soil erosion is typically not a concern where field slopes are less than 0.5% (Figure 3). However, erosion tends to increase exponentially for increasing inflow rate and field slope, with an exponent between 1 and 3 for flow rate, and between 2 and 3 for slope.[12,18,19,20] Increasing inflow rate 20% increased erosion 30% and 70% on the upper quarter of two fields.[4] Increasing inflow rate another 20% increased erosion 50% and 100%, which indicates that the exponent between erosion and flow rate was between 2 and 3.[4] Figure 4 shows soil loss from 10 furrows during a 4 h irrigation at Kimberly, Idaho, with inflow rates randomly set for each furrow.

FIGURE 3 Level furrow irrigation in Arizona. (Photo by Jeff Vanuga, USDA Natural Resources Conservation Service [NRCSAZ02037]).

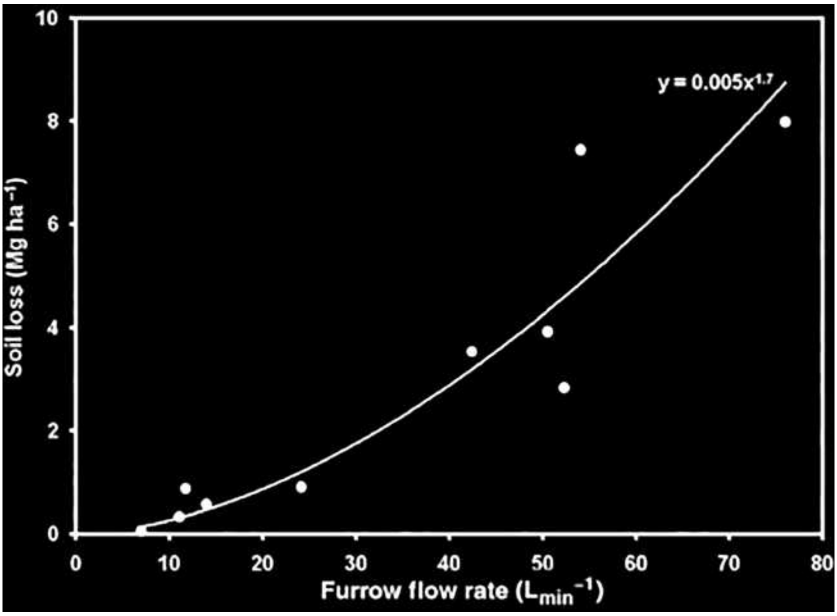

FIGURE 4 Relationship between furrow flow rate and soil loss for 10 and 30 m-long furrows with randomly set inflow rates.

Reducing field slope by grading the land is a costly practice that is not feasible in most situations compared with alternatives like installing a sprinkler-irrigation system. Reducing inflow rate is a good practice as long as the water advances down the field fast enough to uniformly irrigate the field. Slow water advance rates from low inflow rates cause overirrigation on the inflow end of the field and underirrigation on the lower end of the field due to differences in infiltration opportunity time. This results in poor distribution uniformity but little runoff. Soil loss decreases as distribution uniformity decreases.[20] An excellent practice for reducing irrigation erosion without affecting irrigation uniformity is applying small amounts of polyacrylamide (PAM) with irrigation water.[21,22] Dissolving 10 mg L^{-1} of high-molecular-weight, anionic PAM in furrow-irrigation inflow can reduce soil loss 60%–99% compared with untreated furrows. Other technologies like filter strips and sediment ponds on the lower end of the field remove sediment from the water rather than reducing erosion from occurring on the field.

Sprinkler-Irrigation Erosion

Ideally, sprinkler-irrigation systems are designed and managed to have all applied water infiltrate into the soil where it was applied. When all water infiltrates, there is no runoff or soil erosion. Solid-set (sprinklers located in the same position for the entire irrigation season) or set-move (sprinklers remaining in a location for 12 to 24 h, then moved to the next set) irrigation systems usually apply water at a low rate (e.g., 3 to 6 mm h^{-1}), so irrigation application rate does not exceed the soil infiltration rate and no soil erosion occurs. Moving irrigation systems, like center pivots, traveling guns, and lateral-move systems, often apply water faster than the infiltration rate. This occurs because the irrigation system must apply enough water as it moves across the field to meet crop water needs until the next time it irrigates that portion of the field. For example, a center pivot operating at 60 h per revolution needs to apply 20 mm per revolution to meet an 8 mm d^{-1} crop water requirement. The irrigation application rate increases with distance from the center pivot because the lateral irrigates more land as the radial distance from the pivot point increases.[23] Near the pivot point, the mean application rate could be about 4 mm h^{-1} (assuming 15 m wetting diameter). Near the end of the pivot, about 400 m, the mean application rate would be about 60 mm h^{-1}. An important fact about moving irrigation systems is that the application rate is a function of irrigation system capacity, or system flow rate. Operating the system faster decreases only the application depth, not the application rate. For example, the same center pivot operating at 48 h per revolution will apply 16 mm of water at the same application rates.

Center-pivot irrigation is the most popular type of irrigation system in the United States. According to the United States Department of Agriculture (USDA) National Agricultural Statistics Service, center-pivot irrigation was used on 47% of the irrigated land and 83% of the sprinkler-irrigated land in 2008, an increase from 25% of the irrigated land in 1988.[2] More land was irrigated by center pivots in the United States in 2008 (10.4 Mha) than all types of gravity irrigation combined (8.9 Mha). As center pivots gained popularity, researchers began to consider runoff potential, mainly to efficiently apply irrigation water. Most sprinkler-irrigation studies were not concerned with soil erosion, probably because the effects of sprinkler-irrigation erosion tend to occur within the field rather than off site.

A 1969 study evaluated center-pivot runoff from a theoretical perspective and showed the importance of modifying infiltration parameters, determined from pond infiltration tests, for the low initial application rate that occurs with moving irrigation systems.[23] Their theoretical evaluation showed that 0%–40% of the applied water could run off with typical operating conditions. A 1971 field study documented 11%–41% runoff on four center pivots operated by farmers.[24] Runoff with center-pivot irrigation became a more important issue as low-pressure sprinklers began to be used to reduce energy costs. Early types of low-pressure sprinklers applied water to a smaller area, which increased application rates and potential runoff.[25] Low-pressure sprinklers (40 and 100 Pa) averaged 69 or 70 mm of runoff compared with 8 to 10 mm of runoff for high-pressure sprinklers (170 and 345 Pa) during a 4-year field study.[26] Reducing pressure from 380 to 140 Pa increased irrigation runoff 30% for a center pivot with impact sprinklers.[27] Peak application rate at the outer end of a center pivot would be about 30 mm h^{-1} for a high-pressure impact sprinkler with 20 m wetted radius and more than 100 mm h^{-1} for a low-pressure spray sprinkler with 5 m wetted radius.[25] Figure 5 shows two sprinkler application rate curves with time and an infiltration rate curve. The volume of water applied when application rate exceeds infiltration is potential runoff. All of this water may not run off if some is ponded or stored on the soil surface.

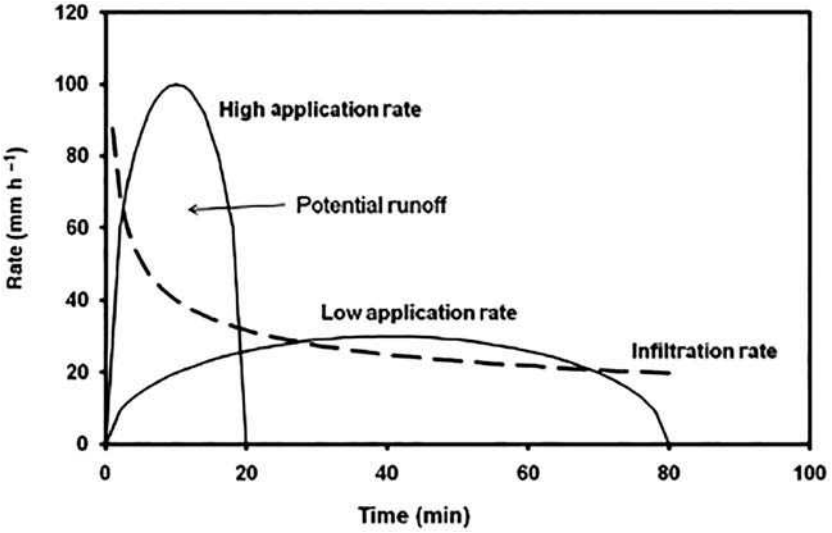

FIGURE 5 Example of soil infiltration rate and sprinkler application rates for high- and low-application-rate sprinklers. Runoff potentially occurs when sprinkler application rate exceeds the soil infiltration rate.

Many types of sprinklers are now available for center pivots. Some apply water in defined streams with a wetted diameter over 20 m with nozzle pressure of 200 Pa or less. Others distribute water evenly over the wetted area with various combinations of droplet sizes. Various sprinkler designs are the result of manufacturers trying to reduce the kinetic energy applied to the soil during irrigation, so all applied water can infiltrate. Kincaid[28] developed a model in 1996 to estimate kinetic energy per unit drop volume for common sprinkler types. Calculating area-weighted kinetic energies per unit drop volume for individual sprinklers showed that sprinklers with the smallest drop size distributions had the lowest kinetic energy. Sprinklers with smaller sized drops tend to have smaller wetted diameters because small drops cannot travel as far as large drops. Larger drops travel farther and therefore cover a greater portion of the circular wetted area for an individual sprinkler. A smaller wetted diameter also results in a higher application rate when sprinkler application patterns are overlapped like occurs on a center pivot. An alternative method for characterizing sprinkler kinetic energy is calculating the rate that energy is applied to the soil, or specific power, as a function of radial distance from the sprinkler.[29] The specific power distribution is energy per drop volume multiplied by the application rate and can be overlapped, like water application rate, to develop a composite specific power profile for a sprinkler system. A flat-plate sprinkler with small-sized drops had higher average composite specific power than two other sprinklers with larger drop sizes and larger wetted diameter.[29] Recent field research on small plots showed that soil erosion was significantly greater with the flat-plate spray sprinkler compared with the two other sprinklers with larger drop size distributions.[30] This directly contradicts previous conventional thinking that sprinklers with smaller drops caused less erosion.

The most effective way to control sprinkler-irrigation erosion is to eliminate runoff, which also increases water application efficiency. One way to control runoff is to increase water storage on the soil surface.[25] Reservoir tillage is a practice that forms small pits in the soil to store water. Each pit can hold 5 to 10 L of water.[31] This is especially important on sloping fields. Reservoir tillage reduced runoff 68% and soil erosion 92% during a 50 mm simulated irrigation on a field with 10% slope.[32] Runoff was not different when field slope was only 1%. Increasing surface residue also decreases sprinkler-irrigation runoff similar to rainfall runoff.[27] Disking corn stubble prior to planting, which left approximately 30% of the soil surface covered with crop residue, reduced runoff to 17% of applied irrigation compared with

25% runoff for moldboard plow plots in a 4 years study.[33] In addition to reducing runoff, disking also reduced soil loss about 50% compared with moldboard plowing.

Applying PAM with sprinkler irrigation can also improve infiltration, which reduces runoff and soil erosion. Field studies have shown that erosion decreased under moving sprinkler systems when 20 kg PAM ha^{-1} was applied to the soil before irrigation.[34,35] Lower PAM application rates can be effective when PAM is applied with irrigation water rather than sprayed directly on the soil surface. In laboratory studies with 2 m^2 soil boxes, applying 2 to 4 kg PAM ha^{-1} at 10 to 20 mg L^{-1} with sprinkler-irrigation water reduced soil erosion 75% compared with untreated soil, but these benefits decreased with subsequent irrigations without PAM.[36] In a similar laboratory study, applying 1 kg PAM ha^{-1} with three consecutive irrigations reduced cumulative runoff 50% compared with untreated soil, while applying 3 kg PAM ha^{-1} with one irrigation only reduced runoff by 35%.[37] Field tests in the United States showed that applying PAM with four irrigations (2 to 3 kg ha^{-1} total applied) significantly reduced soil erosion from 52 and 34 kg ha^{-1} for the control to 21 and 5 kg ha^{-1} for the PAM treatment during the 2 years of the study.[38] Soil erosion was not significantly different for a similar field study in Portugal with lower PAM application rates (0.3 kg ha^{-1}).[38]

Conclusions

Irrigation is vital to world food production, but soil erosion during irrigation threatens the long-term productivity of irrigation. Soil erosion is generally greater from surface irrigation because water flows over the soil during irrigation. Surface-irrigation management is often a tradeoff between irrigation uniformity and erosion. High flow rates can cause erosion; low flow rates can cause poor irrigation uniformity. Ideally, sprinkler irrigation should not have any runoff; however, moving irrigation systems, like center pivots, often apply water faster than it can infiltrate into the soil. Current research is attempting to quantify runoff and erosion potential for various types of center-pivot sprinklers so manufacturers can improve sprinkler designs. Irrigation can be managed to minimize erosion and maintain productivity.

Irrigation: River Flow Impact

Robert W. Hill and
Ivan A. Walter

Introduction

In hydrologic studies it is common engineering practice to quantify the impact upon the stream(s) from which the irrigation water is diverted. The impact upon the stream is actually of two kinds: 1) diversions that decrease the streamflow and 2) return flows that increase the streamflow. The engineering term used to describe the overall impact is "streamflow depletion" which means the net reduction in streamflow resulting from diversion to irrigation uses. Actual stream depletions are a function of many factors including the amount and timing of diversions, the type of diversion structure (well vs. ditch), crops grown, soil type, depth to groundwater, irrigation method, irrigation efficiency, properties of the alluvial aquifer, area irrigated, and evapotranspiration of precipitation, groundwater, and irrigation water.

Depletion

Depletion, in this context, is the consumptive abstraction of water from the hydrologic system as a result of irrigation. It is in addition to consumptive water use that would have occurred in the unmodified natural situation. As an example, waters of the Bear River Basin of Southern Idaho, Northern Utah, and Western Wyoming, because it is an interstate system, are administered by a federally established commission under the authority of the Bear River Compact.[1] Depletion is the basis, in the compact, for allocating Bear River water use among the three states. It is defined by a "Commission Approved Procedure" which includes consideration of land use and incorporates an equation for estimating depletion based on evapotranspiration. In a study for the commission, Hill[5] defined crop depletion as

$$\mathrm{Dpl} = \mathrm{Et} - \mathrm{Smco} - \mathrm{Pef} \tag{1}$$

where Dpl is estimated depletion for a given site or sub-basin; Et is calculated crop water use; SMco is moisture which is "carried over" from the previous non-growing season (October 1–April 30) as stored soil water in the root zone available for crop water use subsequent to May 1; and Pef is an estimate of that portion of precipitation measured at an NWS station during May–September, which could be used by crops.

The carry-over soil moisture (SMco) was estimated by assuming that 67% of adjusted precipitation from October through April could be stored in the root zone. If this exceeded 75% of the available soil water-holding capacity of the average root zone in the sub-basin, the excess was considered as lost to drainage or runoff and not available for crop use. Growing season precipitation was considered to be 80% effective in contributing to crop water use. The effectiveness factor of 80% allowed for precipitation depths throughout a sub-basin that might differ from NWS rain-gage amounts. It also included a reduction for mismatches in timing between rainfall events and irrigation scheduling.

Hydrograph Modification

Diversion of significant amounts of water from rivers and streams for irrigation and subsequent return flows alters the shape and timing of downstream hydrographs. In watersheds where mountain snowmelt provides the irrigation supply, such as in the Western United States, diversion during the spring runoff attenuates the peak flow rate while later return flows extend the flow duration into late summer and early fall.

Reservoir Storage

Storage of water in reservoirs can significantly modify the natural stream hydrograph depending on the timing and quantity of the storage right. Irrigators with junior rights may only be able to store during time periods with low irrigation demand, such as during the winter, or during peak flow periods. Reductions of stream flow during the winter time may have considerable impact on downstream instream flows. Whereas, storage during periods of peak runoff may not affect minimum in-stream flow needs, but could deposit considerable amounts of sediment in the reservoir.

Irrigation Return Flows

Irrigation return flows are comprised of surface runoff and/or subsurface drainage that becomes available for subsequent rediversion from either a surface stream or a groundwater aquifer downstream (hydrologically) of the initial use. Reusable return flow can be estimated as irrigation diversion minus crop related depletions minus additional abstractions. Additional abstractions include incidental consumptive use from water surfaces as in open drains, along with non-crop vegetation. The timing of return flow varies from nearly instantaneous (recaptured tailwater) to delays of weeks and months or perhaps longer with deep percolation subsurface drainage. In a hydrologic model study of the Bear River Basin[4] delay times between diversion and subsequent appearance of the return flow at the next downstream river gage varied from 1.5 months to as long as 6 months. The delay appeared to be related to sub-basin shape and size.

Irrigation Methods

Four general irrigation methods are used: surface, subsurface, sprinkler, and trickle (also known as low flow or drip). Surface methods include wild or controlled flooding, furrow, border-strip, and ponded water (basin, paddy, or low-head bubbler). Hand move, wheel move, and center pivot are examples of sprinkler irrigation. Trickle irrigation includes point source emitters, microspray, bubbler, and line-source drip tape (above or below ground). Whereas the efficiency of surface irrigation is dependent upon the skills and experience of the irrigator, the performance of trickle and sprinkler systems is more dependent on the design. Generally, the more control that the system design (hardware) has on the irrigation system performance, the higher the application efficiency (E_a) can be. Thus, typical wheel move sprinklers have higher E_a values than surface irrigation, but lower values than for center pivots or trickle, assuming better than average management practices for each method.

The impact on river flows can be quite different among the various irrigation methods. The nature of furrow and border surface irrigation generally produces tail water runoff, which can be immediately recaptured and reused, as well as deep percolation, which may not be available for reuse until after a period of time. Tailwater is essentially eliminated and deep percolation reduced with sprinklers (Figure 1) compared to conventional surface irrigation. Whereas, with drip methods, deep percolation can be further reduced. The reduction of deep percolation implies increased salt concentration in the root zone leachate, but, perhaps significant reduction in salt pick-up potential from geologic conditions.

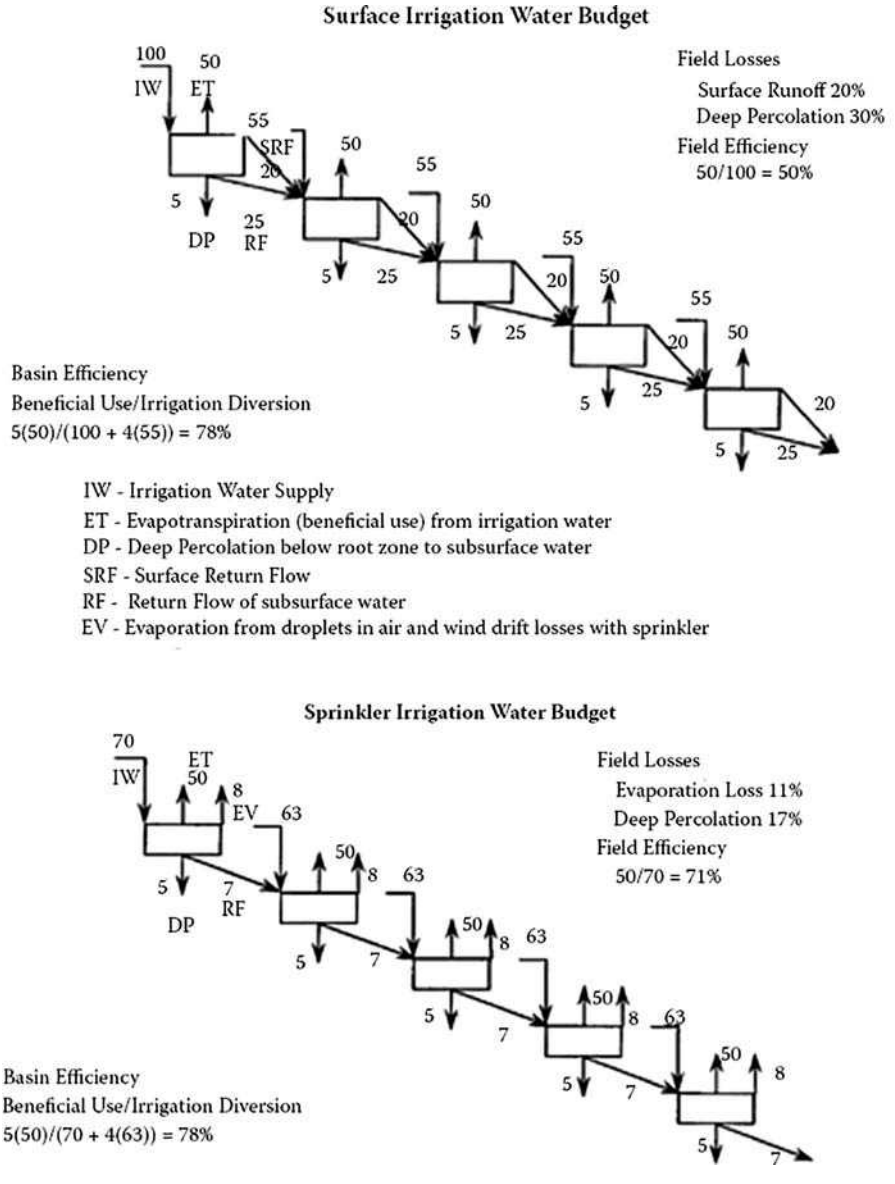

FIGURE 1 Comparison of basin efficiencies between surface and sprinkler irrigation methods with four return flow reuse cycles.

Irrigation Efficiencies

Although a full discussion of the several variations of irrigation efficiency is beyond the scope herein, two terms will be defined and discussed. More complete discussions relating to irrigation efficiencies and water requirements are given elsewhere.[6–9,13] Keller and Bliesner[9] give a particularly thorough presentation of distribution uniformity and efficiencies.

Application efficiency (E_a):

$$E_a = 100 \times \frac{\text{Volume of water stored in the root zone}\left(V_s\right)}{\text{Volume of water delivered in the farm or field}\left(V_f\right)}.$$

Distribution uniformity:

The distribution uniformity is a measure of how evenly the on-farm irrigation system distributes the water across the field. The definition of DU is:

$$\text{DU} = 100 \times \frac{\text{Average of the lowest 25\% of infiltrated water depth}}{\text{Average of all infiltrated water depths across the field}}.$$

On-farm or field application efficiencies can be affected by the distribution uniformity and vary widely for both surface and sprinkle irrigation methods. This is largely due to difference in management practices, appropriateness of design in matching the site conditions (slope, soils, and wind), and the degree of maintenance. In addition, for a given system uniformity, the higher the proportion of the field that is adequately irrigated (i.e., infiltrated water refills the soil water deficit) the lower will be the application efficiency. This is due to greater deep percolation losses in the overirrigated portions of the distribution pattern. Some values determined in recent Utah field evaluations are:

	Observed		
Method	High (%)	Low (%)	Typical (%)
	Surface irrigation		
E_a	72	24	50
Tailwater	55	5	20
Deep percolation	65	20	30
	Sprinkler irrigation		
E_a	84	52	70
Evaporation	45	8	12
Deep percolation	37	8	18

The E_a for a particular field may vary greatly during the season. Cultivation practices, microconsolidation of the soil surface and vegetation will alter surface irrigation efficiency both up and down from the seasonal average. Seasonal and diurnal variations in wind, humidity, and temperature will also affect sprinkle application efficiencies.

Basin Irrigation Efficiency

The actual irrigation efficiency realized for several successive downstream fields where capture and reuse of return flows is experienced is higher than the E_a of an individual field. This notion of "Basin Irrigation Efficiency"[12,13] is illustrated in Figure 1. This simple example comparison of surface and sprinkle methods assumes four reuse cycles. In each of the five "fields" Et is assumed to be 50 units. The surface runoff is captured for reuse on the next field. All of the irrigation-related evaporation is assumed "lost" as well as 5 units of deep percolation. After the fifth field, all surface and subsurface flows are lost. The basin efficiency for surface is 78%, which is the sameas for sprinkle. The surface irrigation basin efficiency increase is dependent upon the surface return flow reuse, which is 20 units in this example. However, the depletion is greater for sprinkler due to the extra evaporation. In a Colorado field study, Walter and Altenhofen[11] found a progressive increase in irrigation efficiencies from field (average E_a of 45%), to farm, to efficiency of ditch or sectors (average of 83%). This was due to the reuse of tailwater (10%–20% of delivery) and deep percolation (46% of delivery).

Environmental Concerns

The process of evapotranspiration, or crop water use, extracts pure water from the soil water reservoir, which leaves behind the dissolved solids (salts) contained in the applied irrigation water. The "evapo-concentration" of salts is an inevitable result of irrigation for crop production. As stated by Bishop and Peterson:[2]

…Other uses add something to the water, but irrigation basically takes some of the water away, concentrating the residual salts. Irrigation may also add substances by leaching natural salts or other materials from the soil or washing them from the surface. Irrigation return flow is a process by which the concentrated salts and other substances are conveyed from agricultural lands to the common stream or the underground water supply…

Water Quality Implications for Agriculture

Irrigated agriculture is dependent upon adequate, reasonably good quality water supplies. As the level of salt increases in an irrigation source, the quality of water for plant growth decreases. Since all irrigation waters contain a mixture of natural salt, irrigated soils will contain a similar mix to that in the applied water, but generally at a higher concentration. This necessitates applying extra irrigation water, or taking advantage of non-growing season precipitation, to leach the salts below the root zone.

Salt Loading Pick-Up

Water percolating below the root zone or leaking from canals and ditches may "pick-up" additional salts from mineral weathering or from salt-bearing geologic formations (such as the Mancos shale of Western Colorado and Eastern Utah). This salt pick-up will increase the salt load of return flows and consequently increase the salinity of receiving waters.

In the Colorado River Basin in the United States and Mexico salinity is a concern because of its adverse effects on agricultural, municipal, and industrial users.[10] The Salinity Control Act of 1974 (Public Law 93–320) created the Colorado River Basin Salinity Control Program to develop projects to reduce salt loading to the Colorado River. Salinity control projects include lining open canals and laterals (or replacing with pipe) and installing sprinklers in place of surface irrigation for the purpose of decreasing salt loading caused by canal leakage and irrigated crop deep percolation. Recently selenium in irrigation return flow has become a concern[3] and may also be reduced by salinity reduction projects.

In-Stream Flow Requirements

Diversions in some reaches in some Western United States streams are "dried up" immediately downstream of diversion structures during times of peak irrigation demand. This condition eliminates any use of the reach for fisheries and other uses which depend on in-stream flow. In some instances, negotiated agreements with senior water rights users have allowed for bypass of minimal amounts of water to sustain the fishery or habitat, and for control of tail-water runoff to reduce agricultural related chemicals in the receiving water.

Irrigation: Saline Water

B.A. Stewart

Introduction

As water becomes more limited, there is increasing use of saline waters for irrigation that were previously considered unsuitable. Rhoades, Kandiah, and Marshali[1] classified saline waters as shown in Table 1. Electrical conductivity is a convenient and practical method for classifying saline waters because there is a direct relationship between the salt content of the water and the conductance of an electrical current through water containing salts. Electrical conductivity values are expressed in siemens (S) at a standard temperature of 25°C.

Most waters used for irrigation have electrical conductivities less than 2 dS m^{-1}.[1] When water higher than this level is used, there can be serious negative effects on both plants and soils. As salinity in the root zone increases, the osmotic potential of the soil solution decreases and therefore reduces the availability of water to plants. At some point, the concentration of salts in the root zone can become so great that water will actually move from the plant cells to the root zone because of the osmotic effect. Salts containing ions such as boron, chloride, and sodium can also be toxic to plants when accumulated in large quantities in the leaves. The extent that plant growth is affected by saline water is dependent on the crop species. Some plants, such as barley and cotton, are much more resistant to salt than crops like beans. Rhoades, Kandiah, and Marshali[1] list the tolerance levels of a wide range of fiber, grain, and special crops; grasses and forage crops; vegetable and fruit crops; woody crops; and ornamental shrubs, trees, and ground cover. Soils are also negatively impacted by salt, particularly sodium salts. Sodium ions tend to disperse clay particles and this has deleterious effects on infiltration rate, structure, and other soil physical properties.

Irrigating with Saline Waters

Water limitations and the need to increase food and fiber production in many parts of the world have resulted in the use of water for irrigation containing increasing levels of salts. The United States, Israel, Tunisia, India, and Egypt have been particularly active in irrigating with saline waters.[1] Rhoades, Kandiah, and Marshali[1] published an extensive paper on the use of saline waters for crop production and it is a valuable guide for anyone interested in the subject. They reported that many drainage waters, including shallow ground waters underlying irrigated lands, fall in the range of 2 dS m^{-1} to 10 dS m^{-1}

TABLE 1 Classification of Saline Waters

Water Class	Electrical Conductivity (dSm–1)	Salt Concentration (mg L–1)	Type of Water
Non-saline	<0.7	<500	Drinking and irrigation
Slightly saline	0.7–2	500–1500	Irrigation
Moderately saline	2–10	1500–7000	Primary drainage and groundwater
Highly saline	10–25	7000–15,000	Secondary drainage and groundwater
Very highly saline	25–45	15,000–35,000	Very saline groundwater
Brine	>45	>45,000	Seawater

in electrical conductivity. Such waters are in ample supply in many developed irrigated lands and have good potential even though they are often discharged to better quality surface waters or to waste outlets. These waters can be successfully used in many cases with proper management. Reuse of second-generation drainage waters with electrical conductivity values of 10 dS m^{-1} to 25 dS m^{-1} is also sometimes possible but to a much lesser degree because the crops that can be grown with these waters are atypical and much less experience exists upon which to base management recommendations.

Miller and Gardiner[2] suggest that successful irrigation with saline water requires three principles. First, the soil should be maintained near field capacity to keep the salt concentration as low as possible. Second, application techniques should avoid any wetting of the foliage. Third, salts accumulating in the soil should be periodically leached. To accomplish these objectives, Miller and Gardiner[2] recommend the following general rules:

- Apply water at or below soil surface. Sprinklers should be used only if they avoid wilting the foliage (such as sprinkling before plant emergence or below-canopy to avoid salt-burn damage).
- Keep water additions almost continuous, but at or below field capacity so that most flow is unsaturated. This maintains adequate aeration.
- Enough water should be added to keep salts moving downward, thus avoiding salt buildup in the root zone.

Miller and Gardiner[2] stress that these rules are difficult to meet and are best satisfied by some form of drip irrigation. They also state that due to the need for high water levels and because of high sodium ratios that sandy soils are more adaptable to the use of saline waters than soils containing high percentages of silt and clay particles.

Rhoades, Kandiah, and Marshali[1] also list specific management practices for producing crops with salty waters. Their list includes the following guidelines:

- Selection of crops or crop varieties that will produce satisfactory yields under the existing or predicted conditions of salinity or sodicity.
- Special planting procedures that minimize or compensate for salt accumulation in the vicinity of the seed.
- Irrigation to maintain a relatively high level of soil moisture and to achieve periodic leaching of the soil.
- Use of land preparation to increase the uniformity of water distribution and infiltration, leaching and removal of salinity.
- Special treatments (such as tillage and additions of chemical amendments, organic matter and growing green manure crops) to maintain soil permeability and tilth. The crop grown, the quality of water used for irrigation, the rainfall pattern and climate, and the soil properties determine to a large degree the kind and extent of management practices needed.

Blending Low-Salt and Salty Waters

Miller and Gardiner[2] reported that countries such as Israel have developed extensive canal and reservoir systems where both low-salt and salty waters are mixed to obtain usable water. Rhoades, Kandiah, and Marshali,[1] however, state that blending or diluting excessively saline waters with good quality water supplies should only be undertaken after consideration is given to how this affects the volumes of consumable water in the combined and separate supplies. They suggest that blending or diluting drainage waters with good quality waters in order to increase water supplies or to meet discharge standards may be inappropriate under certain situations. More crop production can usually be achieved from the total water supply by keeping the water components separated. Serious consideration should be given for keeping saline drainage waters separate from the good quality water, especially when the good quality waters are used for irrigation of salt-sensitive crops. The saline waters can be used more effectively by substituting them for good quality water to irrigate certain crops grown in the rotation after seeding establishment.

Conclusion

There is ample evidence that saline waters once considered unacceptable for irrigation can be used successfully provided that they are properly managed. There is also ample evidence, however, to show that these waters can be highly damaging to the environment and to the soil resource base when improperly managed. Therefore, saline waters should be only used for irrigation after careful study and considering as many factors as possible. Then, when the waters are used for irrigation, a careful monitoring program should be implemented of both the crops produced and of the resulting soil and environmental changes.

Irrigation: Sewage Effluent Use

B.A. Stewart

Introduction

One of the primary functions of soil is to buffer environmental change. This is the result of the biological, chemical, and physical processes that occur in soils. The soil matrix serves as an incubation chamber for decomposing organic wastes including pesticides, sewage, solid wastes, and many other wastes. Soils store, decompose, or immobilize nitrates, phosphorus, pesticides, and other substances that can become pollutants in air or water. Consequently, soil has, for centuries, been used for the application of sewage effluents. Sewage effluent provides farmers with a nutrient-enriched water supply and society with a reliable and inexpensive means of wastewater treatment and disposal. It should not, however, be assumed that irrigation is always the best solution for wastewater disposal. Disposal by irrigation should always be compared with alternative options based on environmental, social, and economic costs and benefits.

While disposal is the primary objective in many cases, the need of water for irrigation is becoming more often the driver for using sewage effluent on land. This is particularly true in areas like the Middle East where population growth is resulting in severe water shortages. The guidelines for using effluent for irrigation vary considerably among countries and other governing bodies. Cameron[1] conducted a literature review and found wide differences of guidelines for effluent irrigation projects being used throughout the world. In general, however, sustainable and environmentally sound systems can be developed in most situations provided proper management practices are followed.

Concerns of Irrigating with Sewage Effluent

In spite of the documented benefits associated with the use of sewage effluent for irrigation, there are numerous concerns. Many industrial wastewaters have been routinely dumped into municipal sewage lines. While this issue has been addressed in some jurisdictions, it has not in many others. In the United States, the Environmental Protection Agency requires that wastewaters be treated prior to disposal into municipal treatment plants or back into groundwater. Irrigating with wastewaters partially cleans water by percolation through the soil, but soluble salts and some inorganic and organic chemicals may continue to flow with the water to groundwater or surface supplies. In general, the Environmental

Protection Agency allows sewage effluents to be used for irrigation only if it does not cause: 1) extensive groundwater pollution; 2) a direct public health hazard; 3) an accumulation in the soil or water of hazardous substances that can get into the food chain; 4) an accumulation of pollutants such as odors into the atmosphere; and 5) other aesthetic losses, within the limits.[2]

Bouwer[3] has also expressed concerns about the use of sewage effluent for irrigation. He is particularly concerned with pathogens and warns that complete removal of viruses, bacteria, and protozoa and other parasites should be required before the effluent can be used to irrigate fruits/vegetables consumed raw or brought into the kitchen, or parks, playgrounds and other areas with free public access. Bouwer also stresses that long-term effects of sewage effluent irrigation on underlying groundwater should be considered in addition to the changes in nitrate and salinity. Ground water in low rainfall regions can be highly affected by percolating sewage effluent because much of the water is used by the growing crops and this greatly concentrates the chemicals in the small amounts of water that actually percolate to the groundwater. These chemicals can include disinfection byproducts, pharmaceutically active chemicals, and compounds derived from humic and fulvic acids formed by the decomposition of plant material. Bouwer claims that many of these chemicals are suspected carcinogens or toxic. Therefore, Bouwer concludes that while sewage irrigation looks good on the surface, a more extensive look reveals a potential for serious contamination of groundwater. He states that municipalities and other entities responsible for irrigation with sewage effluent should do a groundwater impact analysis to develop management protocols and be prepared for liability actions. Those who benefit are local and state institutions in water resources, environmental quality protection, public health, consultants, and operators of effluent irrigation projects.

Reuse Standards

The standards for using sewage effluent for irrigation of agricultural crops vary widely among different countries of the world. Mexico and many South American countries, e.g., use untreated wastewater for irrigation.[4] Most of these countries do not have the resources or capital to treat sewage effluents. Wastewater is utilized after little or no treatment, and health risks are minimized by crop selection. Mexico does not allow wastewater to be used to irrigate lettuce, cabbage, beets, coriander, radishes, carrots, spinach, and parsley. Acceptable crops include alfalfa, cereals, beans, chili, and green tomatoes. In contrast, Israel has very stringent water reuse requirements. Effluent water requires a high level of treatment (large soil-aquifer recharge systems with dewatering) before the water can be reused for irrigation of vegetables to be consumed raw.[5] Health guidelines for irrigation with treated wastewater developed in California indicate that effluent waters used on food crops must be disinfected, oxidized, coagulated, clarified, and filtered.[6] Total coliform counts cannot exceed a median value of 2.2/100 mL or a single sample value of 25/100 mL. Total coliforms must be monitored daily and turbidity cannot exceed 2 nephelometric turbidity units and must be monitored continuously. Less restrictive guidelines developed by Shuval et al.,[7] and adopted by most of the international agencies, suggested that effluent water reuse was relatively safe to use if it contained less than 1 helminth egg L^{-1}, and less than 1000 fecal coliforms/100 mL.

Monitoring Guidelines

Site selection is a critical and necessary step in initiating a sewage effluent irrigation system. The U.S. Environmental Protection Agency[8] published detailed information on site characterization and evaluation. Information was provided on the design of systems, site characteristics, expected quality of the effluent water after land treatment, and typical permeabilities and textural classes suitable for each land treatment process. Information was provided for designing and monitoring site characteristics for slow rate processes (sprinkler and other typical farm irrigation systems), rapid infiltration basins, and overland flow systems. Monitoring requirements will vary considerably among projects depending on the cropping patterns, soil characteristics, and specific environmental concerns. In most cases, monitoring procedures and criteria will be site specific. In all cases, however, the objectives should be to use the resources effectively, protect the land, protect the groundwater, protect the surface water, and protect the community amenity.

Irrigation: Soil Salinity

James D. Rhoades

Introduction

Irrigation is an ancient practice that predates recorded history. While irrigated farmland comprises only about 15% of the worlds' total farmland, it contributes about 36% of the total supply of food and fiber, and it stabilizes production against the vagaries of weather.[1] In 30 years time, irrigated agriculture is expected to have to supply 50% of the worlds' food production requirements.[1] However, over the last 20 years, irrigation growth has actually slowed to a rate that is now inadequate to keep up with the projected expanding food requirements.[1] Furthermore, irrigation has resulted in considerable salination of associated land and water. It has been estimated variably that the salinized area is as low as 20 and as high as 50% of the worlds' irrigated land.[2–4] Worldwide, about 76.6 Mha of land have become degraded by human-induced salination over the last 45–50 years.[3] It has been estimated that the world is losing at least three hectares of arable land every minute to soil salination (about 1.6 Mha per year), second only to erosion as the leading worldwide cause of soil degradation.[5–7] These data imply that the rate of salinization in developed irrigation projects now exceeds the rate of irrigation expansion.[8]

Surviving the salinity threat requires that the seriousness of the problem be recognized more widely, the processes contributing to salination of irrigated lands be understood, effective control measures be developed and implemented that will sustain the viability of irrigated agriculture, and that practical reclamation measures be implemented to rejuvenate the presently degraded lands.[9,10]

Deleterious Effects of Salts on Plants, Soils, and Waters

Salt-affected soils have reduced value for agriculture because of their content and proportions of salts, consisting mainly of sodium, magnesium, calcium, chloride, and sulfate and secondarily of potassium, bicarbonate, carbonate, nitrate, and boron. Saline soils contain excessive amounts of soluble salts for the practical and normal production of most agricultural crops. Sodic soils are those that contain excessive amounts of adsorbed sodium in proportion to calcium and magnesium, given the salinity level of the soil water. An example of a salt-affected irrigated soil is shown in Figure 1.

Soluble salts exert both general and specific effects on plants, both of which reduce crop yield.[11] Excess salinity in the seedbed hinders seedling establishment and in the crop root zone causes a general reduction in growth rate. In addition, certain salt constituents are specifically toxic to some plants. For example, boron is highly toxic to susceptible crops when present in the soil water at concentrations of

FIGURE 1 Photograph of salt-affected irrigated field.

only a few parts per million. In some woody crops sodium and chloride may accumulate in the tissue over time to toxic levels. These toxicity problems are, however, much less prevalent than is the general salinity problem.

Salts may also change soil properties that affect the suitability of the soil as a medium for plant growth.[12] The suitability of soils for cropping depends appreciably on the readiness with which they conduct water and air (permeability) and on their aggregate properties (structure), which control the friability (ease with which crumbled) of the seedbed (tilth). In contrast to saline soils, which are well aggregated and whose tillage properties and permeability to water and air are equal to or higher than those of similar nonsaline soils, sodic soils have reduced permeabilities and poor tilth. These problems are caused by the swelling and dispersion of clay minerals and by the breakdown of soil structure (slaking and crusting), which results in loss of permeability and tilth. Sodic soils are generally less extensive but more difficult to reclaim than saline soils.

Beneficial use of water in irrigation consists of transpiration and leaching for salinity control (the leaching requirement). Plant growth is directly proportional to water consumption through transpiration.[13] From the point of view of irrigated agriculture, the ultimate objective of irrigation is to increase the amount of water available to support transpiration. Salts reduce the fraction of water in a supply (or in the soil profile) that can be consumed beneficially in plant transpiration.[14] In considering the use of a saline water for irrigation and in selecting appropriate policies and practices of irrigation and drainage management, it is important to recognize that the total volume of a saline water supply cannot be consumed beneficially in crop production (i.e., transpired by the plant). A plant will not grow properly when the salt concentration in the soil water exceeds some limit specific to it under the given conditions of climate and management.[11] This is even true for halophytes.[15] Thus, the practice of blending or diluting excessively saline waters with good quality water supplies should be undertaken only after consideration is given to how it affects the volumes of consumable (usable) water in the combined and separated supplies.[14].

Causes of Salination Induced by Irrigation and Drainage

While salt-affected soils occur extensively under natural conditions, the salt problems of greatest importance to agriculture arise when previously productive soils become salinized as a result of agricultural activities (the so-called secondary salination). The extent and salt balance of salt- affected areas has been modified considerably by the redistribution of water (hence salt) through irrigation and drainage.

The development of large-scale irrigation and drainage projects, which involves diversion of rivers, construction of large reservoirs, and irrigation of large landscapes, causes large changes in the natural water and salt balances of entire geohydrologic systems. The impact of such developments can extend well beyond that of the immediate irrigated area. Excessive water diversions and applications are major causes of soil and water salination in irrigated lands. It is not unusual to find that less than 60% of the water diverted for irrigation is used in crop transpiration.[9] This implies that about 40% of the irrigation water eventually ends up as deep percolation. This drainage water contains more salt than that added with the irrigation water because of salt dissolution and mineral weathering[14] within the root zone. It often gains additional salt-load as it dissolves salts of geologic origin from the underlying substrata through which it flows in its down-gradient path. This drainage water often flows laterally to lower lying areas, eventually resulting in shallow saline groundwaters of large areas of land (waterlogging). Salination occurs in soils underlain by saline shallow groundwater through the process of "capillary rise" as groundwater (hence, salt) is driven upwards by the force of evaporation of water from the soil surface. Correspondingly, saline soils and waterlogging are closely associated problems.

Seepage from unlined or inadequately lined delivery canals occurs in many irrigation projects and is often substantial. Law, Skogerboe, and Denit[16] estimated that 20% of the total water diverted for irrigation in the United States is lost by seepage from conveyance and irrigation canals. Biswas[17] estimated that 57% of the total water diverted for irrigation in the world is lost from conveyance and distribution canals. Analogous to on-farm deep percolation resulting from irrigation, these seepage waters typically percolate through the underlying strata (often dissolving additional salts in the process), flow to lower elevation lands or waters, and add to the problems of waterlogging and salt-loading associated with on-farm irrigation there. A classic example of the rise in the water table following the development of irrigation has been documented in Pakistan and is described by Jensen, Rangeley, and Diele-man[9] and Ghassemi, Jakeman, and Nix.[2] The depth to the water table in the irrigated landscape located between three major river-tributaries rose from 20 to 30 m over a period of 80–100 years, i.e., from preirrigated time (about 1860) to the early 1960s, until it was nearly at the soil-surface. In one region, the water table rose nearly linearly from 1929 to 1950, demonstrating that deep percolation and seepage resulting from irrigation were the primary causes. Ahmad[18] concluded that about 50% of the water diverted into irrigation canals in Pakistan eventually goes to the groundwater by seepage and deep percolation.

The role of irrigated agriculture in salinizing soil systems has been well recognized for hundreds of years. It is of relatively more recent recognition that salination of water resources from agricultural activities is a major and widespread phenomenon of likely equal concern to that of soil salination. The causes of water salination are essentially the same as those of soils, only the final reservoir of the discharged salt-load is a water supply in the former case.[14] The volume of the water supply is reduced through irrigation diversions and irrigation; thus, its capacity to assimilate such received salts before reaching use-limiting levels is reduced proportionately. Only in the past 15 years has it become apparent that trace toxic constituents, such as selenium, in agricultural drainage waters can also cause serious pollution problems.[19]

Irrigation and Drainage Management to Control Soil Salinity

The key to overall salinity control is strict control that maintains a net downward movement of soil water in the root zone of irrigated fields over time while minimizing excess irrigation diversions, applications, and deep percolation.[20] The direct effect of salinity on plant growth is minimized by maintaining the soil-water content in the root zone within a narrow range at a relatively high level, while at the same time avoiding surface-ponding and oxygen deletion and minimizing deep percolation. Combined methods of pressurized, high-frequency irrigation and irrigation scheduling have been developed that permit substantially the desired control to be achieved.[21,22] These systems transfer control of water distribution and infiltration from the soil to the irrigation equipment. This results in less excess water (and hence, less salt) being applied overall to the field to meet the needs of a part of the field area having lowest intake rate, as done in the more traditional gravity irrigated systems. However, gravity irrigation systems can be designed to achieve good irrigation efficiency and salinity control, even though surface ponding still does occur. The so-called level-basin, multi-set, cablegation, surge, and tailwater-return systems are among them.[21,22] The need for irrigation and the amount required to meet evapotranspiration and leaching requirement is determined from plant stress measurements, calculations of evapotranspiration amounts, measurements of soil-water depletion, measurements of soil (or soil-water) salinity, or a combination of them.[21,22]

In addition to effective methods of irrigation scheduling and application, appropriate irrigation and salinity management also require an effective delivery system. Delivery systems have generally been designed to provide water on a regular schedule. Efficient irrigation systems require more flexible deliveries that can provide water on demand as each crop and particular field have need of it. Delivery systems can be improved by lining the canals, by containing the water within closed conduits, and by implementing techniques that increase the flexibility of delivery.

As briefly discussed earlier, irrigated agriculture is a major contributor to the salinity of many rivers and groundwaters, as well as soils. Reducing deep percolation generally lessens the salt load that is returned to rivers or groundwater and their pollution.[14] Additionally, saline drainage waters should be intercepted before being allowed to mix with water of better quality. The intercepted saline drainage water should be desalted and reused, disposed of by pond evaporation or by injection into some suitably isolated deep aquifer, or better yet it should be used for irrigation in a situation where brackish water is appropriate. Various irrigation and drainage strategies have been developed for minimizing the pollution of waters from irrigation and for using brackish waters for irrigation.[14,23] Desalination of agricultural drainage waters is not now economically feasible, but improved techniques for doing this exist and some are being implemented. However, more needs to be done in this regard.

Traditionally, the concepts of leaching requirement and salt-balance index have been used to plan and judge the appropriateness of irrigation and drainage systems, operations and practices with respect to salinity control, water use efficiency, and irrigation sustainability. However, these approaches are inadequate. The recommended method is to monitor directly the root-zone salinity levels and distributions across fields as a means to evaluate the effectiveness of salinity, irrigation, and drainage management practices, to detect problems (current and developing), to help determine the underlying causes of problems, and to determine source areas of major water and salt-load contributions to the underlying groundwater. Theory, equipment, and practical technology have been developed for these purposes.[24] More information about irrigation and drainage management to control soil and water salinity is found elsewhere.[25–27]

Managing Water Resources and Hydrological Systems

Honglin Zhong,
Zhuoran Liang,
and Cheng Li

Introduction

Water scarcity has become a global issue as freshwater demand keeps soaring from the rapid increase in population and food demand under fast social-economic development, with additional pressure from altered water supply under climate change driven by anthropogenic emissions (Vörösmarty et al. 2000; Piao et al. 2010). Many regions in the world are already under severe water shortages and may suffer even worse water crisis under projected climate change (Konikow and Kendy 2005). Hotspots, such as the intensive cropped and heavy irrigated fertile major cropping zone of North China Plain (NCP), experience severe environmental problems from underground water over-exploitation for agricultural irrigation. This area is likely to experience more frequent deadly heatwave under projected future climate (Kang and Eltahir 2018). This will threaten both crop production and food security, risk farmer livelihoods, and constrain social-economic development in the future.

As the biggest freshwater consumption sector, agricultural production has achieved great success in food security with vast irrigation expansion since the “green revolution”. Only 20% of the cropland with irrigation produced as much as 40% of the total agricultural production in the world (Molden 2007). However, to achieve these results, irrigated crops consume 70% of global total freshwater withdrawal (Rosegrant et al. 2009) and cause rapid groundwater depletion in many major cropping zones such as North China, Northwestern India, and US high plains (Konikow and Kendy 2005). In NCP, the fast groundwater table decline has already caused severe environmental issues of dried-up rivers and lakes, seawater intrusion, land subsidence, and ground fissures (Xue et al. 2000). Public health may also be threatened when groundwater table drops to a deep level containing toxic levels of fluoride and arsenic (Currell et al. 2012).

Groundwater irrigation-intensive crops should be abandoned, and cropland fallow should be adopted for water-sustainable development (Wang et al. 2015, 2016). Shifting double cropping system (wheat–maize rotation) to single cropping system (winter fallow–spring maize rotation) and wheat fallow subsidy are highly recommended and already adopted by local farmers and government for groundwater recovery in the NCP (Feng et al. 2007; Zhong et al. 2017; Ren et al. 2018).

In this chapter, we reviewed the models, measurements, strategies, and projects for agricultural water consumption, conservation, and adaptation at the field, regional, and global levels. With a specific focus on the NCP, where experienced a significant transformation of agricultural practice and policies from previous water-intensive high-yield production-oriented to recent sustainable agricultural water management and cropland fallow with ecological compensation. With all the existing studies covering physical water saving, freshwater transfer, "virtual water" flow, and water footprint via food trade in the semi-arid NCP, farmers, scientists, stakeholders, and government from other water-deficit regions with heavy food production will get deeper insights into the water crisis and inspire local adaptations for the sustainable social-economic development around the world.

Models for Agricultural Water Consumption Estimation

Hydrological Models

Hydrological models are effective tools to simulate local water resources, hydrological processes, and crop growth at sub-basin/watershed level. Simulating cropland water balance is possible under different crop growth and water management with evapotranspiration, surface runoff, infiltration, percolation, shallow, and deep aquifer flow (Arnold et al. 1998). Major hydrological models include the Soil and Water Assessment Tool (SWAT) (Arnold et al. 1998), Variable Infiltration Capacity model (VIC) (Wood et al. 1992), and Systeme Hydrologique European (SHE) model (Abbott et al. 1986). These models provide a better understanding of the climate variability on hydrological processes and water resources for agricultural production (Sun and Li 2013; Wang et al. 2016). Advantages of the hydrological models are applied in the watershed level to optimize crop irrigation schedules for different crops (Sun and Li 2014) and identify the groundwater depletion from cropland irrigation expansion (Zhang et al. 2016). But the relatively simplified crop growth processes compared with dynamic crop models make the crop module within the macro-scale hydrological models focus more on the change of hydrological resources under given local water management conditions, rather than design the water-saving irrigation technologies or schedules (Xiong et al. 2019). In fact, the optimal crop irrigation schedule for water saving using hydrological model is obtained in tandem with field-based experiments (Yu et al. 2006).

Dynamic Crop Models

Process-based dynamic crop models have great advantages in simulating the interaction between crop growth and the sounding environment at a daily time step. Those models are widely used to determine optimal crop water management. Major crop models include Decision Support System for Agrotechnology Transfer (DSSAT) (Jones et al. 2003), Environmental Policy Integrated Climate (EPIC) (Williams et al. 1989), Agricultural Production Systems sIMulator (APSIM) (McCown et al. 1996), and AquaCrop (Steduto et al. 2009). The DSSAT model was employed to identify the long-term relationship between crop irrigation water consumption and groundwater level depletion in the Piedmont of NCP (Yang et al. 2006). For the regional agricultural water consumption simulation, a spatial parameterization by integrating the agroecological zones with site field information of all the sites was developed for the DSSAT model upscaling (Tian et al. 2012) and applied to simulate crop water consumption under different cropping systems in the NCP (Zhong et al. 2017, 2019; Tian et al. 2018).

Several limitations of the dynamic crop models need to be mentioned: (1) Crop models require heavy inputs for model calibration, validation, and simulation, but detailed information that will affect the

TABLE 1 Models for Agricultural Water Consumption Estimation

Model Types	Model Name	Description	Model References
Hydrological Models	SWAT	The SWAT model is developed to assess the impact of management on water supplies and nonpoint source pollution, and predict the impact of management on water, sediment, and agricultural chemical yields in watersheds.	Arnold et al. (1998)
	SHE/MIKE SHE	The SHE/MIKE SHE is a differential model to simulate the surface water movement from the hydrological processes of mass, energy, and momentum in a river basin.	Abbott et al. (1986)
	VIC	The VIC model simulates land-surface hydrology from infiltration variation, with a simplified approach of estimating infiltration, evaporation, and a base flow.	Wood et al. (1992)
Dynamic crop models	DSSAT	The DSSAT model is a modular structure with separate primary scientific components (soil, crop, weather, and management) and various process-based models that can be added or replaced.	Jones et al. (2003)
	EPIC	The EPIC model is developed to estimate the soil productivity as affected by soil erosion, plant growth, and related processes.	Williams et al. (1989)
	APSIM	The APSIM model focuses more on the "system" aspect of cropping, such as crop growth, rotation, fallow, and dynamic crop management to the soil processes and climate conditions.	McCown et al. (1996)
	AquaCrop	The AquaCrop model is a water-driven process model that focuses on the differential sensitivity to water stress of key plant processes and the biomass water productivity during the crop growth cycle.	Steduto et al. (2009)

total water consumption is lacking at the regional scale, especially the field water management. As most upscaling methods depend on observations from experiment sites, agricultural water consumption will be overestimated as field management levels in those sites are much higher than the farmer's practice (Tian et al. 2012). (2) Because process-based crop models mainly focus on soil water balance in the root zone during the crop growing period, hydrological processes, such as additional water sources from the surface stream, other water bodies, and underground water flow are not included. For example, the mountain-front discharge in the Piedmont of the Hebei Plain is an important groundwater recharge source but only considered in site experiment with field observations (Oort et al. 2016). Groundwater recharge from precipitation and irrigation water deep percolation are usually simplified or ignored (Yang et al. 2015) (Table 1).

Hybrid Models

To overcome the constraint of the process-based models and hydrological models in optimizing agricultural water management, there is a growing trend of integrating/coupling modeling studies. For example, there are case studies in NCP to improve the groundwater depletion simulation by coupling the crop model (DSSAT) with hydrology model (SWAT) and groundwater flow model (MODFLOW) (Hu et al. 2010). The Catchment-based Ecohydrology model was integrated with the crop model (DSSAT) to simulate the impact of agricultural water consumption on groundwater resources (Nakayama et al. 2006). In addition, there is a great potential of applying these model-based studies to identify the sustainable water management for different crops and various cropping systems under future climate projections, which will greatly support the agricultural adaptation decisions for the local farmers, stakeholders, and government.

Environmental Extended Multi-Region Input–Output Model

In addition to the water resources and direct consumption simulated by physical models, the indirect virtual water embodied in interregional food trade is also estimated by using the environmental extended multi-region input–output model (Wiedmann 2009). The virtual water or water footprint represents both the direct and indirect volumes of freshwater consumption to produce goods and services which are consumed by social and economic activities (Hubacek et al. 2009). The agricultural virtual water, which includes irrigation water as blue water, rainwater as green water, and wastewater as gray water, was introduced to identify the embodied water import and export from interregional trade and to design alternative water management strategies (Chapagain and Hoekstra 2004). A more comprehensive understanding of the direct and indirect water consumption, especially the groundwater depletion embodied food trade, will support local agricultural adaptations and reallocation/alleviation of water stress in water-deficit regions via food and product trade (Dalin et al. 2017). For example, by tracking "virtual water" embodied in the global and regional food trade, researchers showed that a great amount of food is exported from the water-deficit arid and semi-arid regions at the expense of greater groundwater depletion, and it is not reasonable for those regions to continue their role as "breadbasket" for other regions in the world (Dalin et al. 2017; Ren et al. 2018).

Water-Sustainable Agricultural Adaptations

As the biggest water consumption sector, agriculture plays a critical role in local water management. Reducing irrigation water and increasing water-use efficiency are critical to the environment and ecosystem sustainability, especially in the major cropping regions under arid and semi-arid climate.

Field Water-Saving Irrigation Technologies

Directly reducing agricultural irrigation is the most prevalent measure to save water. Field experiments have been designed and validated to identify the optimal water management for different crops in the arid and semi-arid regions. There are two major field water-saving practices: (1) water-saving irrigation and optimal irrigation schedule, and (2) plastic/straw mulching and no tillage.

Various water-saving irrigation technologies were developed to reduce the frequency and amount of irrigation. Compared with traditional flood or sprinkler irrigation, the dripping irrigation will significantly increase the water-use efficiency by the crops with little "waste" water from surface runoff and percolation (Alcon and Burton 2011; Ayars et al. 2015). More aggressive deficit irrigation with the tradeoffs of crop yield loss was also adopted in the arid regions (Geerts et al. 2010; Al-Ghobari and Dewidar 2018). Optimizing the irrigation schedule with lower frequency and a focus on the critical crop growth stages is another effective practice (Jiang et al. 2016). Experiments showed that optimal irrigation could reduce irrigation water by about 50 mm compared with local farmer's current practices in the NCP (Sun et al. 2011). Maize irrigation amount could reduce up to 50% in the Yingke irrigation district in Northwest China under the optimal irrigation schedule (Jiang et al. 2016). However, water conservation subsidies for water-efficient irrigation may consume even more water as groundwater recharge reduced while more water was extracted to meet the demand of water-intensive crops, more comprehensive social and economic policies are needed to achieve groundwater conservation instead of solely focusing on water-saving technologies (Ward and Pulido-Velazquez 2008).

Plastic mulching during the crop seedling stage is an effective way to reduce irrigation by decreasing soil evaporation and conserve soil moisture during the dry spring in Northwest China (Ran et al. 2018). Because of the negative environmental impact of plastic film, a more environment-friendly straw residual mulching and no tillage practice was developed: winter wheat straw residuals were left after harvest and no tillage was applied for soil moisture conservation before the following summer crop sowing (Tan et al. 2017). Experiments in the Luancheng Station of the NCP showed that soil evaporation could be reduced up to 40% with higher water-use efficiency of maize (Chen et al. 2007).

Cropping System Adaptations

However, no matter how much efforts were put on reducing irrigation water, the groundwater still dropped in the NCP, even when reducing the irrigation frequency to one time per crop growth cycle (deficit irrigation at the expense of limit crop yield reduction) (Sun et al. 2015). This is because the water requirements of the existing intensive wheat–maize double cropping systems are far more than local water supply. Agricultural deintensification and water-sustainable cropping systems become a feasible alternative (Zhong et al. 2017).

Many groundwater neutral (no groundwater table drop) cropping system with less water demand crops or cropland fallow were introduced to further reduce irrigation. For example, because of the dry winter and spring in NCP, winter wheat required much more irrigation water than other crops. Many alternative cropping system with partially or completely wheat fallow were introduced to replace the dominant wheat–maize cropping system in this region, including single cropping of spring maize (Pei et al. 2015), double cropping per year of early maize and late maize (Meng et al. 2017), and triple harvests in 2 years of WM-S followed by spring maize (Meng et al. 2012), and strip–relay intercropping of wheat followed by spring maize (Gao et al. 2009). A slow adaptation of wheat planting area shifting has happened at the farmer's initiative in the NCP. A "spring maize belt" was established in the driest regions of the NCP. Farmers had already abandoned winter wheat and replaced the wheat–maize double cropping system with spring maize single cropping (Feng et al. 2007; Wang et al. 2016); and, a north–south shift of winter wheat planting area occurred where more wheat was planted in the wetter part of NCP (Wang et al. 2015). Inevitably, the regional total grain production will suffer a loss when less intensive cropping systems are adopted for groundwater recovery. The current situation of groundwater over-exploitation should come to an end before there is "no water" to use when extreme drought happens and a great food production failure under projected warmer and drier climate in NCP (Oort et al. 2016).

Fortunately, policies have been made and implemented in the groundwater over-exploited NCP, where a pilot project has started to leave cropland area fallow. Ecological compensation was also estimated for winter wheat fallow in NCP (Wang et al. 2016). Investments to improve the cropland irrigation infrastructure, such as concrete canals to reduce leakage of water when transferring, are also needed to enhance the water saving and groundwater recovery.

Physical Water Transfer or Virtual Water Flow

Freshwater Diversion Projects

The uneven distribution of freshwater resource (e.g., the arid and semi-arid NCP produces 1/2 and 1/3 of the national total wheat and maize production, respectively, while south China has much more freshwater resources) and the soaring water demand from rapid urbanization and industrialization have driven many massive surface water diversion projects (Aeschbach-Hertig and Gleeson 2012; Zhao et al. 2015). The biggest one is the South-North Water Transfer (SNWT) project, with a designed water delivery capacity of 20 billion m^3 water from the western route, 9.5 billion m^3 water from the central route, and 14.8 billion m^3 water from the eastern route (Liu et al. 2013).

This SNWT project has also raised great controversy because of its huge investment and cost for maintenance/operation every year and the environmental impact to the downstream (Barnett et al. 2015). Moreover, studies also pointed out that even with the supplementary water from SNWT project, the groundwater table level would not stop declining in Shijiazhuang city in North China (Shu et al. 2012).

Adaptations, such as improving agricultural water-use efficiency and reducing crop irrigation, increasing urban water supply from rainwater harvesting and wastewater recycling, should play a more important role for the water sustainability in those regions (Barnett et al. 2015).

Virtual Water Flows via Food Trade

Compared with physical water transfer, the virtual water flow as embodied water in the interregional food and production trade is much bigger. Physical water flows via the major water transfer projects amounted to 4.5% of national water supply, whereas virtual water flows accounted for 35% in 2007 (Zhao et al. 2015). This suggests the demand-oriented water management should be highlighted rather than solely focusing on physical water saving, especially reducing the export of water-intensive products from the water-deficit regions. For example, the physically transferred freshwater was less than the embodied blue water export from Hebei Province to Beijing and Tianjin and had worsened the local groundwater depletion. Moreover, export from Hebei province with much less water-use efficiency to the higher water-use efficient Beijing and Tianjin was also not reasonable (Zhao et al. 2017). Case studies in the NCP indicated that reducing the export from low water-use efficiency and high-water-stress regions will be more effective than transfer freshwater via huge water diversion projects, despite the negative sides of huge investment, cost of maintain and migration, and environment impact to the downstream (Zhang 2009; He et al. 2010). Therefore, reducing the heavy-water-intensity products' export, increasing water-use efficiency, and giving up the role of "breadbasket" for Beijing and Tianjin should be the next step in Hebei Province (Ren et al. 2018). Appropriate subsidies to compensate the local farmers' income loss are critical to the success of cropland fallow in the NCP (Wang et al. 2016), and 87% of the local farmers would adopt the winter wheat fallow policy (Xie et al. 2017).

Conclusions

Soaring global water consumption from agriculture, urbanization, and industrialization, which is expected to grow up to 21% in 2050 (Rosegrant et al. 2009), and the unsustainable use of groundwater have caused severe environmental issues in many arid and semi-arid regions. The potential water crisis has raised great concern from the public and government. As the biggest water consumption sector, improving agricultural water-use efficiency and reducing crop irrigation water consumption is critical to global water sustainability.

Various models, agricultural water-saving adaptations, and water alleviation strategies were developed and tested at the field, regional, and global levels. Many water-saving irrigation technologies showed the potential of reducing crop irrigation and maintaining high level of food production. Initial plans and policies had already taken to slow or stop the drop in the groundwater drop in the over-exploited regions. On the other hand, instead of only focusing on improving field water-saving technologies, water-sustainable cropping systems adaptations, and supplementary freshwater transfer projects to alleviate the water deficit, it is also very important to increase the overall water-use efficiency and reduce the water footprint in all social-economic activities. "Virtual water" flow and economic cost-effective approaches should also be taken into consideration when deciding the local water diversion projects. In addition, a broader view of the water management should include social-economic water demand/consumption and local water resource. The Global Hydro-economic Model (Wada et al. 2016) can provide a feasible solution for the water management under different future climate projections and social-economic development scenarios.

Nevertheless, local water sustainability needs joint efforts from local farmers, government, and even global corporations. Future risks from projected climate change, growing population, and urbanization, shifting to more water-intensive lifestyle in many developing countries, still put global water shortage in an alarming situation, and continued efforts to improve the water management are required for sustainable development.

Runoff Water

Zaneta Polkowska

Introduction

The composition of the stream of wet deposition changes significantly on contact with the substrate, be this natural or artificial. Following contact with the surfaces of artificial objects (e.g., roofs, roads, airport aprons and runways, steel and timber structures, communal and industrial landfill, cultivated fields) or natural surfaces (e.g., trees, shrubs, conifer needles, leaves, grass, vegetated fallow land), precipitation and atmospheric deposits (rain, dew, fog, melting snow, hoar frost, or rime), flow over them (runoff) or, trickling through the soil, replenish groundwaters (Figure 1). The extent of surface runoff depends on the properties of the soil and the degree to which it is covered by plants—the lusher the vegetation, the less runoff there is. Certain properties of the soil, such as minimal adsorption or good permeability, promote the vertical movement of water in the soil, enabling it to reach the groundwater; the intensity of surface runoff is therefore less. Conversely, if the properties of a surface favor runoff (e.g., heavy, impermeable soils, asphalt, or concrete surfaces), pollutants are transported across the land surface.[1,2]

Pollutants in runoff come from three main sources: dry deposition (from the atmosphere), wet deposition (precipitation and atmospheric deposits), and flushing from the surface of the material with which precipitation and deposits come into contact (e.g., roof coverings, the crowns and trunks of trees, cultivated fields, roads and railway lines, landfill sites).[3]

Modification of the Stream of Wet Deposition following Contact with Substances in/on the Substrate

The composition of atmospheric water changes radically on contact with the Earth's surface. The composition of runoff depends to a large extent on the type of surface (including that of the land) in which precipitation falls on. Runoff from fields may contain pesticides and nutrients. Urban areas may be the source of many different substances, such as aliphatic and aromatic hydrocarbons, Polycyclic aromatic hydrocarbons (PAHs), fatty acids, ketones, and heavy metals.

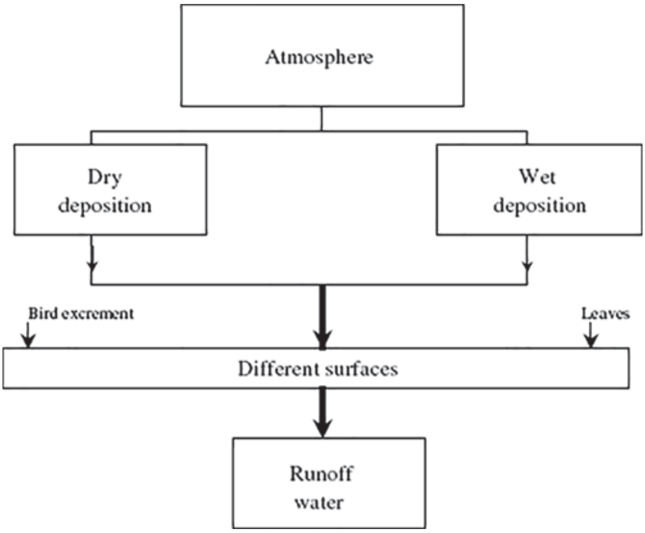

FIGURE 1 Modifications to the flow of wet deposition obstructed by different surfaces (trees, lawns, roofs, roads, motor vehicles, airport aprons and runways, steel and timber structures, communal and industrial landfill sites).

The composition of precipitation in wooded areas changes mainly under the influence of the physiological processes taking place in plants and the dissolution or flushing of atmospheric aerosols and gaseous contaminants from the surfaces of branches, bark, and leaves.[4–15]

Runoff from urban areas may also contain petroleum hydrocarbons. Road runoff contains dusts derived from the wear and tear of asphalt road surfaces and rubber tires.[16–48] The material from which a roof covering or guttering is made is a potential source of pollution taken up by water falling onto these surfaces. The compounds leached out of these materials react with the contaminants in the rainwater, changing its composition and properties. Roof runoff usually contains heavy metals and pesticides.[1,43,49–70] On the other hand, runoff from landfill sites and refuse tips are variously aggressive towards the environment, depending on the state of degradation of the refuse. On this, however, the literature supplies no data. A considerable number of papers have been published on runoff from different surfaces, although there is hardly any information on the concentrations of the constituents of runoff samples collected in Poland; what little there is refers to runoff from the crowns and trunks of trees.[5,15]

Road Runoff

Waters running off motorways contain heavy metals in two forms: suspended solid particles and dissolved forms. Figure 2 gives the results of determinations of different heavy metal ions in samples of road runoff from Europe and the United States. Similar studies were carried out in New Zealand. The results of these studies were the basis for concluding that the content of lead ions in plants (growing near roads) depends significantly on how far from the roadside they are growing.[47]

Road runoff is to a large extent contaminated by organic compounds like petroleum constituents, fuels, fats, and greases. Studies done in Madrid have shown that there is a strict relationship between the intensity of urban road traffic and the levels of PAHs and petroleum hydrocarbons in urban road runoff.[17,19] Vehicle emissions—residues of fuel and its incomplete combustion—are the chief source of these compounds in runoff.[48] Figure 3 illustrates the results of determinations of various PAHs in runoff samples collected in Europe and the United States. The concentrations were highest in the runoff samples collected along roads with a high intensity of traffic (Spain, Poland).

FIGURE 3 PAH content in samples of runoff water collected in England, Hungary, Poland, and Spain.

Studies regarding the presence of volatile organochlorine compounds (VOCCs) in road runoff were carried out in Poland (Tri-City: Gdansk, Sopot, Gdynia). VOCCs were found in every single sample. The most common VOCC analytes were chloroform, dichlorobromomethane, and trichloroethene. Table 1 lists the ranges of concentrations and mean concentrations of analytes in road runoff samples.[74]

Road runoff samples from Poland have also been analyzed for the presence of PAHs. The highest levels were recorded for naphthalene and phenanthrene+anthracene, while fluoranthene, pyrene, benzo(*a*)anthracene+chrysene, benzo(*b*+*k*)fluoranthene, and benzo(*a*)pyrene were also quite frequent. The properties of asphalt road surfaces (rather smooth and impermeable) favor runoff; thus, contaminants derived mainly from road vehicles (exhaust fumes, wear and tear of asphalt, and rubber tires) are transported across the land surface. The levels of PAH analytes rise conspicuously in the winter months (November to January).[75,76]

The organochlorine pesticides usually detected in road runoff samples from Poland include heptachlor epoxide (a product of the metabolization of heptachlor, which is synthesized in plants, the soil, and homeothermic organisms) and *o,p′*-DDE (a derivative of DDT, an insecticide that used to be widely applied). The most common of the organonitrogen and organophosphorus pesticides to be detected in road runoff are propazine and bromofos (selective weed killers). Table 2 lists the mean concentrations and ranges of concentrations of pesticides determined in road runoff samples from the Tri-City area of Poland.[74,77]

The most commonly detected petroleum hydrocarbons in runoff samples from Poland were benzene and toluene, whereby the former compound was present in every sample analyzed. Weather conditions and the street layouts of towns and cities, i.e., the speed and direction of the wind and the proximity of city buildings to one another, are important factors affecting the spread of these pollutants. Table 3 lists the maximum, minimum, and mean concentrations of analytes found in samples; the number of samples in which an analyte was detected is also given.[74,76,77]

Formaldehyde was detected in all samples of road runoff from Poland (from 0.235 to 0.433 mg/L). Figure 4 compares the levels of formaldehyde in samples of rainwater and runoff from roads in the Gdansk area and from roadside sampling points in Poland.

The formaldehyde content in road runoff is high as it is a typical pollutant produced by road vehicles. It is formed as a result of the partial oxidation of fuel in the cylinder due to the chain reactions oxidizing fuel being interrupted by the “extinguishing” effect of the fairly cool cylinder walls or to a local oxygen deficit, and is emitted with the exhaust into the atmosphere, from which it may be scavenged by dry or wet deposition. Investigations have demonstrated unequivocally that formaldehyde levels increase with increasing motor vehicle traffic in both rainwater and runoff.[78,79]

The total concentration of phenol derivatives has also been determined in road runoff samples from Poland. The usual compounds in this respect were phenol and 3,4-di- methylphenol, and the highest levels were recorded for phenol (from 91 to 120 ng/L), chlorophenol (613 ng/L), and p-nitrophenol (469 ng/L). *o*-Cresol was not detected in any of the samples. This level of pollution by phenols in runoff

samples from the Tri-City area is due largely to the intensity of motor vehicle traffic and the proximity of industrial plants in the city, including the oil refinery, which discharges an average of 118 kg/yr of phenol derivatives into surface waters. The phenols present in the samples analyzed were probably formed as a result of photochemical reactions with the products of the incomplete combustion of fuel—benzene, toluene, and xylene.[80]

Roof Runoff

The most systematic investigations into the chemical composition of roof runoff have been carried out in countries where one of the sources of drinking water is water obtained from precipitation. The following factors affect the quality of water running off roofs:[81] the material from which the roof covering is made (its chemical composition, surface roughness, the area of roof covered, age, weather resistance), the physical boundary conditions (parameters) of the roof (surface area, inclination, exposure to the weather), the factors affecting precipitation (the direction and intensity of the wind, levels of pollutants in precipitation), other meteorological factors (season, type of air mass, duration of precipitation), the physicochemical properties of the pollutants (vapor pressure, partition coefficient, solubility in water, Henry's constant), and the concentration of pollutants in the atmosphere (the source and magnitude of emission, transport and spread, decomposition and degradation period, the physical form of the pollutant).

According to the available data, the pH of roof runoff is more basic than that of rainwater. In some cases, the pH may be higher, if basic soil particles have been windblown from eroded soil onto the roof surface. Roofs containing cement (concrete tiles, corrugated asbestos-cement sheet, and gravel) may cause the runoff pH to change, since they contain $CaCO_3$, which dissolves in rainwater. Table 4 presents information on the variability in runoff pH from various types of roofing materials.[54]

An in-depth study of the chemical composition of rainwater and roof runoff was carried out by German investigators. Concentrations of all the ions (except NH_4^+) were nearly twice as high in runoff waters than in rainwaters. The slight differences in the contents of ions in runoff from five types of roofing material suggest that the source of anions is more likely to be dry deposition than the roofing material.[56]

The contamination of roof runoff by heavy metals is widely described in the literature.[50,61,62,82,83] In this case, it is the roofing material that is the main factor affecting the level of these contaminants in water. Metals are the products of the corrosion of roofing and guttering materials; hence, water running off a galvanized sheet roof will contain large amounts of zinc and a certain quantity of cadmium, while roofs

TABLE 4 pH of Runoff Water from Different Types of Roofing Material

Type of Roofing Material	Median	Minimum	Maximum

Gravel roof	7.1	6.8	7.6
Concrete tiles	7.4	7.3	7.5

Source: Kennedy et al.[54]

made from copper sheeting will be a source of copper in the runoff.[64] Nonetheless, the metals present in roof runoff do not get there just as a result of leaching, since large quantities of metals have been found in runoff from roofing made from non-metallic materials, e.g., ceramic tiles, polyester, roofing felt. This does depend, however, on the location of the sampling point.[65] Heavy metal levels in roof runoff were highest in samples from the roofs of buildings situated in urban and industrial areas. Other factors affecting the amounts of heavy metals in roof runoff include the pH of rain and the angle of inclination of the roof.[64] Table 5 sets out the results of relevant research carried out in many scientific centers.

Pesticides and herbicides are frequently encountered in runoff waters. These compounds are increasingly being used in the production of roofing materials to prevent the growth on roofs of mosses and other plants. Evidence that pesticides are leached out of roofing materials was supplied by research carried out in Switzerland by a team of scientists from Eidgenössische Anstalt für Wasserversorgung, Abwasserreinigung und Gewässerschutz (EAWAG). Pesticide concentrations were lowest in runoff from ceramic tile roofs, higher in polyester roof runoff, and the highest from roofs covered with roofing felt. Particularly striking is the very high concentration of (*R*,*S*)-mecoprop in runoff from felt-covered roofs. This compound is not used on farms in Switzerland. The presence of (*R*,*S*)-mecoprop in runoff was due to the hydrolysis of Preventol® B2—a pesticide applied to root crops. It is used in large quantities as an additive to bitumen applied as a thin coating to areas on walls and roofs particularly susceptible to leaks, e.g., at the spot where the roofing felt is stuck to the wall.[51,84]

Table 6 lists the pesticides (and their concentrations) most commonly detected and determined in runoff from different types of roofing. The highest levels were recorded for heptachlor epoxide (roofing

felt, galvanized sheeting, corrugated asbestos-cement sheeting), *p,p′*-DDT (corrugated asbestos-cement sheeting), *o,p′*-DDD (corrugated asbestos-cement sheeting), *p,p′*-DDD (ceramic tiles), *o,p′*- DDE (corrugated asbestos-cement sheeting, ceramic tiles), aldrin (roofing felt, galvanized sheeting), bromofos (metal sheet tiles, ceramic tiles), and atrazine (metal sheet tiles, corrugated asbestos-cement sheeting). The roofing materials from which runoff samples most often contained pesticides were corrugated asbestos-cement sheeting, ceramic tiles, and metal sheet tiles.[85–87]

Table 7 summarizes the concentrations of analytes determined in samples of roof runoff from buildings in Poland. The most frequently detected VOCC analytes were $CHCl_3$ and CQ14. The presence of VOCCs in roof runoff is probably due to the use of many of these compounds as solvents and degreasing agents.

The most frequently detected petroleum hydrocarbons were benzene and toluene. Their presence in roof runoff samples points to the possible leaching of these compounds from roofing materials like roofing felt, tar, and bituminous tiles as well as to the strong adsorption of these analytes to roof surfaces.[85]

TABLE 7 Total Concentrations of Selected Analytes Determined in Samples of Roof Runoff

Bituminous roofing felt	Cl^- (0.05), NO_3^- (0.02), SO_4^2 (0.32), Na^+ (0.08), NH_4^+ (0.04), K^+ (0.01), Mg^{2+} (0.06), Ca^{2+} (0.59)
Teflon	Cl^- (0.02), NO_3^- (0.03), SO_4^{2-} (0.04), Na^+ (0.04), NH_4^+ (0.04), K^+ (0.03), Mg^{2+} (0.02), Ca^{2+} (0.08)

Source: Polkowska.[86]

Roof runoff samples from Poland were also analyzed for the presence of formaldehyde. The highest level of this compound was 1.37 mg/L, while its mean concentration was 0.54 mg/L and was comparable to the mean value recorded in rainwater samples.[78,79]

Table 8 lists the most frequently detected and determined ions (and their concentrations) in samples of runoff from roofs made from different materials.

Chloride and sulfate were found in all the samples analyzed. F^- ions were detected in only 4 of 68 samples analyzed. The highest concentrations of both chlorides and sulfates were found in runoff from ceramic tiled roofs. As far as cations are concerned, Na^+, K^+, Mg^{2+}, and Ca^{2+} were determined in all samples, the highest levels being registered for Na^+ and Ca^{2+}. The highest concentration of sodium ions was recorded in runoff from roofs covered with roofing felt and ceramic tiles, whereas the highest calcium levels were found in samples from roofs covered with tiles and corrugated asbestos-cement sheeting.[85,86]

Throughfall

In forest geoecosystems, precipitation does not reach the substrate directly, but as it trickles through the crowns of trees and down their trunks, it undergoes chemical changes. The chemical composition of rainwater in forest areas changes mainly under the influence of the physiological processes of plants and the dissolution and flushing from branches, bark, and leaves of aerosols and gaseous contaminants absorbed from the air. The species composition of the trees, their age, and health can also alter the properties of rainwater, giving it new physicochemical properties.

The runoff (throughfall) from tree trunks is less interesting than that from tree crowns as it makes up at most a few percent of the rainwater. In addition, trunk runoff is much less in coniferous trees, the branches of which point downwards, taking the rainwater beyond the trunk itself.[3] The proportion of throughfall in the total deposition transported to the forest floor is less than 10%. It has been found that in pine forests, 3% of precipitation reaches the ground as trunk runoff, but 83% as crown runoff.[8] The variety and numbers of different contaminants present in crown runoff are affected primarily by the type of leaves, the density of the crown, the age of the tree, the quantity of precipitation, and the wind direction.[5]

According to the results published in the literature regarding the content of cations and anions in throughfall, the concentrations of particular ions in both crown runoff and trunk runoff are considerably higher than in precipitation falling on open terrain.[88] The elevated levels of potassium, magnesium, calcium, and manganese ions in crown runoff compared to their content in rainwater sampled in open country were due to their being flushed off leaves and needles. This was particularly noticeable in the case of spruce needles, which have a much greater surface area than the leaves/needles of other tree species.

A Japanese study has shown that a high nitrogen load in atmospheric deposition (including dry deposition) may be a factor contributing to the deterioration of pine stands. This was particularly conspicuous in urban areas, where levels of nitrate and ammonium ions in runoff were high.[8,89]

Comparative studies were carried out in Japan and Spain to illustrate the effect of the location of a woodland system on the composition and numbers of contaminants entering the environment. Samples were collected at two sites: in a forest close to a road, traffic, and urban areas (exposed), and in a wood situated far from urban areas (sheltered by mountains), where the effect of pollutants is less. The respective concentrations of nitrate and sulfate ions in trunk and crown runoff were far higher in the urban area (34.4 and 50 μeq/L) than in the mountains beyond the city (4.8 and 28.8 μeq/L) and were several times higher than the levels recorded in free precipitation.[8,12] Table 9 lists the range of concentrations and the mean concentrations of contaminants (including metals from the platinum group) in samples of runoff from tree crowns.

The data on formaldehyde concentrations in throughfall have been published in paper.[79]

Runoff from Farming Areas

Good conditions for farmland runoff containing substantial loads of nutrients exist in spring. At this time of the year, the plant cover is not yet dense enough to prevent surface runoff, and the ground, still frozen after the winter, also facilitates this. Most pesticides and fertilizers are applied directly to the soil or sprayed onto arable land, plantations, and forests; they therefore gain direct entry into the environment and are the source of much contamination (aerosols containing pesticides and nitrogen and phosphorus compounds). The inappropriate storage of pesticides and mineral fertilizers (directly on the ground, without any proper protection from the elements) contributes to the leaching of active substances, which, through the mediation of surface runoff, enter surface waters, causing their eutrophication. This leads to deleterious changes in aquatic ecosystems manifested by an increase in nutrient

TABLE 9 Range of Concentrations, Mean Concentrations and Frequency of Occurrence of Analytes in Throughfall Samples

Parameter	Concentration Range (mean) [μeq/dm³]	Parameter	Concentration Range (mean) [peq/dm³]
pH	4.2–7.4 (5.6)	Fe	0.030–0.55 (0.19)

levels (nitrogen and phosphorus compounds), a drop in the level of dissolved oxygen, and mass blooms of algae. These contaminants can also permeate into the shallow groundwater circulation, which serves as a source of drinking water in rural areas. Studies carried out worldwide confirm that farmland runoff carries very large amounts of nitrogen and phosphorus compounds; Cl^-, K^+, Ca^{2+}, Na^+, and Mg^{2+} ions; and pesticides.[32,90–92]

Runoff from Airports

Air transport is the most modern and the fastest developing type of transport. In 1993–2000, the number of passengers traveling by air in European Union countries increased by ca. 10% each year. Forecasts for the next 20 years put the annual increase in the global number of air passengers at around 5%.

This burgeoning development of air transport also concerns Poland. To a large extent, this is the result of the rapid expansion of the so-called budget airlines onto the Polish market and the reconstruction of many regional airports. Their operation is an unavoidable interference in the natural environment. Air transport contributes to the destruction of the ozone layer, and the harmful effects of air transport are visible on the ground as well. Precipitation runoff from airports affects surface water and groundwater to a substantial extent. Along with rainwater and snowmelt, petroleum derivatives, surfactants, de-icing agents (in winter), and other contaminants get into the environment. However, it is the de-icing agents applied when air temperatures are low that pose the greatest danger of polluting waters running off airport aprons and runways. The composition of airport runoff changes during the year and depends on a number of factors, such as the weather, the quantities of de-icing agents applied, the duration of precipitation, and the intensity of traffic at the airport in question.

Airport authorities use not only the environmentally dangerous ethylene and propylene glycols for de-icing aircraft but also the environmentally rather more friendly mixtures of acetates and formates for de-icing runways, taxiing areas, and aprons.[93,94] Airports do not usually have their own sewage treatment plants, and all the effluents, carrying petroleum derivatives, surfactants, de-icing agents, and other organic and inorganic pollutants, flow with rainwater and snowmelt into the surrounding soil and surface waters. These contaminants may significantly affect the fauna and flora of rivers, causing the death of fish and aquatic vegetation; therefore, it is crucial to monitor the runoff from such areas on a continuous basis.[95–97]

Figures 5–7 show the mean concentrations of selected analytes in samples of runoff collected at airports in Poland (Gdańsk and Warsaw) and the United States.[97,98]

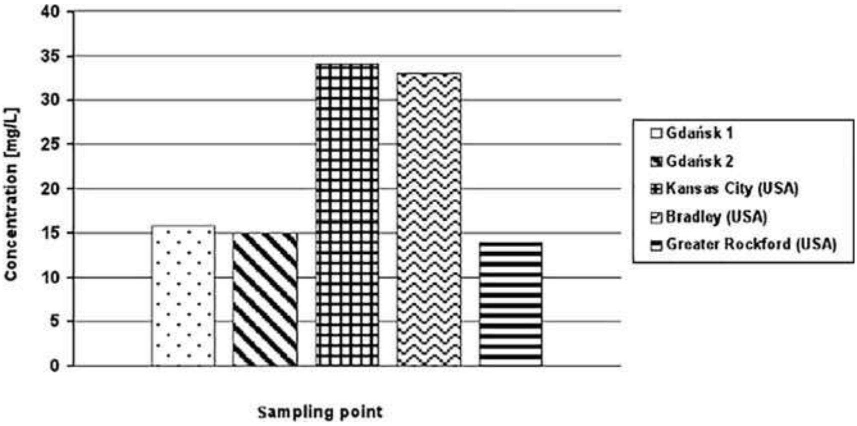

FIGURE 5 Comparison of mean concentrations of Ca in samples of runoff from airports in Gdansk and the United States.

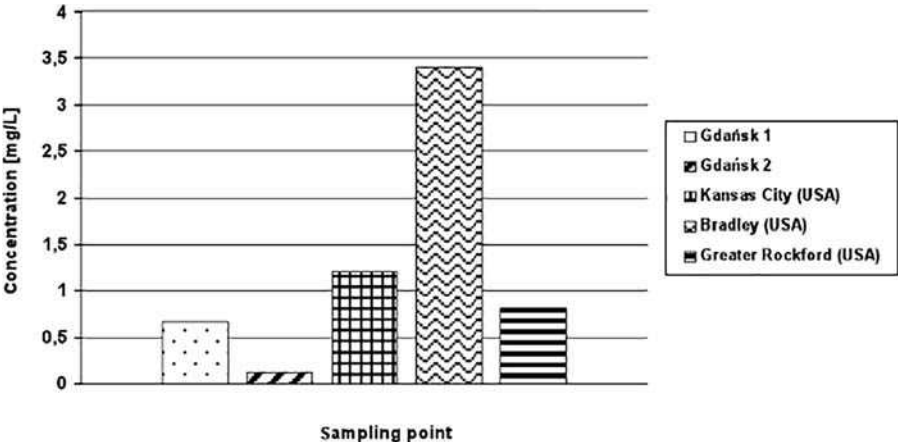

FIGURE 6 Comparison of mean concentrations of Fe in samples of runoff from airports in Gdansk and the United States.

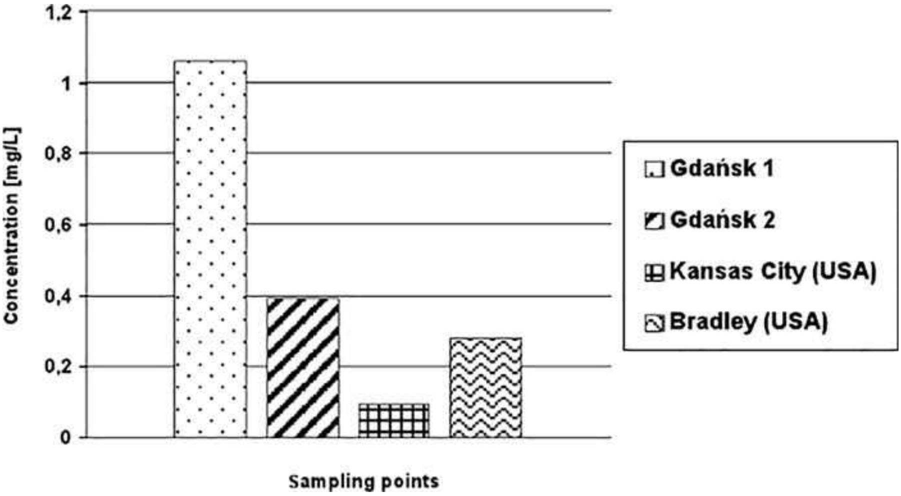

FIGURE 7 Comparison of mean concentrations of sum of phenols in samples of runoff from airports in Gdansk and the United States.

The highest levels of potassium and sodium ions were recorded in runoff from the Gdansk airport in 2009—this may have been due to the large quantities of de-icing agents (sodium and potassium formate) used during the winter. At the other airports, the mean concentrations of these analytes were very much lower. The mean concentrations of calcium ions determined in the runoff from the Gdansk airport were lower than those from American airports.

The highest level of total iron by far was found in samples from the Bradley International Airport (United States); the level of this particular contaminant at Gdansk was lower than those at U.S. airports. Comparison of the mean levels of magnesium ions shows that they have been at similar levels at all the airports, although the Mg level was lowest at Gdańsk.

The highest mean concentration of total phenols was recorded in samples taken in winter at the Gdansk airport, whereas mean Total organic carbon (TOC) levels at this time were comparable in the samples from the airports at Gdansk, Kansas City, and Bradley (United States).

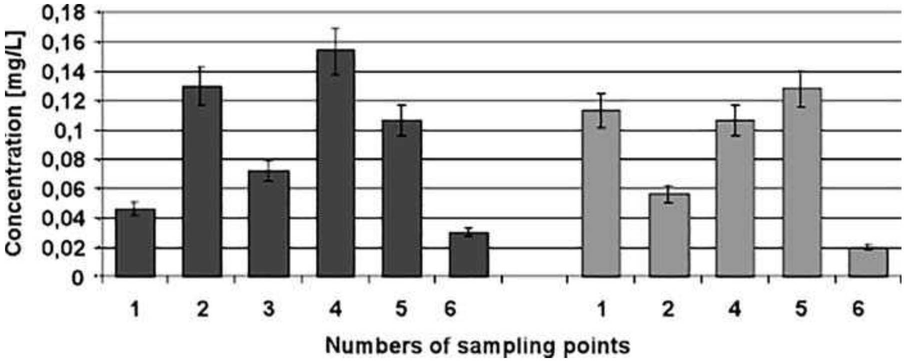

FIGURE 8 Comparison between mean concentrations of organic compounds determined in precipitation and runoff samples; 1–5, runoff samples; 6-precipitation. (March 19, 2008—black; April 8, 2008—gray).

The following organic compounds have been shown to be present in runoff from the Gdansk airport: anionic and cationic detergents, formaldehyde, phenols, PAHs, pesticides, and polychlorinated biphenyls (PCBs). Figure 8 shows the mean concentrations of cationic detergents contained in samples of precipitation and runoff.

Changes in the Composition of Samples Depending on the Moment of Sampling during Precipitation or Runoff

Literature reports indicate that atmospheric contaminants are removed during the early phases of precipitation, usually in the "first flush," and their concentrations in the precipitation drop exponentially as its volume increases. In its simplest form, this relation can be expressed by the equation

$$c = a \cdot \exp(b \cdot V) \tag{1}$$

where *c* is the concentration of contaminant in the precipitation (mol/L), *V* is the volume of precipitation collected (L), and *a* and *b* are constants.[99]

Analysis of the results of studies carried out in Germany and Switzerland shows that concentrations of contaminants (heavy metals, pesticides, cations, anions, PAHs) are the highest in the first phase of precipitation and in the first flow of runoff.[1,56,62,87] Table 10 lists the relevant data.

From these data, it can be inferred that the presence of pesticides and inorganic compounds in the first flush of precipitation and in roof runoff may be influenced by the following: the flushing of dry deposition accumulated in the period preceding rainfall, the leaching of compounds from roofing and guttering materials and the corrosion of these materials, and the reduction in concentration of constituents with increasing amounts of precipitation, as a result of the removal by raindrops of aerosol particles and gases contained in the air.[82]

When rainfall is intense, the period of contact between the rainwater and the roofing material is short and just the contaminants accumulated on its surface are washed away; hence, in this case, the type of roofing material is practically irrelevant. However, when rainfall is less intense, the type of roofing material takes on greater significance, because contaminants are adsorbed on roofs with a rough surface like roofing felt or cement tiles, which is why the first flush of rainwater and the initial runoff do not then contain larger amounts of contaminants. These are only flushed away after a long period of rain.[54]

As far as runoff from tree crowns is concerned, there is a drop in the concentration of ions in precipitation and runoff samples with increasing intensity of rainfall.[5]

TABLE 10 The Values of Some Physicochemical Parameters and the Contents of Selected Constituents in Samples of Precipitation and Runoff

		Runoff	
Parameter (mM)	Precipitation	Initial Phase	After the Initial Phase
pH	6.9	7.0–7.6	7.0–7.6
Ca^{2+}	0.06	0.4–1.3	0.1–0.5
Mg^{2+}	0.01	0.06–0.44	0.01–0.04
Na^+	0.02	0.22–0.56	0.02–0.20
K^+	0.01	0.10–0.35	0.02–0.10
NH_4^+	0.14	0.14–0.29	0.02–0.07
Alkalinity	0.08	0.7–2.8	0.3–0.6
Cl^-	0.01	0.06–0.22	0.02–0.06
SO_4^{2-}	0.04	0.1–0.2	0.01–0.1
NO_3^-	0.06	0.29–0.64	0.02–0.20
N_{total}	–	0.5–1.2	0.07–0.30

Summary

The atmosphere is one of the main non-point sources of pollution, and its dynamics causes a diversity of the ways that it can affect the level of contamination of soils and surface water. The composition of precipitation is closely related to a degree of pollution of air. After passing through developed areas (buildings, roads, woodland, farmland, waste dumps), wet deposition enters the environment almost exclusively as runoff.

The composition of runoff water depends to a large extent on the kind of terrain on which precipitation fell. The road runoff can contain hydrocarbons of petrochemical origin, dust, and heavy metals. The level of contamination of roof runoff depends on the roof material, which can be a source of many organic and inorganic pollutants, such as pesticides and heavy metals (copper, zinc). The dump runoff is characterized by variable aggressiveness towards the environment, dependent on the degree of processing of the refuse while the edge-of-field runoff can contain pesticides and biogenic substances. A large fraction of runoff water with the pollutants present in it enters surface water and groundwater, which can be used as a source of drinking water. Although the flux of pollutants into soil and groundwater is usually small, hazardous chemicals can undergo accumulation over a period of time.

Salt Marsh Resilience and Vulnerability to Sea-Level Rise and Other Environmental Impacts

Daria Nikitina

Introduction

Salt marshes are coastal wetlands within the intertidal zone, characterized by highly saline soils and anoxic conditions associated with tidal flooding and vegetated by macrophytes. Salt marshes occur globally along the low-energy depositional coasts of temporal and sub-Arctic climates both in microtidal and macrotidal regimes (Allen and Pye, 1992). Commonly, salt marshes occupy broad flat areas often referred to as the marsh platform. At the landform scale, salt marshes classify based on the physical settings that include open-coast marshes, poorly developed and vulnerable to wave action (Figure 1a); back-barrier marshes that formed on the sheltered side of barrier islands or spits (Figure 1b and f); estuarine marshes that fringe estuaries and coastal lagoons where muddy sediments accumulate (Figure 1e); embayment marshes that fringe the edge of open or restricted-entrance tidal embayment (Figure 1c and d); ria/loch-head marsh, occurring mostly in Europe (Brittany, Ireland and Scotland) (Figure 1g). Salt marshes can also develop where a gently shelving coast is combined with a high concentration of suspended sediment, such as the chenier plain (Rogers and Woodroffe, 2014).

Salt Marsh Ecosystem Characteristics

While there are several types of salt marshes, in the temporal climates, salt marshes are commonly divided into low marsh vegetated by salt-tolerant *Spartina alterniflora*, high marsh dominated by *Spartina patens*, *Distichlis spicata*, *S. alterniflora* (stunted), and *Juncus roemerianus*, and the upper marsh, the transitional zone from salt marsh to freshwater upland that is commonly occupied by *Phragmites australis*, *Iva frutescens*, *Cladium jamaicense*, *Typha* spp., and *Schoenoplectus* spp. (Adams, 1963; Tiner, 1987; Stuckey and Gould, 2000; Nikitina et al., 2003) (Figure 2).

Low biodiversity of the salt marsh ecosystem is related to frequent disturbance and stressful conditions (i.e., high salinity and hypoxia), where differences in plant community are controlled by surface

elevation, salinity regime, and duration and frequency of inundation (McKee and Patrick, 1988; Morris et al., 2002). Low salt marsh with monotypic stands of *S. alterniflora* occurs between mean tide level (MTL) and mean high water (MHW). Height variations within *S. alterniflora* are common, with interior marsh areas having lower vegetation and edges having taller vegetation. The tall (~1.5 m) herbaceous vegetation creates a dense habitat, both above and below ground, and provides habitat for fish, shellfish, and birds (Allen et al., 2018).

The high marsh lies between MHW and mean high high water (MHHW). Higher elevation zones can be more saline in drier climates, due to evaporative concentration of salts, or less saline in higher rainfall areas, due to frequent flushing of salts by fresh rainwater. In the area with hypersaline conditions, communities of succulent salt marsh plants, *Batis* and *Salicornia* spp. often develop (Allen et al., 2018).

The upper marsh occupies the brackish zone at elevations from MHHW to the highest astronomical tide (HAT) where tides mix with freshwater runoff. In climatic zones with warmer winter temperatures, temperate salt marshes naturally transition to mangrove or, in areas with lower precipitation, to salt flats. Arctic marshes are relatively narrow, species-poor, and uniform.

Salt Marsh Ecosystem Services

Salt marshes are economically important coastal landforms and productive ecosystems. Despite occupying <2% of the land, they provide critical ecosystem functions, such as production of organic material and nutrient cycling (Weinstein and Kreeger, 2000; Hopkinson et al., 2012; Howard et al., 2014). They act as nursery grounds for fisheries (Boesch and Turner, 1984; Tupper and Able, 2000); act as biological filters by sequestering pollutants from terrestrial runoff (Brin et al., 2010; Nelson and Zavaleta, 2012); buffer shorelines from storms by attenuating waves and currents that contribute to coastal inundation and damage (Costanza and Folke, 1997; De Groot et al., 2002); and provide tourism and recreation opportunities, education and research (Barbier et al., 2011).

In addition, coastal salt marshes contain 0.1% of the global sequestered terrestrial carbon and have been identified as a "Blue Carbon" ecosystem that plays a significant role in the Global Carbon System (Chung et al., 2011; Mcleod et al., 2011). Overall, "Blue Carbon" ecosystems are responsible for up to 50% of total ocean C burial and contain up to five times more C per unit area than terrestrial forest sediments and 20 times more than deep-sea sediments (Duarte et al., 2005, Cai, 2011, Ouyang and Lee, 2014).

C storage and accumulation capacity are high in salt marshes due to the continuous accumulation of organic C at a greater rate per unit area than any other "Blue Carbon" ecosystem (Chambers et al., 2001; Schlesinger and Lichter, 2001; Duarte et al., 2005; Murray et al., 2011, Chmura, 2013). Sources of organic C in a salt marsh include cordgrasses (primarily *Spartina* spp.), benthic algae, bacteria, allochthonous material including terrestrial and marine organic matter; however, the majority of C is being produced *in situ* by macrophytes (Ember et al., 1987; Radabaugh et al., 2018). Along the submerging coasts, rising sea level produces accommodation space for organic-rich sediments, thereby increasing the inventory of buried organic C through time, as long as salt marsh accretion keeps pace with the rate of rising sea (Kirwan and Blum, 2011; Kirwan and Mudd, 2012). After microbial decay, some portion of the buried C is sequestered over millennia in the marsh sediments (Mcleod et al., 2011, Chmura, 2013). If salt marshes are left undisturbed, then the C stored in the belowground sediments can remain for thousands of years due to anoxic conditions that prevent decomposition (Murray et al., 2011).

Salt Marsh Sustainability

However, despite protective measures, salt marshes are disappearing around the world at an alarming rate. It is estimated that at least 35% salt marshes have been lost globally (Duarte et al., 2008; Pendleton et al., 2012). In some countries, the loss is 70%–80% in the last 50 years (Hopkinson et al., 2012). Coastal marshes have been declining due to industrial development, aquaculture, agricultural reclamation, coastal erosion, and sea-level rise (French, 1997; Blackwell et al., 2004; Kirwan et al., 2010). Many salt marshes are at risk because of pollution by nutrient fluxes, with the largest increases in N flux occurring at coastlines with large areas of intertidal marshland in the temperate zones (Deegan et al., 2012). However, shoreline erosion and inundation are suggested to be the main mechanisms for current global salt marsh loss (Schwimmer, 2001; Mariotti and Fagherazzi, 2010; Theuerkauf et al., 2015).

In the United States, >96% of salt marsh loss is attributed to conversion of marsh to open water (Stedman and Dahl, 2008). In some places, this process could outpace C storage, especially if the depth of erosion at the seaward marsh edge is equal to or greater than the thickness of the marsh sediments (Theuerkauf et al., 2015). The potential future deterioration of marshes and the resulting conversion of their organic sediment to greenhouse gases (CO_2 and CH_4) represent significant impacts on the Global Carbon Budget contributing to global warming and will create positive feedbacks to sea-level rise and ocean acidification (Cai, 2011; Chmura et al., 2011).

The long-term sustainability of salt marsh ecosystem is dependent upon maintaining its elevation within intertidal zone by accumulating organic matter and trapping inorganic sediments (Stumpf, 1983; Morris et al., 2002). However, the processes controlling salt-marsh surface elevation are complex and operate in response to a number of factors including the rate of sea-level rise, sediment supply, tidal range, type of vegetation and primary production (Stevenson et al., 1986; Reed, 1995).

Despite multiple threats, salt marshes are resilient systems. Their ability to accrete vertically depends on concentration of suspended sediment, time of tidal submergence, and biomass density of the plants. Flooding is the main mechanism for sediment delivery to the marsh platform. During flooding, suspended sediments are transported with the tidal currents and partially deposited in distinctive spatial patterns across the marsh platform (Fagherazzi et al., 2012). While the hydrologic regime is largely determined by marsh position within the intertidal range, it is also controlled by geomorphological setting, mainly the proximity to tidal channel. Sedimentation rates across the salt marsh platform are found to decrease with increasing distance from tidal channels and from the seaward marsh edge (French et al., 1995; Leonard, 1997; Reed et al., 1999; Temmerman et al., 2003). Areas along the channel banks and marsh edge vegetated by dense canopy of *S. alterniflora* trap great amount of sediments (Christiansen et al., 2000). Interior areas, which are generally lower in elevation, are more susceptible to submergence and transition to open water, resulting in a disaggregated marsh landscape (Figure 3).

On the other hand, the lower portions of the marsh platform are flooded more frequently for a longer time period, so that more sediment is supplied and deposited. As sediments accrete vertically, sedimentation rates decrease with increasing platform elevation (Stoddart et al., 1989; Cahoon and Reed, 1995).

Hydrologic regime and marsh morphology can be directly modified by anthropogenic activity, including dredging, channelization, upstream modification of rivers and coastal engineering (Kennish, 2001; Turner, 2010). Indirect human modification of the environment including roads, pipelines, dams, oil and water wells and other structures not directly related to salt marsh may affect water and sediment flow, produce a barrier to plant and/or animal migration and contribute to habitat fragmentation, vegetation disturbance and marsh drowning (Allen et al., 2018). Dense vegetation cover favors sedimentation by decreasing tidal current velocities and turbulence once the water flows from the tidal channels into the marsh platform (Leonard and Luther, 1995; Yang, 1998; Christiansen et al., 2000).

FIGURE 3 Interior salt marsh platform recently converted to a salt pond, Slaughter beach salt marsh, Delaware, USA. (Photo credit: D. Nikitina.)

Perhaps the main threat to salt marshes globally is the recent acceleration in the relative sea-level rise (RSLR). Salt marshes have been developing under rising sea-level regime for the last 4000–7000 years by accreting vertically and keeping pace with rates of sea-level rise (Redfield and Rubin, 1962; Redfield, 1965; Stuiver and Daddario, 1963). During the 20th and early 21st centuries, rates of RSLR varied from 2.5 to 3.7 mm/yr (Kopp et al., 2014). For comparison, RSLR along the US Atlantic coast during the last 4000 years varied between 0.6 and 1.7 mm/yr and was mostly driven by glacio-isostatic adjustment of Earth's crust since the melting of the last ice sheet ~7000 years before present (Carlson et al., 2008; Engelhart et al., 2009). Geological data and the tide-gauge records show that RSLR became more rapid throughout the region since the Industrial Revolution identifying the US mid-Atlantic coast as a "hot spot" for sea-level rise (Kemp et al., 2011; Sallenger et al., 2012; Miller et al., 2013). Similar trends were observed elsewhere, reporting the global average rate of sea-level rise from 1880 to 2006 to be 1.7 ± 0.2 mm/yr, while the rate of global average sea-level rise measured from 1993 to 2013 was almost twice as high (3.2 ± 0.4 mm/yr), and this rate appears to be globally accelerating (Church and White, 2006; Jevrejeva et al., 2008; Nerem et al., 2010; Church et al., 2011; Rignot et al., 2011; Gehrels and Woodworth, 2012; Gregory et al., 2012).

Predicted marsh responses to RSLR is either retreat and conversion to tidal flat, tidal lagoon, or open water, if the future rates of RSLR exceed marshes' ability to maintain their elevation in equilibrium with sea level (Reed, 1995; Morris et al., 2002; French, 2006), keep pace with RSLR, or migrate landward. Analysis of geological data, modern observations and simulation studies suggest that salt marshes are resilient to rates of RSLR of ~7.1 mm/yr and likely to retreat when this value exceeds (Horton et al., 2018). Some landscape models using future projections of RSLR increase up to 20 mm/yr predict up to an 80% decrease in global tidal marsh area by 2100 (Spencer et al., 2016; Kopp et al., 2017).

By contrast, other studies suggest that, through biophysical feedback and inland marsh migration, marsh resilience to retreat is possible at RSLR rates in excess of 10 mm/yr (Rodger et al., 2012). Undisturbed vegetation on the marsh platform is a key factor in supporting equilibrium between marsh platform elevation and rapidly rising sea level (Morris et al., 2016). While salt marsh can rapidly subside and transition to open water, subsidence can be compensated by increased production of *S. alterniflora* regulating the elevation of sediment surface toward an equilibrium with mean sea level (Morris et al., 2002). In addition, dense vegetation canopy reduces peak flow velocities, turbulence and shear stress due to friction, enhancing the deposition of suspended sediment and ability of marsh to maintain its elevation within the tidal frame (Leonard and Luther, 1995; Christiansen et al., 2000; Neumeier and Ciavola, 2004; Bouma et al., 2005; Lightbody and Nepf, 2006; Möller et al., 2014).

Marshes also respond to RSLR by migrating into adjacent uplands where they are not restricted by topographic and anthropogenic barriers (Raabe and Stumpf, 2016). The rate of upslope marsh migration is determined by the slope and availability of suspended sediments. Computer simulations of marsh-upland system evolution under a variety of RSLR rates on a gently sloping upland, typical of Atlantic and Gulf coastal plains, suggest that marsh will contract in width under relatively low RSLR rates and low suspended sediment concentration (SSC) and expand under low-moderate-fast RSLR rates and high SSC (Kirwin et al., 2016). The rate of marsh landward transgression depends on the land use of the marsh-adjoining areas, where agricultural fields are more exposed to projected sea-level rise effects than grasslands or forested uplands (Fagherazzi et al., 2019). Construction of dikes, revetments and seawalls prevents salt marsh migration resulting in "coastal squeeze" that leads to marsh loss because erosion of the seaward salt marsh edge cannot be compensated by landward migration (Van der Wal and Pye, 2004).

Recent geological evidence suggests that salt marshes may be significantly eroded during storms and intense hurricane events (van de Plassche et al., 2006; Nikitina et al., 2014). Storm surges during hurricanes move large volumes of water mainly as fast sheet flow producing very high velocities, bottom shear stresses, and drag forces jeopardizing the stability of the vegetation and underlying sediments (Temmerman et al., 2005). Stripping of vegetation and platform erosion was widespread during hurricanes Katrina and Rita along the coast of Gulf of Mexico, USA (Morton and Barras 2011, Turner et al., 2006). While category 2–4 hurricanes are extreme and relatively rare events, salt marshes are often subject to erosion during the smaller storms because during a surge waves propagate over the marsh platform without impacting the edge of the marsh (Leonardi and Fagherazzi 2014, 2015).

Conclusion

Overall, salt marshes are highly dynamic coastal landforms vulnerable to many environmental stresses, mostly RSLR, storm erosion and anthropogenic impact. On the other hand, they are highly resilient coastal ecosystems. Their emergence and continued survival are driven by the rising sea level over millennia. Numerous feedbacks between tidal flooding, plant growth, organic matter production and sediment transport allow marshes to adapt to a wide range of RSLR rates in the vertical and lateral dimension. The global record of recent salt marsh decline correlates with anthropogenically induced acceleration in sea-level rise superimposed on other human activities (e.g., drainage and conversion to agriculture, coastal development, dredging). In many cases, the lateral expansion, the survival mechanism of salt marshes, is impossible due to the presence of topographic or anthropogenic barriers that limit salt marsh migration. However, the major risk of tidal marsh loss in the 21st century is the future rates of RSLR.

The Evolution of Water Resources Management

Francine van den Brandeler and Joyeeta Gupta

Introduction

Water resources are crucial for lives, livelihoods, biodiversity, ecosystems, and economic development. The adequate management of these water resources is therefore intrinsic to sustainable and inclusive development. Water problems can be broadly characterized in terms of quantity, quality, and the effects of extreme weather events (UNE 2019). Water quantity challenges can be absolute or relative (i.e., dependent on the ratio between water availability and demand), with 'chronic water shortages' defined as annual water supplies below 1000 m^3 per person within a certain area drop and 'absolute water scarcity' as less than 500 m^3 per person (FAO 2012). These challenges may be caused or aggravated by overabstracting water from rivers and groundwater resources. Quantitative challenges can also relate to the unequal distribution of water resources within an area and inequality of access. Qualitative water challenges relate to pollution from point sources (e.g., untreated industrial or domestic wastewater discharge) and diffuse pollution (e.g., fertilizers and pesticides from agriculture and surface runoff in urban areas) (Martinez-Santos et al. 2014; Elmqvist et al. 2013). Water-related risks linked to extreme weather events include droughts, floods, and landslides, with devastating consequences on human settlements, agriculture, and ecosystems (GRID 2018).

These challenges are affected by five driving forces that have put increased pressures on water systems around the world: (1) population dynamics, (2) urbanization, (3) technology development, (4) a constant pursuit of economic growth, and (5) climate change (UNE 2019). These, in turn, affect land use and land-use changes, such as deforestation to clear land for agriculture and urbanization; these lead to further deterioration of water quality by disturbing ecosystems and the hydrological cycle (Azzam et al. 2014; Avissar and Werth 2005). Climate variability and change affect hydrological systems by making extreme weather events more intense and more frequent (IPCC 2014).

Water resources management aims to address these challenges and underlying driving forces. Management encompasses 'the processes of decision-making, coordination, and resource deployment that occur within a given institutional setting assuming no change in rules and norms' (Hatfield-Dodds et al. 2007, 3). Although management approaches rely on scientific and technical knowledge, they are also influenced by available human and financial resources, as well as contextual factors, politics, and power relations. Indeed, "the challenge of the water crisis is first and foremost a 'crisis of governance'" (UNESCO 2006, 1), relating not only to how management systems are designed but also to how water is conceptualized, who owns water, how boundaries are delineated for management purposes, and how links to other issues are framed (Gupta et al. 2013). Water resources management approaches, in this sense, are a particular strategy of governance. They influence the institutional tools selected for allocating, regulating, and preserving water resources, the type of water (blue, black, gray, and green), infrastructure and technologies, and information systems. Water resources management approaches have evolved over time and increasingly incorporate notions of sustainability and inclusiveness, and this is reflected at global level through the adoption of a specific goal on water within the Sustainable Development Goals (SDGs) (UNGA 2015), while many other goals are directly or indirectly linked to water. Nevertheless, as water-related challenges multiply and increase in complexity, there is growing uncertainty about the most adaptive approach to manage water resources. The sections below discuss several of the main paradigms that have shaped water resources management over time, including the control of water resources to consolidate power, which started with the first ancient civilizations; water resources management as an instrument of colonization; the hydraulic paradigm; Integrated Water Resources Management (IWRM); Adaptive Management (AM); the Water–Energy–Food Nexus; and urban-centric approaches to water management.

Water Resources Management in Pre-Modern Times

Rules on managing water first developed in local customary law which later spread through the expansion of the early river basin civilizations (Gupta and Dellapenna 2009). Major rivers historically attracted communities; early states aimed at consolidating power by controlling water resources (Wittfogel 1955). Harnessing water resources was essential for the development of agriculture in Mesopotamia and Egypt, around 5700–3200 BCE, which included systems of communal canals, irrigation works, and legal frameworks to govern these (Angelakis and Zheng 2015; Kornfeld 2009). The Indus Valley civilization developed around the Indus Valley. In ancient Rome, aqueducts, fountains, and pipes on a large-scale supplied freshwater to cities and removed wastewater (Wilson 1998). Complex management systems developed first in areas where water was scarce such as the Middle East and influenced Islamic and Jewish water law and policy. The Aztecs founded Tenochtitlán (now Mexico City) in 1324 on an island surrounded by lakes within an endorheic basin. The lakes protected them from enemy invaders and provided fish and food from floating farms and through canals and irrigation infrastructures (Sosa-Rodriguez 2010). Their dependence on the lakes meant that it was essential for their survival that they preserved the hydrological balance. Exposed to frequent droughts and floods, the Aztecs also suffered from insufficient water supply, low-quality water, and inadequate sanitation. To exercise control over the basin's hydrology, they not only built drains, dams, dikes, floodgates, and aqueducts but also implemented strict rules such as the prohibition of waste disposal into water bodies. In the Netherlands, the water boards established in the 13th century to protect the lowest-lying regions from floods still exist and have been institutionalized into about 200 boards today (Lazaroms and Poos 2004). These democratically elected decentralized government authorities manage local to regional water bodies to manage water quality- and quantity-related issues and are allowed to raise resources through taxes.

The fall of civilizations has frequently been attributed to water mismanagement. The Sumerian and Indus Valley civilizations may have collapsed from soil salinization through irrigated agriculture in an arid climate (Alam et al. 2007). The Maya civilization's downfall in the early 900s may have been caused by a series of drought events that urban elites were unable to adapt to (Lucero et al. 2011). Overall, water resources management and the ability to adapt to changing conditions have been key to both the rise and fall of civilizations.

Colonial Times

During colonial times, water was central for exploration, establishing sovereignty and commercial benefits. River navigation played an important role. Portuguese colonizers in Brazil strategically used navigation to explore the newly conquered territory, map the land, control rivers, and facilitate state integration (Paganini 2008; Leite Farias 2009). In the next stage, administrating colonies required water resources management and institutions for irrigation, flood and drought prevention, and transportation (Bhattacharya 2017). After the fall of ancient civilizations, their sophisticated irrigation techniques and hydraulic works disappeared almost everywhere except in China, but these reappeared in the 19th century, as colonial powers mobilized massive corvée labor and diverted rivers to irrigate alluvial planes and deltas at great social cost (Molle et al. 2009). Colonial powers frequently cast aside indigenous water management knowledge and practices to impose theirs while possessing little understanding of local hydrology. For instance, the Spaniards transformed the basin's hydrology after they invaded Tenochtitlán. They associated the Aztec city's surrounding lakes with an unhealthy environment and a source of disease, and soon began ambitious efforts to drain the lakes, which aggravated recurrent floods (Sosa-Rodriguez 2010).

Water resources management institutions imposed as part of the colonization process often partly or largely replaced customary water regimes and asserted the colonial state's ownership over water resources (Cullet and Gupta 2009). Customary laws often continue to influence water regimes and co-exist with colonial and post-colonial institutions, leading to dual legal regimes (Nilsson and Nyanchaga 2009). In rural early America, water use was considered a community right and, as the nation consolidated, water use acquired some standing as an individual right. Conflicts between the two led to the doctrine of riparian rights, which states that water belongs to the person whose land borders a body of water (Burke 1956). With increasing competition for water resources in the 19th century, the rule of prior appropriation was introduced ('first in time, first in right'), particularly in the western states (Hanak et al. 2011).

Overall, colonialism commodified water resources while dismantling community control, causing the impoverishment of rural populations, as was the case in India where indigenous water harvesting systems were purposely destroyed (D'Souza 2006). Infrastructure and technology for drinking water provision were mainly developed in areas occupied by the colonizers as European powers were reluctant to invest in their overseas colonies unless this would be profitable, but rapidly growing cities, such as Bombay in the British Empire, experienced deterioration in urban conditions and rising tensions (Anand 2011; Nilsson and Nyanchaga 2009; Gandy 2008).

The Hydraulic Paradigm

Scientific developments, fascination with 'scientific irrigation', and ideas such as the domination of nature and the creation of new Edens in deserts cumulated into large public investments in dams and irrigation systems as of the beginning of the 20th century (Molle et al. 2009; Smythe 1905). States developed water systems as part of a 'Hydraulic mission' that aimed to increase food production, raise rural incomes, respond to growing urban water demand, strengthen state building, and legitimize governments (Hanak et al. 2011; Molle et al. 2009). In Spain, this was part of a response to the humiliating loss of colonies and the turn of colonial ambitions inward to dry and poor rural areas (Lopez-Gunn 2009). The state-led hydraulic policy served to legitimize the state, reinvent the economy, and assuage the threat of a discontented peasantry. Technological advancements, such as drilling and gasoline- and diesel-powered pumps, enhanced access to groundwater and further expanded agricultural land in dry regions such as California (Hanak et al. 2011).

The hydraulic paradigm spread worldwide, as water managers and governments strived to control the natural environment through infrastructures for reducing floods, generating hydropower and supplying cities with drinking water (Custódio 2012; Swyngedouw 1999; Lopez-Gunn 2009; Molle et al. 2009), requiring large investments and centralized management (Pahl-Wostl et al., 2007; Huitema and Meijerink, 2017). Within the United States, urban water supply systems were initially often built by small, private companies and mainly served wealthier neighborhoods (Porse 2014). However, seeking more reliable options for public health, flood control, and economic growth in urban areas, water delivery, and stormwater and sewage conveyance services were increasingly centralized and municipalized in the late 19th and early 20th centuries (Rietveld et al. 2016; Domènech 2011). As cities grew, dams and aqueducts were built to bring water from distant locations and replaced dwindling or polluted local sources (Porse 2014; Hanak et al. 2011), and the emphasis was on supply augmentation rather than demand management (Xie 2006).

The creation of national water bureaucracies in the post-World War II period and efforts to modernize customary, state, and colonial water laws soon followed to regulate many issues including large-scale engineering works (Hanak et al. 2011). The physical integration of waterworks in fragmented countries supported their integration and often became a focal point for nation-building (Huitema and Meijerink 2017). However, this process often involved the expropriation of rights from private owners to state bureaucracies in order to further national economic interests by strengthening agriculture and emerging industries. This included local and indigenous water rights under colonial and post-colonial regimes (Boelens 2009). Water management tasks were generally allocated to government agencies at provincial or national levels (Huitema and Meijerink 2017). Different tasks were the responsibility of different sectors (agriculture, domestic use, industry, environmental protection, etc.) with often little coordination between them (Xie 2006).

The Hydraulic Era gave way to different forms of water control. Large-scale, centralized infrastructure provided many societal and economic benefits but could not cover distant areas and vulnerable groups. In California, lakes dried up and rivers became wastewater canals, aquatic species declined sharply, and farmers complained about increasing salinity in their water supplies due to upstream diversions (Hanak et al. 2011). With the start of the environmental movement in the 1970s, demands for regulating pollution of water became more important. This movement spread around the world, strengthening environmental legislation and also emphasizing nature as a legitimate user of water resources (Hanak et al. 2011; Kallis and Coccossis 2002). This was institutionalized through measures such as the establishment of minimum environmental flows and maximum groundwater extractions, environmental impact assessments, and stricter regulations regarding wastewater discharges. This influenced water governance. Another feature influencing water governance was the shift from 'government to governance' and 'governance-beyond-the-state' (Huitema and Meijerink 2017; Swyngedouw 2005) and the rise of the non-state actor. This coincided with the neo-liberal demand for lean states and deregulation and led to water resources being managed by assemblages of public, private, and civil society actors with different approaches to water, shaping not only how they address problems but also how they interact with other actors (Brandeler et al. 2014). Power is transferred to both lower and higher levels. Decentralization processes have brought decision-making closer to those affected, enhancing democratic legitimacy (Dryzek 1997) and resulting in policies more likely to be supported at local levels (Kasemir et al. 2003). However, this has also led to a lack of accountability and patchy institutions that are unable to address society's needs.

Meanwhile, the recognition of global water drivers and cumulative impacts and the need for common norms have increased support for global water governance in order to address the global drivers (Gupta and Pahl-Wostl 2013; Vörösmarty et al. 2013). With the adoption of the SDGs, water governance can no longer be seen as independent of all the other goals. Some scholars see that the IWRM paradigm may have to evolve into a Nexus paradigm in order to be able to preempt the problems of tomorrow.

IWRM – Dominant Paradigm Today

The ideas behind the concept of IWRM emerged in the 1970s through practitioners, and these first appeared in official water policy circles at the global water conference in Mar del Plata in 1977, which emphasized the need for coordinating different users and authorities, participation, and legal frameworks to ensure effective water allocation (WWAP 2009). It was developed in the late 1980s and was adopted in the Dublin

Principles adopted by the International Conference on Water and the Environment in Dublin. The four principles recognized freshwater as ‘a finite and vulnerable resource’, integrated, participatory management at the ‘lowest appropriate level’, emphasis on the central role of water as well as on the economic value of water (ICWE 1992). The Global Water Partnership (GWP) defined IWRM as ‘a process that promotes the coordinated development and management of water, land, and related resources, in order to maximize the resultant economic and social welfare in an equitable manner without compromising the sustainability of vital ecosystems’ (GWP-TAC 2000). IWRM has since become the dominant paradigm for water resources management, having been adopted by international agencies and transnational actors such as the World Bank, the European Union (EU) (e.g., Water Framework Directive and EU Water Initiative), and the United Nations, most recently through the latter’s SDGs (UNGA 2015; Abers and Keck 2013; Wallington et al. 2010; Abers 2007; Molle 2009) but also by a growing number of national governments to frame their laws and policies (Gupta and Pahl-Wostl 2013; UNEP 2012).

IWRM strives to address social equity, including the water-related needs of the poor (Hooper 2005; Rahaman and Varis 2005). It promotes the integration of human and natural systems (Dzwairo et al. 2010), sectoral responses, and viewpoints and interests (Medema et al. 2008; Jønch-Clausen and Fugl 2001). While marginalized people are given a voice, IWRM also mirrors general governance shifts towards greater private sector involvement through emphasis on cost recovery, the establishment of pricing mechanisms and cost-benefit analyses, and allocation to the most beneficial uses (Huitema and Meijerink 2017; Xie 2006). Environmental sustainability is addressed through concerns about the ecological impacts of water resources management activities, including through disruption to the water cycle, pollution control, development planning, demand management, and biodiversity conservation (Medema et al. 2008; Savenije and Van der Zaag 2008; Grigg 2008). In addition, although IWRM works through national-level legislation, policies, and institutions, it emphasizes the river basin as the ideal unit for water resources management and the creation of river basin organizations (RBOs) (Butterworth et al. 2010; Hooper 2005; Abdullah and Christensen 2004). It is considered as crucial to integrate upstream and downstream concerns, to foster bottom-up planning (Molle 2009; Xie 2006). This systems approach is often seen as the key innovation of IWRM (Huitema and Meijerink 2017).

However, there are many criticisms regarding the limitations of the IWRM concept and how to implement it in practice. River basins follow hydrological boundaries and therefore frequently cut across administrative boundaries, including national borders (Butterworth et al. 2010). This can create tensions between hydrological and institutional logics and create cooperation challenges. In addition, achieving effective participation that leads to greater inclusiveness is challenging because, even with the best intentions, it requires significant resources and time commitments from participants, as well as expert knowledge to follow and intervene in discussions (Brandeler et al. 2014; Butterworth et al. 2010). Similarly, the multiple integration goals (i.e., land/water, surface/groundwater, human/nature, upstream/downstream) are unrealistic (Biswas 2008), in particular in contexts of uncertainty, insufficient data, low political will, and limited financial resources (Agyenim 2011; Molle 2008; Watson 2004; Allan 2003). Moreover, the principle of water as an economic good can lead to it being treated as a commodity, at the expense of its nonmonetary value (Rahaman and Varis 2005). IWRM is often depoliticized, even though it is fundamentally a political process, as it involves choices such as the allocation of water between competing users (Jønch-Clausen and Fugl 2001). Despite the legitimacy and mandates that they are given, RBOs are faced with the traditional powerful line agencies, such as irrigation and agriculture authorities, which create obstacles for these organizations to assert themselves as sites of decision-making (Molle 2008; Wester and Warner 2002).

A search was conducted in ScienceDirect for IWRM and other concepts discussed below (Adaptive Water Management or AWM, Water–Energy–Food Nexus, Integrated or Sustainable Urban Water Management or SUWM) in titles, abstracts, and key words for the period 1980–2018. Figure 1 illustrates the sharp rise in publications for all these concepts since the turn of the 21st century. The growing recognition of IWRM’s limitations may explain the concept’s relative loss of ground to other approaches in the past decade.

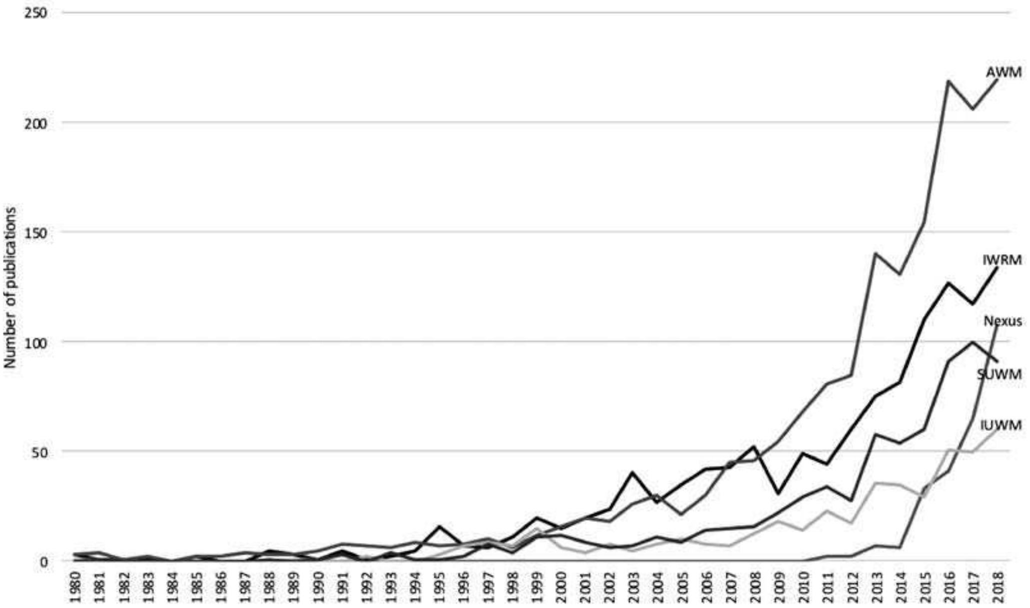

FIGURE 1 Evolution of water resources management approaches within academic literature.

Adaptive Management

AM can be traced back to the late 1970s and is based on the recognition that, although interactions between people and ecosystems can be unpredictable, it is necessary to take management action (Medema et al. 2008; Johnson 1999; Walters and Hilborn 1978; Holling 1978). It arose in a context of rising environmental challenges and public pressure to address these and aimed to support governments and policy makers through new conceptualizations (Hurlbert 2016). AM is a systematic, iterative process, centered on a learning model to not just cope with complex water-related challenges but to learn from them and improve management policies (Medema et al. 2008; Pahl-Wostl 2008). It should enable experimentation and comparison between selected policies and practices (Medema et al. 2008). As IWRM, AM therefore promotes some degree of institutional reform. However, IWRM does not clarify how implementation works within a context of uncertainty nor does it refer explicitly to adaptive capacity (Agyenim 2011; Butterworth et al. 2010). While enhancing democratic legitimacy and contextual responses, the participatory and deliberative forums of IWRM may be unequipped to deal with rapid changes (Brandeler et al. 2018).

AM is not exclusively centered around water resources and the term ‘Adaptive Water Management’ (AWM) is sometimes used to designate an explicit focus on these. As climate change and other global changes impact hydrological systems, the need for adaptive capacity and flexibility, AWM is increasingly recognized, as it allows for speeding up the learning cycle and faster assessments and responses (Pahl-Wostl, Craps, et al. 2007). AM encourages networked forms of governance and participatory processes that enable shared knowledge production and knowledge exchange between sectors and institutions (Pahl-Wostl, Craps, et al. 2007). This can foster social learning – understood as a process of collaborative learning through regular interaction between stakeholder groups – and thereby facilitate joint solutions, leading to more adaptive governance. Social learning processes can be strengthened by building trust and social capital and by providing space for out-of-the-box thinking and experiments

(Pahl-Wostl, Sendzimir, et al. 2007). In addition, more flexible and diverse management measures can reduce vulnerability to unpredictable shocks. AM is increasingly being complemented by adaptive governance, which includes the study of multiple social structures, interconnected resources and actors, and promotes resilience across different scales (Hurlbert and Gupta 2016). This includes measures such as scenario-building and strategic planning to prepare for a range of possible futures.

As with IWRM, AM has been described as difficult to implement and sustain in practice, especially in terms of attaining broad collaboration and the inclusion of stakeholders beyond experts and authorities (Huitema et al. 2009; Medema et al. 2008). The concept has multiple and ambiguous definitions that make it difficult for managers to apply (Medema et al. 2008). Adaptation can also be at odds with water management institutions, which tend to be path dependent and resistant to change due to institutional and technological 'lock-in' effects (Marlow et al. 2013). The large sunk costs and long life cycle of legacy infrastructure disincentivize innovative alternatives (Pahl-Wostl 2007). Another challenge of AM is that it assumes that current management processes are the cause of water resources problems and that these can be untangled, and it ignores the inherent political risks with making management 'experiments' (Medema et al. 2008).

Water–Energy–Food Nexus

In the context of water management, the Nexus approach refers to a set of interrelated activities – typically surrounding water, energy, and the environment – and their linkages as well as the boundary around them, providing a particular frame with which to address water-related problems (Muller 2015; Lofman et al. 2002). The origins of this approach can be traced back to the 1970s. The 1977 UN Water Conference in Mar del Plata highlighted the multiple linkages and interactions between water, food, and energy and the need for a coherent approach to multipurpose water resources development (Muller 2015). However, the Nexus approach gained little traction during the 1980s – seen as a lost decade for international water policy – and was further sidelined by the emergence of IWRM in the 1990s (Scheumann and Klaphake 2001). A search in ScienceDirect for the term 'Water–Energy–Food Nexus' in titles, abstracts, and/or keywords reveals that publications were virtually nonexistent before 2010 but have since grown exponentially (see Figure 1). The Nexus Conference in Bonn in 2011 became the first internationally recognized event on this theme, and it has since been promoted by the EU, the German Development Cooperation, and the United Nations in its SDGs (Benson et al. 2015). This sudden popularity has been described as a response to disillusionment with the IWRM paradigm (Muller 2015).

Through the Nexus approach, water is seen as a crosscutting issue rather than a sector or specific issue area (Gupta et al. 2013). Discussions on 'virtual water' or embodied or embedded water and the role of the food trade in water-scarce regions first highlighted the linkages between water and food (Allan 1998). The focus on the relationship between water and energy arose separately, in particular, regarding electrification in rural areas and groundwater overuse (Shah 2009). Similar to the IWRM approach, the Nexus approach aims for holistic and coordinated management between different aspects of water systems, and it promotes better resource use to allow societies to develop in an environmentally, socially, and economically sustainable way (Benson et al. 2015; Hoff 2011). This is also based on cooperation between actors and citizen participation (Hoff 2011). However, it differs from IWRM, which is a water-centric approach, by granting equal importance to different sectors (Benson et al. 2015). It considers these as inextricably interlinked and seeks to address externalities across them (e.g., energy intensity of desalinization), reduce trade-offs, and increase system efficiency (Olsson 2013; Hoff 2011). In addition, rather than a focus on the river basin with an overarching centralized approach for national policy, the Nexus is implemented in 'problemsheds' where boundaries are drawn around a set of interrelated activities that take place at multiple scales (Muller 2015; Benson et al. 2015; Rouillard et al. 2014).

Criticism of the Nexus approach includes its limited emphasis on integrating water resources management with broader social and economic development activities and its lack of specific emphasis on nature, ethics, power relations, public policies, and other issues (Muller 2015; Leck et al. 2015). This may be a reflection of its focus on cross-sectoral policy coherence rather than on more normative goals, but this also depoliticizes the challenges surrounding water resources management. In addition, implementation of the Nexus approach is challenging at the institutional level, as sectoral decisions often take place at different levels (i.e., national, provincial, local) and remain decoupled (Benson et al. 2015; Scott et al. 2011). Overall, there is a burgeoning literature operationalizing this concept at multiple levels of governance, each using its own approaches and methods.

Water Management in an Increasingly Urban World

The dynamics of a growing world population is accompanied by increasing rural–urban migration with 68% of the population expected to be concentrated in cities by 2050 (UN-DESA 2018). There is a short window of opportunity as many of these cities are expected to be expanded and reach maturity in the next 20–30 years (UNE 2019). The infrastructure that is developed for water is thus critical for the future. Increasing urbanization leads to the concentration of water demand and pressure on water resources in cities' rural hinterlands (ARUP 2018). The economic development often associated with urban growth further increases per capita water use (McDonald et al. 2014). This pressure on water resources can lead to the over-exploitation of aquifers, reliance on inter-basin transfers, and conflicts between users. Urbanization causes water quality degradation due to drastic interferences in ecosystems and the hydrological cycle, including from the inadequate disposal of sewage and solid waste (Azzam et al. 2014). This aggravates regional water stress by reducing water available for use, which tends to disproportionally affect marginalized communities (Varis et al. 2006). Rapid urbanization combined with inadequate urban planning also increases vulnerability to extreme weather events, as populations move into risk-prone areas (UCLG 2016). Urban dwellers are particularly exposed to climate change as many cities are located on river banks and in coastal or flood-prone areas (Varis et al. 2006). It is expected that 40% of urban land will be in high-frequency flood zones in 2030, up from 30% in 2000 (Güneralp et al. 2015).

IWRM may not be an adequate framework to address the challenges of water in and around cities. Although it aims to coordinate between all users, it does not specifically clarify how to address urban water challenges (Brandeler et al. 2018). Cities, and in particular large metropolitan areas, are characterized by complex institutional landscapes with multiple jurisdictions and differing or even conflicting interests. This can lead to fragmented decision-making; a challenge for IWRM (i.e., integrated management and participation), Adaptive Management and Governance (i.e., social learning through collaborative processes), or the Nexus approach (i.e., dominance of urban interests over those of other sectors). Moreover, there are often important power imbalances between urban and rural areas, which affect users' ability to access water resources (Swyngedouw et al. 2002). In heavily urbanized basins where water resources are relatively scarce, competition and conflict between urban and rural users may arise due to water resources allocation regimes (Molle and Mamanpoush 2012).

City-centric frameworks, such as Integrated Urban Water Management (IUWM) and SUWM, have emerged, with roots in IWRM (Bahri 2012). IUWM promotes a holistic view of the urban water cycle, involving stakeholder participation and a flexible mode of strategic planning (Closas et al. 2012; Varis et al. 2006; Brown 2005). SUWM frames water as central to sustainability in cities and a potential starting point for urban planning (Daigger 2011). It aims to combine large and centralized infrastructure with alternative, decentralized and hybrid systems, such as green infrastructure and water reuse (Closas et al. 2012; Younos 2011; Van de Meene et al. 2011). However, such shifts are often hindered in practice by investment and technological 'lock-in' (Marlow et al. 2013). Institutional inertia, caused by factors such as overcentralization, bureaucratic inefficiencies, and a lack of sustainable finance, further limits the implementation of IUWM and SUWM, in particular as urban water challenges become increasingly large and complex (Brown and Farrelly 2007; Lee 2000). Another issue with

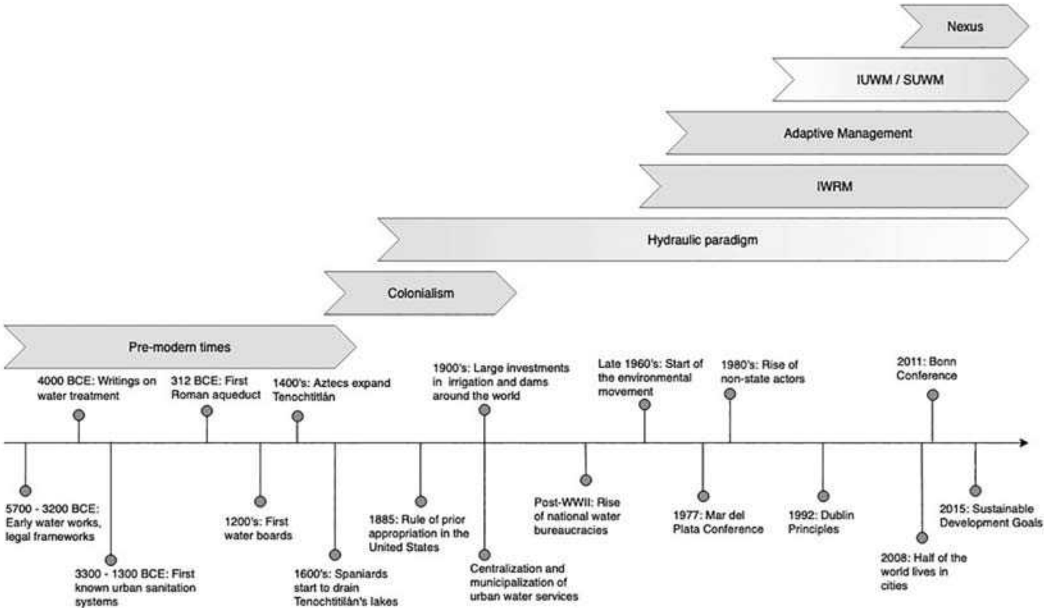

FIGURE 2 Timeline of water resources management approaches.

these frameworks is that they do not address water resources beyond urban boundaries (Brandeler et al. 2018). Ultimately, water management approaches are in constant flux (see Figure 2). As climate change and urbanization increasingly shape water-related challenges, water management approaches will need to adjust to these drivers.

Conclusion

This overview of a few of the dominant approaches to water resources management throughout history highlights society's constant struggle with harnessing the potential of water resources while mitigating its associated risks and challenges. Management approaches have had to adjust to new types of challenges, as population growth has increased water demand and competition between users and sectors and with climate change as a risk-multiplier. In the past three decades, multiple paradigms have emerged. Despite their differences, these approaches shared multiple commonalities, such as decentralization, the integration of issues and sectors, the inclusion of a larger range of actors at multiple levels, and a shift away from exclusively engineering-based solutions towards conservation, efficient water use, and green infrastructure. Around the world, water resources management actors have incorporated good governance principles within laws and policies.

However, institutional change is slow, in particular, due to path dependency and the 'lock-in' effect and as power relations often favor the status quo, leading to a lack of adherence to good governance principles in practice. To support changes in practice, it is crucial that water managers have access to reliable data and that actors across sectors and at multiple levels can effectively share knowledge and information. Decentralization has supported more inclusive and context-relevant decision-making, but effective coordination mechanisms are necessary to avoid fragmentation between actors and incoherent responses. In addition, cash-strapped agencies struggle to carry out their responsibilities, especially in the Global South. This requires not only adequate pricing mechanisms but also political will and a long-term perspective from leaders seeking fast results.

There is an urgent need to preempt possible future damage through better institutional and infrastructural design today. Although there are no panaceas to address complex water resources challenges, lessons can be learned from the advantages and limitations of past and present management approaches.

Wastewater and Water Utilities

Rudolf Marloth

Introduction

Municipalities are normally responsible for providing water and disposing of wastewater, either by privately or publicly owned utilities. A water utility is responsible for the source, transmission, treatment, and distribution of potable water. Water usage is metered at the user. A wastewater treatment utility is responsible for collection, treatment, and disposal. Industrial wastewater is often metered. Residential wastewater charges are based on water usage.

Municipalities are also responsible for the collection and disposal of runoff, which consists of stormwater, misplaced or excessive irrigation, domestic car washing, etc. Runoff collects in gutters or holding ponds; then goes to storm sewers; and is dumped into a nearby river or, in coastal cities, directly into the ocean. This water carries with it a variety of pollutants: fertilizer, animal waste, oils, tire dust, etc. For municipalities that do not have combined storm and sanitary sewers, this runoff is dumped without treatment. Worse, in severe storms, combined sewer systems are likely to dump runoff combined with untreated sewage. Furthermore, runoff is not metered, so the municipality bears the cost of installing and maintaining the infrastructure. Possible approaches to reducing pollution of natural waters are (a) enactment of ordinances to make property owners responsible for reducing runoff and its pollutants, (b) diverting light flow or the first flow in a storm to a wastewater treatment plant (WWTP), and (c) installing treatment facilities to make runoff suitable for reuse. (The city of Santa Monica, California recently demonstrated its SMURRF (Santa Monica Urban Runoff Recycling Facility), the first of its kind in the nation.)

Water

The primary objective of water treatment is to make it safe for human consumption at a reasonable cost. It is possible to produce safe water that has objectionable taste, odor, or color, so a secondary goal is to make the water appealing to the consumer. Turbidity and color are qualities apparent to the naked eye.

The former is caused by particles in suspension and is measured in nephalometric turbidity units (NTU) by passing light through a sample. These particles can be removed by settling or filtering. Colloidal particles will not settle in a reasonable amount of time and must be removed by other physical processes. Dissolved substances are removed or transformed by chemical treatment. Color may be caused either by materials in solution (true color) or in suspension (apparent color).[1]

History

Early water treatment focused on what was apparent to the senses: appearance, taste, and odor. These qualities were improved by removing turbidity through filtration or precipitation. It was found much later that particles in the water harbored pathogens, which were largely removed while clarifying the water.

A slow sand filter (SSF) designed by James Simpson was commissioned in 1829, but it was some time before its full importance was realized. This simple device is essentially a tank filled with sand with water introduced at the top and removed at the bottom. Sometime after the filter is started up (a few days to a few weeks), the upper layer of sand becomes coated with a gelatinous biological layer called the schmutzedecke, made up of algae, bacteria, protozoa, and small invertebrates. This sticky layer is biologically active and converts organic matter in the water to water, carbon dioxide, and harmless salts (i.e., it is mineralized). Later, research showed the importance of biological removal and also showed that the SSF was very effective in that respect. In particular, the SSF is effective in removing *Giardia* and *Cryptosporidium* oocysts, which are nearly unaffected by chlorination.[1,2]

In the famous Broad Street pump episode of 1854, an outbreak of cholera in the Soho district of London killed more than 600 people. Dr. John Snow, who had theorized that the disease was spread by contaminated water, traced it to water from the Broad Street pump. The likely cause was from a leaking and cholera-infested cesspool located only three feet from the Broad Street well. In fact, cesspits lay under many of the houses in the district.[3] Acceptance of Snow's theory was slow, as was conversion to a sewer system that conveyed wastewater to central plants.

Recently, the Centers for Disease Control and Prevention and the National Academy of Engineering named water treatment as one of the most significant public health advancements of the 20th century.[4] This is rightly so, for in the first half of the 20th century, life expectancy in the United States increased dramatically, primarily because of water treatment, which has greatly reduced the incidence of waterborne bacterial infections such as cholera, typhoid fever, and dysentery. Even so, waterborne disease does occur in this country, the most well-known instance of which is the cryptosporidiosis outbreak of 1973 in Milwaukee. Most episodes are due to contamination of raw or treated water, inadequate treatment, and cross-contamination between sewers and water mains.

Standards and Monitoring

The Safe Drinking Water Act of 1974 and its amendments of 1986 and 1996 are the primary pieces of federal legislation protecting drinking water supplied by public water systems. Primary regulations under the act are for the protection of public health; secondary regulations are for regulations pertaining to taste, odor, and appearance.

The Surface Water Treatment Rule mandates that surface water or groundwater under the influence of surface water must be treated to remove or inactivate 99.9% of *Giardia lamblia* cysts and 99.99% of enteric viruses. These requirements are commonly stated as "log removals," where n-log removal is removal of a $1–10^{-n}$ fraction of the pollutant. Treatment processes using filtration are judged to comply by providing an adequate concentration/ contact time (Ct) product, where C is the concentration of the disinfectant in mg/L and t is the time in minutes.[5]

The Enhanced Surface Water Treatment Rule requires a 2-log removal of *Cryptosporidium*. Systems using filtration are granted credit if they meet certain turbidity criteria. The Filter Backwash Recycling

Rule requires treatment plants to recycle filter backwash water through the entire process cycle. The Disinfectants/Disinfection Byproduct Rule establishes maximum contaminant levels (MCLs) on total trihalomethanes, haloacetic acids, bromate ion, and chlorite ion.[5]

The most common way of testing the quality of drinking water is the coliform test, as specified by the U.S. Environmental Protection Agency. Coliforms are bacteria that are gram-negative, aerobic and facultative anaerobic, nonspore-forming rods, which ferment lactose with gas formation in 48 h at 35°C. When a sample tests positive for coliforms, it must be tested for fecal coliforms. Fecal or thermotolerant coliforms include all coliforms that can ferment lactose at 44.5°C. It is common to identify *Escherichia coli* uniquely with fecal coliforms.[5]

Sources and Transmission

Large-scale sources are primarily surface water and groundwater. Desalinated ocean water is not yet a major source in the United States, although Spain is a major producer and user of desalinated water. In the past 30 years, the energy required for desalination has fallen from 12 to 3 or 4 kWh/m^3 using reverse osmosis.[6] In a few areas, recycled water (treated wastewater) is used for irrigation. Water is transmitted by way of natural water courses, lined open channels, or pressure pipe. Los Angeles, for example, receives water from the Sacramento Delta via a concrete-lined open channel, from snowmelt in the Sierra via a natural watercourse that is diverted into an iron pipe aqueduct. New York reservoirs supply water to treatment plants through a series of underground tunnels. In some cases, water treatment plants are located right at the site where water is drawn from a river or lake.

Treatment

Treatment is tailored somewhat to the characteristics of the influent and the effluent limits, but in general, large particles are removed first by screening and then by settling. Next are particles that will float or settle with some assistance, such as air floatation or mixing with coagulants. Colloids and dissolved materials are removed last. The water should be nearly clear before disinfection so that contaminants may not hide in turbidity.

Standard water treatment (Figure 1) consists of coagulation, flocculation (aggregation into a wooly mass), sedimentation, filtration, and disinfection. The size of the units and major equipment are determined by the hydraulic loading. The examples below are based on a plant with an average flow of 24 mgd (million gal per day). Plants are commonly designed for a maximum daily flow that is 1.5 times the average daily flow. Plants whose main supply is groundwater will have a somewhat different process chain because the water will contain less settleable and suspended solids but probably more dissolved metals. Plants that draw from a river should have at their head a coarse screen for tree branches, etc., and a grit chamber for sand and silt, because this kind of grit will cause a serious maintenance problem with pumps.

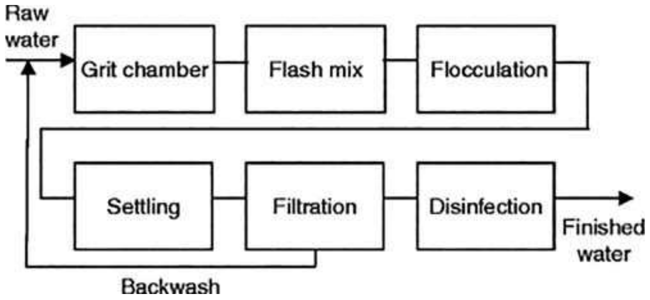

FIGURE 1 Water treatment.

The coagulation operation consists of the addition and flash mixing of chemicals meant to remove the charge on colloids and suspended solids so that they will aggregate in the flocculation step. Depending on the type of chemical used, flash mixing should occur in about one to five seconds. The addition of more than the optimum amount of chemicals can compensate for less-than-optimum mixing. A potential problem in this step is the clogging of feed lines. Various methods of flash mixing are available, the best of which are diffusion mixing by water jets and inline static mixing. Proper operation at this step requires choosing the right chemicals and quantities in response to the raw water quality and flow rate. Chemicals used in this step include aluminum sulfate (alum), polyaluminum chloride, various iron compounds, polymers, and bentonite.[5]

Flocculation is slow mixing that increases the rate of collisions between particles whose electrostatic repulsive forces have been neutralized in the coagulation step. Now the particles will stick together into sizes that will settle. Flocculation mixing is performed by mechanical mixers, baffles, or other methods. Paddle reels with a horizontal axle perform well. In a reasonable design for two parallel, 12-mgd floc tanks, each of three chambers in a tank might be about 13.5 ft^2 in cross section so that a 13-ft horizontal paddle reel would nearly fill a chamber. Perforated baffle walls separate the chambers to promote good mixing. Proper operation of this step requires continual monitoring of and adjusting for the floc size, and removing scum from the surface of the water, sludge from the bottom of the tank, and algae from the vertical surfaces (walls and baffles). Transfer of the flocculated water to the sedimentation tank must be done at low velocity to avoid breaking up the floc.

Four progressive stages of sedimentation are distinguished. Type I sediment consists of separate, destabilized particles. Type II is made of larger groups of flocculated particles. In Type III, the particles have formed a blanket that initiates hindered settling. Type IV settling is compression of the sludge blanket at the bottom of the tank.

A typical filter bed is made up of a layer of sand and a layer of coal, charcoal, or granular activated carbon. The water from the sedimentation tank is introduced at the top of the filter and moves by gravity down through the media to the underdrain. It is most desirable to have the filter backwashed once per day. Thus, the design depends upon the quality of the raw water, the required throughput, the local climate, and the skill level of the operators. The backwash water is required to be recirculated to the head of the plant.

Filter efficiency is determined by the unit filter run volume (UFRV), which is the ratio of the amount of water processed during a filter cycle to the amount that could be processed if no backwashing were necessary. The effective filtration rate, R_e, is

$$R_e = (\text{UFRV} - \text{UBWV})/T$$

where UBWV (unit backwash volume), gal/ft^2; T, filter cycle time, min; and

$$\text{UFRV} = V_f/A \quad \text{UBWV} = V_b/A$$

where V_f, volume filtered per filter cycle, gal; A, area of filter, ft^2; V_f, volume of backwash water, gal.

The design filtration rate, R_d, is the maximum filtration rate, which can be achieved only if no backwash were necessary. Then the production efficiency is

$$R_e/R_d = (\text{UFRV} - \text{UBWV})/\text{UFRBV}$$

Example 1. Find the production efficiency and the filter cycle time for a filter with UFRV equal to 7500 gal/ft^2, UBWV equal to 200 gal/ft^2, and design filtration rate equal to 5 gpm/ft^2.

Solution. ***The effective filtration rate, filter efficiency, and filter cycle time are***

$$\begin{aligned} R_e &= (5\ \text{gpm/ft}^2)\left[(7500\ \text{gal/ft}^2) - (200\ \text{gal/ft}^2)\right]/(7500\ \text{gal/ft}^2) \\ &= 4.87\ \text{gpm/ft}^2 \end{aligned}$$

$$= R_e/R_d\left[\left(7500\ \text{gal/ft}^2\right)-\left(200\ \text{gal/ft}^2\right)\right]/\left(7500\ \text{gal/ft}^2\right)$$

$$= 0.973$$

and

$$T = \left[\left(7500\ \text{gal/ft}^2\right)-\left(200\ \text{gal/ft}^2\right)\right]/\left(4.87\text{gpm/ft}^2\right)$$

$$= 1499\ \text{min}$$

Note that the filter cycle time is very close to one day (1440 min). Also, increasing the filtration rate will not necessarily increase the amount of water filtered per day. Increasing the rate increases the amount of deposition on the filter media, reducing the filter run time.

Most of the water treatment plants in this country disinfect with chlorine. Common alternatives are ozone, chloramine, and ultraviolet light. The disinfectant is sometimes added at the head of the plant to give an adequate concentration-contact time product. When chlorine is used, disinfection byproducts can be formed—most notably, tri- halomethanes. To suppress this, ammonia might be added at the end of sedimentation to form chloramines. Then the water is lightly rechlorinated in the clearwell to suppress regrowth of pollutants in the distribution system.

In small municipalities across the heartland, treated water is pumped into elevated tanks emblazoned with the name of the town. These towers serve to keep the water clean, meet surges in demand, and supply even pressure at the tap. Large cities tend to keep the water in open reservoirs, an unfortunate but perhaps necessary practice that leaves the water subject to the reintroduction of various undesirable substances.

Hydraulics

Flow through the plant is described by Bernoulli's equation, where all the components are expressed in terms of head in feet,

$$z_1 + P_1/\gamma + V_1^2/2\text{g} = z_2 + P_2/\gamma + V_2^2/2\text{g} + H_\text{L}$$

and z_i, distance of water level above datum; P_i/γ, pressure head at surface; $V_i^2/2\text{g}$, velocity head; H_L, head loss; $i = 1$, upstream; $i = 2$, downstream.

The head-loss term is made up of entrance and exit losses, pipe friction losses, and minor losses. Hydraulic calculations are best made starting at the clearwell and working upstream.[1]

It is preferable to have the water flow through the plant by gravity. The head losses through the A particle with settling velocity satisfying HRT $= D/V_\text{s}$ will reach the bottom of the tank before being swept up and out (as will particles with V_s greater than this). Then processes are approximately (a) rapid mixing, 1 ft; (b) flocculation, 2 ft; (c) sedimentation, 2 ft; (d) and filtration, 10 ft, for a total of 15 ft. If the water comes into the plant at the level of the clearwell, this head and the friction losses in the lift pipe must be provided by a pump. At the pump discharge, the water horsepower is HP_w; the pump input is the motor brake horsepower, HP_b; and the power required to drive the motor is P, where

$$HP_\text{w} = QH/C_1 \qquad HP_\text{b} = QH/C_1e_\text{P}$$

$$P = C_2HP_b/e_\text{m}$$

and Q, pump flow rate, gal/min; H, pump discharge head, ft; C_1, constant, (550 ft-lb/s-hp) (60 s/min)/(8.34 lb/gal) 3960 ft-gal/min-hp; e_p, pump efficiency; C_2, constant, 0.746 kW/hp; e_m, motor and drive efficiency.

Example 2. Size the motor, and find the input power required to provide 15 ft of head for a 24-mgd water treatment plant. Ignore plumbing losses. Take the pump efficiency to be 70% and the motor/drive efficiency to be 90%.

Solution. ***The flow rate is (24×10^6 gal/da)/[(24 h/da) (60 min/h)] = 16,667 gal/min. Thus***

$$HP_b QH/C_1 e_p = (16{,}667\ \text{gal/min})(15\ \text{ft})/\left[(3960\ \text{ft} - \text{gal/min} - \text{hp})(0.70)\right] = 90\text{hp}$$

and

$$P = C_2 HP_b / e_m = (0.76\text{kW/hp})(90\text{hp})/(0.90) = 75\text{kW}$$

Because a motor is just as efficient at 75% load as at full load, a 125-hp motor should be installed.

The important hydraulic parameters of a sedimentation tank (Figure 2) are the hydraulic retention time (HRT), the horizontal velocity of the water through the tank (V_h), and the surface overflow rate (SOR). For a tank with dimensions *L, W, D* for length, width, and depth, the volume $\forall$, is LWD; the surface area, A_s, is *LW*; and the vertical crosssectional area is $A_c = WD$. Therefore, the horizontal velocity and the SOR are

$$V_h = Q/A_c = Q/DW \text{ and } \text{SOR} = Q/A_s$$

The HRT is

$$\text{HRT} = L/V_h = L/(Q/DW) = \forall/Q$$

A particle with settling velocity satisfying HRT = D/V_s will reach the bottom of the tank before being swept up and out (as will particles with V_s greater than this). Then

$$V/Q = D/V_s$$
$$\text{or } V_s = DQ/V = Q/LW = \text{SOR}$$

That is, for a particle to settle, the settling velocity must be equal to the SOR (or greater).

The power (*P*) required for mixing or flocculation with an impeller in a tank is dependent upon the average velocity gradient (G) in the fluid, dynamic viscosity (μ) of the fluid, and volume ($\forall$) of the tank: $P = G^2 \mu \forall$ For wastewater treatment, the average velocity gradient for rapid mixing is about 500–1500/s and for flocculation is about 50–100/s.[5]

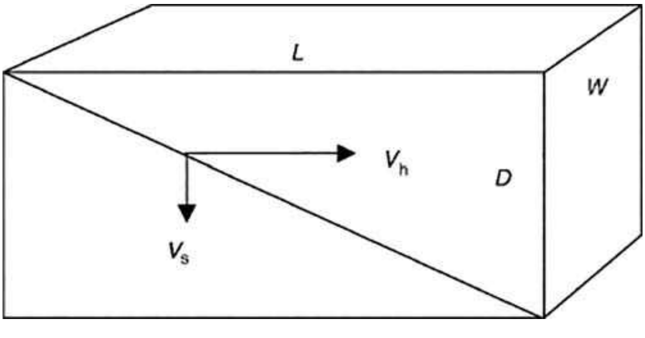

FIGURE 2 Sedimentation parameters.

Example 3. Find the power (P) required to achieve an average velocity gradient (G) of 100/s in a 1 million-gal flocculation tank whose contents are at a temperature (T) of 40°F.

Solution. ***The dynamic viscosity of water at 40°F is*** $\mu = 2.359\times10^{-5}$ ***lb-s/ft***^{2}***. Therefore,***

$$P = (100/\text{s})^2\left(2.359\times10^{-5}1\text{b}-\text{s/ft}^2\right)\left(10^6\ \text{gal}\right)$$

$$\times\left(0.746\ \text{kW/hp}\right)/\left[\left(550\ \text{ft}-1\text{b/s}-\text{hp}\right)\left(7.48\ \text{gal/ft}^3\right)\right]$$

$$= 42.8\ \text{kW}$$

Example 4. Consider a plant with an input flow rate of $Q = 24$ mgd $= 24\times10^6$ gal/da. The two sedimentation tanks are 300 ft long, 40 ft wide, and 13 ft deep. Find the HRT, the velocity of the water through the tank, and the SOR.

Solution. ***The flow rate through each tank is*** $Q = (24/2\times10^6\ \text{gal/da})/[(24\ \text{h/da})(60\ \text{min/h})] = 8333\ \text{gal/min} = (8333\ \text{gal/ min})/[(7.48\ \text{gal/ft}^3)\ (1440\ \text{min/da})] = 1114\ \text{ft}^3/\text{min}$***. Therefore, the velocity in each tank is*** $V = (1114\ \text{ft}^3/\text{min})/[(40\ \text{ft})\ (13\ \text{ft})] = 2.14\ \text{ft/min}$***, and the surface overflow rate is*** $SOR = (8333\ \text{gal/min})/[(40\ \text{ft})\ (300\ \text{ft})] = 0.694\ \text{gal/min-ft}^2$***.***

Wastewater

Some authors make the following distinction: wastewater is water that has been used for domestic, industrial, or commercial purposes, whereas sewage is more inclusive in that it can include water that has not been used, such as rain runoff. In the past 50 years, sanitation agencies have made a great effort to confine runoff to storm sewers and out of treatment plants, so the term WWTP is appropriate. These facilities are also called publicly owned treatment works (POTWs).

History

The history of wastewater treatment is a sordid one of determined ignorance and apathy. Until 1965, for example, Salt Lake City was dumping raw sewage into a 9-mi open canal that emptied into the Great Salt Lake.[7] In other parts of the world, this kind of practice continues to the present day.

Dr. John Snow in London convincingly linked cholera with the consumption of contaminated waters. This most famous episode in the history of both epidemiology and water treatment occurred in the late summer of 1854. Repeated outbreaks of cholera had occurred between 1831 and 1854 in the industrial cities of England, with little being done to prevent or contain it. The particularly sudden and violent episode in and around Broad Street in September gave Dr. Snow the opportunity to verify his belief that the cause was in contaminated water. When he persuaded the authorities to remove the handle from the Broad Street pump, the spread of the disease was halted. Later, Snow established that wastes from a single infected individual had been dumped into a leaking cesspit near the Broad Street well. After some time, people accepted the fact that fecal contamination of drinking water was a major cause of disease.[3]

With better water supplies and sewer systems, there was a sharp decrease in the incidence of waterborne diseases, even before the agents were identified. After half a century of research, the concept of waterborne disease was established. The cause was known to be microorganisms in the digestive tract and the associated health hazards had been proven. Then work proceeded on two fronts: analytical methods for the detection of fecal pollution and the development of treatment methods and facilities. Research led to publication of the first edition of *Standard Methods* in 1901,[8] and the SSF was an early and very effective method for treatment. (In fact, the newer and faster conventional rapid sand filter does not remove dissolved constituents as effectively.)

Standards and Monitoring

The Clean Water Act of 1972 and subsequent legislation placed increased emphasis on the importance of reducing the discharge of pollutants to natural waters. The minimum national standards now for secondary treatment are the "30/30" rule: a 30-day average of no more than 30 mg/L of BOD_5 (5-day biochemical oxygen demand) and TSS (total suspended solids), as well as pH to be between 6.0 and 9.0 at all times. Unfortunately, meeting these standards does not guarantee the absence of disease-causing agents—notably, *Giardia lamblia* and *Cryptosporidium parvum*. Increased sophistication of monitoring techniques is leading to better treatment techniques and stricter standards.[9]

Sources and Collection

Sanitary sewers receive some groundwater infiltration and stormwater. Otherwise, 90% or more of the intended influent is of residential or commercial origin. Industrial users are either direct dischargers dumping into a waterway or indirect dischargers dumping into a POTW. (Some industrial liquid waste may also be hauled off.)

Influent is collected in closed pipe, mostly by gravity flow. When pump lift is necessary, the flow is into short runs of pressure pipe, eventually returning to gravity flow lines. Because plants are often located next to natural waters, they are typically at the low points of terrain, which keeps pumping to a minimum.

Treatment

Several levels of increasing care are defined. Preliminary treatment is the removal of large items, sand and grit, floatables, and grease. Wastewater typically contains floatable materials—particularly fats, oils, and grease (FOG)—whereas (fresh) water does not. Removal is accomplished purely by physical processes such as screening and gravity, and is intended to protect the plant equipment. Primary treatment is the removal of suspended solids and organic matter, often by the addition of chemicals. Secondary treatment is a biological process that removes organics and suspended solids (and sometimes nitrogen and phosphorus), followed by disinfection. Tertiary treatment removes remaining suspended solids by fine filtering, and may include disinfection and nutrient removal. The standard today for wastewater is full secondary treatment, meaning that all the influent to a plant is given secondary treatment. When a plant cannot handle the flow, partial secondary treatment means that all the influent is given preliminary and primary treatment, but only part of it is given secondary treatment.

A typical process chain for secondary treatment is the activated sludge process shown in Figure 3.[9] Large items are screened out. Dense noncontaminants are removed purely by gravity in the grit chamber. Primary treatment is a chemical/physical process, whereby small particles agglomerate (flocculate)

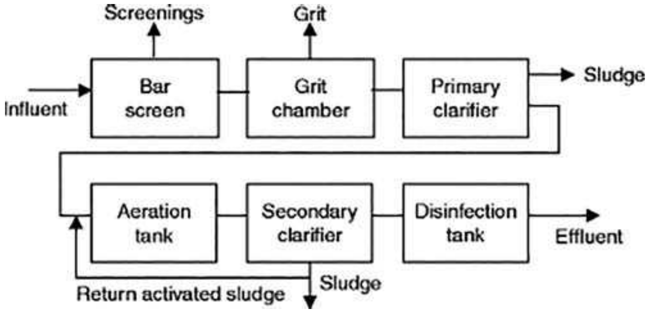

FIGURE 3 Activated sludge wastewater treatment.

and gravitate out. Secondary treatment is biological, in which microbes consume the dissolved and suspended organic matter. Disinfection kills most of the remaining contaminants.

Preliminary and primary treatment for wastewater is much like that for water. Preliminary screening of wastewater is necessary because large objects sometimes find their way into the sewer, an unfortunate example being construction debris illegally dumped into a manhole (alternatively, "maintenance hole"). (Note that a manhole cover is round for at least three reasons: (a) It will not fall through the hole, no matter how oriented; (b) it is easy to move by rolling; and (c) it need not be rotated to fit.) Primary treatment for both is nominally flash mix, flocculation, and sedimentation. Wastewater undergoes secondary treatment, in which microbes remove biological pollutants.

Both organic and inorganic particulates may be removed by settling, flotation, or filtering, depending on particle size and density. Carbon filtration is preferable to vaporizing, because the latter merely moves the substance from the water to the atmosphere.

Most reactions in waste treatment are of first order—that is, the rate of reaction is proportional to the concentration of the pollutant.

$$\mathrm{d}C/\mathrm{d}t = -kC$$

where C is concentration of pollutant (mg/L); t is time (min); k is reaction constant (mg/L-min).

Reactors are of three types: complete mix (or batch), plug flow, and dispersed flow. In a complete mix reactor, the reactor is filled; the reaction is allowed to take place; and then the reactor is emptied. The concentration of pollutant is equal throughout the tank. Complete mix reactors are approximately cubical and can be set up in sequence to provide an increasing proportion of removal. In a plug flow reactor, the flow moves through the reactor with the reaction taking place so that the concentration of pollutant is less at the outlet than at the inlet. These tanks are long in proportion to their length and width. Turbulence should be minimized to retain the form of the plug. Most reactors are of the dispersed flow type, intermediate between the other 2.[9]

Liquid and Solids Disposal

By the principle of conservation of mass, treatment does not make the contaminants disappear; it merely separates them from the water that bears them. When most of the contaminants have been removed and the water is sufficiently clean, it may be discharged to a natural waterway, such as a river, lake, or ocean. Most of the processes in Figure 3 produce residuals. These impurities—such as sediment, sludge, waste washwater, and brine—are left behind to be treated and disposed of in other ways. Large items from screening and grit from the grit chamber are sent to landfill. Sludges from primary and secondary treatment are sent to a digester, which itself produces waste. Waste washwater from the filters is recycled, but because it adds to the throughput volume, it should be kept to a minimum.

Industrial Waste

For both direct dischargers and indirect dischargers, the content of industrial wastewater is regulated. Industrial users are allowed to send the first fraction of runoff from rainstorms to the sanitary sewer, for the purpose of keeping pollutants out of the storm sewers and, ultimately, out of natural waters after which it must be diverted to storm sewers.

Because POTWs are set up to treat organic waste, much industrial waste is incompatible with public treatment systems, so is usually subject to pretreatment. The objectives of such treatment are to prevent interference with the process in the POTW, to prevent pass-through of pollutants to the receiving waters, and to make possible reuse of the effluent and sludge from the POTW.[10]

Some treatment strategies are flow equalization to prevent shock loading to the POTW; solids removal by straining or settling; removal of FOG by dissolved air floatation or centrifuging; neutralization of high-pH or low-pH solutions; and hydroxide precipitation of heavy metals. A notable exception to the last is the removal of Cr^{+6}, which will not respond to hydroxide precipitation. Instead, it is converted by chemical reduction at low pH to Cr^{+3}, which can be removed by hydroxide precipitation. Dissolved inorganics may be removed by hydroxide precipitation, ion exchange, or membrane filtering.[10] It should be noted that diluting industrial wastewater to reduce the concentration of pollutants is not acceptable, and that "dilution of pollution is not a solution, and can lead to prosecution." The most important principle is segregation: keeping the pollutants separated so that they can be treated individually.

Issues

Wastewater treatment plants are designed to treat organic wastes. Other substances (nutrients in fertilizer, pharmaceuticals, etc.), can pass through and cause problems in receiving waters (e.g., algal growth and abnormal growth in fauna). Yet others, such as heavy metals and toxic chemicals, can cause interference (also called upset)—disruption of the process in the biological reactor.

Failed equipment can cause raw or partially treated wastewater to flow into storm drains and then into natural waters. Runoff from heavy storms can flow into sanitary sewers and overwhelm treatment plants. Cities with combined sewers are especially subject to this problem. Inadequately sized treatment plants will discharge partially treated wastewater in times of heavy flow.

Everything removed from wastewater must be disposed of. Sometimes, objections are raised to the release of volatiles into the atmosphere. Although the creators believe that digested sludge is a fertilizer rich in nutrients, others are not convinced.[11]

More radically, some have questioned the wisdom of the whole process of fouling great quantities of cleaned water and then cleaning it again.[12]

Conclusion

A basic requirement of human existence is an adequate supply of clean water. Today, very few have access to clean, untreated water. Wealthy societies obtain clean water by treating it, while poor ones often rely on polluted sources and suffer from the resulting waterborne diseases.

The idea that many municipalities draw from surface waters that are used for the disposal of wastewater is sobering, if not chilling. In the United States, the Safe Drinking Water Act mandates water treatment standards, and the Clean Water Act mandates wastewater treatment standards. Observance of these standards has made the practice of having a common source and sink acceptable.

The conventional water treatment process described in this entry has been very effective in removing bacterial pathogens. Dechlorination to control disinfection byproducts created by chlorination was instituted as a result of the Safe Drinking Water Act. The most recent major issue is the resistance of *Cryptosporidium* oocysts to chlorination. Membrane filtration is an effective way to remove these and other very small suspended pathogens. New water treatment plants are likely to be based on this technique because of its effectiveness and ease of operation.[5]

The most important developments required in wastewater treatment are (a) building or expanding facilities to provide the capacity to subject all flow to complete secondary treatment, (b) repairing and maintaining the collection system to ensure that all wastewater reaches the treatment plant, and (c) finding practicable ways to dispose of the residual solids.

Wastewater: Municipal

Sven Erik Jørgensen

Municipal Wastewater

The composition of domestic sewage varies surprisingly little from place to place, although to a certain extent, it reflects the economic status of the society.

A typical composition including biochemical oxygen demand (BOD_5), chemical oxygen demand (COD), suspended matter, and nutrients is shown in Table 1.

Most industrialized countries require treatment of municipal wastewater. The standards vary for the European Union, the United States, Canada, Australia, New Zealand, and Japan, but it is generally required to reduce BOD_5 to about 10 mg/L, nitrogen to about 10 mg/L, and the phosphorus concentration to 1–2 mg/L. To obtain the required reductions, a combination of the methods presented in the entry "Waste Water Treatment: Overview of Conventional Methods" can be applied. The combinations of methods applied for the treatment of municipal wastewater are presented in the next sections, and

TABLE 1 Typical Composition of Municipal Wastewater (in milligrams per liter)

Constituent	Soluble	Particulate	Total
BOD_5	100–200	50–100	150–300
COD	200–500	100–200	200–700
Ammonium-N	20–40	0	20–40
Nitrate-N	5–20	0	5–20
Organic nitrogen	0	5–20	25–60
Suspended matter	–	40–80	40–80
Carbohydrates	20–40	10–15	30–55
Amino acids	10–15	15–25	25–40
Fatty acids	0	50–80	50–80
Surfactants	10–20	5–10	15–30
Creatinine	3–5	0	3–5
Phosphorus	2–4	4–10	6–14

Source: Jørgensen[1] and Jørgensen.[2]

it will be demonstrated that it is possible by a suitable combination of methods to meet all realistic effluent standards. Municipal wastewater can, however, also be treated by ecotechnological methods, for instance, by waste stabilization ponds and by constructed or natural wetlands. These methods are presented in the entries *Pollution: Point and Non-Point Source Low Cost Treatment* (p. 2174), *Waste: Stabilization Ponds* (p. 2652), *Wetlands* (p. 2846), and *Wetlands: Treatment System Use* (p. 2885).

Combinations of Methods for the Treatment of Municipal Wastewater (Reduction of Bod$_5$)

Models are used increasingly to design and optimize wastewater treatment methods. For details about the applied models, see Jørgensen's *Handbook of Ecological Models Used in Ecosystem and Environmental Management*,[1] which has a comprehensive entry devoted to models of wastewater treatment systems.

There are a number of different possible designs of biological treatment plants.[2]

The use of mechanical-biological wastewater treatment is a classical method, or rather the combination of the two methods. Figure 1 shows the flowchart of a classical mechanical and activated sludge plan as it is generally used all over the world. The processes involve screening, a separation of grease and sand in the grit chamber, a primary settling, and an aeration step followed by sedimentation. Chlorine is often added before discharge to the receiving water, particularly when it is used for swimming and bathing. The sludge is most often digested anaerobically, which produces biogas. In the activated sludge plant, a rapid adsorption and flocculation of suspended matter take place. Organic matter is oxidized

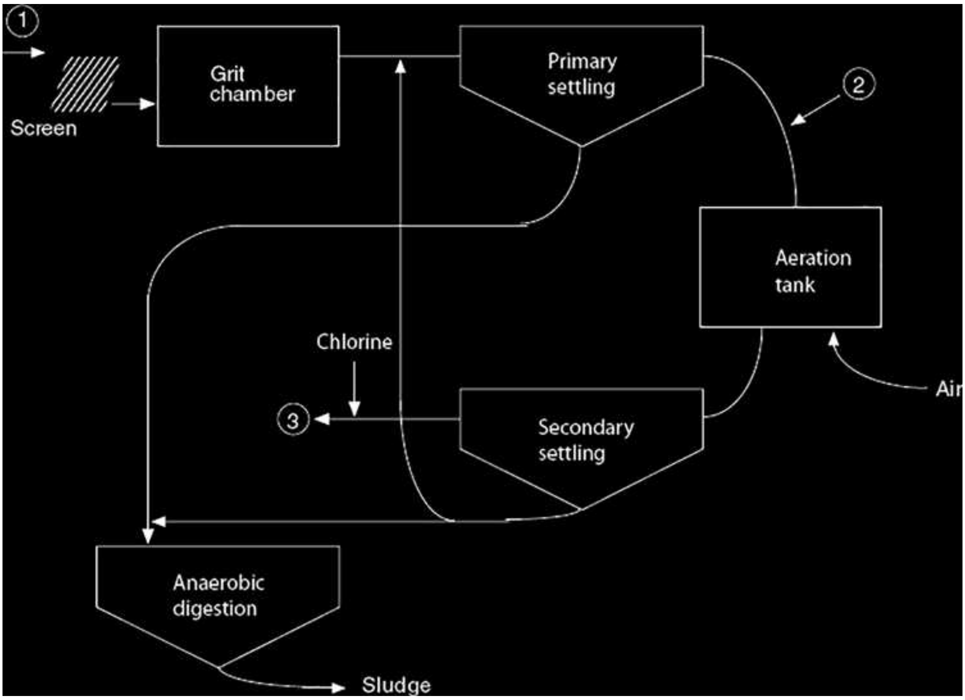

FIGURE 1 A flow diagram of a conventional activated sludge plant. It is widely used to treat municipal wastewater. Number 1 is untreated municipal wastewater that would have a BOD$_5$ of about 150–300 mg/L, total nitrogen of about 25–45 mg/L, and total phosphorus of about 6–12 mg/L. The mechanical treatment (sample at point 2) will reduce BOD$_5$ and total N by about 25%–40%, while the reduction of total phosphorus will be minor. The totally treated wastewater (point 3) will have a BOD$_5$ of about 10–15 mg/L, while the nitrogen is only reduced 35%–50% and the phosphorus concentration only about 10%–20%.

and decomposed. Sludge particles are dispersed and settled by the secondary settling. The processes are conceptualized in Figure 2.

Oxidation ditches (see Figure 3) can replace the activated sludge plant and the secondary settling. The rotor provides the aeration to oxidize the organic matter. The influent and the rotor are usually stopped during the night, when the inflow is low anyhow, to allow settling. The supernatant is withdrawn through an effluent launder. The retention time is usually 2–5 days.

A trickling filter is a bed packed with rocks, although recently, plastic media (celite pellets[3]) and bioblocks with a high surface area due to the high porosity are also applied. They require substantially less space than the stone-packed trickling filter. They have usually a specific surface of 100 m^2/m^3 or even more. It is at least 2–3 times the specific surface for a rock trickling filter. The medium is covered by a slimy microbiological film. The wastewater is passed through the bed and oxygen and organic matter diffuse into the film, where oxidation occurs. Recirculation improves the removal efficiency. A flowchart of a treatment plant combining a trickling filter and an activated sludge plant is shown in Figure 4. The alternative ecotechnological methods used for BOD_5 reduction, lagoons, and waste stabilization ponds are presented in the entry "Waste Stabilization Ponds." Various solutions to reduce BOD_5 based on natural and constructed wetlands are covered by several entries, all with wetlands as the key word in the title.

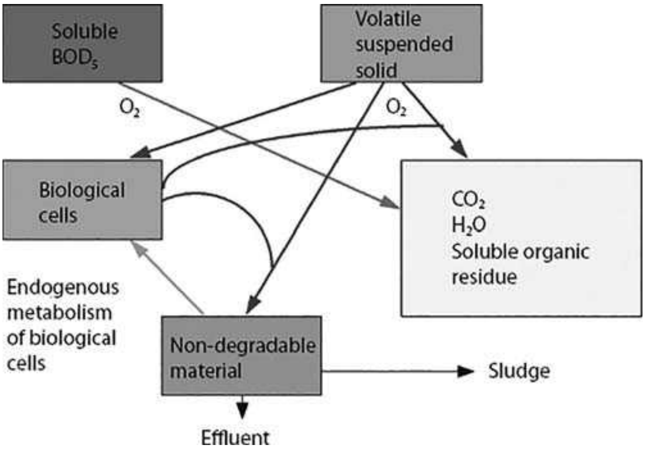

FIGURE 2 Processes characteristic for the biological treatment.

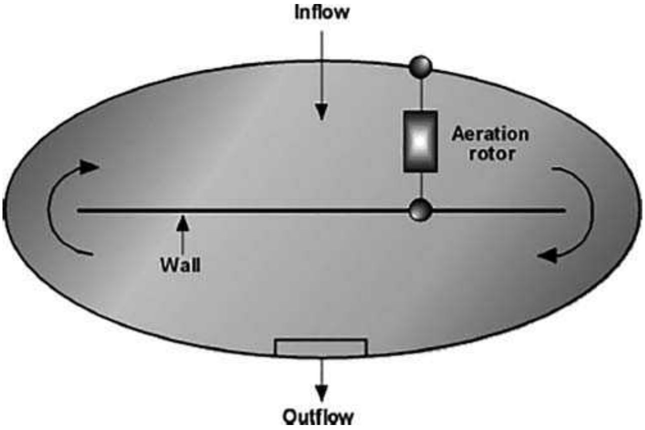

FIGURE 3 Oxidation ditch.

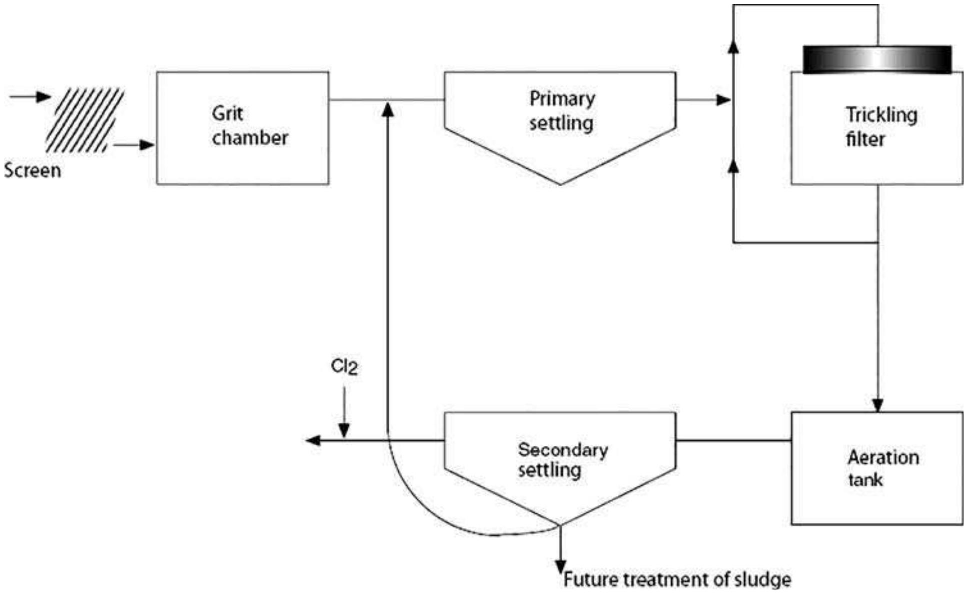

FIGURE 4 Treatment of municipal wastewater, combining trickling filter and activated sludge treatment.

Physical–chemical methods have been proposed to replace mechanical–biological treatment, for instance, the so-called AWT system, which is based on the application of a combination of mechanical treatment, precipitation, adsorption on activated carbon, and sand filtration (see Figure 5).

It has been considered that recovering proteins and grease could at least partially cover the costs of the treatment of wastewater in slaughterhouses, fish industries, starch factories, and other foodstuff industries. Figure 6 shows a method that has been applied in several, but still relatively few, cases.

If the wastewater has high concentration of grease, oil, and fat, it is possible to apply a flotation unit, offering an alternative to sedimentation. A portion of water is pressurized by 3–10 atm, and when this water is returned to the normal atmospheric pressure in the flotation unit, air bubbles are created. The air bubbles attach themselves to particles, and the air-solute mixture rises to the surface where it can be skimmed off, while the clarified water is removed from the bottom of the flotation unit. Figure 7 shows

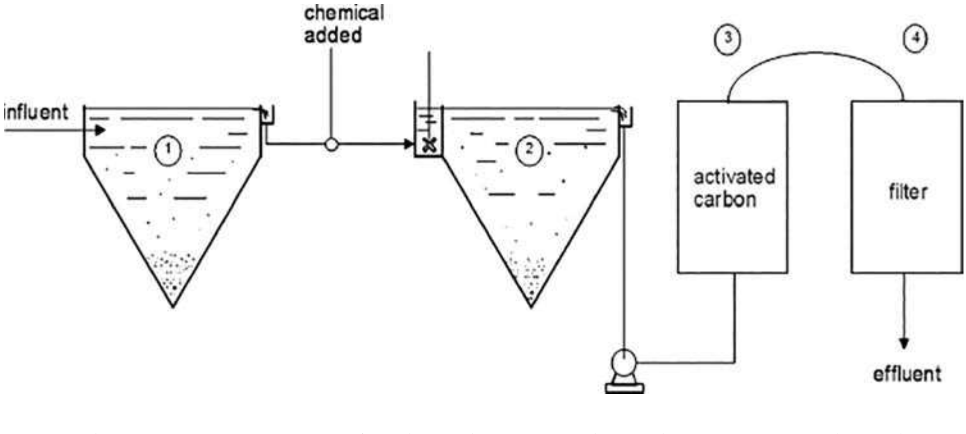

FIGURE 5 The AWT system consisting of mechanical treatment, chemical precipitation, settling, adsorption on activated carbon, and filtration. The method is not used very much. It has the advantage that it is easier to control but it is also more expensive with respect to both investment and operation.

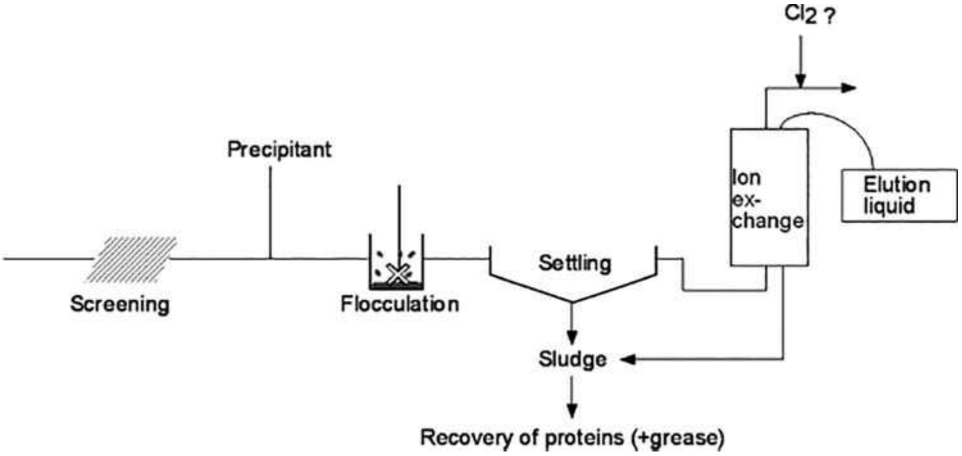

FIGURE 6 Recovery of proteins and grease from the wastewater discharge from the foodstuff industries is possible by a combination of precipitation and ion exchange. The recovery pays partially for the treatment of the wastewater by the process.

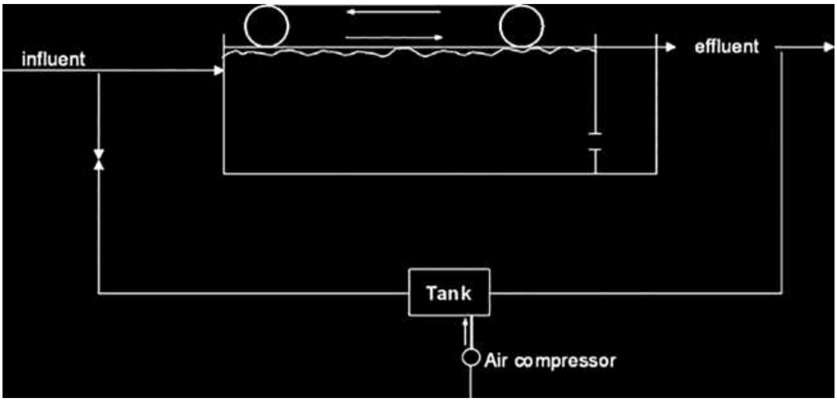

FIGURE 7 Flotation unit.

a flotation unit. Usually, the retention time in a flotation unit is 3–6 times less than for a settling unit, which means that a significant volume reduction is obtained. Flotation has therefore most frequently replaced sedimentation in slaughterhouses, fish industries, and oil industries.

Methods for the Treatment of Municipal Wastewater (Reduction of the Phosphorus Concentration)

Nutrient removal is most frequently carried out by chemical precipitation, often combined with mechanical–biological treatment. Chemical precipitation can be applied at three different points in the mechanical–biological plant as shown in Figure 8. Sometimes, both direct precipitation and posttreatment is applied, which together with sand filtration makes it possible to obtain 0.1 mg P/L or less in the effluent. In many cases where such a low phosphorus concentration is needed for particular sensitive receiving waters (mainly lakes), this double precipitation is a very attractive method, because it is

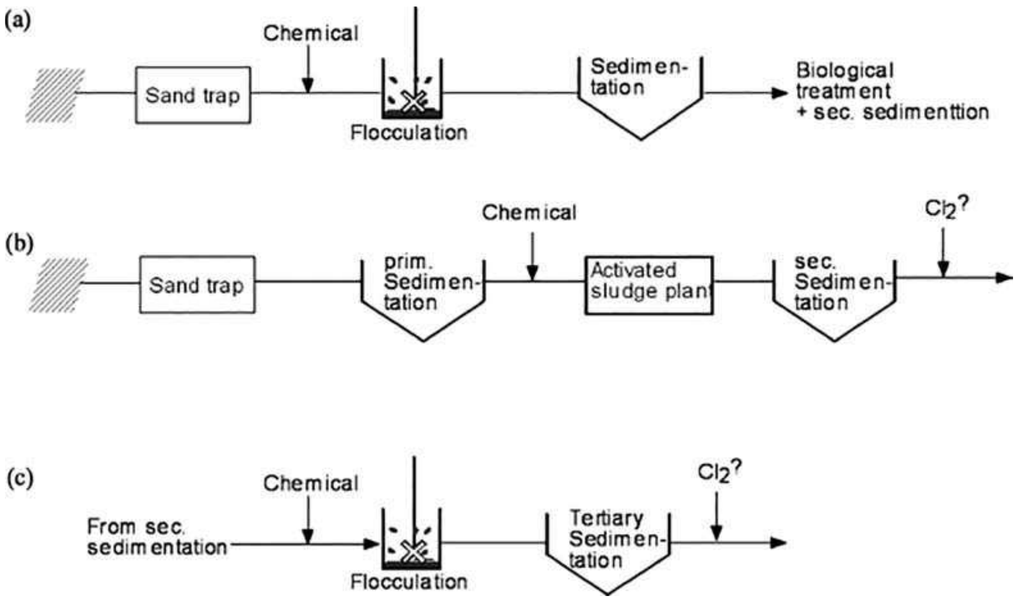

FIGURE 8 Precipitation by aluminum sulfate or other aluminum compounds, iron(III) chloride, and calcium hydroxide is able to reduce the phosphorus concentration in wastewater significantly. The precipitation is applied often in combination with mechanical biological treatment and can be carried out after the sandtrap: (a) direct precipitation, before the activated sludge plan: (b) simultaneous precipitation or after the mechanical–biological treatment: (c) posttreatment. The arrow+"Chemical" indicates the three different possibilities for addition of the precipitation chemical and "chlorine?" indicates where chlorine eventually can be added.

relatively cost moderate compared with other alternatives. Without the sand filtration and only a single precipitation, it is usually relatively easy to obtain a concentration of phosphorus in the effluent between 1.0 and 1.5 mg/L.

Aluminum sulfate, various polyaluminates, calcium hydroxide, and iron(III) chloride can be applied for the precipitation. The amount of hydrated lime or calcium hydroxide needed for the precipitation is usually 2.5–6 times higher than for the aluminum and iron compounds, because a high efficiency of the precipitation requires a pH of 10.0 or higher, which, dependent on the hardness of the water, is not possible without the indicated amount of calcium hydroxide. For a hardness of 15–30 hardness degrees, the amount is 100–480 mg calcium hydroxide per liter. It would usually give an efficiency of 90%–95% precipitation of the phosphorous compounds, which is slightly better than for most precipitations with aluminum and iron compounds. The disadvantage of precipitation with lime is the high pH, which makes adjustment of the pH after the precipitation and settling necessary. Carbon dioxide produced by incineration of the sludge or solid waste can be used for this purpose. If the sludge is incinerated, it is possible to partially recycle the calcium hydroxide and thereby reduce the costs of precipitation chemicals. Recycling 3–5 times is possible, and afterwards it can be applied as fertilizer, as it has a relatively high phosphorus concentration. A flowchart with direct precipitation and recycling of calcium hydroxide is shown in Figure 9.

If the sludge after calcium hydroxide precipitation cannot be incinerated, an adjustment of pH is needed before anaerobic digestion or aerobic sludge treatment. Heavy metals are removed more effectively by the use of calcium hydroxide than by aluminum and iron compounds. Lead, copper, and chromium are removed by a very high efficiency by all the mentioned precipitation chemicals, while only calcium hydroxide would give a high removal efficiency for cadmium and zinc.

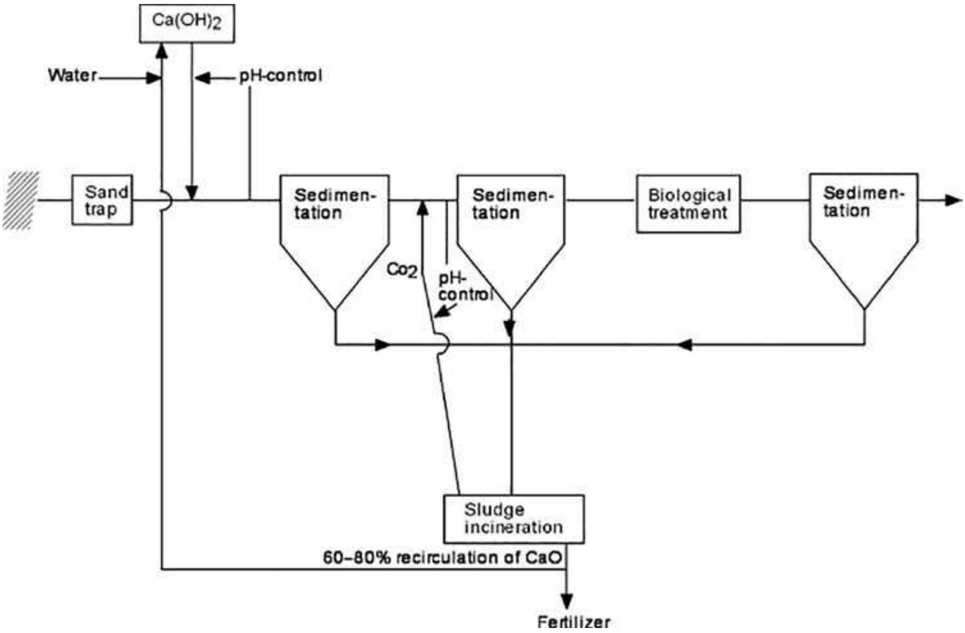

FIGURE 9 Chemical precipitation with partial recirculation of calcium hydroxide and use of carbon dioxide from incineration of the sludge for pH adjustment.
Source: Jørgensen.[1]

The amount of aluminum and iron compounds can be found in Figures 10 and 11 or by the use of the following equation based on Freundlich adsorption isotherms:

$$(C_O - C)/n = a^{*}\ C^{b}$$

where C_o is the initial concentration of phosphorus (mg P/L), C is the final concentration, n is the dose of chemical expressed as milligrams of Al per liter or milligrams of Fe per liter, and a and b are characteristic constants that can be found in Table 2.

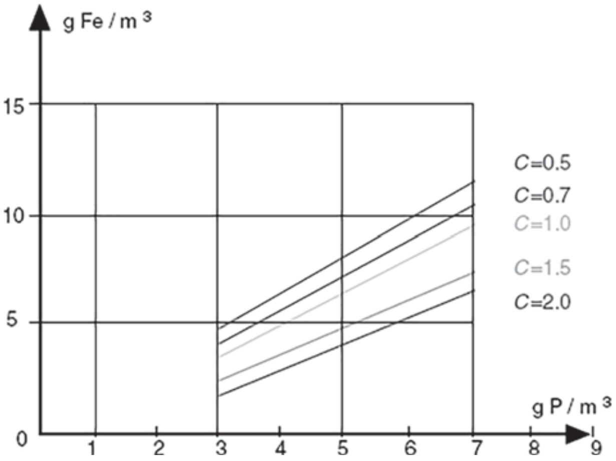

FIGURE 10 Addition of iron (III) as f(P-concentrations) at different P-concentrations in the effluent.

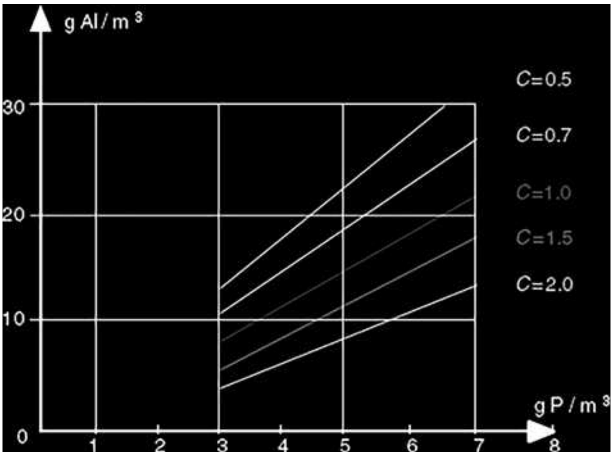

FIGURE 11 Addition of aluminum salts as f(P-concentrations) at different P-concentrations in the effluent.

TABLE 2 TThe Constants in Freundlich's Adsorption Isotherms for Aluminum Sulfate and Iron (III) Chloride

Precipitation with	a	b
Aluminum sulfate	0.63	0.2
Iron(III) c]hloride	0.26	0.4

Source: Jørgensen.[2]

Note: With good approximation, the constants for aluminum sulfate can also be applied for other aluminum compounds.

A more rapid flocculation, precipitation, and settling can be obtained by the addition of synthetic organic polymeric flocculants. They may be cationic polyelectrolytes, anionic polyelectrolytes, or non-ionic polymers. It is hardly possible to indicate which one of the polymeric flocculants would give the best result, as the ionic characteristics of municipal wastewater vary significantly. It is recommendable to test the various types of polyflocculants from case to case. The optimum design of a flocculator, before the settling of the precipitated material, should be based on a mathematical model (see Dharmappa et al.[4] and Thomas et al.[5]).

It is possible to remove phosphorus by biological treatment. Activated sludge systems with anaerobic and aerobic zones in sequence have been developed to achieve a higher phosphorus removal. The system is called EDPR—enhanced biological phosphorus removal. The shift between aerobic and anaerobic conditions activates the microorganisms to take considerably more phosphorus than under aerobic conditions, particularly if the wastewater contains relatively high concentrations of easily biodegradable organic matter. With a P/BOD_5 ratio of more than 20, a phosphorus removal of 80%–90% can be obtained.

Methods for the Treatment of Municipal Wastewater (Reduction of Nitrogen Concentration)

A combination of biological *nitrification and denitrification* can significantly reduce the nitrogen concentration in the effluent. The applied chemical processes are

$$NH_4^+ + 2O_2 \rightarrow NO_3^- + H_2O + 2H^+$$

$$4NO_3^- + 5C + H_2O \rightarrow 5HCO_3^- + 2N_2 + H^+$$

The ammonium is oxidized to nitrate and the nitrate is used to oxidize organic matter by anaerobic conditions—here indicated just as C. Thereby, the nitrate is reduced to dinitrogen, which is released to the atmosphere, where there is about 78% dinitrogen, and a minor addition of dinitrogen is therefore harmless.

Effective nitrification occurs when the sludge age is greater than the reciprocal rate of the constant of the nitrifying microorganisms.[6] The sludge age is defined as $X/\Delta X$, where X is the mass of sludge in the system and ΔX is the sludge yield per unit of time. Usually, the time unit applied is 24 hours. The relationship between nitrification efficiency in percentage and the sludge age is shown in Figure 12.

The nitrification process is a two-step biological process. Firstly, ammonia is oxidized to nitrite by *Nitrosomonas*. Secondly, nitrite is oxidized to nitrate by *Nitrobacter.* The optimum pH range for the nitrification is 6.7–7.0.[7] The oxygen concentration for the nitrification has to be at least 2 mg/L. Heavy metal ions are toxic to the nitrification at rather low concentrations. Toxic levels of about 0.2 mg/L are reported for chromium, nickel, and zinc. The nitrification process is sensitive to the temperature and an Arrhenius expression can be applied:

$$\mathrm{Kn}\left(\text{rate constant } 1/24\text{h}\right) = 0.18{*}1.128^{(\text{temperature} - 15)}$$

The denitrification takes place by a number of heterotrophic bacteria present in activated sludge. Anaerobic conditions are absolutely required. The optimum pH for this process is about 7.0. About 3 times as much BOD_5 as nitrate-N (both expressed in milligrams per liter) should be applied to ensure adequate denitrification. The process can be realized even at high concentrations of nitrate or at high salinities.[2] Addition of organic carbon—for instance, methanol—has been proposed to ensure proper denitrification, but it is of course not an attractive method to apply. Alternatives are as follows:

1. To switch between aerobic and anaerobic conditions. It is called alternative operation (for more details, see Diab et al.[8] and Halling-Sørensen and Jørgensen[9]).
2. To recycle a patty of the wastewater containing nitrate after the treatment is completed.

Both methods work properly. Other possibilities are the use of zeolite ion exchange material to obtain simultaneous nitrification and denitrification,[9] the use of electrolysis for denitrification,[10] and the use of activated carbon to enhance the denitrification.[11]

Ammonia can be removed by blowing air through the wastewater. The process is called *stripping,* and the equipment shown in Figure 13 can be used. It is of course required that the pH is sufficiently high

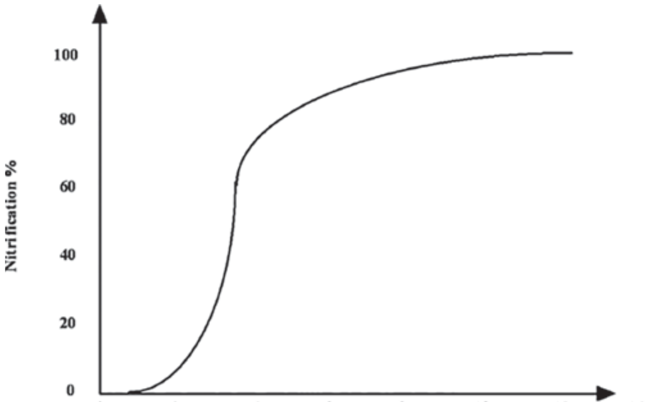

FIGURE 12 Nitrification efficiency as function of sludge age.

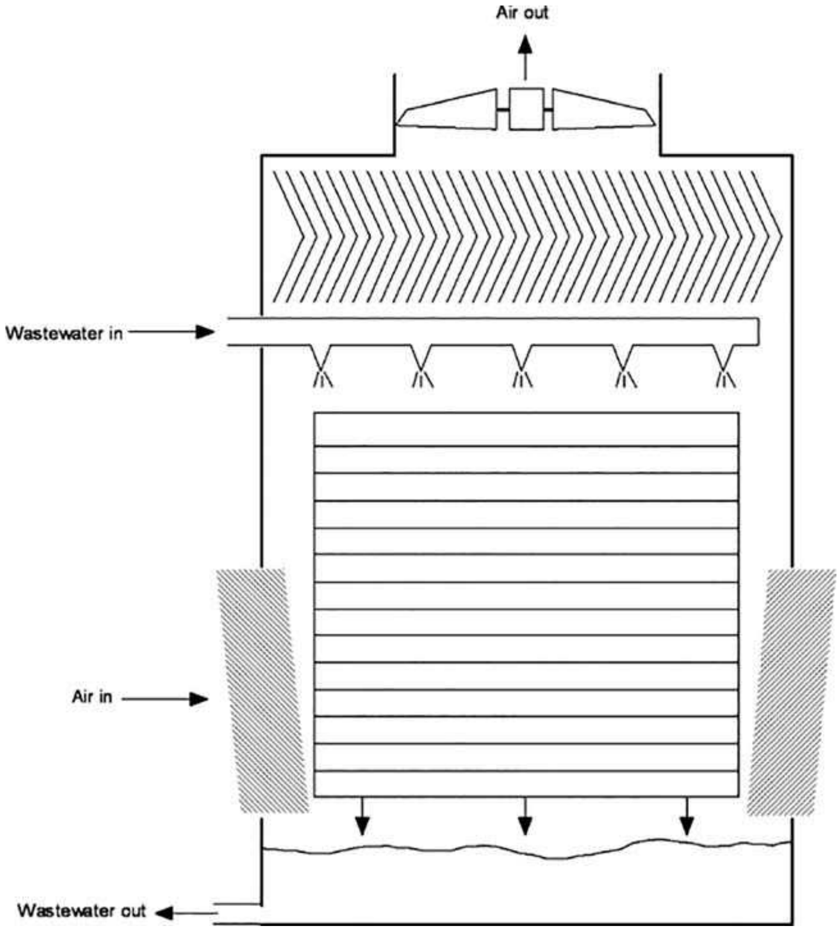

FIGURE 13 A sketch of a stripping tower is shown. The efficiency of the process is dependent on 1) pH; 2) temperature; 3) the amount of air relatively to the amount of water; and 4) the stripping tower height. Figures. 14 and 15 show how these factors influence the efficiency. As the air volume-to-water volume ratio is very high, there is a significant evaporation in the tower, which will cool the water.

enough to ensure that the gas ammonia is present. The equilibrium between ammonium and ammonia can be expressed by the following equation:

$$\mathrm{pH} = \mathrm{pK} + \log\ [\text{ammonia}]/[\text{ammonium}],$$

where pK is 9.3 for water with low concentrations of ions.

The cost of stripping is relatively low, but the process has three crucial limitations:

1. It is practically impossible to work at temperatures lower than 7°C due to the cooling effect of the evaporation.
2. Deposition of calcium carbonate can reduce the efficiency or even block the tower.
3. After the ammonia removal, pH is high and must be adjusted to 8.0 or below.

Ammonia can be removed by *chlorination* and *adsorption on activated carbon*. Chlorine can oxidize ammonia to NH_2Cl, $NHCl_2$, and NCl_3, and the activated carbon is able to adsorb the chloramines formed by these oxidation processes. By the adsorption process, it is most likely that dinitrogen and

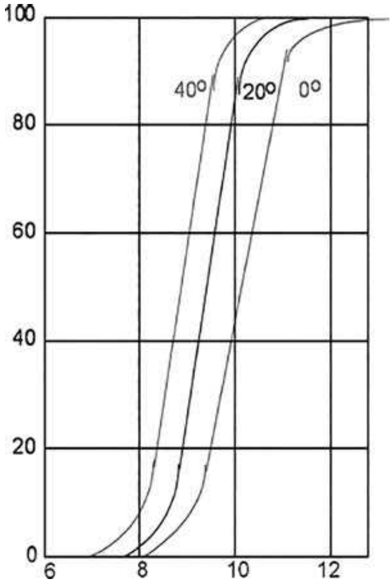

FIGURE 14 Stripping efficiency as function of temperature and pH.

chloride ions are formed. In the order of 10 parts by weight of chlorine are required for each part of ammonium-N. As the wastewater may typically contain 30 mg ammonium-N/L, 300 mg/L of chlorine is required. It would give a cost of \$0.10 per cubic meter to cover only the costs of chlorine. When the capital costs and the costs of the recovery of activated carbon are added, the total costs per cubic meter may reach about \$0.30. The method has therefore not found a wide application due to the high costs. The method has however a high removal efficiency even if the ammonium concentration is low, provided that sufficient chlorine is applied. Chlorination followed by active carbon adsorption can therefore be used as the last treatment for the removal of ammonium, where very low concentrations are required in the effluent.

Ion exchange by the use of the natural clay material clinoptilolite can be used for the removal of ammonium ions.[9] Clinoptilolite has a high selectivity for ammonium ions and about one-third to one-half of the ion exchange capacity, which is about 1.5 eq/L, and can, in many practical cases, be applied for the uptake of ammonium ions. It means that 1 L of clinoptilolite will be able to remove at least 1.5*14/3 g of ammonium-N = 7 g ammonium-N.

Ion exchange has furthermore been applied to remove nitrate from drinking water. A general anion exchanger is applied. It has an ion exchange capacity of about 2.5–3.0 eq/L, but the selectivity is not very high. It is however not necessary to remove the nitrate ions completely but to reduce the concentrations to the regional standards for nitrate in drinking water.

For further details about the ion exchange of wastewater and drinking water, see the entry denoted “Ion Exchange.”

Recycling of Municipal Wastewater

By a combination of the available treatment methods, it is possible to recycle municipal wastewater, i.e., to produce drinking water from municipal wastewater. The recycling takes about 8–10 days from toilets back to the water taps. All drinking water is in principle recycled. It takes normally nature a couple of thousands years to recycle water on average, which of course ensures a much better water quality than a recycling with a duration of 8–10 days.

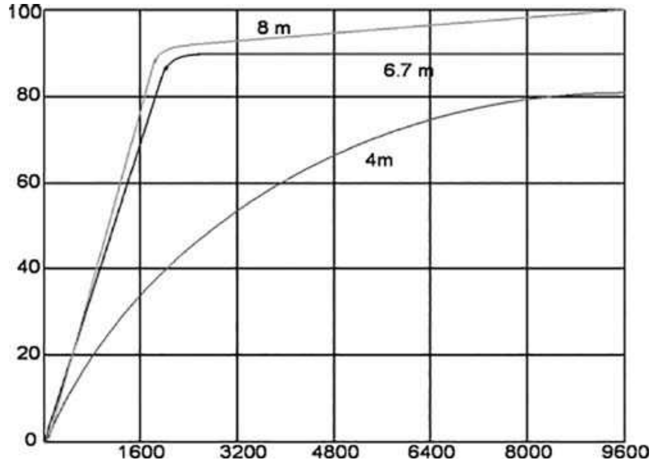

FIGURE 15 Efficiency of stripping process versus air/water ratio and tower height. Efficiency versus m^3 air/m^3 water for three different tower depths. The three tower depths are 4 m (insufficient), 6.7 m and 8 m. Tower height of 7–8 m is recommended.

Recycling of wastewater has been applied in Pretoria, South Africa, and in Windhoek, Namibia, due to an insufficient supply of natural water for production of potable water. In Pretoria, a treatment consisting of the following steps is applied: mechanical-biological treatment, aeration, lime precipitation, ammonia stripping, sand filtration, chlorination, adsorption on activated carbon, and a second chlorination. The plant in Windhoek has the same steps except ammonia stripping.

Water Quality and Quantity: Globalization

Kristi Denise Caravella and Jocilyn Danise Martinez

Introduction

Water is one of our most precious natural resources, covering nearly 70% of the Earth's surface, but only 2.5% of the Earth's water is fresh and suitable for consumption.[1] Thus, it is quite an understatement to say that freshwater is a scarce resource for the nearly 7 billion people living on Earth today.[2] Many nations around the world are currently ill equipped to deal with the demand for water. Nearly 1 billion people lack access to safe water.[3] The health and economic impacts of inaccessibility to water are staggering.

It is predicted that the problem will worsen with the increase in human population and the continued growth of the global economy. By 2050, the world population is expected to grow to more than 9 billion people, placing a strain on water utility systems around the world to meet the growing demand for the human consumption of water that is necessary for survival coupled with the need to utilize water as a tool of industry to maintain a competitive edge in the global marketplace.[3] Nations around the world must develop a coherent plan of action to deal with this problem. This entry discusses management issues related to water quality and quantity concerns that have occurred as a result of increased globalization. The purpose of discussing these issues is to mitigate water quality and quantity concerns that can have an adverse effect on human health and the environment on a global scale.

The results of globalization have created an international environment whereby economic integration is essential. Since World War II, the global trend toward greater interdependence among nation-states in the exchange of goods, services, and investments has accelerated. Much of this growth can be attributed to transnational corporations who have used technology to capitalize on expanding trade partnerships and exchanges. This increased international trade has led to an increase in global production, which has placed a strain on the environment. With regard to global water resources, urbanization led to heavy exploitation due to major advances in geological knowledge, well drilling, pump technology, and rural electrification. Given these circumstances, it is becoming increasingly important to put issues such as water quality and quantity in a global context.

The environment, water, and food production are closely interrelated at the international, local, and regional levels. Water is the major limiting factor for world agricultural production and implicitly tied to global food production.[4] As the human population continues to swell, food production will hinge on the ability to manage, preserve, and enhance global water resources.

Throughout the world, freshwater is used for drinking, industrial production, irrigation, transportation, recreation, waste processing, hydroelectric power, and a habitat for aquatic life.[5] Therefore, issues of contamination and local water depletion are intimately connected to the global economy. Increased global environmental trade, which increases the demand for “virtual” water, or water used to produce crops traded in international markets, can result in declines in water quality and quantity.[6] This entry discusses these important water resource topics from a global environmental management perspective.

Globalization and Water Resources

As globalization has become a more pervasive force, nations around the world have created development plans that prioritize industry over the protection of natural resources such as water.[7] This has become an increasingly notable trend in poorer nations. Many leaders in these nations see the growth of industry as the only realistic way to grow national industry in order to become a competitive force in the global economy and to increase quality of life standards for their citizens. These developing nations have been industrializing at a much faster pace than ever before, which can place an extreme burden on the environment. Some Asian countries (i.e., China) are industrializing in 20 years or less whereas the United States and Europe spent more than 100 years industrializing. However, following in the footsteps at the rate of developing nations such as Europe, Japan, and the United States can lead to a severe degradation of the environment.[7] The Millennium Ecosystem Assessment conducted by the United Nations (UN) finds that although there have been substantial gains in human well-being over the past 50 years due to industrial growth, broad ecosystems around the world are now degraded and under pressure.[8]

With rapidly increasing water demands, the competition among household, industrial, environmental, and agricultural water uses has been escalating in many regions as they are already limited by the amount and quality of available water. Human impacts on the quality and quantity of freshwater threaten economic prosperity, social stability, and the resilience of ecosystem services and natural capital.[5] According to Meyer and Turner,[9] human production and consumption is “unprecedented in its magnitude and rate and has truly reached a global scale” (p. 39).

Not only is human consumption of water an important aspect of water management, the environmental impacts of the changing hydrologic cycle can have an adverse effect on our accessibility to water. It is estimated that “less than 3 percent of all water is fresh enough to drink or to irrigate crops, and of that total, more than two-thirds is locked in glaciers and ice caps”[5] (p. 1029). In the coming century, global climate change and a growing imbalance among freshwater supply, consumption, and population will alter the water cycle dramatically.

Environmental changes that involve the “flow of materials and energy through the chain of extraction, production, consumption, and disposal of modem industrial society” or the “alteration of the land surface (i.e. wetlands, rainforests) and its biotic cover” become global either by “affecting a globally fluid system (the atmosphere, world climate, sea level) or by occurring in a localized or patchwork fashion in enough places to sum up to a globally significant total”[9] (p. 39). It is these two types of environmental change that can affect water resources at a global level.

Political Control and Global Water Management: Policies and Political Structure

With the growing demands on freshwater resources globally, there is an urgent need to link water policy research with improved water management strategies. Water resources sustainability means using water wisely and protecting complex ecosystems with future generations in mind.[10] Better monitoring, assessment, and forecasting of water resources will be needed to allocate water more efficiently among competing needs and to achieve water resource sustainability.[5] This will require coordination from a broad, ideally a global, perspective.

On an international level, the United Nations (UN) plays a critical role in water policy discussions. The UN defines public water policy as "the legislation and regulations that underpin water management"[11] (p. 7). The UN supports the goal of sustainable water management that "holistically addresses equity, economy, and the environment in a way that maintains the supply and quality of water for a variety of needs over the long-term, and ensures meaningful participation by all water resource management stakeholders"[11] (p. 7). The UN supports four dimensions of sustainability that include social sustainability (ensuring that the public has access to adequate and affordable water services), environmental sustainability (protecting against threats to the environment), economic sustainability (balancing costs), and institutional sustainability (establishing institutional frameworks that can function over a long-term period).

Much of the trouble in creating a framework that provides for international consensus, however, is that policymaking at the international level is decentralized and fragmented with multiple stakeholders. The primary stakeholders that serve as official and unofficial actors in issues of global water policy include government agencies at multiple levels, regulatory agencies, private sector firms, consultants, scientists, trade union groups, civil society, and religious groups.[12] Each of these stakeholders seeks to pursue their own individual agendas. While this statement is easily applicable to a variety of global policy issues, it is particularly well suited to global water policy issues because of the disparity in terms of how water policy is treated among nations. Essentially, public water policymaking occurs at all levels of government. The primary legislative framework is developed at the national level, whereas management and operational aspects are implemented at the local level. For example, American water policy involves a combination of state, local, and federal laws dealing with surface water and groundwater allocation and quality protection. Surface water and groundwater allocation is almost exclusively the province of state law, whereas surface water and groundwater quality protection is a mixture of state, local, and federal laws.[13] This fragmented decision-making structure leads to an increase in the number of stakeholders that influence water policymaking within and, inevitably, among nations.

There is fragmentation on water policy not only at the international level but also at the national level. Another aspect of fragmented water policy occurs when discussing specific hydrologic cycle issues and ecological water budgets. Precise data about regional hydrologic cycle issues and area-specific estimates of water supply and demand are difficult to achieve at the national level.[14] Because water policy decision making occurs at the national level in most nations, region-specific issues are the responsibility of state and local policymakers and not applicable to other regions. For example, it is often the case that hydrological knowledge and methodologies obtained for one specific geographic region cannot necessarily be adapted to other regions. This is especially problematic in large nations that have a multitude of differing geographical conditions within its political boundaries, such as the United States and the European Union. Policy fragmentation also occurs as a result in a changing conceptualization of the hydrologic cycle. Classical thinking about the hydrologic cycle has focused on the large-scale (or macro) aspects of the cycle, while largely ignoring the smaller microcycles that occur within it. These microcycles are an important factor in water resource recovery that can help to restore the natural functions of aquatic systems around the world to help achieve sustainability within watersheds. Restructuring these thoughts about water policymaking to include the smaller microcycles that occur in the classic hydrologic cycle model can be a positive step toward the successful regeneration of these ecological systems, but does little to achieve cohesion in national water policymaking.

A negative side effect of this fragmented policymaking is the lack of collaboration and equity in the context of water development and management with nations. When policy fragmentation occurs in this way, the design of policies, interventions, and programs aimed at the equitable distribution of benefits from water resources becomes impossible. It also leads to deficiency and irregularity in data collection and interpretation, which makes cohesive policymaking efforts next to impossible.[14]

Balance sheets of micro-, meso-, and macro-watersheds are another challenge in the policy environment of water policymaking. Evolving a robust and rigorous methodology for assessing the impact of watershed (or river basin) projects at the micro, meso, and macro levels is a major challenge facing academicians, policymakers, and practitioners.[15] Watershed development projects are a continuous process, rather than time-bound projects with a well-defined set of activities and clearly earmarked funds, which creates methodological problems for studying them. This leads to difficulties in creating policy that incorporates these resources. In addition, there has been disagreement on the indicators for success. Overall, studies at the watershed scale have been inconclusive with regard to positive effects on soil conservation, sustainability, or environmental regeneration.[15] Despite limitations, watershed projects have led to at least two positive outcomes, "creation of a large number of structures for soil water conservation; and … setting up of participatory institutions for management of the local resources"[15] (p. 1). Recent watershed studies include studies in India, the Indo-German Watershed Project, Latin America and the Caribbean, the Nile Basin (Africa), the Thukela river basin of South Africa, and the Pangani river basin of Tanzania.

In order for watershed projects to have significance in the development of water policy, Shah et al.[15] state the following issues must be addressed: "technology, physical treatments and economic returns; (creating) institutions that ensure equity and efficiency in resource use; and (creating) market linkages essential for enabling the project to sustain beyond the initial funding, and for spreading out to larger number of beneficiaries as well as areas" (p. 5). At the micro level, watershed projects will inherently require negotiation among territories. At the meso and macro levels, watershed projects will require extensive (often international), integrated collaboration among participatory institutions that can be very costly.[16] Finally, water policy that seeks to address issues at the watershed scale must address socioeconomic issues that affect utilization of these resources.

There is a large disparity between water policymaking when looking at developed and developing countries.[17] There is also disparity when looking at water policymaking among different developed nations. In many developed nations, issues of water quality and quantity are managed by a well-established regulatory framework that monitors the public water supply. Many developing nations do not have such a political framework in place at the national level, leaving most of the policymaking decisions for local leaders. This can lead to duplication in implementation and inaction at the local level. Ultimately, this can surmount to even greater disparity within nations, which further limits abilities to develop a cohesive national water policy agenda and regulatory framework.

Global Surface Water and Groundwater Concerns and Issues: Introduction

William Jury and Henry Vaux, at a colloquium held in 2004 to address emerging global water problems, stated that the "optimum management of global water resources presents one of the most crucial challenges of the 21st century" (p. 15,715). Of all the water resource problems, scarcity is considered to be the most serious. According to Jury and Vaux,[18] in much of the world, existing water supplies are already insufficient to meet all of the urban, industrial, agricultural, and environmental demands.

Globalization also has led to an increase in the contamination of water resources through urbanization, agricultural intensification, and land degradation. The lack of a global water quality standard has led to varying levels of water quality around the world. This is significant as water resource contamination can have global effects on human health and the environment through increased international trade and resource sharing.

Global water concerns can be divided into two main areas: water contamination and groundwater, or aquifer, depletion. The next two sections outline the major causes of these two concerns and current issues that are being explored to rectify these issues from a global perspective.

Surface Water and Groundwater Contamination

Quality surface water and groundwater in abundance is needed for human health, agriculture, industry, and recreation. Our surface water resources have a long history of being adversely affected by point sources such as industrial and municipal waste disposal, animal waste, recreational vehicles, hazardous product spills, and air deposition of particulates. Surface water is typically heavily contaminated and is not available for usage in the water supply. According to the Food and Agriculture Organization of the UN, more than 5 million people die annually from waterborne illnesses from both surface water and groundwater contamination. Roads, railways, pipelines, hydroelectric corridors, runoff from mines and mine wastes, quarries, well sites, a large variety of recreational land uses including ski resorts, boating and marinas, campgrounds, and parks, leachates, and gases (as a result of irrigation) contribute to surface water and, eventually, groundwater contamination.

Groundwater is water that is present below the surface of the Earth in underground sources (i.e., streams and aquifers). It is one of the most important natural resources in any nation and serves as a major source of water in communities around the world for households, industries, and agricultural purposes. In comparison to surface water, it is generally considered to be much less susceptible to contamination. Hence, groundwater becomes the main source for potable water in many parts of the world.

Groundwater contamination is one of the most serious problems that can have an impact on water quality. In the past 50 years, groundwater contamination has become one of the most serious environmental problems in the world because once polluted, the remediation of aquifers may be very difficult and even impossible.[19] A groundwater contaminant is any substance that impacts the quality of groundwater. Groundwater contaminants include substances found in storage tanks, septic systems, hazardous waste sites, landfills, road salts, fertilizers, pesticides, and other chemicals.

Problems with water quality have increased primarily due to contaminations associated with human and land-use activities including agricultural activities, leaking municipal sewage treatment facilities, poor septic management, uncontrolled cattle access to water bodies, effluents from industries, and runoff from urban areas.[19] This is a particularly dangerous problem when, as noted, groundwater sources constitute the main drinking water supply in a community, as is the case in most nations. Groundwater contamination also can occur as a result of contamination in surface waters. If contaminants are present in other parts of the hydrologic cycle (i.e., surface water), these contaminants can also be transferred into groundwater supplies.

Typically, groundwater contamination does not occur as a result of a lack of legislation that establishes rules and guidelines regarding groundwater contamination. In other words, much of the problem is not that anticontamination laws do not exist, but that these laws are not necessarily enforced. In China, the major culprit of worsening groundwater pollution is industrial wastes.[20] Many industrial plants discharge waste without proper treatment because environmental protection laws are not enforced. This lack of enforcement coupled with the increase in human activities, largely due to population growth and increasing industrialization, has led to an increase in groundwater contamination. In India, the primary sources of groundwater contamination include untreated wastewater (which can lead to death and disease from sewage-borne infection), large quantities of industrial effluents being discharged, and agricultural runoff filled with hazardous chemicals found in fertilizers and pesticides that taints groundwater sources.[21] These factors are largely attributed to the fact that contamination laws are not enforced. Lack of enforcement can lead not only to decreasing water quality but also to human fatalities. For example, high levels of arsenic found in the surficial aquifer Simav Plain in Kutahya, Turkey, have been linked to an increase in deaths related to gastrointestinal cancers from 1995 to 2005.[22]

Because groundwater serves as the primary source of potable water in many communities, water quality is a critical aspect of the international water crisis. Part of the problem in regulating these systems on a global level is the large amount of diversity observed in the provision of water and policy approaches to contamination among nations around the world and the different regulatory models adopted in different countries. National programs of water quality monitoring throughout the world range from limited to non-existent. Few developing countries include water quality within a meaningful national water policy context. Water supply is considered to be a national issue while contamination is often considered to be a local problem. This can be problematic as national policy frameworks develop that fail to take into consideration the differences in regions.

Many of the national programs that do exist are dysfunctional due to years of neglect, chronic underfunding, and lack of focus. In some countries, water utilities are natural monopolies whereby public or private owners of the system are able to exercise considerable control over pricing and service quality. This places users of that system in a vulnerable situation whereby they may have no other options for water access. In some developing countries, there may be more competition among water utility vendors. This gives users greater options in terms of accessing quality water.

Yet, the regulation of water systems is critical for economic and social development of a nation. Regulatory agencies have been created and established in many different countries to help police utility systems and ensure that water quality guidelines are followed. A recent study conducted by Marques[17] identified 136 water service regulatory authorities worldwide (in January 2008). These regulators are spread across 57 countries, 12 of which are in Africa, 5 in Asia, 16 in Europe (2 in Euro-Asia), 2 in Oceania, and 22 in America. About 25% of countries have regulators for the water sector. Marques[17] suggests that the trend is moving toward nations creating new agencies to provide for the regulation of their water utilities.

In terms of water quality issues, many national governments in developed countries have created a system of rules and guidelines that establish minimum criteria that utility systems must follow in the provision of drinking water to users of that system. Although the implementation of such rules can provide heavy cost burdens on those utilities, the framework provides a uniform standardization mechanism that can assure the public that the water they are consuming is safe.

However, even among developed countries, there is little consistency among the treatment of water quality issues at the national level. Some have well-developed regulatory frameworks, while others do not. The United States passed the Safe Water Drinking Act of 1974 to regulate the nation's public drinking water supply in an effort to protect public health. The Act authorizes the United States Environmental Protection Agency (USEPA) to set national health-based standards for drinking water to protect against both naturally occurring and man-made contaminants that may be found in drinking water. USEPA, individual states, and water systems then work together to make sure that these standards are met. The European Union established a Drinking Water Directive in 1983 that protects human health by establishing healthiness and purity requirements for water. The directive set quality standards for drinking water at the tap and obliges member states to regularly monitor drinking water quality.[23] The Japanese national government has not only established Environmental Water Quality Standards and water pollution control measures but also established uniform water quality regulations for public water and groundwater that operators of utility systems must implement.[24]

Surprisingly, even some larger developed countries lack an established framework. In Canada, there is no national strategy in place to address water issues and no federal leadership to conserve, protect, and regulate Canada's water. The Federal Water Policy is more than 30 years old and needs to be updated to establish more rigid criteria for water quality monitoring. It is ironic that Canada's economy is built on the myth of an abundance of freshwater, yet only 1% of Canada's freshwater is considered renewable [25] Often associated with increased regulations is a shift toward computerized water quality monitoring. Data-driven approaches to water quality can be costly and difficult to implement in developing countries.[26] Over the last several decades, there has been a large shift toward the purchase of technological upgrades that help monitor water quality and collect data in developing countries. Water quality monitoring, as developed in Western countries, is based on the premise that with enough data, a well-designed program can answer most types of water quality management issues. Traditionally, developing countries are data-poor environments. This poses a major challenge for environmental management and decision making because nations that lack water monitoring technology are not able to obtain data about the water quality in order to make appropriate surface water and groundwater contamination policy.[26] In light of the lack of enforceable regulatory systems and lack of knowledge about the actual quality of water in many nations, surface water and groundwater contamination are critical concerns for many nations around the world in a national context. Because of the diverse nature of water quality monitoring in individual nations, forming a cohesive policy regarding groundwater contamination at an international level presents considerable challenges.

Groundwater and Aquifer Depletion

By far, the most abundant and available source of freshwater is underground water supplies or well-springs known as *aquifers.* Groundwater is the primary source of water for drinking and irrigation. At least one-fourth of the world's population draws its water from underground aquifers and approximately 99% of all liquid freshwater is found in underground aquifers.[5] Serious difficulties exist in fairly allocating the world's freshwater resources between and within countries.[27]

Conflicts are escalating among new industrial, agricultural, and urban sectors. According to the Global Environment Facility, worldwide such conflicts have increased from an average of 5 per year in the 1980s to 22 in 2000.[27] In 23 countries for which data are available, the cost of conflicts related to the agricultural use of water was an estimated $55 billion between 1990 and 1997. At least 20 nations obtain more than half their water from rivers that cross national boundaries,[28] and 14 countries receive 70% or more of their surface water resources from rivers that are outside their borders.[29,30] One way that governments have sought to deal with this imbalance has been to pass laws that set limits on water allocations.

Some of the major causes of groundwater depletion include population growth and increased demand for food supply, increased trade, increased agricultural irrigation, and environmental changes including changes in rainfall, temperature, evaporation rates, soil quality, vegetation type, and water runoff. This section reviews these causes and discusses remedies where available.

In the next 30 years, the Earth's population is projected to rise by approximately one-third (or 3 billion people).[5] This growth in global population is projected to be at least 3 times greater than accessible freshwater runoff. The growth in global population and water consumption will place additional pressure on freshwater resources. People use freshwater for many purposes including irrigation for crop production, industrial and commercial activities, and residential activities. Some water that is used by people can be reused; herein lays the difference between water consumption and water use. Water consumption occurs when there is no ability to reuse the water.[27] For example, when humans use water for sanitation, it can be reused and is therefore not consumed.

To make matters worse, most of the world's population growth will occur in developing countries where water is already critically short and many of the residents are impoverished. It is estimated that, today, more than 1 billion people do not have access to safe and affordable drinking water and perhaps twice that many lack adequate sanitation services.[18] Particularly in cities and towns around the world where there is population density, there is just not large enough a recharge area to support the needs of their inhabitants on a sustainable basis.[31] For example, in Beijing, China, a highly populated city, prohibitions have been placed on farmers from using local water for irrigation. Also in the Gulf Coast countries (Bahrain, Kuwait, Oman, Qatar, Saudi Arabia, and the United Arab Emirates) where there is arid climate, these countries are experiencing a severe water shortage problem that "threatens the sustainable development and hinders the national plans for human, industrial and agricultural development" throughout the region[32] (p. 59).

While floodwater is one way to replenish global water resources, floodwater requires large-scale management and coordination of water systems including reservoirs and dams. Water for irrigation, industry, and household uses must be delivered in controlled quantities at specific times, making floodwater an impractical solution to renewing water resources without the necessary management in place.

Also, as the human population has increased, so has trade among nations and more water is used to produce these goods and services. As a result of this increase in environmental trade and urbanization, countries have tried to overproduce in an effort to maintain a competitive edge in the global marketplace. This has placed a burden on the groundwater sources in many nations that have overpumped aquifers in an effort to increase production and trade. This is most notable in the agricultural community. For example, the three main grain producers, China, United States, and India, have all felt the effects of overpumping, or pumping that exceeds the long-term average rate of replenishment. Ultimately, overpumping can lead to a depletion of aquifers and consumption of aquifer reserves, which may lead to cutbacks in grain harvests. Evidence of substantial and widespread drawdown of the piezometric surface beneath many Asian cities, as a result of heavy exploitation of aquifers, also has been accumulating since the early 1970s.

The increase in agricultural production, in both crops and livestock, is significant as much of the water that is used for production cannot be recovered or reused; in essence, it is consumed. According to the United Nations Educational, Scientific and Cultural Organization (UNESCO), world agriculture consumes 70% of the freshwater withdrawn per year.[27]

Increased crop production and irrigation negatively affects soil quality and water runoff. Irrigation causes soil erosion, which diminishes the soil quality by reducing soil depth and soil nutrients. Other problems and failures of irrigated agriculture include groundwater overdraft, water quality reduction, water logging, and salinization.[33] While these various forms of soil degradation are proven to affect water resources, on a global level, they are very hard to track.[9]

Increased livestock production directly and indirectly affects the depletion of water resources in that not only do livestock directly consume freshwater but water is also consumed in the production of grains that are fed to the livestock. According to the U.S. Department of Agriculture (USDA), increased crop and livestock production during the next five to seven decades will significantly increase the demand on all water resources, especially in the western, southern, and central United States and in many regions of the world with low rainfall.[27] Strategies such as crop rotation, replacement of trees and shrubs, soil maintenance, and the use of organic mulch promote water conservation by limiting the damage done by crop production.[27]

Appropriate water pricing is important for improved water demand and conservation of water.[27] The relatively high cost of treating and delivering water has led many world governments to subsidize water for agricultural and household use. For example, some U.S. farmers pay as little as $0.01 to $0.05 per 1000 L used in irrigation, while the public pays $0.30 to $0.80 per 1000 L treated water for personal use.[34] According to the World Bank,[35] the objectives of fair water pricing are 1) to seek revenue to pay for the operations and maintenance of water availability; 2) to improve water use efficiency; and 3) to recover the full costs of water pumping and treatment.[36]

Finally, there is a growing scientific consensus that the buildup of greenhouse gases in the atmosphere is warming the Earth.[5] The continued loss of forests and other vegetation and the accumulation of carbon dioxide, methane gas, and nitrous oxide in the atmosphere are projected to lead to global climate change or global warming. Over time, such changes may alter precipitation and temperature patterns throughout the world.[27] These temperature changes might increase soil erosion and deforestation, which could result in greater reductions in water availability worldwide. Salati and Vose[37] claim that regional forest clearance would have severe climatic consequences. Because of the high proportion of water recycled by the rainforest, deforestation would significantly lessen rainfall and increase temperatures.

Global Water Resource Policy: Toward a Potential Framework

As noted throughout this entry, there are many efforts at the national level to conserve water resources, but what is lacking is an integrated worldwide water resource management system. A well-coordinated international plan for managing the diverse and growing pressures on freshwater systems and for establishing goals and research priorities for cross-cutting water issues is required. At the most basic level, water resource management must address how to "secure water and related services, avoid degradation of water and land resources and of ecosystem integrity, and foresee changes (climate, population, diet preferences etc.)"[38] (p. 14).

This plan will have to incorporate the many national, transnational, and private organizations that already exist into global water resources conglomerations or networks. Collaboration among this myriad of agencies will inevitably require a change in the culture of water management where water agencies have been known to be proprietary in nature. In addition, a redefinition of water policy from a political, economic, cultural, and social perspective is needed.

Foster and Chilton[39] note that nations and stakeholders need to "appreciate their social and economic dependency on groundwater, and to invest in strengthening institutional provisions and building institutional capacity for its improved management" (p. 1970). This can be achieved by creating global communication strategies to fuse the dialogue between the many water management stakeholders including scientists, policymakers, water managers, and citizens.[18]

Foster and Chilton[39] also state that local field agencies might have to change their roles to aid in the development of a broader global water management system. Jury and Vaux[18] agree that many existing water management institutions were "created in times and eras when the problems of developing and managing water resources were very different from what they are today" and would therefore require substantial changes to their institutional arrangements. Currently, water management institutions tend to focus on a narrow set of interests, but with the global nature of water resources management today, these institutional arrangements will no longer be beneficial to solving world water problems.

For example, Benvenisti[40] argues that there is enough freshwater in the world to meet the existing and future needs of the world's population but that this water is poorly distributed, making the management of global water resources predominately about redistribution. Shah et al.[31] agrees that redistribution and "the co-existence of regions with undeveloped (water) resource and those with overdeveloped (water) resource" is central to the future of water management policy.

Redistribution policy management inevitably will bring into play the competing priorities of different uses and users, and since most water resources traverse political boundaries, these competing priorities often become regional conflicts between states. Policies aimed at redistribution across political boundaries must then be of "collective action despite the varied self-interest" of these regions[40] (p. 385). Benvenisti recommends an international law policy framework that borrows aspects of game theory, economics, contract legal theory, international relations theory, and international negotiations theory to encourage the cooperation needed for the redistribution of global water resources.

In addition, to move toward a global policy framework, much more precise and spatially congruent data are needed. Meyer and Turner[9] note that the reluctance of national and international institutions to fund the collection of social data is an obstacle that must be addressed. Foster and Chilton[39] note that, globally, current data used to assess the status of aquifer degradation are of questionable reliability, inadequate coverage, and poor compilation. Since data on aquifer depletion and water contamination are collected by many different agencies that might focus on different aspects of water management including engineering sciences, hydrology, climatology, and geology, institutional arrangements that can bring together these interdisciplinary concepts into a comprehensive data management system will have to be created.[18]

Finally, while there is a general consensus on some of the future challenges in a global water management system, there are still many unknown factors that may arise. Jackson et al.[5] state that "uncertainty will be the most important feature of freshwater forecasts" and that by "evaluating uncertainties, forecasters can help decision makers to anticipate the range of possible outcomes and to design flexible responses" (p. 1038). Planning for uncertainties requires "adaptive management" or the "process of designing management interventions to decrease the variance of future forecasts and recommend alternative management options" (p. 1038). Future global management of freshwater systems must, therefore, incorporate adaptive management strategies.

Conclusion

The major water concerns discussed in this entry are associated with the prevailing cultural, political, economic, scientific, and social perceptions about how humans should interact with the environment. A redefinition of water policy may lead to changes in these perceptions. On a larger scale, the global water discussion requires a redefinition of the relationships between industry and environment. A redefinition of water policy may lead to changes in human behavior that can help address some of the concerns discussed in this entry. For decades, the primary engine that has driven the growth of the global market is a continued focus of economic gain among nations. This tendency toward capitalist values has continually placed a greater value on industry at the expense of protecting the environment. Strategic thinking at the international level should emphasize sustainable development. There must be some consensus among policymakers on water policy goals. A global water policy agenda that focuses on sustainable development is necessary to meet the goals of protecting the Earth's water while meeting human water demand.

Water: Cost

Atif Kubursi and
Matthew Agarwala

Introduction

Is water really different from other commodities? While water is versatile and has many uses, it is generally considered as an asset, a consumer good, and a factor of production. If it is a resource, is it a renewable or a "non-renewable resource?" Is its value infinite and "thicker than blood?" Can a price for water be determined much like for any other commodity? Can water or water permits be traded? What constitutes an equitable distribution of this scarce resource? What is a fair price for water? What is the full-cost price of water that incorporates its many environmental functions?

These complex questions are provocative and can incite passionate debate, yet they are central to water resource management. In this note, we show that economics sheds useful light on how to address these questions. This is not to suggest that economics alone can answer all of them. There are complex social, environmental, moral, and strategic issues that need to be factored into such an analysis. These add complications to the general structure within which water prices will be considered but do not change in any fundamental way the conclusions reached.

Before going any further in answering some of these questions, it is useful to outline some of the specific attributes of water that distinguish it from other commodities. These attributes will also influence the way water prices are set and optimal allocations of this scarce resource may be affected.

- Water is a fugitive, reusable, and stochastically supplied resource whose production can be subject to economies of scale, which give rise to natural monopoly situations. In this respect, water has many of the characteristics of a common property resource and a quasi-public good.
- Water is typically a non-traded commodity that is rarely sold in a competitive market. There are few overt water markets where suppliers and demanders exchange water. Markets in water rights have emerged in several parts of the world; the most notable examples are in Australia, Colorado, California, and Argentina.[1–3] However, most of these markets are within national entities, are heavily regulated, and often represent simulated market solutions. There are few international examples of water trade, but it is not difficult to conceive schemes that would involve this trade.

- Water scarcity is not only about physical scarcity, but it is also complicated by economic scarcity where actual prices for water are typically only a fraction of the true scarcity price. When prices are below scarcity prices, waste and overuse are quickly observed.
- Water values generally differ from the price that would obtain in a free and competitive market. The distinction between price and value is crucial. A family's visit to a local park may have a price of $0, but the value of such a visit may be much greater. When prices and values diverge, market forces produce inefficient outcomes. Water often has social value that is above what private users are willing to pay for it.[4] The allocation of water often reflects national and social policies and priorities toward agriculture, the environment, food security, and national security that go beyond serving the interests of private farmers. Social and policy considerations apart, the diversion of actual prices from their scarcity values imposes social costs on the domestic economy as well as on neighboring countries. Water is part of the tragedy of the commons.[5]
- Water is not only a desirable commodity, but its availability is also critical for life. At subsistence levels, it has no substitute. Furthermore, that every person is entitled to a minimum quantity that is considered consistent with human dignity is now enshrined in international human rights law.[6,7]
- The secure supply of water in many regions of the world is quite low. Security of supply is defined here as the probability of its average flow availability for 9 out of 10 years. In Canada, a country rich in water, this probability is less than 30%, whereas it is less than 5% in the Middle East.[8]
- While the total water supply may be limited and few, if any, substitutes exist for it, there exist substantial possibilities for intersectoral and interregional substitutions. As well, there are a number of technologies and conservation programs that rationalize demand and raise the efficiency of its use.
- Part of the water scarcity crisis is the fact that agriculture on average uses about 70% of the total global supply.[9] It is typically the case that other needs are suppressed, but this leaves a wide room for intersectoral reallocations and shuffling water between users and uses.
- While the quantity of water is in short supply, concern for preserving its quality is perhaps more pressing. Pollution and saline intrusion of the aquifers are being increasingly recognized as critical factors in planning for the future.
- Water is the "universal solvent."[10] It performs numerous ecosystem services including the absorption, transportation, and dilution of pollutants. Water is indispensable to the environment's pollution abatement capacity.[11]

Competitive Markets and Water Prices

The scarcity of water suggests that it should have a price that reflects this scarcity. Since economics is particularly suited for dealing with how scarce resources are, or should be, allocated to various uses and users, it can shed useful light on its use and value.

Indeed, water has a value as does any scarce resource, input, or asset. There is a monetary equivalent to water, although this is not the way people typically speak about water. This value need not emerge from competitive markets. However, it has or could be constructed to have many of the characteristics that are associated with competitive prices. The price should reflect the scarcity of water and disseminate information about this relative scarcity. It should also invite, if not provoke, the correct responses (incentives) that prices in general are expected to do. Higher prices persuade consumers to economize on its use and suppliers to raise their quantities offered. In competitive markets, the market price is what buyers are willing to spend for an additional unit of the commodity and the extra cost of producing it (marginal cost). If the price is larger than the marginal cost of the last unit of water, this provides a signal that more is needed of the commodity and more should be produced.[12] Conversely, if the price is below marginal cost, additional units will not be produced as society will have to sacrifice more than what people would value the additional units.

It is generally accepted, however, that water is not bought and sold in competitive markets. This is because in the case of water, at least five of the basic properties of competitive markets are generally absent.[4] These five properties include the following:

- Free markets lead to an efficient allocation of scarce resources if these markets are characterized by competitive structures, that is, these markets include a large number of independent small sellers and a similarly large number of independent small buyers that no single supplier or buyer is significant enough to influence the price. Each and every buyer and seller in this market is a price taker.
- Competitive markets require freedom of entry and exit and that no barriers that preclude easy entrance or exit exist.
- The product must be homogeneous enough that each unit is quite similar to any other unit.
- For a free market to lead to an efficient allocation, externalities must be absent. In economics, an externality or spillover of an economic transaction is an impact on a party that is not directly involved in the transaction. An efficient allocation can emerge from a free market when social costs coincide with private costs. Water production, however, involves many "externalities."[4] In particular, extraction of water in one place reduces the amount available in another. Further, pumping water from an aquifer in one location can affect the cost of pumping elsewhere. Such externalities do not typically enter the private calculations of individual producers and drive a wedge between private and social costs.
- In a free market that efficiently allocates scarce resources, social benefits must coincide with private ones. If not, then (as in the case of cost externalities) the pursuit of private ends will not lead to socially optimal results. In the case of water, many uses have social benefits that exceed the private ones. The use of water in agriculture may result in benefits that exceed the private returns to farmers. Among these are food security, border security, environmental objectives, and national interest.

These conditions are often violated in the case of water, where water sources are relatively few; barriers to entry are real and high (high cost of infrastructure); a large gap exists between private and social costs; and benefits and water units are not homogeneous, with a large spectrum of different qualities observed. This, perhaps, is why it is often the case that water production facilities are owned by the state. In many respects, water is not a private good; it has what we alluded to above, many of the characteristics of quasi-public goods.

Although water is not bought or sold in competitive markets, it is possible to develop prices that reflect its value.[13–15] In practice, the full value of water is not revealed in competitive markets. It is possible, however, to build specific models of water allocations that simulate competitive conditions and where the optimal nature of markets is restored. The model can explicitly optimize the benefits to be obtained from water, taking into account the five points made above. It is also true that now we have a rich body of literature that informs the setting of water prices and tariffs to overcome some of the five points listed above. The prices that emerge from formal optimization models not only maximize profits for the producers (producer surplus) but also maximize the utility of the consumer (consumer surplus). Furthermore, as is shown later, a multi-objective framework can be developed to design prices that satisfy goals beyond pure economic efficiency. These constructed prices permit the optimal allocation of water to its best uses as would emerge under competitive conditions. In many respects, the constructed prices are designed to serve as guides to consumers and producers in much the same way as competitive prices.

Optimizing Model: Simulating a Competitive Water Market

The underlying economic theory of the "optimizing model" is simple and compelling.[14,16,17] (This section draws heavily on Fisher[4] and Fisher and Huber-Lee.[17]) In Figure 1, we show an individual household's demand curve for water, with the amounts of water (on the horizontal axis) that the household

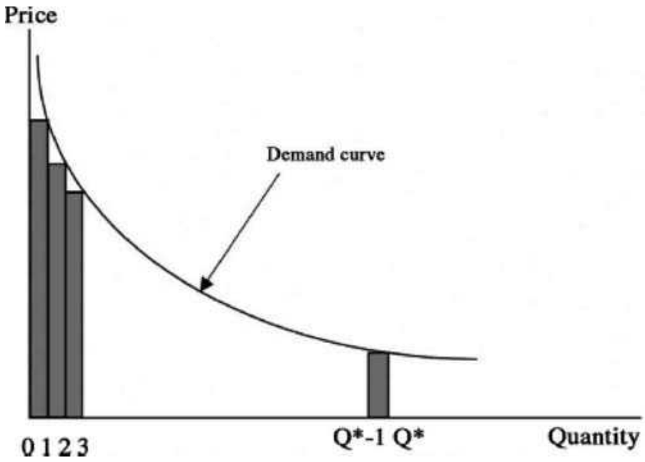

FIGURE 1 Demand curve for water.

will buy at various prices (on the vertical axis). The curve slopes down, representing the fact that the first few units of water are very valuable, while later units will be used for purposes less essential than drinking and cooking.

Now consider how much it will be worth to the household in question to have a quantity of water, *Q**, as depicted in Figure 1. We begin by asking how much the household would be willing to pay for the first small unit of water. The price that would be paid is given by a point on the curve above the interval on the horizontal axis from 0 to 1. Thus, the amount that would be paid is (approximately) the area of the leftmost vertical strip in Figure 1 (one unit of water times the price in question). Similarly, the amount that would be paid for a second unit can be approximated by the area of the second-to-left vertical strip, and so on until we reach *Q**. It is easy to see that if we make the size of the units of water smaller and smaller, the total amount that the household would be willing to pay to get *Q** approaches the area under the demand curve to the left of *Q**.

It is quite simple to reinterpret Figure 1 so that it represents not the demand curve of an individual household but the aggregate demand curve of all households in a given region. The gross (private) benefits from the water flow *Q** can thus be represented as the total area under the demand curve to the left of *Q**. These benefits are gross benefits as the cost of providing this water is not subtracted. To derive the net benefits from *Q**, we must subtract the costs of providing *Q**.

In Figure 2, the line labeled "marginal cost" shows the cost of providing an additional unit of water. That cost increases as more expensive sources of water are used. The area under the marginal-cost curve to the left of *Q** is the total cost of providing the supply, *Q**, to the households involved. Thus, the net benefit from providing *Q** to these households is the shaded area in the diagram, the area between the demand curve and the marginal-cost curve.

The amount of water that should be delivered so as to maximize the net benefits (the sum of consumer and producer surpluses) from water is *Q**, where the two curves intersect. This is the largest area between the two curves and represents the sum of the consumer surplus, defined as the difference of what households would be willing to pay and what they actually pay (the price that rules in the market at the intersection between supply and demand), and the producer surplus, defined as the amount of profits producers realize as the price of water exceeds its marginal cost. Both of these areas are defined in Figure 2.

Social value of water can exceed its private value as society may value this water beyond the benefits individuals would derive from it. A national policy to subsidize water for agriculture by say, 10 cents per cubic meter, at all quantities simply means that water to agriculture is worth 10 cents per cubic meter more to society than farmers are willing to pay for it.[17] This is represented in Figure 3. The lower

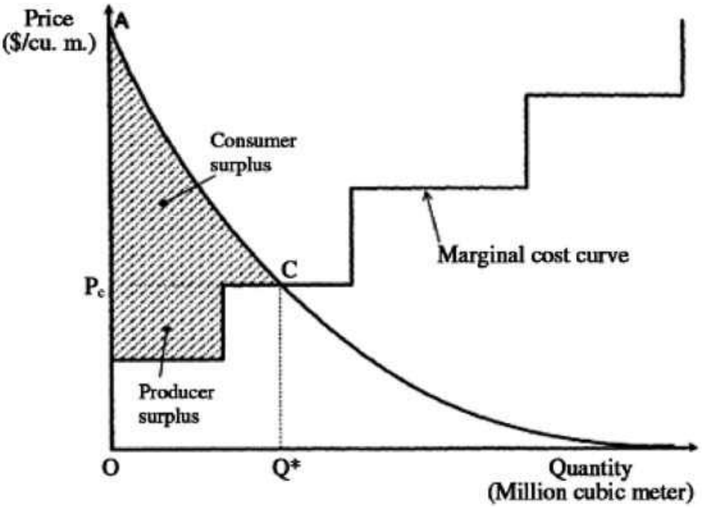

FIGURE 2 Net benefits from water.

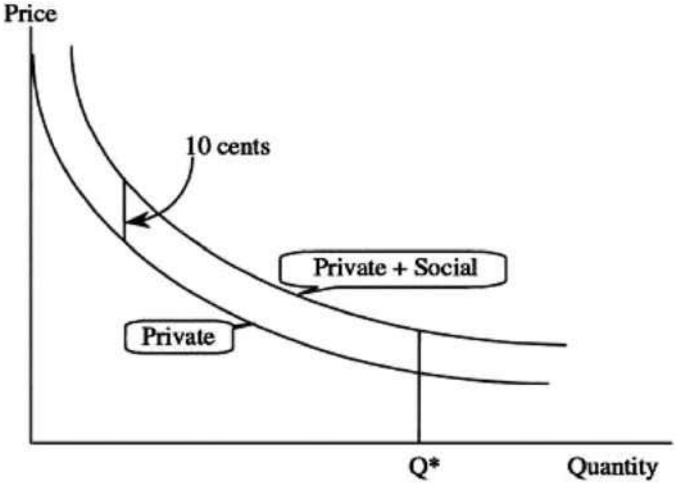

FIGURE 3 Social value of water as revealed by a subsidy.

demand curve represents the private value of water to agriculture; the upper demand curve also includes the additional public value as reflected in the policy, an additional value of 10 cents per cubic meter. As this illustrates, any consistent water policy can be represented as a change in the demand curve for water. Once such a policy has been included in the demand curves, the methods used above can be employed to measure net benefits.

Shadow Prices and Scarcity Rents

(This section too draws heavily on Fisher.[4])

As already discussed, purely private markets and the prices they generate cannot be expected to optimize net social benefits of water. Nevertheless, prices in an optimizing model can play a role very similar to that which they play in a system of competitive markets. Dr. Franklin M. Fisher[4] and his team developed such a model, called "WAS" (for "Water Allocation System") at Harvard University.[18] The model allocates water so as to maximize the net benefits (consumer surplus plus producer surplus) obtained from this allocation. The maximization of net benefits is done subject to constraints. An example of such constraints includes that at each location, the amount of water consumed cannot exceed the amount produced there plus net imports (imports minus exports) into that location.

Corresponding to the optimum quantities, there is a dual solution that defines the associated prices at the optimized level of activities. It is a general theorem that when maximization involves one or more constraints, there is a system of prices involved in the solution. These prices are called "shadow prices" or "Lagrange multipliers." Each shadow price shows the rate at which the quantity being maximized (here, net benefits from water) would increase if the associated constraint were relaxed by one unit at the optimal solution. In effect, the shadow price is the amount the maximizer would be just willing to pay (in terms of the quantity being maximized) to obtain an additional unit of the associated constrained quantity.[19]

The Role of Shadow Prices

Since water does not generally command a market price, economists have constructed models that estimate the scarcity (shadow) price of water that reflects many of its competitive equilibrium characteristics. The shadow price associated with any particular constraint shows the extent by which the net benefits from water would increase if that constraint were loosened by one unit. For example, where a pipeline is limited in capacity, the associated shadow price shows the amount by which benefits would increase per unit of pipeline capacity if that capacity were slightly increased. This is the amount that those benefiting would just be willing to pay for more capacity.

The shadow price of water at a given location is the amount by which the benefits to water users (consumers and producers) would increase were there an additional cubic meter per year available at that location. It is also the price that the buyers at that location who value additional water the most would just be willing to pay to obtain an additional cubic meter per year.

There are a number of defining characteristics of the shadow prices that need further explanation.[4] These include the following:

- Shadow prices are not necessarily the prices that water consumers are charged. That would be true in a purely private, free market system. However, in the WAS model, as in reality, the prices charged to some or all consumers can (and often will) be a matter of social or national policy. When such policy-driven prices are charged, the shadow prices of water will reflect the net benefits of additional water given the policies adopted.
- Shadow prices are outputs of the model solution, not inputs specified a priori. They depend on the policies and constraints put in by the user of the model.
- The shadow price of water in a given location does not generally equal the marginal cost of providing it there. If demand for water from a source is sufficiently high, the shadow price of that water will not be zero even if it costs nothing to produce it; benefits to water users would be increased if the capacity of the source were greater. Equivalently, buyers will be willing to pay a nonzero price for water in short supply, even though its direct marginal costs are zero.
- When demand at the source exceeds capacity, it is not costless to provide a particular user with an additional unit of water. That water can be provided only by depriving some other user of its benefits; that loss of benefits represents an opportunity cost. In other words, scarce resources have positive values and positive prices even if their direct marginal cost of production is zero. Such a positive value, the shadow price of the water in situ, is called a "scarcity rent."
- The shadow price of water used in any location equals the direct marginal cost plus the scarcity rent. For water in situ, the shadow price is the scarcity rent.

- Water will be produced at a given location only if the shadow price of water at that location exceeds the marginal cost of production. Equivalently, water will be produced only from sources whose scarcity rents are nonnegative.
- If water can be transported from location A to location B, then the shadow price of water at B can never exceed the shadow price at A by more than the cost of transporting water from A to B. If water is transported from A to B, then the shadow price at B will equal the shadow price at A plus the transportation costs. Equivalently, if water is transported from A to B, then the scarcity rent of that water should be the same in both locations.

Shadow prices generalize the role of market prices,[4] as can be seen from the following propositions:

- Where there are only private values involved, at each location, the shadow value of water is the price at which buyers of water would be just willing to buy and sellers of water just willing to sell an additional unit of water.
- Where social values do not coincide with private values, this need not hold. In particular, the shadow price of water at a given location is the price at which the user of water would be just willing to buy or sell an additional unit of water. That payment is calculated in terms of net benefits measured according to the user's own standards and values.
- Water in situ should be valued at its scarcity rent. That value is the price at which additional water is valued at any location at which it is used, less the direct marginal costs involved in transporting it there.

Structuring a Price (Tariff) of Water

Water utilities routinely design water tariffs and prices. Their choice of the price is motivated by considerations other than pure economics. They simply choose the price at a level that would help cover their operating costs plus a capital charge in addition to several other objectives, particularly environmental and sustainability objectives. Few utilities, if any, seek solely to generate sufficient revenue to cover their private costs. The generation of revenue is rarely the only purpose of a tariff, nor is it the sole consideration.[20] It has been generally recognized that water tariffs are powerful management tools with a number of complex and important functions. The tariff could create incentives for the efficient production and use of water. In this way, the tariff promotes environmental sustainability. As well, tariffs can be set to recover the full cost (including externalities, both economic and environmental) of an activity or structured to subsidize poorer customers.

Rogers, Bhatia, and Huber[21] make an interesting distinction between economic and environmental externalities. Economic externalities are more readily quantifiable and involve costs such as those imposed on downstream users by upstream diverters and polluters. Environmental externalities include the value of ecosystem degradation; the loss of biodiversity; and the health effects on human, plant, and animal populations. Each objective would lead to a different tariff design. The "best" design is the "one that strikes the most desirable balance among the different objectives."[20] However, is the "best" tariff the optimal one? Standard optimization theory tells us that net social benefits are maximized where marginal social benefit equals marginal cost. However, there is more than one cost perspective to consider when structuring an optimal tariff or price for water. Given the many different definitions for full supply cost, full economic cost, and full cost, the question remains as to which marginal cost should be equated with the marginal benefit. Full-cost pricing requires a quantitative assessment of water's intrinsic and cultural values, as well as the net of environmental externalities. The legitimacy of any such quantification is, however, severely limited by the subjectivity and unavailability of relevant data.[11,21,22] However, optimality requires quantification, and this has become a major issue in setting the optimal water tariff. The different definitions and their relevance for designing the optimal water tariff are presented in the table below.

Opportunity Cost

The opportunity cost of a commodity or service is the value of its next-best alternative use. If good X has only two possible uses, A and B, the opportunity cost of using good X for use A is the foregone benefit of employing it in use B. Similarly, the opportunity cost of using X for B is A. That is, it is the value of the foregone best alternative use. As Rogers, Bhatia, and Huber[21] argue, neglecting the value of water's opportunity costs "undervalues water, leads to failures to invest, and causes serious misallocation of the resource between users."

Full Supply Cost

This is the sum of costs directly involved in delivering water to the end user. This may include pumping, purification, storage, fixed infrastructure costs, capital investment costs, government taxes, and connection and metering costs. Full supply costs exclude all externalities and opportunity costs.[21] Capital and infrastructure costs are particularly heterogeneous vectors that vary widely depending on the types of delivery systems involved. Wells, house connections, pipes of various flow capacities, desalination projects, and recycled and treated water can lead to vastly different nominal values for full supply cost.[23]

Full Economic Cost

This is an economic concept that refers to the full supply cost plus the opportunity costs and net of economic externalities.

Full Cost

This is the full economic cost plus environmental externalities (these are more diffused and indirect and not easily quantifiable; Figure 4).

Substitutability and Environmental Considerations

Economic theory predicts that as the price of natural resource inputs rises, agents will substitute produced capital to take their place. The feasibility of the substitution of produced capital for natural resources is mixed. In some areas, the argument offers a viable solution. For example, the scarcity of whale oil, which resulted from overfishing, was made nearly irrelevant by the introduction of the electric light bulb. In telecommunications, fiber optics has been heavily substituted for copper. High energy costs promote the substitution of higher-quality insulation for fuel.[24–26] It is important to recognize and

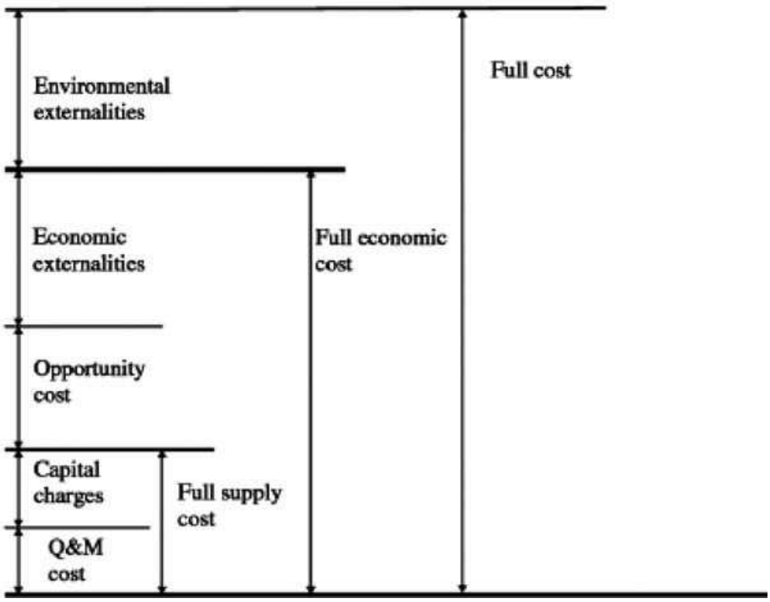

FIGURE 4 Full-cost prices.
Source: Rogers, Bhatia, and Huber.[21]

exploit the ability to substitute produced capital for natural resource inputs, but it is also important to recognize that these abilities are not universal and that they are not infinite.

This is particularly the case when it comes to water where the possibilities of substitution are more limited. As prices rise due to the introduction of full-cost pricing, human capital may be substituted for water in the form of genetically engineered seeds that yield a better harvest index. Water-scarce regions may shift production away from water-intensive activities to reflect relative scarcities (from producing wheat to producing barley) or import embodied water (virtual water, particularly agricultural products such as fruits and vegetables). Irrigation technologies that minimize evaporation and leakages will become more attractive in the face of rising water prices. Despite these possibilities, the inimitability of water and its centrality to life severely limit the potential scope and scale of substituting produced capital for water.

Given the fact that water prices are not determined in competitive markets, there exists an opportunity for economic policy makers to develop a pricing structure that incorporates broader goals. The multiple identities of water as an asset of society, a factor of production, and a consumer good are complementary and interdependent while simultaneously being rivalrous and independent. This presents a unique set of challenges for policy makers interested in setting the "right" price for water. Such a price must balance these competing identities while facilitating cooperation where they overlap. (We have abstracted in this entry from issues of intertemporal allocations of water. The models we have used are steady-state models. Treating water as an asset carries serious implications for intergenerational allocations. Suffice it to say here that sustainability requires that annual water extractions must not exceed the replenishment rates. A price that does not reflect this intertemporal conservation will misallocate resources over time.) Water as a factor of production and as an asset of society is inextricably linked by the concept of sustainable development. Similarly, the asset of society and the consumer goods are connected by the cultural and social identities associated with water use. Finally, the consumer goods and the factor of production are related by the externalities they impose upon each other. This analysis is not limited to the national level, and it is equally applicable in bilateral, multilateral, and global contexts. Given these relationships, the following principles and objectives have been identified as necessary ingredients in determining a price for water. Each of these is broadly defined and adopted in varying degrees with different weights placed on each from case to case. In Figure 5, we sketch a multiple-criteria framework for choosing prices that deal with complex objectives that balance economic, environmental, and sociocultural issues.

Economic Efficiency

Here, efficiency also incorporates multiple goals. Fees for water services must be sufficient to ensure that the utility recovers at least the full supply cost of delivery to the end user, a concept known as revenue sufficiency. Any fraction less than this fails to send the signal that water is a scarce resource; withholds information from consumers, the utility, and the regulatory agency; and prevents the proper inter-agent allocation of water (Figure 5).

It is worth noting that the standard approach to economic efficiency includes the concept of "full cost recovery," which the United Nations World Water Development Report defines as a situation in which "users pay the full cost of obtaining, collecting, treating, and distributing water, as well as collecting, treating, and disposing of wastewater."[27] In practice, as well as in theory, full cost recovery and revenue sufficiency refer only to the full supply cost.[20,21,28–30] We argue below that this is undesirable. This particular characterization is, however, of interest because it directly addresses the management of wastewater. That the importance of the economics of wastewater management has been largely ignored is demonstrated by the vast differences in progress toward the achievement of the Millennium Development Goals (MDG), and the new Sustainable Development Goals (SDGs) for water and sanitation.[27]

In stark contrast to convention, we argue that pricing at the full cost of supply does not support true economic efficiency. Supply-cost pricing brings us closer to the outcome that would exist if water were

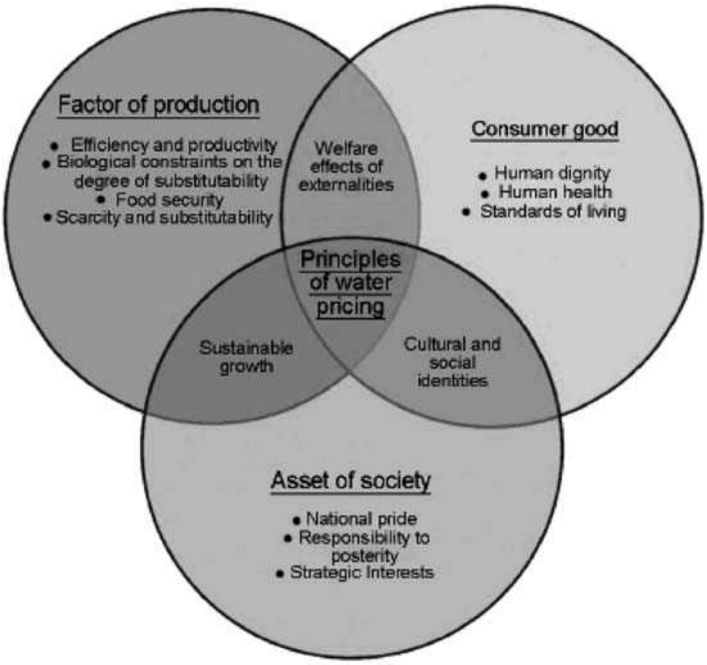

FIGURE 5 Multiple-criteria framework of prices.

traded in a perfectly competitive market. This price for water would fail to properly incorporate the value of opportunity costs, economic externalities, and environmental externalities.[21,31] Any such price prevents socially optimal allocations by promoting overuse, undervaluation, and waste. For this reason, we argue that wherever possible, full cost or full economic cost, as they are defined above, be used in the development of water tariffs.

Equity and Fairness

The principles of equity and fairness are contentious and have evoked controversy. However, given the increased recognition that a minimum amount of water is a basic human right, fairness imposes a constraint on water tariff setting. There are two dimensions to equity. On the one hand, equity has been defined as "treating equals equally" in the sense that those who purchase water that has identical costs should face identical prices.[20] On the other hand, equity and fairness are also grounded in the ideas of social justice, and water as a human right suggests that treating equals equally may satisfy only one dimension of equity. A balanced view of equity would also require treating unequals unequally. In areas of high-income inequality, poor users may be unable to afford even the minimum amount of water necessary to sustain basic human health and dignity. In such cases, some form of subsidy is required. This can take the form of internal cross-subsidization embedded in the pricing structure or of government transfers and income redistribution from other areas of the economy. The complexity of equity and fairness is hard to overstate, and policy makers are often forced to make difficult choices. The relative merits of different objectives for water subsidies are discussed in detail below.

Simplicity

Prices serve multiple objectives; one of the most important is to synthesize and convey information. Complex pricing structures confuse this information, making it difficult for producers, consumers, and regulators to respond appropriately to price signals. Simplicity and transparency also limit the potential for corruption. Insofar as simplicity facilitates the gathering and dissemination of information and economic signals, it promotes conservation, socially optimal allocations, and economic efficiency.

Sustainability

The concept of sustainability is central to each of water's roles depicted in Figure 5. Prices need to reflect this by encouraging conservation and substitution where possible.[22] A fundamental feature of the economics of sustainability is that assets are maintained over time. Water is a crucial component of natural capital. Depletion, diversion, and degradation of water assets represent an erosion of this natural capital asset, and therefore a depletion of society's wealth.

Stability and Quality

Here, stability refers to price stability, service stability, and revenue stability, all of which are interdependent. Stable prices convey stable information, avoid confusion, and promote smooth consumption. Revenue stability promotes and attracts investment while protecting service providers from shocks. Service stability reduces waste by eliminating the need to "hoard," eliminates time and travel costs of finding alternative sources of supply, promotes investment in connection to the system (which in turn increases the customer base, decreasing costs per user via economies of scale), and has the potential to raise revenue for producers as well as increase consumer surplus.

Evidence has shown that even in poor areas of developing countries, willingness to pay for improved service stability is well above current water prices. There are several reasons for this. First, the poor incur significant costs resulting from low-quality service, including travel and time costs, purification costs, reduced labor productivity due to illness and workdays lost, investment in individual water storage tanks, and purchasing expensive bottled water from private vendors.[29,32,33] A study conducted in Kathmandu, Nepal, showed that nearly 80% of respondents with a piped connection would be willing to pay as much as four times their current monthly water bill for improved water quality, stability, and more transparent billing.[32]

Water Tariffs and Pricing Strategies

The water tariff is the primary tool with which a policy maker can combine the various objectives and considerations into a socially optimal price regime. The tariff is central to the utility's ability to attract capital, creates incentives for efficiency in production and consumption, and distributes costs across consumers and time.[20]

Traditionally, decreasing block tariff (DBT) pricing strategies have been employed in water delivery systems for several reasons.[34] The DBT, as shown in Figure 6, involves prices based on quantity consumed.

The initial block, or quantity of water, costs the most, and prices decrease as consumption rises. DBTs score well on stability grounds as revenue is insulated from climatic shocks (to both supply and demand) and because the largest share of revenue comes from the initial units of water consumed. They exploit the economies of scale that arise from falling average costs as quantities supplied rise.[34] The problem, however, is that on grounds of efficiency, equity, and sustainability, this structure has less to offer than an increasing block tariff (IBT) scheme. In terms of efficiency, DBTs send exactly the wrong message to consumers. They fail to convey the fact that water is a scarce resource that must be conserved; they promote waste and fail to encourage socially optimal interagent, intersectoral, and intertemporal allocations. Furthermore, as the utility reaches capacity, the marginal cost of supply it faces rises; however, under the DBT regime, the marginal cost faced by consumers is falling. In terms of equity and fairness, the DBT fails to treat equals equally because consumers of water with identical costs of supply face

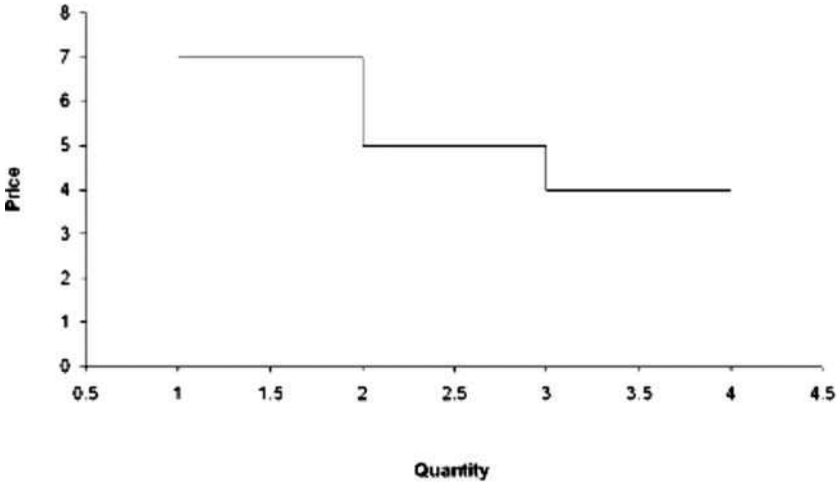

FIGURE 6 Decreasing block tariffs.

different prices. By charging higher prices for the initial units of water, the DBT also ensures that the poor who consume the least water face the highest prices (Figure 6).

In recent years, DBTs have largely been replaced by IBTs, which have become the strategy of choice in the developing world. This is because they have gained preference by donor institutions; management, engineering, and financial advisors; and water experts as being the most effective way of synthesizing the goals and principles of water supply and demand.[29] The IBT (the pricing scheme depicted in Figure 2) also features different prices based on quantities consumed; however, in this case, prices rise with quantity consumed.

In terms of economic efficiency, this is a significant improvement over the DBT. Here, tariffs are consistent with marginal-cost pricing and create an incentive structure that conveys the necessary signals to encourage socially optimal use. IBTs score well on fairness grounds because income and water demand are positively correlated and the prices faced by consumers rise with consumption. That is, IBTs are progressive, so wealthier customers that consume more water face higher prices. Furthermore, IBTs can exhibit “internal subsidization” or cross-subsidization in which large consumers pay sufficiently high prices that the first units of water consumed can be sold below cost. This feature enables the utility to provide water to the poor below the full cost of supply without violating the principle of revenue sufficiency.

The practical implementation of IBTs has yielded mixed results. If blocks are not properly structured in quantities that are relevant for the consumers in question, the benefits of IBTs are lost.[20,28,30,31,35] Specifically, the compatibility of fairness with the other principles of water pricing requires that the first block be sufficient to cover the basic requirements of human health and dignity but not more. Much attention must be paid to determining the relative block sizes and their prices, and finding the appropriate values for both requires data that are frequently unavailable.

It is possible that in some cases, low initial block prices may yield a result in which metering costs may exceed the revenue collected from low-income users. In such situations, the utility provider incurs a loss not only from the provision of water below full supply cost but also on the metering operations.[30] Alternatively, if tariffs faced by large-scale consumers such as heavy industry and agriculture are sufficiently high, these consumers may opt to disconnect from the utility and seek alternative sources of water, such as in-house direct extraction.[29,30] Even where this is illegal, government capacity to enforce such laws is frequently limited. The effect of this would be to remove the highest-paying customers, which in turn would eliminate the feasibility of internal subsidization, increase average costs, and distribute fixed-capital costs across a smaller customer base. That is, the benefits of IBTs are highly dependent upon the participation of the highest-paying customers; however, these are exactly the customers who have the greatest incentive to search for alternative sources of water.

Even where subsidies are absolutely necessary in order for the poor to meet their basic needs, it may not be ideal to provide these subsidies through the tariff structure. Chile subsidizes water consumption for the poor via transfer payments from municipal and national budgets. Many have claimed that this approach enhances equity and economic efficiency because the tariff received by the utility treats equals as equals.[30] Although we accept Yepes'[30] claim in principle, we do so with some trepidation. For the argument to hold, it must be shown that the welfare loss incurred by using the tariff structure to internally subsidize water for the poor is greater than that incurred by appropriating funds from elsewhere in the economy to fund government transfers. This reservation may be especially relevant in developing countries, where the tax base is small, government capacity is limited, and corruption is significant.

An interesting extension to the principle of IBTs involves the concept of two-tariff design. The price that end users face for water can be divided into two components: volumetric usage charges and fixed-rate charges, commonly referred to as connection fees. The two-tariff system provides an economic incentive for end users to conserve water through its volumetric component while providing an element of revenue security for the supplier through its fixed-rate component. This structure has evolved into the structure of choice in most Organization for Economic Cooperation and Development (OECD) countries.[31,34]

A two-tariff system can be carried out in the context of an IBT scheme so that a fixed cost is paid for "connection," but low levels of water can still be provided at a rate that is subsidized by larger consumers. In many areas, connection fees are sufficiently high that they exclude the poorest consumers. Since the cross-subsidization inherent in the IBT structure is beneficial only to those with connections, an argument can be made for higher subsidies on connection costs combined with lower subsidies on volumetric consumption. This approach incorporates the poorest strata of society while continuing to expand the customer base, which decreases average costs for all.

This is especially important in situations where land tenure rights are insecure. In such cases, the incentives and capacity for household investment in connection to the water utility are extremely low. It may be the case that these areas realize their greatest economic surplus by providing shared public taps that face a fixed rate rather than an IBT. There is already some evidence to support such a conclusion. Poor neighborhoods that face IBT prices often share a single connection between multiple households. These meters read high volumes of consumption, so the absolute poorest face higher prices due to the structure of the IBT.

Raising the price of water to its full cost would enhance economic efficiency and sustainability. Furthermore, Rogers, de Silva, and Bhatia[31] argue that this can be done without sacrificing equity and fairness. Situations exist in which Pareto improvements (improvements that leave at least some agents better off without making others any worse off) are possible even in cases where relative equity decreases.[29]

Conclusions

Water is not traded in competitive markets. High infrastructure costs raise barriers to entry, ruling out competitive conditions, whereas economies of scale, limited substitutes, human rights issues, and environmental externalities combine to complicate the design of a fair, efficient, and sufficient price for water.

The multiple roles that water plays in the economy, society, and the environment increase the complexity of structuring prices that capture scarcity and the multiple values of water. Economics alone cannot deal with this complex commodity, resource, and input. However, optimal allocations of this scarce resource among competing users and uses are basically an economic issue. The optimality criteria could be salvaged and applied where net social benefits are maximized within an idealized model capable of simulating competitive conditions. The shadow prices for water that emerge from the model solutions can be used to guide allocation of this scarce resource to optimize net social and environmental benefits. It is also feasible to construct a price-designing exercise where it is possible to capture the full cost of producing and delivering water and to preserve and balance multiple objectives. Many utilities do that now on a routine basis.

Water is valuable, but it is not thicker than blood, and an economic price can be set that embodies many of the competitive efficiency criteria in addition to other valuable societal and environmental objectives. Of particular importance is the sustainability consideration where the present generation must limit its water consumption to preserve quality and sufficient quantity for future generations. The emphasis must be particularly on quality, as increasingly societies face major issues of degradation of water quality and desertification.

Wetlands: Methane Emission

Anna Ekberg
and Tørben Røjle
Christensen

Introduction

Methane (CH_4) is a radiatively active trace gas that plays an important role for atmospheric chemistry and the energy balance of the Earth. At present, its contribution to the greenhouse effect is about 22%, which can be compared to carbon dioxide (CO_2) that contributes approximately 65% to the climate forcing of all long-lived greenhouse gases (excluding water vapor).[1] In addition to the direct warming effects, where infrared radiation is absorbed and returned to the Earth's surface, chemical and photochemical reactions with CH_4 in the troposphere and stratosphere indirectly cause greenhouse warming. The preindustrial atmospheric concentration of CH_4 was about 0.75ppmv (parts per million by volume) and since then it has more than doubled to approximately 1.73ppmv.[1] Anthropogenic sources of CH_4 include cattle (about 15% of the annual CH_4 release), rice paddies (20%), coal mining and oil production (14%), biomass burning (10%), natural gas leaks, and landfills and sewage disposal, while the major natural sources include wetlands (20%–25%) and termites (5%).[2] Because of the substantial contribution from natural wetlands, knowledge about the dynamics leading to CH_4 formation and emission is of great importance to understand how these ecosystems interact with the climate and how they would respond to climate change.

Methane Production and Consumption

Methane is produced by strictly anaerobic archaebacteria that are limited to the use of only a few simple substrates for biosynthesis and energy production.[3] If available carbon compounds are not directly supplied, they depend on other groups of micro-organisms for the initial breakdown of more complex organic structures into simpler molecules. The reduction of CO_2 with hydrogen is a common pathway to CH_4 formation, but acetate and formate are also important precursors of CH_4 in natural environments. Growth of methanogenic bacteria further requires a very low redox potential (E_h below −400mV) and the ideal environmental conditions are often met in permanently waterlogged wetlands. However, CH_4 efflux from wetlands to the atmosphere depends not only on the rate of production (methanogenesis), but also on the extent of CH_4 consumption (methanotrophy) that may occur in oxic surface layers and in the close vicinity of plant roots.[4–6] In this process, CH_4 is oxidized to CO_2, and the rate of CH_4 emission that can be measured at the surface is hence the net result of two counteracting processes—methanogenesis and methanotrophy.

Environmental Controls on Methane Emissions

Water Table Position

Water table position in relation to the surface is considered to be the most important factor controlling CH_4 flux, because it indicates the boundary between anaerobic CH_4 production and aerobic CH_4 consumption (Figure 1). Negative correlations between water table depth and rates of CH_4 emission have frequently been reported.[7–9] It has also been found that the lowering of the water table may result in increased CH_4 emissions when episodic releases of CH_4 trapped in pore water occur and the diffusivity

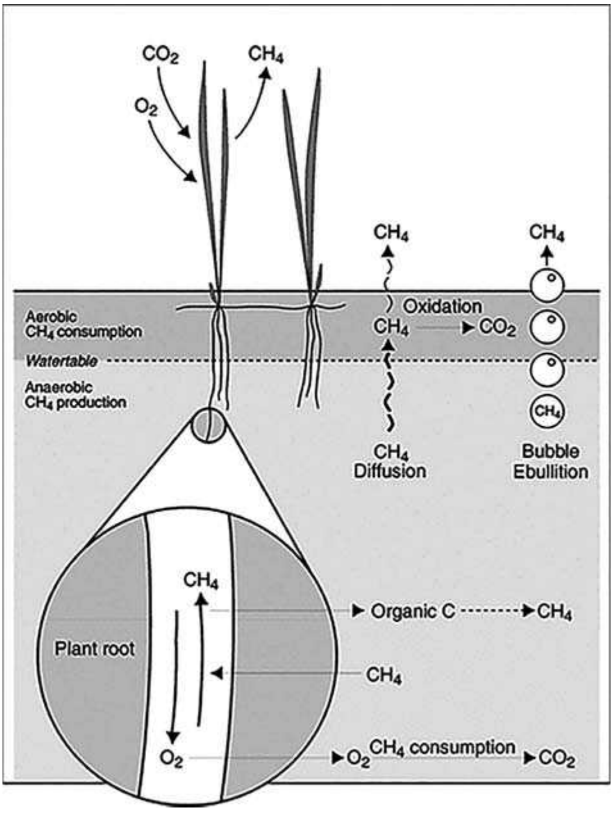

FIGURE 1 The depth of the water table is important in determining net CH_4 emissions from natural wetlands because it indicates the boundary between anaerobic CH_4 production and aerobic CH_4 consumption. Methane may be transported from the soil to the atmosphere via diffusion through the soil profile, by bubble ebullition or by plant-mediated transport. In the first case, CH_4 is subjected to methanotrophic oxidation as it passes through the oxic surface layer and this acts to decrease net CH_4 emissions. Bubbles are quite stable, meaning that little oxidation takes place, and the same is also true when CH_4 is transported through vascular plants. Vascular plants are sources of methanogenic substrate because they release labile carbon compounds into the soil via root exudation and root turnover. Leakage of O_2 from roots may lead to inhibition of methanogenesis and methanotrophic CH_4 consumption in the otherwise anoxic soil.

of gases in air-filled pore spaces increases.[10,11] Field experiments in peat-forming wetlands reveal a high spatial variability of CH_4 emissions caused by distinct microtopographical features on the wetland surface.[12] Interactions between vascular plants and mosses create differences in elevation, and therefore distance to the water table within a radius of less than a meter.[13] Scaling up of spot CH_4 emission measurements to larger areas without careful consideration of experimental plot location may therefore be misleading. Laboratory incubations have shown that there is a potential for CH_4 production both above and below the water table,[14] but the actual production in the field peaks at approximately 5–15 cm below the water table.[8] For methanotrophic CH_4 consumption to occur, a simultaneous supply of both CH_4 and oxygen is necessary. The abundance and activity of methanotrophic bacteria are therefore highest at the interface between anoxic and oxic conditions, i.e., at the depth of the water table.[5,14] Watson et al.[5] used a model to show a high capacity for CH_4 oxidation in peat, where methanotrophy accounted for 85% of the oxygen uptake potential when both oxygen and CH_4 were present in excess. In the absence of CH_4, maximum oxygen uptake potential was near the surface.

Soil Temperature

Correlations between soil temperature and CH_4 production and emission have been found at scales ranging from laboratory incubations and monolith experiments[8,11,15] to field investigations at the plot[16] and landscape scale.[9] There is a direct effect of temperature on the metabolic rate of CH_4-producing micro-organisms, but the sensitivity to temperature change is different for methanogens and methanotrophs.[11,17] In a study carried out with peat slurries under laboratory conditions, Dunfield et al.[17] found that CH_4 production in peat samples from temperate and subarctic areas was more sensitive to changes in temperature as compared to CH_4 consumption in the same samples. Increasing or decreasing temperatures also interact with other parameters with potential to control CH_4 production and emission to the atmosphere. One such interactive effect would be the relationship between temperature and water table position, where increasing temperatures lead to enhanced evaporation and plant transpiration, with lowering of the water table as a consequence.[18] It has also been suggested that the temperature dependence of CH_4 production is constrained by substrate limitation and that temperature has an effect on methanogenesis mainly via its influence on substrate availability.[19] In peat samples from a Swedish acid mire, CH_4 production was stimulated by increased temperatures only when substrate (glucose) would be the relationship between temperature and increased.[15] It has further been found that decomposition of labile material is more strongly controlled by temperature than decomposition of more recalcitrant components.[18] From the same study, it was also concluded that substrate availability lagged behind rapid temperature changes and that the thermal/hydrological history of the soil was important to determine the rate of CH_4 production.

Methane Transport: Diffusion, Bubble Ebullition, and Transport through Plants

The solubility of CH_4 in water is low, and it escapes through waterlogged soil to the atmosphere by diffusion, bubble ebullition, or by transport through vascular plants (Figure 1). The rate of CH_4 emission is largely controlled by the mode of transport because the different transportation pathways are associated with more or less extensive CH_4 consumption in the soil profile. Methane diffusing through oxic environments is subjected to methanotrophic oxidation to CO_2, and a water table depth of only a few centimeters may cause considerable reductions of CH_4 emissions to the atmosphere. Bubbles form when the rate of CH_4 production causes the sum of the partial pressures of dissolved gases to exceed the value of the hydrostatic pressure in the soil. However, the concentration of CH_4 in bubbles will be at equlibrium with dissolved pore water CH_4. At low rates of methanogenesis and with no vascular plants present, the main release of CH_4 to the atmosphere is likely to be by diffusion, but bubbles begin to form when the production rate exceeds the capacity for diffusive loss.[20] Once formed, bubbles are quite stable, meaning that little methanotrophic CH_4 oxidation occurs even as they pass through oxic environments. Studies conducted in rice paddies have shown that bubble formation tends to decrease as the plants mature because the progressively better developed rooting system acts as gas conduits and efficiently transports gases out of the soil.[21] However, a close relationship between vascular plant production and the availability of methanogenic substrate (discussed in the next section) may also speed up the rate of methanogenesis to such an extent that bubble formation is promoted. In order to supply oxygen for respiration to submerged structures, certain vascular plant species develop lacunae in stems, roots, and rhizomes.[22] Depending on the species, the ventilation of growing roots is carried out either by pressurized bulk flow or by simple diffusion that follows concentration gradients between the atmosphere and the soil. Leakage of oxygen may give rise to CH_4 oxidation and inhibition of methanogenesis in the close vicinity of the roots.[5,6] However, net CH_4 emission is generally enhanced by the presence of vascular plants with a deep rooting system because of a "chimney effect," where CH_4 transported from the soil to the atmosphere within plant lacunae is withdrawn from consumption in oxic conditions.[12,23,24]

Vascular Plants and Substrate for Methane Production

Vascular plants are sources of substrates for CH_4 production because they easily release degradable carbon compounds into the soil via root exudation and root turnover (Figure 1).[20,24,25] In peat-forming wetlands, the organic matter becomes increasingly recalcitrant with depth[26] and several studies have pointed out that plant-derived inputs of labile carbon compounds could significantly contribute to increased CH_4 production.[20,23,27] This "loading" of substrates into the soil may further be correlated to the photosynthetic rate of the vascular plants in the ecosystem,[24,28] because the amount of carbon allocated to belowground plant structures and eventually released to the soil is likely proportional to the CO_2 fixation rate.[24] The overall primary productivity in the ecosystem may therefore be of great importance for the CH_4 emission rates from a wetland area.

Alexandria Lake Maryut: Integrated Environmental Management

Lindsay Beevers

Introduction

Lake Maryut is located on the Mediterranean coast of Egypt, in the delta of the River Nile and defines the southern boundary of the city of Alexandria.[1] The lake extends for about 80 km along the northwest coast of Alexandria and 30 km south and has a wetted surface area of 65 km^2 (Figure 1). It is a shallow water lake[2] with a water depth of approximately 1.5 m across the different basins and, unlike any of the other Nile deltaic lakes, is not directly connected to the Mediterranean Sea. The water level of the lake is kept below mean sea level, and freshwater is supplied, through irrigation canals, from the Rosetta branch of the Nile.[3] Throughout literature, the lake is referred to variously as Mariout, Mariut, or Maryut Lake. For this entry, the lake will be identified as Lake Maryut.

The lake has been in existence for more than 6000 years, as part of the Nile deltaic formation. In an extensive study of the evolution of the lake,[4] several drivers for the current form of the lake were established, namely, eustatic sea level, climate oscillations, compaction, sediment transport, and more recent anthropogenic influences such as land reclamation, irrigation, and agricultural practices. It is a mixture of these anthropogenic influences that has shaped the development of the lake in more recent years, along with its connection to the city of Alexandria.

During the Greco-Roman period, Alexandria was an active port, serving as a key navigational route from the Mediterranean, through Lake Maryut, up the Nile to Cairo. Canals linked the lake with the sea to the north and the Nile to the east. However, the siltation of the canopic mouth of the Nile in the 12th century[5,6] severed the freshwater influx to the lake and with it the navigational links. During this period, the city of Alexandria went into a phase of decline, and the lake went through several phases, which included coastal connection and influx and coastal disconnection and drying out.

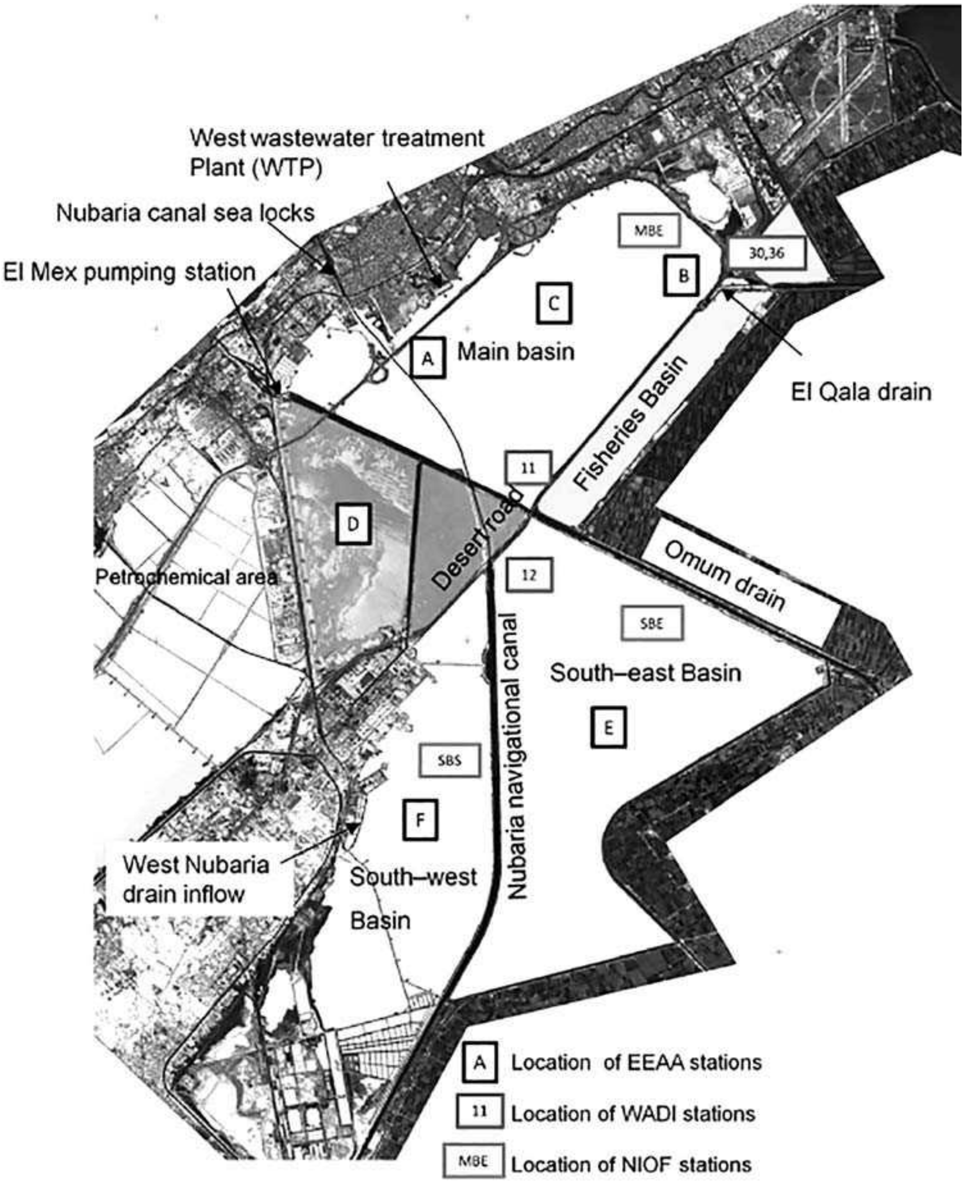

FIGURE 1 Lake Maryut: location map.

In 1892, the irrigation system of the Beheirah district was established, which restored a flow of freshwater to the lake. The lake remained disconnected from the coast, with excess water pumped to the bay through El Mex station (Figure 1), and navigation permitted through sea locks.[7] This is similar to the form the lake takes today, where the principal drainage inflows arise from agricultural irrigation channels fed by the main River Nile.

Over the years, Lake Maryut has provided Alexandria and Egypt with a source of fish, and currently, part of the lake is dedicated to aquaculture (Fisheries Basin, Figure 1). Over 7000 fishermen have rights to fish in the lake, and recent pollution levels and increased vegetation growth affect their catch.[8] *Tilapia* species are the predominant catch, representing approximately 90% of the total.[9] In addition to fisheries, the lake acts as a source of water for irrigation and for raising animals and provides areas for dwelling beside its shores.

In its current form, canals divide the lake water body into several basins. The earth embankments along the canals have several breaches that allow water to flow from the canals into the basins and vice versa, creating interaction between water bodies. There are three main inflows to the Lake Maryut: the Qala drain located to the northeast part of the lake, the Omum drain located at the east of the lake, and the Nubaria navigational canal located at the south of the lake (Figure 1). In addition to this, there are three minor inflows: one from the West Nubaria drain, one from the petrochemical industrial area, and the third from the West Wastewater Treatment Plant (WWWTP) (see Figure 1). The main outflow from the Lake Maryut is El Mex pumping station, which consists of two buildings, each housing six pumps with nominal capacities of 12.5 m^3/sec.[7] Small flows are lost to the system through the navigational locks as well as through evaporation.

As a consequence of high nutrient loadings due to the agricultural and industrial activities upstream and in its surrounds, Lake Maryut has become a highly polluted and eutrophic lake. Eutrophication of lakes is a natural process that can be accelerated by human activities (Figure 2) that introduce an excess of nutrients together with other pollutants.[10] The main sources of nutrients and pollutants to Lake Maryut are human sewage, industrial waste, farm, and urban runoff.[11,12]

Eutrophic lakes often experience an excessive growth of algae and larger aquatic plants. Such growth consumes dissolved oxygen (DO), vital for the fish and other animal life.[10] This growth and subsequent proliferation of vegetation occurs in Lake Maryut due to the high nutrient loadings that has entered the lake for a number of years. Currently, 60% of the surface area of the lake is covered by vegetation (*Phragmites australis* and *Eichornia crassipes*), which reduces the DO concentrations in the lake, especially in the main basin. Significant discharge of domestic sewage (with basic primary treatment) from the Qala drain and the East Wastewater Treatment Plant (EWWTP) enter the lake. The Omum and Nubaria Canals are less polluted than the Qala drain; however, they also contribute nutrient loadings to the lake, albeit to a lesser extent. Finally, nonpoint sources such as agricultural runoff containing pesticides and fertilizers contribute to the deterioration of the environmental quality of the lake.

The lake also suffers from other anthropogenic pressures including urbanization, unplanned settlements, and land reclamation (which has reduced the surface area of the lake gradually). An analysis of the stakeholders directly responsible for managing the lake was undertaken in 2007.[13] This showed that Alex Company for Sanitary and Drainage, the Fishing Authority, and The Ministries of Industry, Water Resources, and Environment are the main authorities responsible for the lake. The coordination

FIGURE 2 Fishing activities on the lake.

and communication regarding the management of the lake between these authorities are known to be poor, with each developing management plans in isolation.

Between 2007 and 2009, a European Union (EU)-funded SMAP III project was set up to analyze the current functioning of the lake in more detail and to develop an integrated action plan for the environmental management of the lake. This entry will cover the development of this plan, specifically focusing on the scientific models set up to support the plan development and to investigate the results of different interventions.

Current State of Lake Maryut

The current functioning of the lake has been investigated through a mixture of studies commissioned to gather specific information and ongoing monitoring surveys. Hydraulic information was gathered through a United States Agency for International Development (USAID) project in 1996,[7] hydrologic information was sourced from the local airport weather station (Nouzha airport), and a longer data series was obtained from the weather station at Port Alexandria.[14] Bathymetric information of the lake came from a survey completed in 2008 by the National Institute of Oceanography and Fisheries (NIOF).[15] The ecosystem functioning and health of the basin were constructed using a number of surveys, principally the long-term monitoring strategy undertaken annually by the Egyptian Environmental Affairs Authority (EEAA),[16] a comprehensive sampling campaign by NIOF[15] in 2008 and the EU-funded Water Demand Integration (WADI) project.[8]

Using these data, a comprehensive picture of the lake can be assembled.

Hydraulic and Hydrological Functioning

Table 1 shows the monthly average meteorological data for the lake. It is clear that, generally, precipitation in the region is very low, with the lowest values recorded between April and October. During the same period, along with significant sunlight hours recorded, evapotranspiration is highest.

Table 2 summarizes the main inflows to the lake (Figure 1) over the year. These flows are known to remain reasonably steady throughout the year, though rising slightly in the months of August to February due to the connection with the main river (Nile) and agricultural requirements. The Omum drain carries the greatest flow to the basin. Direct inputs to the lake from the WWWTP, West Nubaria drain, and the petrochemical area (Figure 1) are detailed in Table 3. These flows are considered to be

TABLE 1 Average Monthly Meteorological Data

constant inflows to the lake. El Mex pumping station manages the outflow of the lake. Twelve pumps with nominal capacities of 12.5 m^3/ sec[7] maintains the water level in the lake to –2.8 m below sea level [7,17] In addition, small flows are lost from the lake through the navigational locks and of course through evaporation. Water depths vary throughout the lake, with the deepest occurring in the canals due to the navigational requirements. Depths in the basins vary between 0.5 and 1.2 m,[15] and in places, this is maintained by dredging and vegetation removal.

The flow direction in the lake is generally concentrated down the canals. Interaction of the canal water with the basin water occurs through the breached bunds; however, velocities and, hence, mixing in these sections are low. The point where the greatest interaction of canal and basin flow can be observed is at the junction between the Omum and Nubaria Canals in the main basin.

Water Quality and Ecosystems

Table 4 shows the time period available for each of the data sources, and Figure 1 shows the location of the sampling points. As a whole, the data of these sources were consistent and a similar magnitude was observed between sources. Table 5 presents the seasonal values available from the EEAA[16] data. Typical effluent concentrations from treatment plants with primary treatment can be found in literature.[18,19]

The data clearly show that the most polluted basin is the main basin, and the source of that pollution comes from the Qala drain, which carries with it effluent from the EWWTP. The highest. Biological oxygen demand (BOD) values and the lowest DO% values are found at station B (Figure 1) at the entrance of the Qala drain. Similarly, the highest nitrogen loading enters the main basin through the Qala drain, along with the highest phosphorus loading. Station C shows generally lower values of the N and P as the water from the drain enters the lake and becomes mixed.

In general, the proportion of total N arising from ammonia was higher than that from nitrates, particularly in the main basin. It is thought that this is due in part to the source of pollution arising from the Qala drain and the low DO values recorded. In the West Basin, the proportion of ammonia is lower than that in the main basin, which is corroborated by the findings of El Rayis.[21] Since the levels of DO are also higher in this basin, it is believed that the nitrification process is more evident here.

This poor water quality has led to a drastic reduction in biodiversity.[8] The eutrophic nature of the lake results in a significant dominance of *P. australis,* while at the outfalls from the WWTPs, significant growths of the lead tolerant species *E. crassipes* is found. Periodic cutting of the *Phragmites* is practiced to increase the nitrogen removal from the lake. This intervention is necessary to prevent the lake area being dominated by vegetation, which in turn reduces the area available for fish habitat.

It is clear that in its present state, Lake Maryut is severely polluted with reduced biodiversity. A continual deterioration in the status of the basin will lead to a significant reduction in economic and industrial development potential.

Social Considerations and Governance

There are no specific studies that survey those living by the lake. However, the Integrated Action Plan research[22] identifies three main groups, namely, fishermen, poorer communities, and a scattered population, totaling approximately 30,000. It is estimated that 62% of the population is aged between 15 and 55, which is the average employment age in Egypt. There are high unemployment rates (up to 15%–20%) within this group, leading to low annual incomes. High illiteracy, poor health services, high mortality rates, high crime levels, and a tendency to marry young are also characteristics of the demographic.

A significant proportion of the population are living in settlements and accommodation that are temporary or informal. In these scattered settlements, some common issues arise: 1) lack of, or poor infrastructure coverage, particularly water supply and sanitation/wastewater networks and paved roads; 2) inadequate local services, especially health care, education, and youth facilities; 3) poor housing conditions; 4) lack of secure land tenure in the squatter settlements; and 5) high unemployment.

An analysis of the stakeholders directly responsible for managing the lake was undertaken in 2007.[13] This showed that the Alex Company for Sanitary and Drainage, the Fishing Authority, and The Ministries of Industry, Water Resources, and Environment are the main authorities responsible for the lake. The coordination and communication regarding the management of the lake between these authorities are known to be poor. Each authority makes strategic plans for the lake in isolation, with little discussion; hence, an integrated vision of the lake did not exist.

Integrated Environmental Management

Integrated Plan Concept

The integrated action plan for Lake Maryut draws on the principles of Integrated Coastal Zone Management (ICZM) to develop integrated actions for the sustainable development of Lake Maryut. Central to the ICZM approach is participation from stakeholders in the development of a plan that integrates strategic actions to address the environmental, economic, administrative, social, and urban issues of the lake.[22] The outcomes of this process defined four specific objectives of the action plan:

- Improve the ecological and chemical status of Lake Maryut.
- Enhance levels of economic, urban, and social development in a sustainable manner.
- Increase the potential for industrial activities around the lake and their environmental management.
- Adapt the governance system of the lake to execute the plan.

Strategic actions were proposed for each of the objectives, following analysis of the current state of the lake, and where feasible, these actions were tested. This entry will focus on the process completed for the first objective in detail and will present a short summary of the actions identified for the other three objectives.

Scenario Identification

The geographic scope of the plan was taken as the general boundary of the lake (Figure 1) and the natural extension to these boundaries according to the interaction of the lake. To the north, the plan includes the navigational locks and the El Mex pumping stations (necessary connections to the sea). To the east, the limit is bounded by the main road to Alexandria from Cairo, plus the position of the EWWTP and the Qala drain. To the west, the limit was the industrial area and a 500 m perimeter to the lake, and finally, the 500 m perimeter was extended to the south of the lake as the limit to the plan.

Through a participatory process, which included four training events and six participation workshops, a series of scenarios and potential actions for the improvement of the water ecosystem were defined by key stakeholders. These can be summarized as follows:

- Redevelopment of the waterfront and potential development of islands in the lake for urban regeneration projects.
- Improve lake mixing.
- Removal or improvement of the WWTP discharges into the lake.
- Vegetation management and sediment management.
- Industrial effluent improvement.
- Installation of wetland areas for nutrient removal.

Model Development

To assess the impact of certain actions, tools were developed to predict the hydrodynamic functioning and ecosystem functioning of the lake. Given the level of information available to create these tools and the complex nature of the processes in the lake, a mixture of approaches was proposed. To investigate the hydrodynamics and mixing of Lake Maryut, a two-dimensional (2D) hydrodynamic model was developed. To investigate the ecological improvements as a result of intervention, a point model of ecosystem functioning of different basins was set up.[23]

Hydraulic Model

Using the data set out in Tables 1–3, a 2D hydraulic model of the lake was built using MIKE21 software.[24] The computational mesh is shown in Figure 3, which defines the principal flow routes through the canal. A roughness map was developed to represent vegetation growth in the basins.[25] The model was calibrated for water levels but not velocities due to lack of data. A comprehensive sensitivity study was undertaken, which showed that the main control on the lake's hydraulic system is the pumping station at El Mex.[26] Figure 4 shows the general circulation patterns predicted by the model. The interactions are mainly driven by the drain inflows and clear areas of the lake where no vegetation is found.

To investigate the impact of particular actions on the hydraulics, a number of simulations were undertaken (Figure 5). These included the land reclamation from the lake and addition of islands to

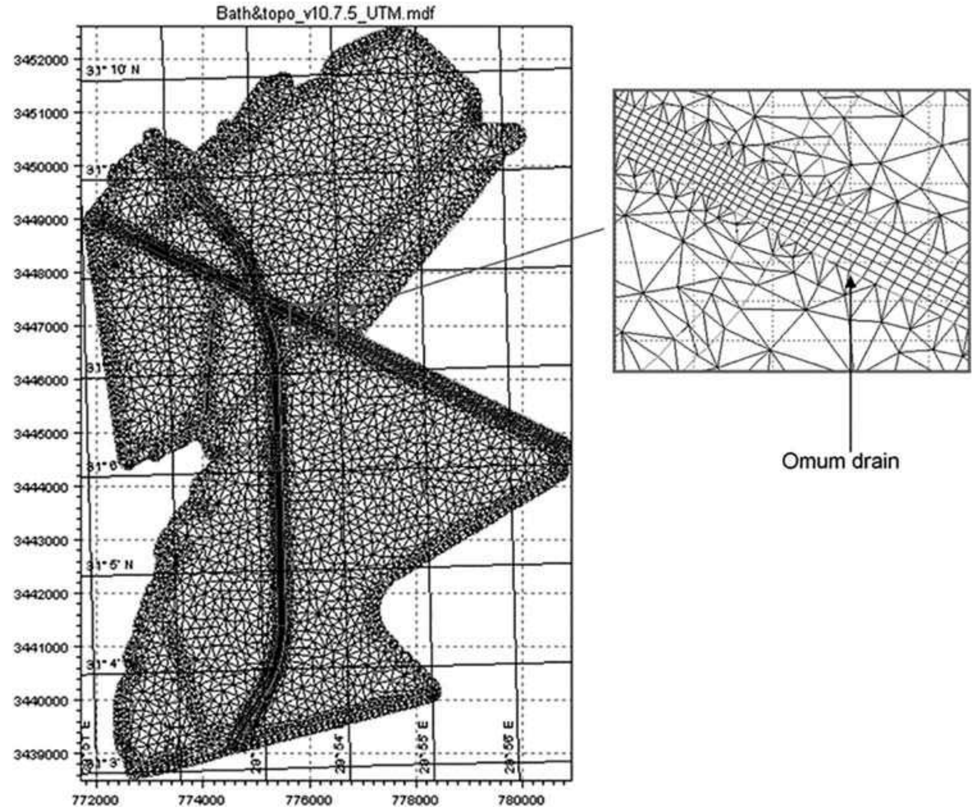

FIGURE 3 Computational mesh: Hydraulic model.
Source: Duran and Beevers.[26]

promote urban regeneration of the lakeshore, as well as the design of different entry configurations for the Qala drain to promote mixing. Figure 6 shows the magnitude of velocities predicted in the basin following these interventions. The change in velocities is highest in the main basin where most interventions are proposed; however, the magnitude of change is only in the order of a 9% increase.[26] While areas in the main basin become better mixed, areas of stagnation occur, most notably around the islands. From these results, it becomes clear that increasing mixing significantly would be difficult unless an increase to the inflow to the lake could be facilitated.

Ecological Model

Using the data set out in Tables 1–5, a dynamic 0-dimension ecological model was built for the different basins of Lake Maryut. The software PCLAKE describes the dominant ecological interaction in a shallow lake ecosystem.[23] This model was chosen for its ability to model the complex processes and allow a number of different proposed actions to be modeled, including vegetation management on a seasonal basis, dredging, wetland installation, and improvements to discharges. It should be noted that the model assumes mixing across a basin, which, for Lake Maryut, is a simplification; however, the model is detailed enough to give an indication of the potential change caused by an action.

The model was built using the seasonal data available from the EEAA monitoring for the inflows, and this was complemented by the WADI and NIOF data. Calibration was possible, comparing monitoring data available in the lake itself.

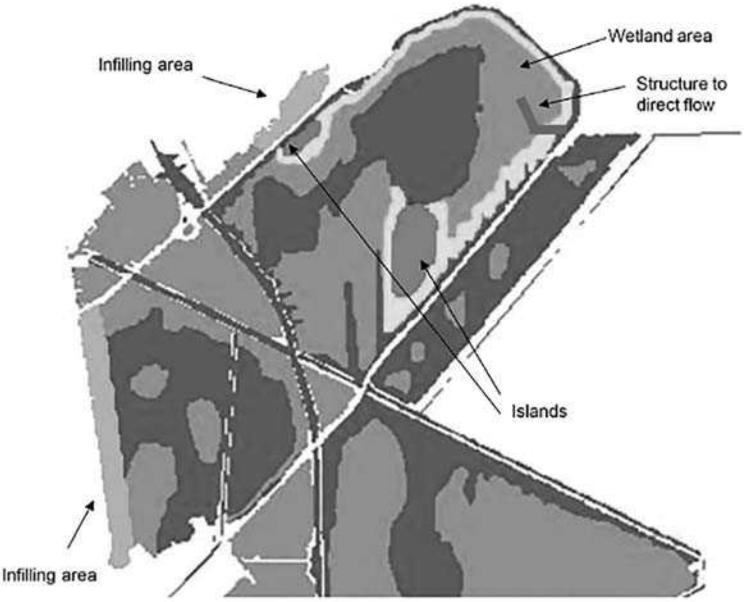

FIGURE 5 Scenario modifications: Hydraulic model.
Source: Duran and Beevers.[26]

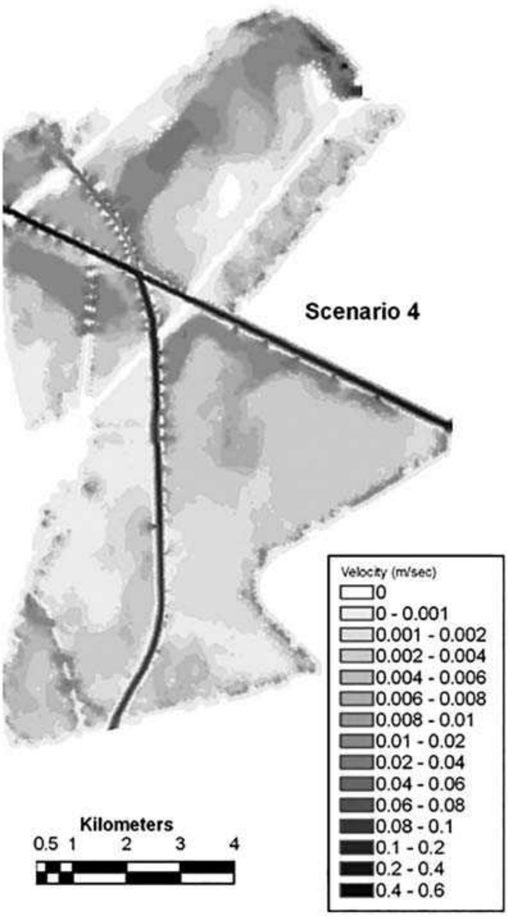

FIGURE 6 Velocity predictions: Hydraulic model.
Source: Duran and Beevers.[26]

A significant number of actions were tested in the ecological model. Available literature was used to represent the actions in the lake:

- Secondary treatment of effluent from the WWTPs.[27]
- Addition of aluminum to the WWTP process.[18]
- Installation and removal efficiencies of constructed wetlands (for the Qala drain).[28–31]
- Vegetation and sediment management.
- Table 6 shows the predicted improvement to different parameters if the following actions are taken:
- Removal of the WWWTP from the lake (outfall to the sea) after upgrade to secondary treatment.
- Upgrade of EWWTP to secondary treatment plus additional treatment using aluminum.
- Upgrade of industrial effluent through improved environmental management.
- Dredge sediments in the Qala drain and installation of a constructed wetland.
- Aquatic vegetation management.

The oxygen consumption in Lake Maryut is mainly attributed to the respiration of aquatic organisms including plankton and aerobic bacteria and the oxidation of organic matter.[32] High values of organic carbon have been reported in sediments close to the treatment plants.[21] The oxidation of these

TABLE 6 Ecological Model Results

			Improvement with Stated Actions

sediments, rich in organic matter, is one of the factors that increases the DO consumption and therefore decreases the DO concentrations in the water column. Improving the treatment processes for the treatment plants has a significant impact on the model results, indicating up to a 300% improvement to DO levels in the main basin.

Ammonium is generated by heterotrophic bacteria as the primary nitrogenous end product of decomposition of organic matter. NH_4-N concentrations are usually low in oxygenated waters of oligotrophic lakes since it is utilized by plants in the nitrification process. However, at low DO concentrations, nitrification ceases, the absorptive capacity of the sediments is reduced, and an increase of the release of NH4-N from the sediments occurs. As a result, the NH_4-N concentration of shallow lakes would increase.[33] Increasing the levels of DO through improved treatment of wastewater and a reduction in pollutant loads arriving to the lake as a result of constructed wetlands has the potential to reduce overall ammonia levels in the main basin by up to 47%.

Chlorophyll-a is a primary productivity indicator and a very good estimate for monitoring and assessing the eutrophication status of lakes.[34] The supply of P and N is considered to be one of the main factors that determine the magnitude of the primary production.[35] In cases where pollution is caused by domestic wastewater with a high nutrient content, the algae production in the recipient watercourse increases considerably.[34] With the improvement to N and P and the increase in the DO predicted, a decrease in chlorophyll-a of up to 85% could be achieved for the lake.

Finally, the Secchi depth is a measure of the transparency of a water column. Secchi readings between 0.1 and 0.4 m were reported in the main basin,[32] which are directly related to the high production rate of phytoplankton. Eutrophic lakes present low values of Secchi depth due to the high concentrations of algae and detritus that increase turbidity and therefore decrease transparency. With the proposed measures and reduction in detritus, an increase in the transparency of the lake is predicted to be greater than 370%.[36]

Proposed Actions

The modeling component tested a number of actions for the improvement of the water ecosystem and showed that a significant improvement could be achieved. In addition to these, actions were proposed to address the other strategic objectives of the plan.[22] The following is a summary of such objectives:

- Prepare a Lake Maryut land and water plan.
- Promote urban regeneration around the lake shoreline and create ports and markets in the main basin.

- Promote ecotourism and encourage new ecological economic activities.
- Upgrade informal settlement areas and integrate social housing into urban development projects.
- Plan and develop fisheries activities.
- Prepare online monitoring systems along with water quantity and quality maps.
- Regulate specific limits for industrial water discharge into Lake Maryut.
- Establish a Lake Maryut Authority and set up a management unit with a clear structure and purpose.
- Establish a robust monitoring system for water quality.

The plan aims to address all four strategic objectives defined at the outset. To monitor the effect of any potential implemented action as part of the plan, a monitoring program is suggested. The implementation of such a monitoring plan would allow the incorporation of adaptive management techniques should unexpected impacts become evident.

Conclusions

An integrated action plan for Lake Maryut is proposed, using a participatory process and supported by a technical modeling study that was used to predict the impact of potential actions. It is clear from the study that significant improvement to the lake can be achieved, thus encouraging economic development and urban regeneration. However, this improvement requires substantial investment. The plan suggests that to achieve this, a financial strategy that links the urban and industrial future development potential with the environmental interventions is required to improve the lake, thereby linking potential future economic gains to the required lake renovation.

Since the completion of the proposed plan in 2009, there have been follow-up activities that move towards the adoption of a sustainable development strategy for the lake. A lake management unit is established and receives technical input from Centre for Environment and Development for the Arab Region and Europe (CEDARE) for Geographical Information System (GIS) support and NARSS (National Authority for Remote Sensing and Space Sciences of Egypt) for model development. In addition, the Ministry for Housing has proposed to use the outcomes of the study for the development of a new urban territorial plan for Alexandria that includes an integrated sustainable development vision for the Lake Maryut zone.

The study has shown that, with a coordinated and integrated approach to environmental management, the current deteriorating trend of Lake Maryut could be reversed. However, to achieve this goal, actions addressing environmental, social, and governance issues must be implemented.

Acknowledgments

The author would like to acknowledge the official partners of the ALAMIM project: MEDCITIES, Barcelona Metropolitan Area, CEDARE, Alexandria Governorate, the EEAA, NARSS, City of Marseilles, Environment and Housing Ministry of the Catalan Government, UNESCO-IHE, and the EUCC—The Coastal Union. In particular, the author is grateful to Mr. Joan Parpal, the project leader, and Ms. Roxan Duran and Ms. Gabriela Alvarez-Mieles.

Aral Sea Disaster

Guy Fipps

Introduction

The cause is attributed to a vast expansion of irrigation in the Central Asian Republics beginning in the 1950s, which greatly reduced inflows to the Sea. The diversion of water for massive irrigation development was done deliberately by Soviet Union officials, unconcerned about the consequences of their actions.

The environmental, social, and economic damage has been immense. Winds pick up dust from the dry seabed and deposit it over a large populated area. The dust likely contains pesticide and chemical residues that are blamed for the serious rise in mortality and health problems in the region. The Sea, and the now exposed dry seabed, may also be contaminated by runoff from a former Soviet military base and a biological weapons lab. The ecosystem of the Aral Sea has collapsed, and climate changes in the Aral Sea Basin have been documented. Hundreds of agreements have been signed since 1980s on programs designed to address the "Aral Sea Problem" which, to date, have not been effective at preventing the continuing shrinking of the sea.

Aral Sea Basin

The Aral Sea is located in Central Asia and lies between Uzbekistan and Kazakhstan in a vast geological depression, the Turan lowlands, in the Kyzylkum and Karakum Deserts. In the 1950s, the sea covered 66,000 km^2, contained about 1090 km^3 of water, and had a maximum depth of about 70 m. The Aral Sea supported vast fisheries and shipping industries. At that time the sea was fed by two rivers, the Amu Darya (2540 km) and the Syr Darya (2200 km), which originate in the mountain ranges of central Asia and flow through the five republics of Uzbekistan, Kazakhstan, Kyrgyzstan, Tajikistan, and Turkmenistan.

The two rivers provide most of the fresh water used in Central Asia. In the last 50 years, about 20 dams and reservoirs and 60 major irrigation schemes have been constructed. About 82% of river diversions are for agricultural use and 14% is for municipal and industrial use (Table 1).

Water demand due to population growth and industrial expansion continues to increase (Table 2). Since 1960, the population of the Central Asian republics has increased 140% and totals over 50

TABLE 1 Average Water Supply and Demand in the Aral Sea Basin

million. Likewise, industrial production using large amounts of water has also increased. Examples include steel production which rose 200%, cement production by 170%, and electricity generation by a factor of 12.

The total inflows to the Aral Sea began decreasing rapidly in the 1960s, and by 1990 the storage volume of the sea has decreased by 600 km^3 (Table 3). As the water level fell, salinity levels have tripled, rising from about 1000 ppm to just under 3000 ppm today. By the 1980s, as the Aral Sea problem became well known in the Soviet Union, government officials proposed ambitious projects to divert water from other rivers, including ones in South Russia and Siberia, to be transported to the Aral Sea in massive canals. However, these plans died with the breakup of the Soviet Union.

The decrease in sea level has now split the Aral Sea into two separate water bodies: the Small and Large Aral Seas (Maloe More and Bol'shiye More) each separately fed by the Syr Darya and the Amu Darya, respectively. The once vast Amu Darya delta which once covered 550,000 ha has now shrunk to less than 20,000 ha.

TABLE 3 Decline of the Aral Sea during the 1980s and Total Estimated Inflows from the Amu Darya and Syr Darya Rivers

		Aral Sea	
Year	Inflows (km^3)	Volume (km^3)	Surface Area (km^2)
1911–1960	56.0	1064	66,100
1981	6.0	618	50,500

Irrigation and Cotton

For thousands of years, Central Asian farmers diverted water from the Amu Darya and Syr Darya Rivers, transforming desert into green oases and supporting great civilizations. Historically, irrigation water use was conducted at a sustainable level. The creation of the Soviet Union and the collectivization of farmlands resulted in the end for traditional agricultural practices. Beginning as early as 1918, Soviet leaders began expanding irrigated land in Central Asia for export and hard currency. Cotton was known as "white gold." The USSR became a net exporter of cotton by the 1930s, and by the 1980s, was ranked fourth in the world in cotton production.

The policy of emphasizing cotton production was accelerated in the 1950s as Central Asia's irrigated agriculture was expanded and mechanized. In 1956, the Kara Kum Canal was opened, diverting one-third of the flow in the Amu Darya to new cultivated areas in the deserts of Uzbekistan and Turkmenistan. The year 1960 represents the critical junction when the Aral Sea began to drop. Irrigated cotton production and water diversions continued to be expanded until the break-up of the Soviet Union (Table 4).

Estimates are that upwards of 80% of the workforce is employed in agriculture. The main agricultural crops in the basin are cotton (6.4 million ha), forage (1.7 million ha), rice (0.4 million ha), and tree crops (0.4 million ha).

Some Central Asian irrigation experts estimate that only 20%–25% of the water diverted from the rivers is actually used by the crops, the rest being lost in the canals that transport the water to the fields and due to inefficient irrigation practices used on-farm. It is believed that over the past decade, adequate maintenance, repair, and renovation of the irrigation infrastructure were not performed at a meaningful level, and water losses from deteriorating canals, gates, and other facilities have increased.

Most land is under furrow irrigation, with drip irrigation accounting for about 5% of the irrigated cropland (used primarily on orchard crops), and sprinkler irrigation accounts for about 3%. Even though the

TABLE 4 Cultivated Land along the Amu Darya and Syr Darya Rivers

	Before 1917	1960	1980	1992
Millions of hectares	5.2	10	15	18.3

water saving benefits of gated pipe are well known in the region, less than one-sixth of the farms use this technology. Reasons may include costs and product availability. Most farms follow the centuries' old practice of cutting earthen canals with shovels in order to divert water into the field. The volume of water available at these farm ditches is not sufficient to provide an even distribution of water over the field. As a result, water logging and soil salinity now affects about 40% of all the cultivated land in the region.

Muynak and Aralsk

Of all the villages affected by the drying of the Aral Sea, Muynak is the best known. Historically, Muynak was located on an island of the vast Aral Sea delta at the convergence of the Amu Darya River in Karakalpakstan (a semi-autonomist republic in Uzbekistan). In 1962, the island became a peninsula. By 1970 the former seaport was 10 km from the sea. The retreat of the sea accelerated and the town was 40 km from the sea by 1980, 70 km in 1995, and close to 100 km today.

Over 3000 fishermen once worked the abundant waters around Muynak which supported 22 different commercial species of fish. In 1957, Muynak fishermen harvested 26,000 tons of fish, about half of the total catch that year taken from the Aral Sea. Muynak also produced 1.1 million farmed muskrat skins which were used to produce coats and hats.

The Kazakhstan city of Aralsk, was once located on the northern edge of the Aral Sea, and like Muynak, had major fisheries and commerce industries. A major shipping and transport industry existed between these two cities. As the Aral Sea skunk, Aralsk found itself farther and farther from the shore which had retreated nearly 129 km by the 1980s. In the early 1990s, a dam was built just to the south of the mouth of the Syr Darya, to protect the northern part of the Aral Sea, letting the southern portion of the Aral Sea evaporate. Although only 10% of the water in the Syr Darya River reaches the northern part of the Aral Sea, the Little Aral has risen 3 m since the construction of the dam, and the shoreline has crept to within 16 km of the town.

Environmental Problems

The Aral Sea is an unfortunate example of an old Uzbek proverb: "at the beginning you drink water, at the end you drink poison." As the rivers flow through cultivated areas, they pick up fertilizers, pesticides, and salts from runoff, drainage water and groundwater flow. In the 1960s, it was common for about 550 kg ha^{-1} of chemicals to be applied to cotton fields in Central Asia, compared to an average of 25 kg used for other crops in the Soviet Union. Residues of these chemicals are now found on the dry seabed. Estimates are that millions of tons of dust are picked up from the seabed and distributed over the Aral Sea region.

The Sea may have been contaminated from runoff from by two former USSR military installations in the area. A chemical weapons testing facility was located on the Ust-Jurt Plateau (north shore), and was closed in the mid-1980s. Renaissance Island (Vozrozhdeniya Island), located in the central Aral Sea, was the site of the former USSR Government's Microbiological Warfare Group which produced the deadly Anthrax virus. Some scientists believe that some containers holding the virus were not properly stored or destroyed. As the Aral Sea continues to dry and water levels recede, the ever-expanding island will soon connect to the surrounding land. Scientists fear that reptiles, including snakes that have been exposed to the various viruses, will move onto the surrounding land and possibly infect the humans living around the shores of the Aral Sea.

The Aral Sea once supported a complex ecosystem, an oasis in the vast desert. Over 20 species of fish are now extinct. Karakalpakstan scientists believe that a total of about 100 species of fish and animals that once flourished in the region are now extinct, as are many unique plants.

Residents believe that there is a direct correlation between the drying of the sea and changes in climate of the Aral Sea Basin. The moderating effect of the sea has diminished and temperatures are now about 2.5°C higher in the summer and lower in the winter. Rainfall in the already arid basin has decreased by about 20 mm.

Human Tragedy

Over the last 50 years, there has been a large increase in mortality, illnesses, and poor health in the region. Some estimate that 70%–90% of the population of Karakalpakstan suffer some an environmentally induced malady. Tuberculosis is rampant. Hardest hit are women and children. Common health problems include kidney diseases, thyroid dysfunctions, anemia, bronchitis, and cancers.

Conclusion

Some accounts are that since 1984, hundreds of international agreements have been signed to address Aral Sea problems. The early agreements had the goals of first stabilizing the Sea, then slowly increasing flows to restore its ecosystem. In 1992, the Interstate Commission for Water Coordination was formed by the five central Asian republics, which also accepted, in principle, to adhere to the limits on water diversions as set during the Soviet era in 1984 and 1987. To date, however, no progress has been made on stabilizing or reversing the declining inflows. With no water reaching the Aral Sea from the Amu Darya, scientists predict that this portion of the sea (the Large Aral Sea) will disappear by 2020 (Figure 1).

FIGURE 1 This NASA photograph (STS085–503-119) was taken in August 1997 and looks toward the southeast. The Amu Darya River is visible to the right and the Syr Darya on the left. The Aral Sea is now separated into the Small Aral to the north and the Large Aral to the south. Shown are the approximate extent of the Aral Sea in 1957 before a massive expansion of irrigation diversions from the rivers.

Chesapeake Bay

Sean M. Smith

Introduction

The Chesapeake Bay is the largest estuary within the U.S.A.[1] Fresh water flows to the Chesapeake Bay from a watershed that covers an estimated 166,709 km^2, including portions of Delaware, Maryland, New York, Pennsylvania, Virginia, Washington, DC, and West Virginia (Figure 1). The ecological productivity of the estuary has made it an important resource for Native Americans, European immigrants, and current residents in the region.[2] The population in the contributing watershed in recent years has swelled to over 15 million people, resulting in extensive direct and indirect impacts that are now a focus of a large-scale restoration effort led by the US Environmental Protection Agency.[1]

Discussion

Located along the Mid-Atlantic coast of the U.S.A. within the limits of Maryland and Virginia, the Bay is approximately 304-km long, has an estimated surface area of 11,603 km^2, a width that ranges from 5.5 to 56 km, and an average depth of approximately 6.4 m.[1] Salinity in the tidal portions of the estuary transition from "fresh" conditions (i.e., 0–5 parts per thousand (ppt) salt concentration) at the northern-most end to "marine" conditions (30–35 ppt salt concentration) at the southern boundary with the Atlantic Ocean.

Evidence indicates that the modern Chesapeake Bay began forming approximately 35 million years ago with a meteorite impact in the proximity of what is now the confluence of the Bay with the Atlantic Ocean.[2,3] The impact created a topographic depression that influenced the location and alignments of several large river valleys, including those associated with the present day Susquehanna, Rappahannock, and James Rivers. Since then, the river valleys have been periodically exposed and flooded in response to cycles of global glaciation and associated fluctuations in sea level. The most recent, the Wisconsin glaciation, began retreating approximately 18,000 years ago. The retreat resulted in a rise in sea level by almost ninety meters, drowning the river valleys and forming the current Bay.

Eleven large rivers drain the Bay's watershed, the Susquehanna River from Pennsylvania and New York providing the largest contribution with an average of 98 million m^3/day flowing into the northern end of the estuary. The rivers drain one or more of five different physiographic provinces within the watershed, including the Appalachian Plateau, Ridge and Valley, Blue Ridge, Piedmont, and Coastal Plain (Figure 1).[4] Each province's geologic composition and history creates dramatically different landscape settings from the western to eastern sides of the drainage basin. The Appalachian, Ridge and Valley, and Blue Ridge are characterized by mountainous terrain, a dominance of sandstone along ridge tops, and several carbonate valleys. The Piedmont has less relief, is dominated by metamorphic rocks, and is characterized by a surface that has been dissected by dendritic stream channel networks. Further to the east, the Coastal Plain is characterized by thick layers of unconsolidated geologic materials overlying bedrock deep beneath the surface. Waterways that flow from the Piedmont into the Coastal Plain traverse the "Fall Zone," a region that is easily distinguished by waterfalls coincident with an abrupt drop in the underlying bedrock elevations. Major ports and cities were developed along the Fall Zone, including Washington, DC, Baltimore, Maryland, and Richmond, Virginia, because of their locations at the upstream terminus of navigation from tidal waters and proximity to hydropower sources.

The Chesapeake Bay estuary is naturally dynamic and characterized by physical conditions that can be stressful to aquatic organisms. The salinity gradient broadly governs the spatial distribution of aquatic habitat types. Alterations in currents, wind, and freshwater inputs can cause salinity conditions to vary over time. The shallow depths also cause colder winter and warmer summer water temperatures compared to the open ocean. These spatial and temporal fluctuations can create physiologically challenging conditions. However, many organisms have adapted and use the abundant nutrients and physical habitat in different portions of the estuary for specific periods of their life cycles or seasons of the year. As a result, the Bay supports an estimated 3600 species of plants, fish, and animals, including 348 finfish and 173 shellfish species. Some of the most notable of these include striped bass, American shad, blueback herring, blue crab, and the American oyster.[5] The name "Chesapeake" itself was coined from the Algonquin American-Indian word "Chesepiooc" meaning "great shellfish bay."[5]

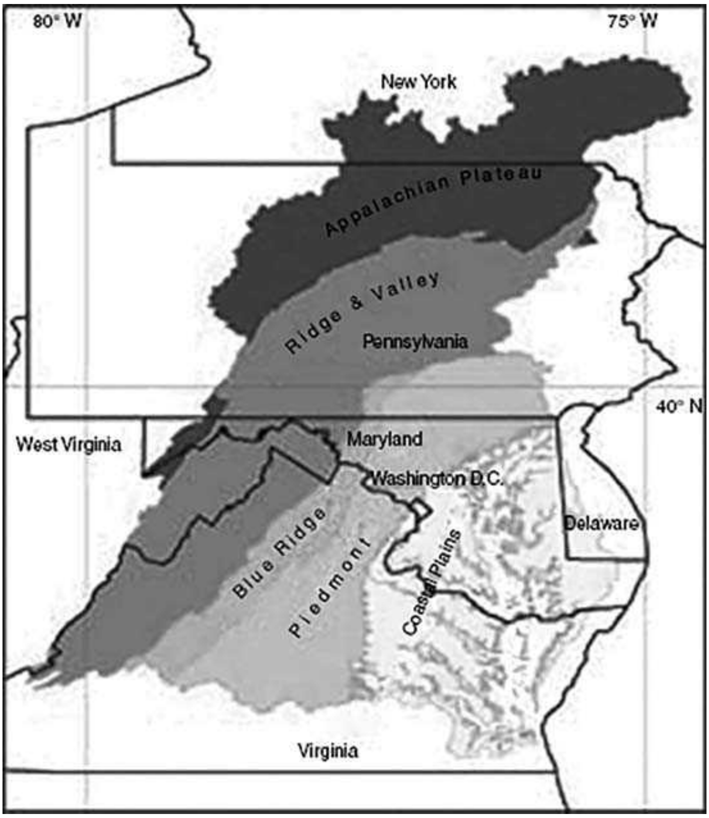

FIGURE 1 The Chesapeake Bay estuary and its watershed, including physiographic provinces and state boundaries. (Courtesy of M. Herrmann, Maryland Department of Natural Resources.)

Archaeologists estimate that Native American inhabitants first arrived in the Bay region from the south or west approximately 12,000 years ago as the ice sheets associated with the Wisconsin glaciation began to retreat and temperatures increased.[2] The first inhabitants are presumed to have been nomadic; however, archeological evidence suggests that selective food production started as early as 5000 years ago and settled towns began to be formed approximately 1300 years ago as the population density in the region increased. Recovered artifacts provide evidence of the extensive use of the Bay by the early inhabitants for travel, communication, tools, and food.

The first recorded European contact with the Chesapeake Bay region was by the Italian captain, Giovanni da Verrazano in 1524.[2] The English established one of the most well known early settlements at Jamestown, Virginia in 1607. English colonization expanded through expeditions to the north in the Bay, partly led by the famed Captain John Smith. Immigration to the region increased throughout the 1600s and much of the area was settled by the mid-1700s. The colonists made extensive use of the resources provided by the estuary, its wetlands, and tributaries. Shellfish, including oysters, blue crabs, and hard and soft clams, were harvested from shallow water areas.[2] The numerous piles of oyster shells that can be found near Coastal Plain tidal areas provide support for written claims of the extensive oyster beds that existed in the Bay when the European colonists arrived. Traps and nets were used to harvest finfish, including herring, striped bass, and shad. Migratory waterfowl, such as ducks and geese, were also plentiful food sources.

The rapid growth in the human population since European colonization of the Chesapeake Bay region dramatically increased the harvest of finfish, shellfish, waterfowl, and mammals naturally supported by the estuary. Extensive landscape alterations also caused direct and indirect physical changes to the Bay and its tributaries. The combination of overharvesting, pollution, and physical alterations has severely impacted the ecosystem and many of the species that historically flourished in the estuary.[1] Dramatic declines have been documented by the harvest records of popular commercial fisheries such as shad and striped bass. Records indicate a decline in the catch of blue crabs per unit of effort since the 1940s. The oyster harvest is currently at less than 1% of historic levels, although this reduction is partly attributed to disease. Many other species not harvested commercially have also been affected by the alterations in the Bay ecology that have accompanied European settlement and population growth.

One of the most important impacts to the Chesapeake Bay has been the increased erosion rates and downstream sedimentation caused by extensive deforestation of the watershed.[6] The influx of sediment into the tidal estuary has reduced the water depths in many embayments that once served as navigable ports.[7] Elevated suspended sediment inputs during storm events also increase turbidity in the tidal water column.[6] The resulting decrease in water clarity, which has been exacerbated by algal blooms associated with nutrient runoff pollution, reduces submerged aquatic vegetation (SAV) growth in shallow areas (i.e., depths less than 2 m). SAV coverage on the Bay bottom is estimated to have declined from approximately 80,900 hectares in 1937 to 15,400 hectares in 1984.[1] The loss has negative implications for a variety of species that use the vegetation for habitat, including blue crabs and juvenile finfish.

An extensive effort to restore the Bay has been undertaken by the US federal government in coordination with states in the watershed.[1,8] A large part of this effort has been focused on the recovery of the historic SAV distributions, as well as reversal of the abnormally low oxygen levels that now occur in the main stem of the Bay and its major tidal tributaries during summer months.[1,9] As with the water clarity problems, the low dissolved oxygen is related to excess nutrient inputs, mainly nitrogen and phosphorous, which stimulate algal production. The oxygen depletion occurs because of algal decomposition, resulting in, estuarine habitat degradation. Substantial reductions in nutrients from watershed runoff have been concluded to be necessary to achieve restoration goals related to both SAV and low dissolved oxygen.[1,9]

Conclusions

The Chesapeake Bay is a large and historically productive estuary on the Mid-Atlantic coast of the U.S.A., with extensive fisheries and wildlife resources. The Bay ecosystem has been impaired by watershed alterations and overharvesting accompanying human population growth in the region, thereby inspiring an extensive government-supported restoration effort. A large part of the restoration focuses on sediment and nutrient pollution associated with runoff from the contributing watershed.

Giant Reed (*Arundo donax*): Streams and Water Resources

Gretchen C. Coffman

Introduction

Both natural and anthropogenic disturbances along rivers in Mediterranean-type climates are thought to promote the spread of invasive plant species in natural as well as altered riparian ecosystems.[1–5] A large bamboo-like member of the grass family (Poaceae), giant reed (*Arundo donax* L.), is one of the greatest invasive species threats to streams in arid and Mediterranean-type climate regions. *A. donax* forms extensive monotypic stands, successfully invading rivers in these regions. Infestations of *A. donax* are known to increase risks of flooding, compete with indigenous riparian species for scarce water resources, create unnatural fire hazards, and reduce the value of riparian habitat for most wildlife. Although many organizations are actively removing small areas of *A. donax* from streams in California, larger strategic watershed-scale removal is necessary to prevent further invasion and impacts to water resources.

Biology and Ecology

A. donax is one of the most successful weedy invaders in the highly dynamic, disturbance-defined rivers and riparian ecosystems of arid and Mediterranean-type climate regions[6,7] (Figure 1). *A. donax* is a tall, erect perennial grass species with culms 1–4 cm in diameter and 2–10 m in height, with two ranked leaves 2–6 cm wide at the base tapering to a point and up to 70 cm in length or more, and tough fibrous roots that penetrate more than 8 ft deep emanating from large horizontal creeping rhizomes. Although the seeds of this reed-like grass species are mostly sterile outside its native range,[8,9] *A. donax* colonizes readily via vegetative propagation; it is dispersed downstream when small pieces of its culm or rhizome break off during flooding and land on bare, moist substrates.[1,6,7,10,11] Fragments of the rhizome or culm as small as 2 cm^2 sprout under most soil types, depths, and soil moisture conditions.[7,10,11] Growing at an extremely rapid rate (up to 6.25 cm per day under optimal conditions), *A. donax* quickly establishes on exposed or sparsely vegetated soil and grows to more than 8 m in height after only a few months.[12,13]

FIGURE 1 *A. donax* infestation along the Santa Clara River in Ventura County, California.

Once established, *A. donax* clumps expand outward by clonal propagation (large rhizomes), crowding and displacing indigenous shrubs, herbs and grasses, and trees, especially under elevated soil moisture, nutrient, and light conditions.[8] In this manner, *A. donax* forms extensive stands, or monocultures, along floodplains and terraces of river and stream systems. *A. donax* is able to persist in ecosystems that experience seasonal drought by storing carbohydrate reserves in large rhizomes and sharing water resources through clonal integration.[14,15] When stressful conditions subside, shoots emerge.

A. donax is thought to be indigenous to freshwaters of Eurasia,[16] extending from Southeast Asia to the Mediterranean Basin, although the precise extent of its native distribution is unclear. Herbivore diversity suggests that it is Mediterranean in origin, but its native range may extend much farther. Several thousand years ago, *A. donax* was thought to have been spread around the Mediterranean Basin for use in erosion control; production of reeds for wind instruments; and construction of roofs, ceilings, fences, and baskets.[17] It has been introduced to most tropical and warm, temperate regions worldwide, including North and South America, Southern Africa, and Australia, and thrives below 350 m in elevation.[6,18] In North America, *A. donax* has become especially devastating to riparian habitats in California's Mediterranean climate region, creating significant impacts to natural river functioning and sustainability.[19] In Southern California, *A. donax* was originally planted along irrigation canals for erosion control and used as building materials and windbreaks.[20] Carried by floodwaters, *A. donax* eventually made its way to adjacent streams and rivers, and by the 1820s, patches were commonly found along floodplains of many streams, including the Los Angeles River.[20] However, it appears that *A. donax* has only recently succeeded in invading natural riparian ecosystems in Southern California (i.e., replacing native riparian vegetation).

Because of its clonal growth strategy, ability to colonize rapidly after disturbance, use of available resources, tolerance of stress, and high growth rate, *A. donax* is one of the most successful riparian weedy invaders in arid and Mediterranean-type climates.[12] Following an era of human alterations to river systems in Southern California, it was widely dispersed throughout riparian ecosystems in the floods of 1969, established in terrace and floodplain locations, and is now thriving in riparian ecosystems throughout this region.[21] Factors such as water, nutrients, light, and fire that are abundant in highly modified riparian ecosystems of arid and Mediterranean-climate regions increase the competitive ability of *A. donax*.[21] Although *A. donax* grows primarily in floodplains and terraces of low-gradient river and stream systems,[21,22] it may be found on beaches, around homes, in higher elevations, and next to hot springs where planted. *A. donax* forms huge infestations in open floodplains with high soil moisture and excess nutrients and in areas susceptible to wildfire.[21] *A. donax* successfully invades areas consisting of any soil type and once established can grow well in many soil moisture regimes.[7,21,23] Established stands recover readily after aboveground biomass is removed by wildfire, floods, frost, or mechanical means. In fact, the natural flood and wildfire regime characteristic of Mediterranean-type climates promotes growth and invasion of *A. donax*.[21]

From the time of early human settlement in arid and Mediterranean-type climates, humans have dammed, channelized, mined, diverted, and developed along rivers.[24,25] These alterations have magnified the susceptibility of streams in these regions to plant invasions by weedy species.[26,27] Human alterations associated with urbanization of watersheds in California in addition to the natural flood and wildfire processes have created ideal conditions for *A. donax* invasion. Increased water, nutrients, and light availability, as well as occurrence of fire in riparian ecosystems in Southern California, are thought to promote *A. donax* invasion.[6,21,28,29] Ever-expanding residential and agricultural development in coastal Southern California has led to increased water availability and nutrient loading of riparian ecosystems. The once vast low-lying areas of riparian forest continue to be removed to make room for agriculture, golf courses, and residential and commercial development. Consequently, open areas along floodplains formed by floods and clearing of terraces for development create an ideal location for *A. donax* to establish and invade riparian ecosystems. Furthermore, fire is more frequent in riparian corridors owing to anthropogenic ignition during the dry summer and fall months when *A. donax*-infested areas provide a large amount of dry fuel.[21,30] Because of higher post-fire growth rate and immediate growth response compared to native plant species, fire appears to contribute to the *A. donax* invasion process, especially in riparian terraces located next to fire-prone shrublands.[21]

Effects on Streams and Water Resources

Infestations of *A. donax* have created serious physical and biological problems along streams in arid and Mediterranean-type climates.[6,13,22,29] Where it grows extensively along floodplains, *A. donax* physically obstructs natural water flow, thereby increasing the risk of flooding. *A. donax* uses more water than native plant species, outcompetes native riparian species, thus reducing the value of riparian habitats for wildlife, and creating unnatural fire hazards.[21]

Flooding

Large infestations of *A. donax* within the active floodplains increase stream roughness during moderate to large flood events, forcing flood stages to higher levels and flooding adjacent property. During very high winter flows in California, *A. donax* is removed from the floodplain, floats downstream, and creates debris dams at bridges and culverts.[22] In addition, *A. donax* biomass collects in large piles along beaches after large flood events (Figure 2). Although originally planted to assist in erosion control, it now acts as an agent of erosion in California streams. The shallow rhizomes of the large, top-heavy plants growing along stream banks are undercut by high flows, causing bank erosion and instability. Economic losses due to effects of *A. donax* invasion include costs associated with repair of flood damage to property and bridges, beach cleanup, and bank stabilization repair.

Water Use

Water loss due to high evapotranspiration (ET) of *A. donax* infestations is of increasing concern in arid and Mediterranean-type climates where water resources are scarce and the plant continues to spread.

FIGURE 2 *A. donax* debris litters beaches in California after winter storms.

Using transpiration rates of rice (another C_3 species thought to have similar transpiration rates), estimates of *A. donax* water use suggest that it uses three times more water than native riparian species.[31] Other studies using a variety of methods indicate that ET of *A. donax* (1.2–7.5 m/yr) may be much higher than that of native riparian vegetation such as *Salix* spp., *Populus* spp. (1.0–3.3 m/yr), and mixed riparian communities of arid and Mediterranean-type climates (0.11–1.6 m/yr).[32–35] On the Santa Ana River alone, *A. donax* was estimated to transpire 37,500 acre-feet more water per year than native plants worth approximately $12 million at drinking water costs.[31] However, comprehensive studies are needed that compare water-use efficiency (WUE) of *A. donax* to various native species under different environmental conditions to determine exactly how much water is lost due to this invasive species. Excess water used in *A. donax* transpiration could be salvaged for groundwater recharge, drinking water supply, agricultural irrigation, and augmentation of in-stream flow for native vegetation and wildlife.[36] Furthermore, saturated soils that persist after flood events provide a lasting legacy to sustain plants over longer timescales. Using oxygen ($\delta^{18}O$) and hydrogen (δ^2H) stable isotopes analyses, Moore et al.[37] found that groundwater was not the dominant source for *A. donax* when soil moisture was sufficient for plant uptake following a flood.

Recent studies focused on water use, photosynthetic performance, and growth of *A. donax* under varying levels of soil moisture, carbon dioxide, and drought conditions. Watts and Moore[38] found that stands of *A. donax* used approximately 8.8 ± 0.9 mm of water per day during the peak of the growing season on the Lower Rio Grande in South Texas, the high end of the spectrum for plants. They also found that transpiration and leaf area index declined as water availability decreased, suggesting a sensitivity to drought and declining water tables. In another study, *A. donax* plants were subjected to a gradual drought stress for 3 weeks, after which they were returned to fully hydrated soil conditions for 1 week.[39] Overall, plant dry weight and key growth parameters were not significantly affected; however, photosynthetic performance was impaired. Physiological functions were restored after rewatering, reflecting the environmental plasticity of *A. donax*. Both atmospheric enrichment of carbon dioxide (CO_2) and increased drought are predicted to occur in regions where *A. donax* grows in arid and Mediterranean regions of the United States. Nackley et al.[40] found that increased CO_2 affected growth and water use of *A. donax*, reducing transpiration rates significantly. Reduced transpiration delayed drought responses, increased WUEs, and extended periods of assimilation but could not prevent desiccation and photosynthetic decline during extreme drought.

Wildfire

Wildfires ignited by humans at unnatural and dangerous times of the year burn rapidly through riparian corridors infested with *A. donax* and may help spread fires across watersheds and along riparian corridors.[21] Historically, dense biomass that accumulated over a period of 30–50 years or more in chaparral communities of California and shrublands in other Mediterranean-type climate regions caused fires to ignite.[41–44] Although fire was once a natural part of shrubland ecosystems in many Mediterranean-type regions, large riparian ecosystems provided natural firebreaks because native vegetation retained foliar water that resisted ignition.[13] Lightning was the primary cause of wildfires, especially during July and August under dry, low-humidity conditions and would commonly burn slowly for months.[42] Currently, however, most wildfires in these areas are anthropogenic in origin, occur much more frequently, and during strong Santa Ana wind conditions starting in September. For example, all 14 concurrent fires in October 2003 (739,597 acres burned) resulted from human activities.[41]

Invasion of annual grass species has been linked to altered fire regimes in rangelands, deserts, and wild lands of California and the Western United States.[41,47–49] However, *A. donax* may be an even bigger problem in riparian ecosystems of altered Southern California fire regimes because of its perennial growth form (the large volume of biomass produced) and rapid recovery after fire (Figure 3a and b).[21] Several accounts suggest that infestations of giant reed have increased fuel load as well as fire frequency and intensity along riparian corridors.[12,13,30,50] Thus, *A. donax* invasion appears to have created a positive feedback cycle or an invasive plant-fire regime[21] similar to those presented by other grass species.[45,46]

Biodiversity and Wildlife

A. donax has little habitat or food value for wildlife because of its dense growth structure and high content of noxious chemicals.[6,12,13] The federally endangered least Bell's vireo (*Vireo bellii pusillus*) and other riparian birds require structural diversity provided by riparian scrub and mature forest communities for breeding.[6,13,51] When naturally diverse riparian vegetation types are replaced by thick stands of *A. donax*, bird species abundance and other native wildlife have been found to decline.[6,13,45,46] Movement of medium to large mammals is most likely impaired by dense *A. donax* infestations. Herrera and Dudley[52] showed that arthropod abundance and diversity associated with native riparian vegetation was twice that associated with *A. donax* infestations. In addition, fish and aquatic invertebrates may be affected by increased stream temperature owing to lack of shading where *A. donax* has replaced mature riparian forests.[6]

Control Methods, Restoration, and Revegetation

Tens of millions of dollars ($7–$25 thousand per acre) have been spent in efforts to remove *A. donax* from riparian ecosystems in the Central Valley and coastal California. Although most attempts have been successful in removing small infestations on riparian terraces, *A. donax* continues to thrive in floodplains. An understanding of the ecological conditions that promote continued growth and invasion of *A. donax* is needed for its effective control. Management strategies for the control and removal of *A. donax* should be based on the location and size of the infestation. Priority should be given to removal of *A. donax* from riparian terrace habitats where infested areas are easily accessible and require less maintenance than along floodplains, especially infestations located adjacent to fire-prone shrubland plant communities.[53] Removal of large *A. donax* infestations on riparian terraces with high soil moisture and nutrient availability will be most difficult but is essential in removing the largest source of propagules to prevent future reinfestation. Active revegetation with native plants after *A. donax* removal

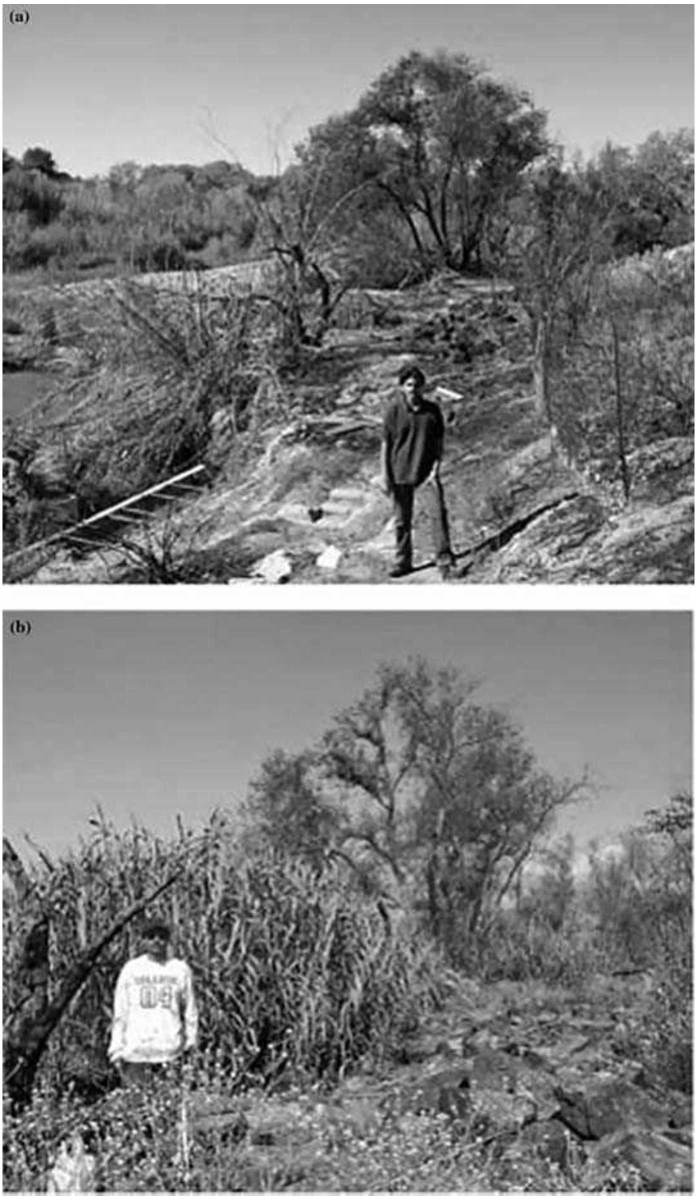

FIGURE 3 Three weeks (a) and 6 months (b) after Verdale–Simi Fire, *A. donax* invades riparian terrace along Santa Clara River in Ventura County.

is recommended to prevent reinfestation of *A. donax* or other weeds and restore functional riparian ecosystems. Unless *A. donax* is removed from floodplains on a watershed-scale working from the headwaters downstream, it is likely to recolonize removal areas after flood events. Watershed removal planning is underway in several large streams in Southern California to eradicate *A. donax* from floodplains, including the Santa Clara and Santa Ana Rivers.

Both mechanical and hand clearing techniques may be used to remove *A. donax*. Mechanical clearing methods include mulching or total excavation of all aboveground and belowground biomass. Hand clearing methods include either painting of *A. donax* stumps with herbicide after cutting or foliar applications of herbicide (glyphosate).[54] Research on biocontrol agents for *A. donax* is underway on the Santa Clara River, California and in Weslaco, Texas (Dudley, *Personal Communication*, 2006).

Conclusions

One of the biggest threats to streams and water resources in Mediterranean-type climates is invasion of *A. donax*. Forming large monocultures under ideal resource conditions along streams, *A. donax* increases flooding, promotes the spread of wildfire, outcompetes natives for water resources, and decreases wildlife value of riparian habitat. Although millions of dollars are spent every year to remove *A. donax* in California, many rivers and streams are still heavily infested. Effective removal and control strategies must be based on an ecological understanding of the invasion process and removal areas prioritized based on gaining the greatest ecological benefit for the least effort. Control of *A. donax* from watersheds in Mediterranean-type climates is an important initial step in restoration and long-term sustainability of riparian ecosystems.

Inland Seas and Lakes: Central Asia Case Study

Andrey G.
Kostianoy

Introduction

Shallowing, desiccation, and degradation of freshwater and salt lakes and inland seas are among the major environmental problems at the beginning of the 21st century. All over the globe, water is being diverted for industrial, agricultural, and household uses, and many lakes are suffering from the resulting lack of inflow. There are clear indications that the growth of human population and the increasing use of natural resources, especially water, combined with climate changes, exert a considerable stress on closed or semi-enclosed seas and lakes. In many regions of the world, marine and lacustrine hydrosystems are or have been the objects of severe or fatal alterations ranging from changes in regional hydrological regimes and/or modifications of the quantity or quality of water resources, deterioration of geochemical balances (increased salinity, oxygen depletion, etc.), to mutations of ecosystems (eutrophication, decrease in biological diversity, etc.), to socioeconomic perturbations, which have been the consequences or may soon be in the near future.[1]

About 97.5% of earth's water is saltwater in oceans and seas.[1] Around 1% of that is brackish groundwater. The remaining 2.5% is freshwater. Nearly 70% of the world's freshwater is frozen in the Antarctic and Greenland ice sheets, glaciers, and permanent snow cover and ice. About 30% of all freshwater is groundwater. Lakes and rivers contain only about 0.25% of all freshwater. In 2002, the United Nations Environment Program (UNEP) announced that about 3 billion people would face severe water shortages by 2025, if the present consumption rates persist. Global and regional climate change, global and regional warming, and droughts amplify the freshwater problem. According to NASA Goddard Institute for Space Studies, the year 2018 was the fourth warmest since 1880. It was ranked behind those of 2016, 2017, and 2015. The past 5 years were the warmest years in the modern record.[2]

The goal of this chapter is to pay attention to the degradation of inland seas and lakes all over the world. They are very often called "dying" or "critical," meaning that the lake or inland sea is facing either a severe anthropogenic pressure in some form or a rapid change of its physical conditions owing to regional/global climate change.[3–6] In many cases, both mechanisms work together, and it is really very difficult to discriminate between natural and anthropogenic impact and to quantitatively assess them.

In this chapter, we address the most known examples of the degradation of the lakes all over the world, and then we focus on two Central Asia case studies—the Aral Sea and the Kara-Bogaz-Gol Bay. Conclusions summarize this chapter and briefly touch on future prospects related to the state of the Central Asia water bodies.

Degradation of Lakes in the World

A significant fall in the water level and/or increase in salinity of many large saline lakes and inland seas have taken place worldwide during the past century.[3–6] Examples include the following: in North America—Great Salt Lake (Utah), Walker and Pyramid lakes (Nevada), Lake Mead (Nevada, Arizona), Owens and Mono lakes and the Salton Sea (California), and Deadmoose Lake (Canada); in South America—Llancanelo (Argentina); in the Middle East—the Dead Sea (Israel/Jordan/West Bank) and Lake Van (Turkey); in Central Asia—the Aral and Caspian seas and Kara-Bogaz-Gol Bay (Turkmenistan), Lake Balkhash (Kazakhstan), and Lake Issyk-Kul (Kyrgyzstan); in China—Lop Nor and Qinghai Hu lakes; in Africa—Lake Chad and Lake Elmenteita (Kenya); in Japan—Lake Biwa; and in Australia—Keilambete, Eyre, Corangamite, Gnotuk, and Bullenmerri lakes.[5]

The most striking examples include (1) the Lop Nor Lake in China, which completely dried up by 1972; (2) the Aral Sea, which is following such a fate; (3) the Dead Sea, whose level dropped 23 m from 1970 to 2006; and (4) Lake Chad, which at the same time shrunk to about 5% of its size in 1963.

Northern and northwestern China has been experiencing a desiccation process since the 1950s owing to a decrease in precipitation by at least 30%.[3] As a result, Lake Lop Nor vanished completely in 1972 and became a nuclear testing site; the depth of Lake Ohlin at the head of the Yellow River dropped by more than 2 cm annually; the Qinghai Hu Lake water level decreased by an average of 10 cm/yr between 1959 and 1982 owing to a decrease in rainfall, groundwater supply, and the unsustainable use of the water for irrigation (the total drop since 1908 reached 11.7 m; the lake salinity increased from 5.6 to 12 g/L since 1950). Because of rapid population growth, the surface of Ebi Nor, the largest salt lake in northwest China's Xinjiang Uygur Autonomous Region, has shrunk to 530 km^2 in the past five decades (its surface was 1200 km^2 in the 1950s). As a result, many plant and animal species living in and around the lake have been extirpated.

The Dead Sea is a 378 m deep salty terminal lake at the border between Israel, Jordan, and the West Bank. The Dead Sea waters are among the saltiest (340 g/L) and densest (1.237 g/cm^3) lake waters/seawaters in the world.[7] Its level is determined by the balance between river runoff, precipitation, and evaporation. Since the 1960s, the hydrological regime of the Dead Sea has been strongly influenced by use of its watershed by Israel, Syria, and Jordan. Moreover, Israel and Jordan use the seawaters for mineral production at salt evaporation ponds located south of the sea, responsible for 25%–30% of the total Dead Sea evaporation. As a result, evaporation exceeded freshwater inflow to the sea. Since 1977, the length of the sea decreased from 80 to 50 km and the level has dropped by 23 m (1970–2006) at rates of 0.6–1.0 m/yr.[7] From 2000 to 2018, the sea level has dropped with a rate of 1.1 m/yr. The Dead Sea level drop has been followed by a groundwater level drop, causing brines in the underground layers near the shoreline to be flushed out by freshwater. This is the cause of the recent appearance of large sinkholes along the western shore. Plans have been developed to construct a pipeline to bring water from the Red Sea into the Dead Sea to stabilize or raise the water level. The pipeline, referred to as the "Peace Conduit" project, would bring about 450×10^6 m^3 of Red Sea water into the Dead Sea annually.[4] In May 2009 at the World Economic Forum, Jordan announced its plans to construct the "Jordan National Red Sea Development Project" (JRSP). This is a plan to convey seawater from the Red Sea near the Gulf of Aqaba to the Dead Sea. Water would be desalinated along the route to provide freshwater to Jordan, with the brine discharge sent to the Dead Sea for replenishment. In 2016, Ministry of Water and Irrigation of Jordan announced that the project will be completed by 2021.

Global warming (during the 20th century, the mean land surface temperature in Africa has increased by 0.9°C) and withdrawal and/or diversion of water from inflowing rivers are the reasons for the water level drop in several African lakes.[3–5] Lake Chad, once one of the largest in Africa, has been a source of freshwater for irrigation projects in Chad, Niger, Nigeria, and Cameroon. Since 1963, the lake has shrunk to nearly 1/20th of its original size (from 25,000 to 1,350 km^2 in 2000), owing to both climatic changes (including a 50% decline in rainfall) and high agricultural water (between 1983 and 1994, irrigation water use increased fourfold). The UNEP says that about half of the lake's decrease is attributable to human water use such as inefficient damming and irrigation methods. The other half of the shrinkage is due to regional climate change. There are considerations that the lake will shrink further and perhaps even disappear in the course of the 21st century.

Lake Victoria, shared by Kenya, Uganda, and Tanzania, with a surface area of 68,000 km^2, is the world's second largest and the largest African body of freshwater in terms of surface area.[3] It is of great socioeconomic importance for 20 million people living in the basin. Over the past few decades, Lake Victoria has been subjected to drastic ecological and water quality changes owing to pollution (including sewage discharges and agricultural runoff), sediments resulting from soil erosion in the catchment area because of deforestation and overgrazing and industrial pollution from many local industries. All these factors have resulted in the eutrophication of the lake because of the increase in nutrient supply to the lake, algal blooms, and massive fish deaths. Moreover, the introduction of exotic fish species such as the Nile perch has altered the freshwater ecosystem of the lake and driven several hundred species of native cichlids to extinction or near extinction. The water hyacinth *Eichhornia crassipes*, a native of the tropical Americas, was introduced by colonists to Rwanda and then advanced by natural means to Lake Victoria where it was first sighted in 1988. Without any natural enemies, it became an ecological plague. By forming thick mats of vegetation, it causes difficulties to transportation, fishing, hydroelectric power generation, and drinking water supply.

A number of lakes in North America have also experienced desiccation in the past century.[3,5] For instance, the Pyramid Lake in Nevada experienced a 21 m level drop since 1910, accompanied by a salinity increase from 3.8 to 5.5 g/L between 1933 and 1980.

In California, Owens Lake (once 280 km^2 large and 7–15 m deep) dried completely by 1926 due to irrigation diversions and withdrawals. The dry bed of Owens Lake has produced enormous amounts of windblown dust since the desiccation of the lake. The lake bed is probably the largest single source of PM10 dust (aerosol particles smaller than 10 microns in aerodynamic diameter) in the United States (by one estimate, 900,000–8,000,000 metric tons per year).[8] Unusually fine-grained, alkaline dust storms from the dry lake bed are a significant health hazard to residents of Owens Valley and nearby areas and impact air quality in a large region (40 km) around the lake bed.

In California, the Mono Lake's level dropped 17 m from 1919 to 1982 owing to diversions of their tributary system to the Los Angeles Aqueduct system. By 1982, the lake was reduced to 153 km^2, having lost 31% of its 1941 surface area. Before 1941, average salinity was approximately 50 g/L, but in January 1982, when the lake reached its lowest level (1942 m), the salinity had nearly doubled to 99 g/L. In 2002, it was measured at 78 g/L and is expected to stabilize at an average of 69 g/L as the lake replenishes (in August 2019, its level was at 1946 m).

Even the world's largest freshwater system, the North American Great Lakes, may be shrinking. They contain about 95% of the fresh surface water supply for the United States and 20% for the world. In 2002, the aggregate level of the five Great Lakes was at the lowest in more than 30 years. Since 1997, Lakes Huron, Michigan, and Erie have dropped over 1 m, and an additional drop of 0.5–1 m has been predicted. These changes are attributed to decrease in precipitation, enhanced evapotranspiration, and reduced ice cover because of higher temperatures and irreversible loss of water for urban and industrial uses (e.g., Chicago sends its used water taken from the lakes to the Mississippi basin after treatment, instead of back to the Great Lakes).

From the late 1990s until 2005, a multiyear drought in the Upper Colorado River Basin caused water level drop in Lake Powell. As people's demands on the river overcame the rate of recharge, the volume of the lake dropped to only 33% of capacity in 2005.[9]

In August 2010, Lake Mead reached its lowest level since 1956. The largest reservoir in the United States was straining from 12 years of persistent drought and increasing human demand after decades of population growth in the American Southwest. In August 2010, Lake Mead held just 37% of the lake's capacity (35 km^3). The lake level dropped 39 m since August 1985. Refilling the lake depends almost entirely on snowmelt from the Rocky Mountains and how much of that water is released from dams and reservoirs in the upper basin of the Colorado River (Wyoming, Colorado, Utah, and New Mexico).[10]

The Aral Sea

Before 1960, the Aral Sea (Figure 1) was a water-abundant sea lake in Central Asia that was the fourth largest in the world list of lakes after the Caspian Sea (USSR, Iran), Great Lakes (United States, Canada), and Victoria Lake (Africa).[11–18] The Aral Sea was about the size of the Netherlands and Belgium taken together. It is located in the largest deserts—Karakum and Kyzylkum. Navigation and the fishery (yearly catches of 44,000 tons) were developed here. The deltas of the Amu Darya, the major river of Central Asia, and Syr Darya bringing their waters into the Aral Sea were famous for their biodiversity, fishery, muskrat rearing, and reed production. The local population found occupation in the spheres related to the water infrastructure. This was a natural and stable period of the Aral Sea evolution that since 1960 was followed by the anthropogenic one, which continues until the present day.

The Aral Sea existed thanks to runoff from the two main rivers of Central Asia—Amudarya and Syrdarya. However, since 1960, riverine water resources have been irrationally used for increasing irrigation of agricultural lands and creation of artificial water reservoirs. As a result, the Aral Sea water balance was disrupted and irreversible alterations in the sea regime appeared that later escalated into one of the "largest ecological disasters of the 20th century." During the last 50 years, we have observed a progressive degradation of the Aral Sea and its environment. During this time period, the sea shrunk in size from 66,100 km^2 (in 1961) to 10,400 km^2 (in 2008), its volume decreased from 1066 to 110 km^3, the sea level dropped by 24 m (maximum depth of 69 m was observed in 1961), and its salinity (mineralization) rose from 10 to 116 g/L in the Western Large Aral Sea and about 210 g/L in the Eastern Large Aral

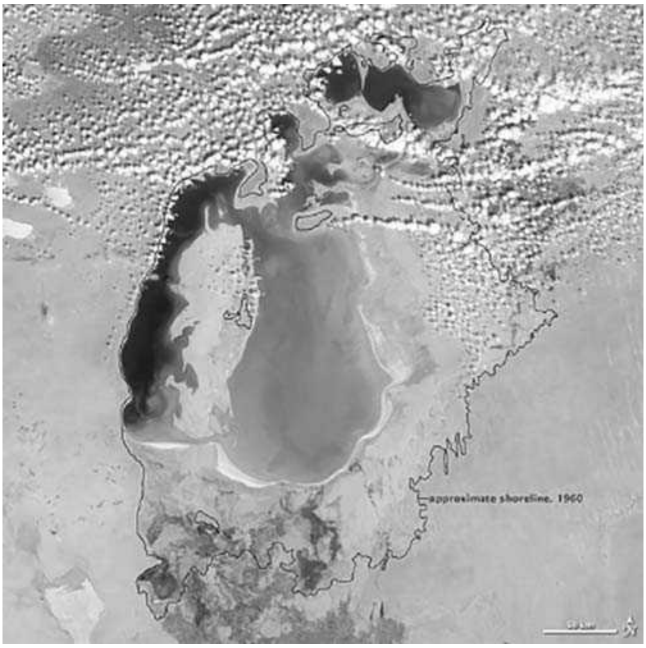

FIGURE 1 Satellite image (MODIS-Terra, 250 m resolution) of the Aral Sea on August 19, 2000, with a black line indicating the 1960 shoreline (http://earthobservatory.nasa.gov/Features/WorldOfChange/aral_sea.php, accessed on October 15, 2010).

Sea (Figure 1).[15,18,19] Today, the Aral Sea represents two isolated water bodies—a narrow and relatively deep the Western Large Aral Sea and the Small Aral Sea located in the north-eastern part of the satellite image presented in Figure 2. The former bottom of the Large Aral Sea is now a desert which is often called the Aralkum. Recent measurements (May 2019) of physical and chemical characteristics in the Western Large Aral Sea, performed by P.P. Shirshov Institute of Oceanology, Russian Academy of Sciences yearly since 2002, have recorded that the sea level has dropped by 30 m since 1961, and salinity is of 121 g/L (Personal communication by P.O. Zavialov). The ongoing desiccation, shallowing, and salinization of the Aral Sea have resulted in profound changes in its shape and its physical, chemical, and biological regime. The Aral Sea lost its economic importance, and the aftermath of its degradation represents a serious threat to the local population due to a lack of freshwater, water quality loss, salinization of soils, dust and salt storms, climate deterioration, various diseases, etc.

Until the 1960s, the deltas of the Amudarya and Syrdarya rivers, which received a lot of water and sediments, were among the most dynamic in the world, were notable for their high biodiversity and biological productivity, and resisted well against the deserts of Central Asia. As a result of dramatic man-induced reduction of river flow and a drop of the Aral Sea level, the deltas of the Amudarya and Syrdarya rivers, their hydrographic network, and landscapes have undergone severe degradation.

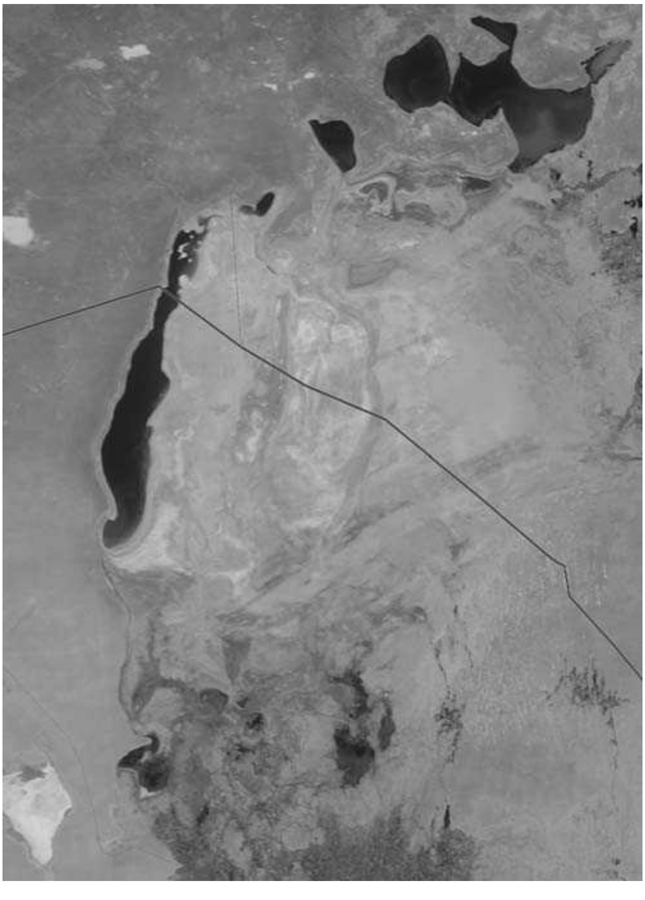

FIGURE 2 Satellite image (MODIS-Terra, 250 m resolution) of the Aral Sea on August 9, 2019 (https://wvs.earthdata.nasa.gov/?LAYERS=MODIS_Terra_CorrectedReflectance_TrueColor,Reference_Features&CRS=EPSG:4326&TIME=2019-08-09&COORDINATES=42.967532,57.612308,46.834720,61.596683&FORMAT=image/jpeg&AUTOSCALE=TRUE&RESOLUTION=250m, accessed on August 11, 2019).

The ongoing desiccation of the Aral Sea has resulted in significant changes in the distributions of dissolved gases in the residual water body. In particular, the once fully oxygenized sea developed anoxic conditions and intermittent hydrogen sulfide contamination in the bottom layers. The sulfide content depends on the density stratification and is mainly controlled by the physical regime of the sea. However, H_2S is a variable rather than a permanent feature of the present Aral Sea.[15,17]

In the first half of the 20th century in the Aral Sea, 33 species of fishes, 61 species of bottom invertebrates, 49 species of zooplankton, 306 species of phytoplankton, and 37 species of macrophytes were found. The Aral Sea accounted for 7% of the total internal waters fishery of the USSR. The main trade species were roach, sazan, and bream. From 1960 until now, the fauna of the Aral Sea evolved from mainly freshwater to hyperhalinic with the increase in water salinity. During the first decade of salinization, more than 70% of the species of fish and invertebrates vanished. By 2004, when mineralization had reached 90 ppt in the Large Aral Sea, fish fauna of the Large Aral had progressively disappeared. In 2008, zooplankton was represented by only one hypersaline species, *Artemia parthenogenetica,* introduced into the Aral Sea in 1996.[17]

It is generally accepted that the main reason for desiccation of the Aral Sea has been irrational use of Amudarya and Syrdarya waters for development of irrigation of agricultural lands and the filling of artificial water reservoirs, but regional climate change (rise of air temperature and decrease of atmospheric precipitation) also plays an important role in this process. According to estimates of the Intergovernmental Panel on Climate Change (IPCC), the trend of the mean annual air temperature in the Aral region in 1901–2005 was 1.1°C–1.7°C per 100 years, and only in 1979–2005, it was 0.3°C–0.7°C per 100 years. The results of these estimates presented in the *Fourth Assessment Report* of the IPCC have indicated that by the late 21st century, the air temperature in the Aral region depending on the emission scenarios may become 2°C–7°C higher compared to 1981–2000.[20] Our estimates of the amount of water precipitated from the atmosphere over the catchment areas of the Amudarya and Syrdarya rivers for the period 1979–2001 revealed a marked decreasing trend for the Amudarya catchment area from 7–8 to 4–5 km^3/mo on average.[21] Thus, both the effects of regional climate change significantly influenced the water balance of the Aral Sea in the past 40 years leading to its supplementary desiccation.

By the mid-1980s, the Aral crisis had been acknowledged by the whole world and became one of the most significant environment protection issues.[11–16] The Aral Sea crisis redoubled when, after disintegration of the USSR in 1990–1991, the investigations and monitoring of the sea practically ceased. Almost all hydrometeorological stations have been closed, sea expeditions have been stopped, and assessments of ongoing quick changes in the Aral Sea environment have ceased. At the same time, the interest in the Aral Sea problem has risen sharply on the international level. Many United Nations (UN) organizations (UN University, UNDP, UNESCO, UNEP, UNIDO, FAO, WMO, UN High Commissioner for Refugees, and the International Labor Organization), financial organizations (World Bank, Asian Development Bank, European Bank for Reconstruction and Development, International Monetary Fund, and Global Environment Facility), European Union Programs (TACIS, INTAS, INCO-Copernicus, OSCE, and TEMPUS), international nongovernmental organizations ("Doctors Without Borders"), regional organizations (International Fund for Saving of the Aral Sea, Interstate Coordination Water Commission, Commission on Sustainable Development, and Central Asian Economic Community), and bilateral organizations [U.S. Agency for International Development, Soros Foundation (United States), Konrad Adenauer Foundation, Friedrich Ebert Foundation, Germany Agency for Technical Cooperation (Germany), NOVIB (the Netherlands), NATO Program "Science for Peace," JAIKA, Global Infrastructure Fund Research Foundation (Japan), and others] were involved in the implementation of several hundreds of projects.[16,17]

Many of the abovementioned projects produced a lot of interesting scientific results, which traced in detail the development of the environmental crisis, but unfortunately did not result in real measures promoting salvation of the Aral Sea. Scientists, researchers, designers, and politicians could not come to a consensus on a strategy for the preservation and restoration of the Aral Sea. By the end of 2019, we can state that the main progress made towards saving of the Aral Sea occurred only in Kazakhstan with the construction of the Kokaral dam between the Small Aral Sea and Eastern Large Aral Sea in August 2005. Thus, the Small Aral Sea is now slowly reviving, while the Large Aral Sea continues to disappear progressively (Figure 2).

Kara-Bogaz-Gol Bay

Kara-Bogaz-Gol is a bay that incises deeply into the mainland and forms a highly saline bay on the eastern side of the Caspian Sea (Figure 3).[22–24] Kara-Bogaz-Gol is a Turkmen name that means "Black Trap Bay." Ancient legends say that in the bay, there was a very deep hollow that trapped the Caspian waters and even the ships that took a risk to call at this vast lagoon. This is the Caspian's largest salt-generating lagoon separated from the sea with two sand spits extending meridionally for more than 90 km (Figure 4). These sand spits form a strait 7–9 km long, 120–800 m wide, and 3–6 m deep. Due to the difference of water levels in the Caspian Sea and the bay, the waters from the sea rush at a speed of 50–100 cm/s along the strait to the bay where they evaporate completely (at a rate of 800–1000 mm/yr, on the average). Therefore, with the average annual atmospheric precipitations in this region being no more than 110 mm, Kara-Bogaz-Gol represents an enormous natural evaporation basin of seawater. Due to high evaporation, the bay is filled with brine, the salinity of which reaches 270‰–300‰ and even more. This brine is a concentrated solution of salts such as chlorides of sodium, magnesium, and potassium; magnesium sulfate; and small quantities of rare earth elements. The Kara-Bogaz-Gol Bay is the largest salt deposit where up to 20 salt minerals are found. The salt deposits of the bay accumulated a dozen billion tons of various salts that make the most valuable raw material for development of the chemical industry, agriculture, nonferrous metallurgy, medicine, and other branches of the economics.[23,24]

In the first decades of the 20th century, the level difference between the sea and the bay was about 0.5 m, and they were hydraulically linked. The level in Kara-Bogaz-Gol was close to –26.5 m relative to the world ocean. The area of the bay (in the beginning of the 20th century and after 1996) was greater than 18,300 km^2, the volume of water was 130 km^3, and the prevailing depths were 8–10 m (maximum depth was 13 m).

Starting from the 1930s, the nature of Kara-Bogaz-Gol Bay has experienced significant changes related to the sharp fall in the level of the Caspian Sea.[22] In 1939, the supply of seawater to the bay decreased to 6 km^3/yr (from 20 to 25 km^3/yr in 1929–1930) and the water balance was distorted. The maximum depth of the bay decreased from 12 m in the 1920s–1930s to 4.5 m in the early 1950s. The decrease in the water volume of Kara-Bogaz-Gol Bay, accompanied by the long-term sea-level fall and related growth in the salt concentration in the brine and changes in its chemical composition, negatively affected the conditions of sulfate mining.

In the 1960s, the difference between the levels of the sea and the bay became larger and the world's only sea waterfall about 3.7 m high (1970) was formed in the strait mouth. The maximum flow velocity in this waterfall was more than 2.5 m/s. In the 1960s to early 1970s with the water flow being 9–10 km^3, the bay area varied around 10,000–11,500 km^2, while the volume of water was 25–29 km^3 and the maximum depth of the bay decreased to 3.5 m. In the late 1970s, the Caspian water flux into the bay reduced to 5–7 km^3/yr, the water level in the lagoon dropped to –32 m, the area decreased to 10,000 km^2, and the volume of water decreased to 20–22 km^3, while the brine concentration increased to 270‰–300‰.[24] In order to reduce the Caspian Sea water use and retard the fall of the water level in the Caspian Sea that in 1977 reached its absolute minimum for the last 400 years (–29 m), in March 1980, the strait was dammed, thus stopping the inflow of seawater into the bay.

Construction of a dam led in late 1983 to complete desiccation of the bay and considerable reduction of chemical products manufactured here (sodium sulfate, etc.). By the end of 1983, the area of the bay was only 1000 km^2, its volume was 0.2 km^3, and its depth was 0.1–0.3 m. Brine salinity reached 330‰–380‰. By late August 1984, no common brine surface remained. In September 1984, tubes were installed in the dam body to direct the seawater into the bay in the amount of 1.6–1.8 km^3/yr. Such restricted supply of seawater lasted for nearly a decade and did not result in noticeable improvement of the hydrological

and hydrochemical situation in the bay. In June 1992, the Turkmenistan president ordered to dismantle the dam, and by 1996, the bay was filled with Caspian water until its equilibrium state (Figure 4). At the high water level in the Caspian Sea in 1993–1995, the annual water flow reached 37–52 km^3/yr and the difference between levels in the sea and bay decreased from 6.9 m in June 1992 to 0.2–0.6 m in 1996.[24] The situation became stable, the behavior of the bay returned back to its natural conditions related to the Caspian Sea, and the salt production increased.

Conclusions

The history of Kara-Bogaz-Gol Bay has been instructive and showed that without multidisciplinary and comprehensive research of the ecological, economic, and social aftereffects, one should not alter natural equilibriums reached over thousands of years, and human intervention into the complicated environmental processes may lead to catastrophic results.

Within a life span of only two generations, the Aral Sea as a single natural water body practically ceased to exist, and the main reason for this should be sought in man's economic activities. Since 1960, riverine water resources have been irrationally used for increasing irrigation of agricultural lands and creation of artificial water reservoirs. From the other side, regional climate change significantly influenced the water balance of the Aral Sea in the past 30 years leading to its supplementary desiccation. Thus, both effects have led the Aral Sea to one of the "largest ecological disasters of the 20th century."

Desiccation of the Aral Sea in the so-called anthropogenic period (since 1961) led not only to considerable changes in its morphometric, physical, chemical, biological, and other parameters but also to the disappearance of infrastructure in the coastal zone, including meteorological and sea-level gauge stations, ships, ports, villages, and roads. The current lack of reliable in situ measurements and time series for sea surface temperature, sea level, ice cover, and morphometric characteristics since the mid-1980s may be successfully replaced by using corresponding satellite information available directly from satellites or through the world databases.[19,21,25,26] Images from the Advanced Very High-Resolution Radiometers (AVHRR onboard National Oceanic and Atmospheric Administration (NOAA) satellites) and Moderate Resolution Imaging Spectroradiometers (MODIS onboard Terra and Aqua satellites) provide a possibility to follow the changes in the sea's coastline and observe interesting phenomena in the water, in the atmosphere, and on the dried parts of the Aral Sea.[19]

Regular measurements of the sea/lake level are practically absent in many regions such as Central Asia and Africa. Monitoring of the evolution of these and other water bodies worldwide may be accomplished by satellite altimetry from the TOPEX/Poseidon, Jason-1/-2/-3, ERS-1, ERS-2, GFO, and Envisat satellites.[26–31]

In 1986, the International Lake Environment Committee and UNEP started a project called "Survey of the State of World Lakes," aimed at collecting and analyzing environmental data on >500 lakes from 73 countries.[32,33] The results have indicated that environmental problems, common for the lakes in all continents, may be classified in the following categories:[32]

1. Lake shallowing and salinization owing to overuse of water from lakes and/or tributary rivers, resulting in a degradation of water quality and lake ecosystems.
2. Accelerated sedimentation in lakes and reservoirs resulting from anthropogenic or natural soil erosion.
3. Lake water acidification resulting from acid precipitation, which may result in the extinction of ecosystems and contamination of water with toxic agricultural and/or industrial chemicals.
4. Eutrophication owing to inflow of nitrogen and phosphorus compounds or other nutrients in the discharged water or wastewater inflows, strongly affecting biodiversity.
5. In extreme cases, a complete collapse of aquatic ecosystems and desiccation of lakes.

Increased freshwater consumption for agricultural, industrial, and urban uses and uncontrolled irrigation pose a serious threat to inland seas, lakes, rivers, and wetlands as well. In addition, shallowing and desiccation of inland seas often lead to nonhydrologic consequences, such as air pollution from dust/salt storms caused by wind erosion of exposed lake beds.

Global warming is expected to lead to large air and water temperature anomalies and make droughts and desertification more severe in the future. Climate change is also the reason for the water level drop. Shallowing or desiccation of lakes has caused local climate changes in numerous drainage basins, and if the present climatic trends persist, global climate changes could trigger almost untenable environmental effects for people and aquatic ecosystems. One of the principal tasks for future research is the delimitation of the anthropogenic and natural climate change impacts on lakes and inland seas. Degradation of many inland water bodies is a continuing global environmental problem, and its social and economic implications have attracted the growing attention of many individuals, organizations, and governments, resulting in many national and international research projects.

Oil Pollution: The Baltic Sea

Andrey G.
Kostianoy

Introduction

Detection of oil pollution is among the most important goals of monitoring a coastal zone. Public interest in the problem of oil pollution arises mainly during dramatic tanker and oil platform catastrophes such as those that involved the following: *Amoco Cadiz* (France, 1978), *Ixtoc I* (Gulf of Mexico, 1979–1980), *Exxon Valdez* (Alaska, 1989), *The Sea Empress* (Wales, 1996), *Erica* (France, 1999), *Prestige* (Spain, 2002), and *Deepwater Horizon* (Gulf of Mexico, 2010). However, tanker and oil platform catastrophes are only one among the many causes of oil pollution. Oil and oil product spillages at sea take place all the time, and it would be a delusion to consider tanker accidents as the main environmental danger. According to the International Tanker Owners Pollution Federation (ITOPF), over the period of 1970–2017, spillages resulting from collisions, groundings, tanker holes, and fires amounted to 52% of total leakages during tanker loading/unloading and bunkering operations.[1] In the category of 7–700 tons, some 38% of spills occurred during routine operations, most especially loading or discharging (31%). Accidents were the main cause of large spills (>700 tons), with groundings and collisions accounting for 61% of the total during the period 1970–2017.[1] Other significant causes included hull failures and fire/explosion. Discharge of wastewater containing oil products is another important source, by pollutant volume comparable to offshore oil extraction and damaged underwater pipelines. The greatest but hardest-to-estimate oil inputs come from domestic and industrial discharges, direct or via rivers, and natural hydrocarbon seeps. The long-term effects of this chronic pollution are arguably more harmful to the coastal environment than a single, large-scale accident.

Each year, ships and industries damage delicate coastal ecosystems in many parts of the world by releasing oil or pollutants into ocean, coastal waters, and rivers. Offshore environments are polluted by mineral oil mainly due to tanker accidents, illegal oil discharges by ships, and natural oil seepage. Shipping activities in European coastal seas, including oil transport and oil handled in harbors, have a number of negative impacts on the marine environment and coastal zone. Oil discharges from ships represent a significant threat to marine ecosystems. Oil spills cause the contamination of seawater, sediments, shores, and beaches, which may persist for several months and even years and represent a threat to marine resources.[1,2]

As highlighted by Oceana in its report *The Other Side of Oil Slicks*, chronic hydrocarbon contamination from washing out tanks and dumping bilge water and other oily waste represents a danger at least three times higher than that posed by the oil slicks resulting from oil tanker accidents.[3,4] For example, in the North Sea, the volume of illegal hydrocarbon dumping is estimated at 15,000–60,000 tons/year, added to which are another 10,000–20,000 tons of authorized dumping. Oil and gas platforms account for 75% of the oil pollution in the North Sea via seepage and the intentional release of oil-based drilling muds.[5] In the Mediterranean Sea, it is estimated at 400,000–1,000,000 tons/year. Of this, about 50% comes from routine ship operations and the remaining 50% comes from land-based sources via surface runoff.[5] In the Baltic Sea, this volume is estimated at 1750–5000 tons/year.[3,4] In 2004, the Finnish Environment Institute[6] estimated the total annual number of oil spills in the Baltic Sea to be 10,000 and the total amount of oil running into the sea to be as much as 10,000 tons, which is considerably more than the amount of oil pouring into the sea in accidents. In 2014, an analysis of different sources of information on oil pollution gave annual values of 20–20,000 tons for the Baltic Sea.[7] It is impressive to note that the total amount of oil spilled annually worldwide from all sources to the ocean is estimated as 1.7–8.8 million tons (the more realistic value was about 3.2 million tons) in the 1970s, 0.47–8.3 (1.3) million tons in the 1990s, and 2.6–4.8 million tons in the 2000s, which is about 0.05%–0.1% from the world oil production (4.76 billion tons in 2011).[7]

One of the most important goals of the ecological monitoring of European seas is monitoring and detection of oil pollution.[8–11] After a tanker accident or illegal oil discharge, the biggest problem is to obtain an overall view of the phenomenon, getting a clear idea of the extent of the slick and predicting the way it will move. For natural and man-made oil spills, it is necessary to operate regular and operational monitoring. Oil pollution monitoring in the Mediterranean Sea, North Sea, and Baltic Sea is normally carried out by aircrafts or ships. This is expensive and is constrained by the limited availability of resources. Aerial surveys over large areas of the seas to check for the presence of oil are limited to the daylight hours, good weather conditions, and maritime boundaries between countries.

Satellite imagery can help greatly in identifying probable spills over very large areas and in guiding aerial surveys for precise observation of specific locations. The synthetic aperture radar (SAR) instrument, which can collect data independently of weather and light conditions, is an excellent tool to monitor and detect oil on water surfaces.[7–11] This instrument offers the most effective means of monitoring oil pollution: oil slicks appear as dark patches on SAR images because of the damping effect of the oil on the backscattered signals from the radar instrument. This type of instrument is currently on board the European Space Agency's (ESA's) *Sentinel-1A and -1B* satellites, the Canadian Space Agency's *RADARSAT-2* satellite, the German Earth observation satellite *TerraSAR-X*, and other spacecraft. ASAR/SAR (advanced synthetic aperture radar) instrument is used for mapping sea ice and oil slick monitoring, measurements of ocean surface features (currents, fronts, eddies, internal waves), ship detection, oil and gas exploration, etc. Users of remotely sensed data for oil spill applications include the Coast Guard, national environmental protection agencies and departments, oil companies, shipping, insurance and fishing industries, national departments of fisheries and oceans, and other organizations.

In this entry, we will focus on oil pollution in the Baltic Sea, briefly describing main sources of oil pollution, the number of oil spills observed yearly, the results of operational satellite monitoring and numerical modeling of oil spills, and the remaining problems.

Main Sources of Oil Pollution in the Baltic Sea

Crude oil and petroleum products account for about 40% of the total exports of Russia. Russian Federation stands as one of the leading operators in the international oil business, being the largest oil exporter after Saudi Arabia. In 2000, Russia exported approximately 145 million tons of crude oil and

50 million tons of petroleum products. Since 2000, exports of petroleum and petroleum products began to grow and virtually doubled for the period from 1996 to 2005. According to the Federal Customs Service of Russia, in 2008, Russia exported 221.6 million tons, and in 2017, 253 million tons of oil.

The ports on the Baltic Sea play a huge role in the export of oil from Russia. The main oil terminals here used to be the Latvian port of Ventspils and the Port of Tallinn, Estonia. In the last 20 years, a number of new oil terminals have been built in the Baltic Sea area, resulting in increased transport of oil by ships and, consequently, an increased risk of accidents and increased risk of pollution of the marine environment. Today, in the Gulf of Finland, there are more than 20 oil terminals in Russia, Finland, and Estonia. The following are the major existing and projected oil terminals in the Gulf of Finland from Russia: Primorsk, Vysotsk, Big Port of St. Petersburg, Ust-Luga, Batareinaya, Vistino, Gorki, and Lomonosov.[12,13]

Primorsk is the largest Baltic oil terminal located on Russian territory. In 2008, 75.6 million tons of oil products were exported from Primorsk, 13.6 million tons from Vysotsk, and 14.4 million tons from the St. Petersburg oil terminal. In 2018, 53.5 million tons of oil were exported from Primorsk, maximum export possibility of the Primorsk terminal is estimated at 120 million tons, while that of Vysotsk is at 20.5 million tons. In November 2000, Lukoil has opened an oil terminal in Kaliningrad. In 2001, the company built another terminal in Kaliningrad with a declared capacity of 2.5 million tons. These terminals can overload up to 3–5 million tons of oil annually.

According to estimates of the Centre for Maritime Studies at the University of Turku (Finland), in 2007, 263 million tons of cargo were transported through the Gulf of Finland, among which the share of oil is 56%.[13] Russian ports handled 60% of goods, Finnish ports handled 23%, and Estonian ports handled 17%. The share of imports was 22%, that of export was 76%, and that of local transportation was 2%. Russian ports held 68.6% of the total turnover of petroleum products, Estonian ports held 17.2%, and Finnish ports held 14.2%.[13] The major ports were the following: Primorsk (74.2 million tons), St. Petersburg (59.5 million tons), Tallinn (35.9 million tons), Skoldvik (19.8 million tons), Vysotsk (16.5 million tons), and Helsinki (13.4 million tons). In 2007, the ports of the Gulf of Finland carried out about 53,600 ship calls, most of which were in St. Petersburg (14,651), Helsinki (11,727), and Tallinn (10,614). In 2009, vessels entered or left the Baltic Sea via Skaw 62,743 times; this is 20% more than in 2006. Approximately 21% of those ships were tankers, 46% were other cargo ships, and 4.5% were passenger ships.[14]

The growth of oil and other cargo through the terminals and the Baltic ports inevitably leads to an increase in the number of tankers and other types of vessels, which then leads to an increase in chronic sea pollution and a higher probability of ship accidents. According to statistics, shipping accounts for 45% of oil pollution in the ocean, while oil production at the shelf accounts for only 2%. In the Baltic Sea, about 2000 large ships and tankers are at sea every day; thus, shipping, including oil transport, has a major negative impact on the marine environment and coastal zone. Illegal discharges of oil and petroleum products from ships, ship accidents, collisions, and groundings represent a significant threat to the Baltic Sea.[8]

According to Global Marine Oil Pollution Information Gateway,[15] major oil spills in the region in 1970–2007 resulted from the following ship accidents: *Othello* (1970, Tralhavet Bay, Sweden, spill of 60,000 tons), *Tsesis* (1977, off Nynäshamn, Sweden, spill of 1000 tons), *Antonio Gramsci* (1979, off Ventspils, Latvia, spill of 5500 tons; another incident in 1985, off Porvoo, Finland, spill of 580 tons), *Jose Marti* (1981, off Dalarö, Sweden, spill of 1000 tons), *Globe Asimi* (1982, off Klaipeda, Lithuania, spill of 16,000 tons), *Sivona* (1984, in The Sound, Sweden, spill of 800 tons), *Volgoneft* (1990, off Karlskrona, Sweden, spill of 1000 tons), *Baltic Carrier* (2001, international waters between Denmark and Germany, spill of 2700 tons), *Fu Shan Hai* (2003, between the Danish island of Bornholm and coast of Sweden, spill of 1200 tons), *Haaga* (2003, St. Petersburg port, Russia, spill of 1300 tons), and *Golden Sky* (2007, off Ventspils, Latvia, spill of 25,000 tons).

According to HELCOM data (http://www.helcom.fi), the total number of accidents on ships in 2000–2004 is 374, of which 29 resulted in the pollution of marine waters. The number of accidents has risen since 2006, which can be linked to the 20% increase in ship traffic. Now, there are 120–140 shipping accidents yearly in the Baltic Sea area.[14] The majority of accidents are groundings and collisions. The share of groundings in the total number of accidents is higher for the Baltic Sea than for other European waters. On average, 7% of the shipping accidents in the Baltic Sea result in some kind of pollution, usually containing not more than 0.1–1 ton of oil. For the last 10 years, no major accidental oil spill has happened in the Baltic Sea.[14]

As far as oil exploitation at sea and on the coast is concerned, offshore operations have been taking place for some years in Polish waters (two jack-up rigs); Germany operated two platforms very close to the coast; in March 2004, Russia started oil production at Lukoil D-6 platform in the waters between the Kaliningrad area (Russian Federation) and Lithuania, and Latvia plans to drill for oil in the waters between them and Lithuania.[15]

Oil Spill Observations, Statistics, and Tendencies

Every ship entering the Baltic Sea must comply with the antipollution regulations of the Helsinki Convention and MARPOL (marine pollution) Convention. Even though strict controls over ships' discharges have been established by the Baltic Sea countries, illegal spills and discharges continue to happen.[14] Fortunately, the number of illegal oil spills detected by aerial surveillance has been reduced significantly over the last 30 years, from 763 spills in 1989 to 52 spills in 2017 (Table 1 and Figure 1). Also, the volume of the spills has been decreasing—most are between 1 and 0.1 m^3 today.[14,16]

A decreasing trend in the number of observed illegal oil discharges despite rapidly growing density of shipping, increased frequency of surveillance flights (Figure 1 and Table 2), and usage of satellite imagery, provided by the CleanSeaNet satellite service of the European Maritime Safety Agency (EMSA) (http://cleanseanet.emsa.europa.eu/), illustrates the positive results of the complex set of measures known as the Baltic Strategy, implemented by the Contracting Parties to the Helsinki Convention.[16]

Source: Annual Report on discharges observed during aerial surveillance in the Baltic Sea in 2017.[16]

In order to obtain the geographical distribution of oil spills, we put the spills observed in 1988–2002 on the same map (Figure 2). Analysis of Tables 1 and 2 and Figure 2 shows the following:

1. HELCOM data seem to be underestimated in figures in comparison with other estimates.[3,4,6,7]
2. Since 1993, Russia does not carry out aerial surveillance in the Southeastern Baltic Sea and in the Gulf of Finland.
3. Since 1994, Lithuania seems to have no regular and effective aerial surveillance, because no oil spills have been detected.
4. Since 2005, Latvia seems to have no effective aerial surveillance, because 0–5 oil spills yearly are not realistic figures.
5. Traces of oil spills in Figure 2 show the main ship routes in the Baltic Sea, as well as the approaches to major sea ports and oil terminals.
6. Figure 2 proves that ships are primarily responsible for the oil pollution in the Baltic Sea.

Source: Annual report on discharges observed during aerial surveillance in the Baltic Sea in 2017.[16]

The Baltic Sea States aerial surveillance fleet today consists of more than 20 airplanes and helicopters, most of which are equipped with up-to-date remote-sensing equipment—side-looking airborne radar, SAR, infrared (IR) and ultraviolet scanner, microwave radiometer, laser fluorosensor (lidar), and forward-looking infrared (FLIR) high-resolution camera. The Baltic Sea States have to conduct aerial surveillance for detecting oil pollution and suspected ships at a minimum of twice per week over regular traffic zones including approaches to major sea ports as well as in regions with regular offshore activities. Other regions with sporadic traffic and fishing activities should be covered once per week.[16] Also, the Coordinated Extended Pollution Control Flights, which constitutes continuous surveillance of specific areas in the Baltic Sea for 24 hours or more, should be carried out twice a year.[16] Although the number of observations of illegal oil discharges shows a decreasing trend over 30 years, it should be noted that for some areas and countries, aerial surveillance is not evenly and regularly carried out and therefore there are no reliable figures for these areas.[16]

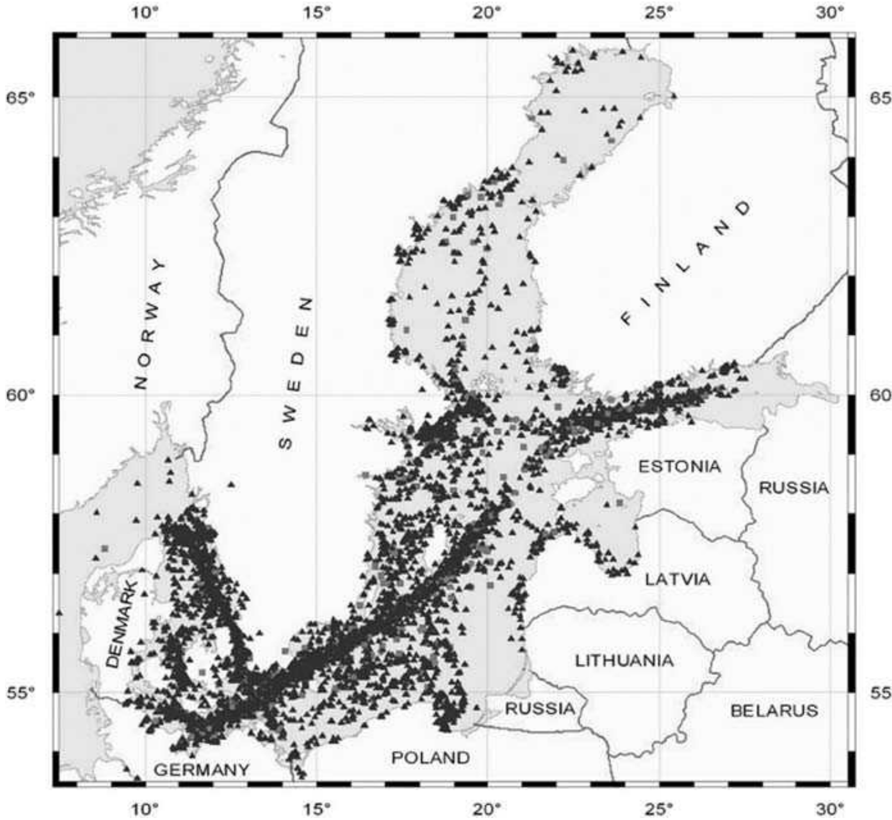

FIGURE 2 Oil spills detected in the Baltic Sea by aerial survey in 1989–2002 based on HELCOM data. (Kostianoy et al.[19])

Since 2007, aerial surveillance in the Baltic Sea was supported by the satellite remote-sensing technique for oil spill detection. CleanSeaNet is a near-real-time satellite-based oil spill and vessel-monitoring service.[8] It entered into operation on April 16, 2007.[16] The service is continually being expanded and improved and provides a range of different products to the Commission and European Union member states. The legal basis for the CleanSeaNet service is Directive 2005/35/EC on ship-source pollution and on the introduction of penalties, including criminal penalties, for pollution offenses (as amended by Directive 2009/123/EC). EMSA has been tasked to "work with the Member States in developing technical solutions and providing technical assistance in relation to the implementation of this Directive, in actions such as tracing discharges by satellite monitoring and surveillance."[16]

Operational Satellite Monitoring of Oil Pollution

A satellite-based remote-sensing system is capable of ensuring a relatively low-cost, high-standard observational system for oil pollution monitoring. SAR is the best instrument for the detection of oil slicks on the sea surface from space because slicks modify seawater viscosity and damp short waves measured by SAR. SAR images can be acquired regardless of cloud cover and light conditions. Along with 300–400 km wide swath, this is the main advantage of SAR in comparison with aerial surveillance. However, oil spill detection by SAR has a problem of distinguishing oil slicks from look-alikes, such as sea areas covered by organic films, algal bloom, sea ice, wind shadows, rain cells, and upwelling zones. Therefore, reliable automatic detection of oil spills on the basis of SAR data is not yet achieved and there is a risk of false alarms. This problem can be significantly reduced by a new approach, which consists in the combined use of all available quasi-concurrent satellite, oceanographic, and meteorological information, along with numerical modeling of oil spill transport. This operational system was specially elaborated in the beginning of 2004 for monitoring oil pollution in the vicinity of the Lukoil D-6 oil platform in the Southeastern Baltic, Russian Federation.[8,17–21]

Since 1993, regular aerial surveillance of the oil spills in the Russian sector of the Southeastern Baltic Sea and in the Gulf of Finland has stopped (Tables 1 and 2, Figure 2). In June 2004, we organized daily service for monitoring of oil spills in the Southeastern Baltic Sea based on the operational receiving and analysis of ASAR *ENVISAT* and SAR *RADARSAT-1* data as well as of other satellite IR and optical (VIS) data, meteorological information, and numerical modeling of currents required for the identification of the slick nature in the sea and forecast of the oil spill drift.[8,17–21] This work was initiated and financed by Lukoil-Kaliningradmorneft (Kaliningrad, Russia) in connection with the start of oil production from the continental shelf of Russia in March 2004. The principal differences from the existing projects and satellite services were (1) an operational monitoring regime of 24 hours/day, 7 days/week for 18 months and (2) a complex approach to the oil spill detection and forecast of their drift.

The general goals of the satellite oil pollution monitoring in the Baltic Sea were as follows:

1. Correct detection of oil spills in the vicinity of the D-6 oil platform as well as in the large area of the Southeastern Baltic Sea between 54°20′–58°N and 18°–22°E
2. Identification of sources of oil pollution
3. Forecast of the oil spill drift by different methods
4. Data systematization and archiving
5. Cooperation with authorities.

Operational monitoring of oil pollution in the sea was based on the processing and analysis of ASAR *ENVISAT* (every pass over the Southeastern Baltic Sea, frame of 400×400 km, 75 m/pixel spatial resolution) and SAR *RADARSAT-1* (300×300 km, 25 m/pixel resolution) images received from KSAT Station (Kongsberg Satellite Services, Tromsø, Norway) in operational regime (1–2 hour after the satellite's overpass). For interpretation of ASAR *ENVISAT* imagery and forecast of the oil spill drift, IR and VIS AVHRR (the Advanced Very High-Resolution Radiometer aboard the National Oceanic and Atmospheric Administration (NOAA) satellites) and Moderate Resolution Imaging Spectroradiometer (MODIS) (*Terra* and *Aqua*) images were received, processed, and analyzed, as well as the *QuikSCAT* scatterometer and the *Jason-1* altimeter data.[18–21] The total area covered by the monitoring was equal to about 60,000 km^2, which is almost one-sixth of the Baltic Sea total surface.

The satellite receiving station at the Marine Hydrophysical Institute (MHI) in Sevastopol was used for operational (24 hours/day, 7 days/week) receiving of the AVHRR NOAA data for the construction of the sea surface temperature (SST), optical characteristics of seawater, and currents maps. SST variability and intensive algae bloom (high concentration of blue–green algae on the sea surface in the summertime) allow one to highlight meso- and small-scale water dynamics in the Baltic Sea and to follow movements of currents, eddies, dipoles, jets, filaments, river plumes, and outflows from the Vistula and Curonian bays. Sequence of daily MODIS IR and VIS imagery allows reconstruction of a real field of surface currents (direction and velocity) with 0.25–1 km resolution, which is very important for a forecast of a direction and velocity of a potential pollution drift including oil spills. The combination of ASAR *ENVISAT* images with high-resolution VIS and IR MODIS images allows understanding of the observed form of the detected oil spills and prediction of their transport by currents.[18–21]

Sea wind speed fields were derived from scatterometer data from every path of the *QuikSCAT* satellite over the Baltic Sea (twice a day). These data were combined with data from coastal meteorological stations in Russia, Lithuania, Latvia, Estonia, Finland, Sweden, Denmark, Germany, and Poland and numerical weather models. Altimetry data from every track of the *Jason-1* satellite over the Baltic Sea were used for compilation of sea wave height charts, which include the results of the FNMOC (Fleet Numerical Meteorology and Oceanography Center, the United States) World War III Model. Both data were used for the analysis of the ASAR *ENVISAT* imagery and estimates of the oil spill drift direction and velocity.[18–21]

In total, 274 oil spills were detected in 230 ASAR *ENVISAT* images and 17 SAR *RADARSAT-1* images received during 18 months (June 2004 to November 2005).[8,20] One example from the oil spill gallery is shown in Figure 3 where an illegal release of oil from three ships was detected on August 25, 2005.

The interactive numerical model Seatrack Web of the Swedish Meteorological and Hydrological Institute (SMHI) was used for a forecast of the drift of satellite-detected oil spills and ecological risk assessment of the Lukoil D-6 oil platform.[18–20]

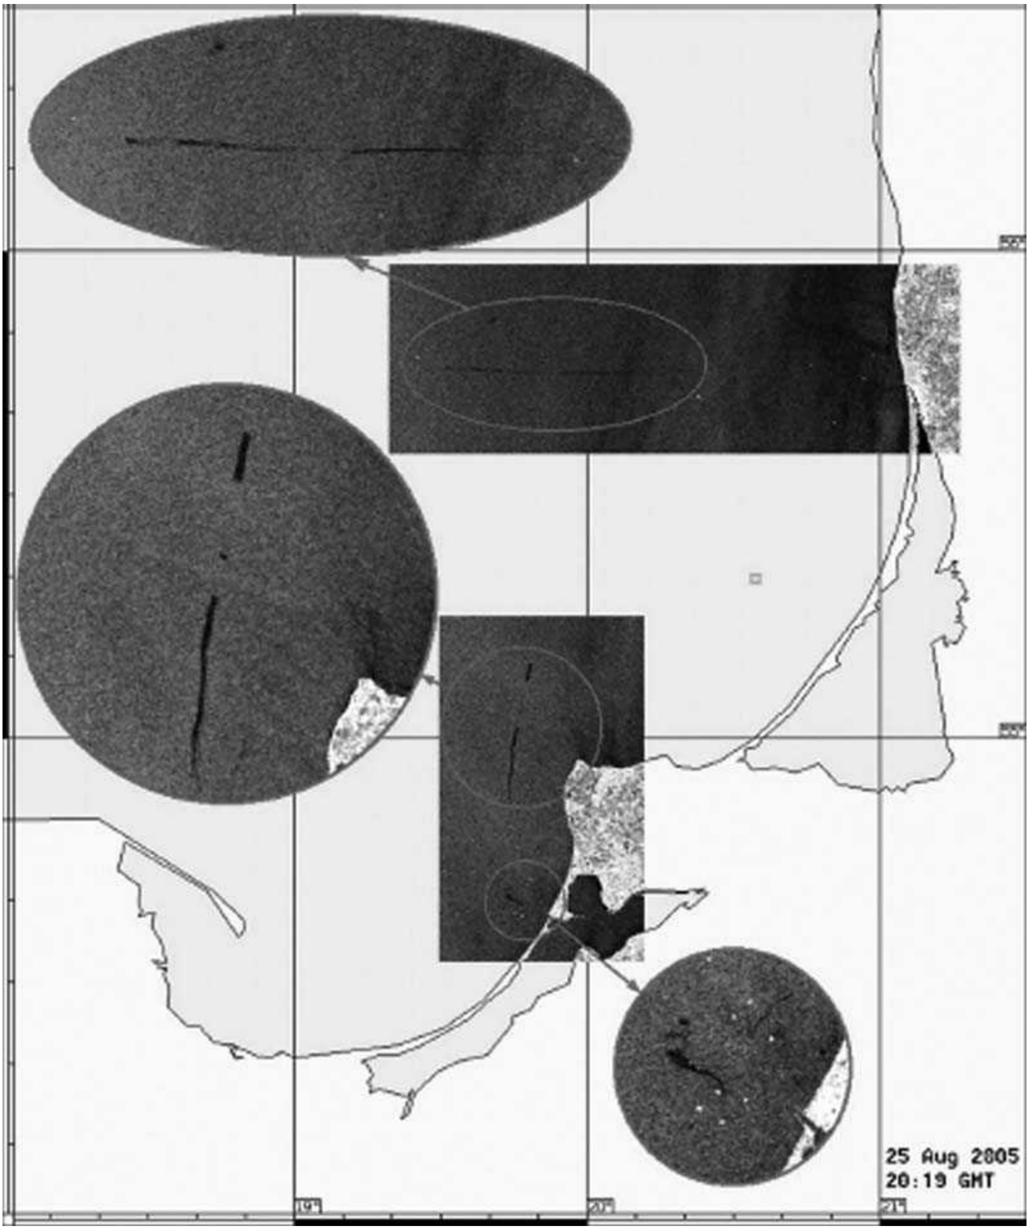

FIGURE 3 A release of oil from three ships on August 25, 2005 (ASAR *ENVISAT*). The length of the spill in front of Klaipeda is 33.6 km, surface—8.6 km^2. The length of another long spill is 22 km.

Since 2006, the satellite monitoring of the D-6 oil platform was transformed, reduced in size to about 24,000 km^2, and unfortunately, it lost its main peculiarity—a complex approach to the oil spill detection and forecast of their drift. In 2006–2009, 638 oil spills have been identified on 804 ASAR images, from which 319 spills were detected in this reduced area.[21] Combined analysis of the location and shape of the detected spills with location of the ships thanks to AIS (Automatic Identification System for ships) clearly indicates that the major source of sea pollution is shipping. In the Southeastern Baltic Sea, an area with no HELCOM statistical data, we also observe a decreasing trend in oil spill number and their total surface. In 2006, the total number of oil spills (and area of oil pollution) amounted to 114 (371.7 km^2); in 2007, 94 spills (213.7 km^2); in 2008, 67 spills (198.7 km^2); and in 2009, 44 spills (81.7 km^2).[21]

The satellite monitoring of the D-6 oil platform continues till present.[21–28] A map of all oil spills detected by the analysis of the ASAR *ENVISAT, RADARSAT-1, RADARSAT-2, Cosmo-SkyMED-1, -2, -3, -4*, and *TerraSAR-X* imagery in the given area of the Southeastern Baltic Sea from June 12, 2004, until December 31, 2015, is shown in Figure 4. A real form and dimension of oil spills are shown. A square southwestward of Klaipeda shows the location of the D-6 oil platform. Oil spills clearly revealed the main ship routes in the Baltic Sea directed to ports of Ventspils, Liepaja, Klaipeda (routes from different directions), Kaliningrad, and along Gotland Island (Figure 4). No spills originated from the D-6 oil platform were observed.

From June 12, 2004, to December 31, 2015, 1232 oil spills were detected with clear interannual tendency to reduction of oil pollution in the Southeastern Baltic Sea from 2006 to 2011 when 44 oil spills (147 km^2) were recorded. In 2012, an increase in the number of detected oil spills (86), and as a result, increase of a total area of oil pollution (470 km^2) was observed. In 2013, with a relatively small number of oil spills (52), we have observed a high total area of oil pollution (341 km^2) what is explained by huge oil

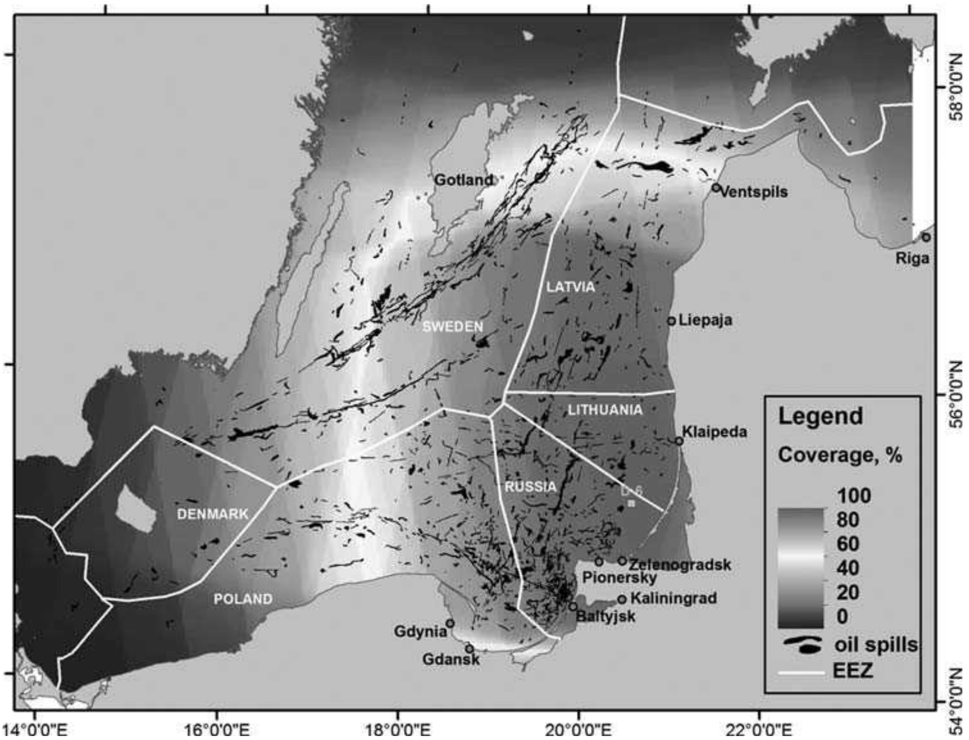

FIGURE 4 Map of all oil spills detected by the analysis of the ASAR/SAR satellite imagery from June 2004 to December 2015.

spills detected on September 13, 2013, and September 20, 2013. In 2014 and 2015, the number of oil spills has reduced to 47 and 39 with a total surface of about 188 km^2 for both years.[26]

A significant seasonal variability in oil spill detection is observed. During autumn and winter, we detect oil spills four times less than in spring and summer.[27] This huge difference is explained by limitations of the SAR method to detect oil spills when the wind is stronger than 10 m/s, which is very often during the cold season in the Baltic Sea. In addition, strong wind-wave mixing contributes to more rapid formation of emulsions ("water in oil" and "oil in water"), thus preventing formation of the oil slicks on the sea surface.

Image comparison of the number of detected oil spills in the morning (about 11:00 local time) and in the evening (about 22:00 local time) for 2006–2009 showed that the probability of finding oil pollution in the morning is about 40% higher than that in the afternoon and evening.[21] This fact indicates that the illegal discharge of oil from vessels occurs more often at night, when it is impossible for patrol aircraft or ships to record this fact by photo and video camera. This once again confirms the advantages of satellite radar imagery for monitoring of oil pollution.

Based on the number of oil spills detected in 2014 and 2015 (about 40 spills yearly on the area of about 24,000 km^2), we can estimate the total number of oil spills for the Baltic Sea (377,000 km^2) as about 630 yearly and the total surface of oil pollution as about 3000 km^2 yearly. These values are six to seven times higher than reported by HELCOM for the same years (Table 1). These values may double and even triple if we take into account the following: (1) SAR satellites pass over a specific area in the Baltic Sea every 2 days in average, (2) significant reduction of oil spill observation in autumn and winter due to unfavorable weather conditions, and (3) spatial resolution of SAR/ASAR imagery of 25–75 m/pixel.

Numerical Modeling of Oil Spill Drift

The abovementioned satellite monitoring of the Southeastern Baltic Sea was coupled with numerical modeling of oil spill transport. The interactive numerical model Seatrack Web SMHI was used for a forecast of the drift of (1) all large oil spills detected by ASAR *ENVISAT* in the Southeastern Baltic Sea and (2) virtual (simulated) oil spills from the Lukoil D-6 platform. The latter was done daily for the operational correction of the action plan for accident elimination at the D-6 and ecological risk assessment (oil pollution of the sea and the Curonian Spit).

This version of a numerical model on the Internet platform has been developed at the SMHI in close cooperation with the Danish Maritime Safety Administration, Bundesamt fur Seeschifffahrt und Hafen, and the Finnish Environment Institute.[29] The first version of Seatrack Web was introduced in 1995, and since then, Seatrack Web has been used successfully for oil spill drift forecast. It was developed to be a friendly tool for authorities responsible for oil spill response in the Baltic Sea region. Seatrack Web's main purpose is to calculate the drift and transformation of oil spills in the Gulf of Bothnia, the Gulf of Finland, the Baltic Sea Proper, the Sounds, the Kattegat, the Skagerrak, and part of the North Sea (to 3°E).[29] The program can also be used for substances other than oil, such as chemicals, algae, and floating objects. In addition to an oil drift forecast, it is possible to make a backward calculation. Then, calculation starts at the position where a substance was found and the program calculates the drift backward in time and traces the origin of the substance or an object.

Today, the Seatrack Web is hosted by SMHI and developed together by SMHI in close cooperation with the FCOO (Defence Centre for Operational Oceanography) in Denmark, the BSH (Federal Maritime and Hydrographic Agency) in Germany, and the FMI (Finnish Meteorological Institute) in Finland. Current fields are modeled with the NEMO-Nordic model (Nucleus of European Modeling of the Ocean), which is a three-dimensional circulation model covering the Gulf of Bothnia, the Gulf of Finland, the Baltic Sea, the Sounds, the Kattegat, the Skagerack, the North Sea, and the English Channel. The meteorological model used in Seatrack Web is ECMWF (the European Centre for Medium-Range Weather Forecasts), forecast for 4 days ahead and 6 days backward. The Seatrack Web provides oil spill drift with a time step of 15 min and 2 n.m. spatial resolution.

The oil spreading calculation is added to the currents, as well as oil evaporation, emulsification, sinking, stranding, and dispersion.[30]

The AIS functionality in Seatrack Web is a tool to identify the ship that causes an oil spill. The AIS function gives the ship tracks in the area where the spill was detected and backward to its probable origin. By using the ship tracks simultaneously with the oil tracks, the probability of identifying a suspected ship increases. This powerful system was recommended by HELCOM for operational use in the Baltic countries.[30]

The Seatrack Web model was very useful for ecological risk assessment related to exploitation of the Lukoil D-6 oil platform, which is installed 22.5 km from the Curonian Spit, a UNESCO World Heritage Site. Virtual (simulated) oil spills of 10 m^3 were released daily from the platform for 6 months in order to calculate the shape, direction, distance, and velocity of their drift. Then, all 180 oil tracks were accumulated on one map showing the potential impact of oil pollution in case of an accident at the platform. Statistics, based on daily forecast of the oil spill drift in July–December 2004, shows potential probability (%) of the appearance of an oil spill in any point of the area during 48 hours after an accidental release of 10 m^3 of oil (Figure 5). The probability of the oil spill drift directed to the Curonian Spit (150° sector from D-6) is equal to 67%, but only in half of these cases did oil spills reach the coast due to a coastal current.[18,20] This new technology allowed a quantitative assessment of ecological risks in the whole Baltic Sea.[31]

Later, the same methodology was applied to the risk assessment of the Nord Stream gas pipeline construction and assessment of the impact of oil pollution along the ship routes on the Baltic Sea Marine Protected Areas (BSPAs).[24,31] Figures 6 and 7 show two examples of oil spill drift modeling and a probability of the drift for specific points along main ship routes in the Gulf of Finland and southward of Gotland Island for July and August 2007. Figure 6a shows a drift of a virtual oil spill of 10 m^3 during 48 hours, which

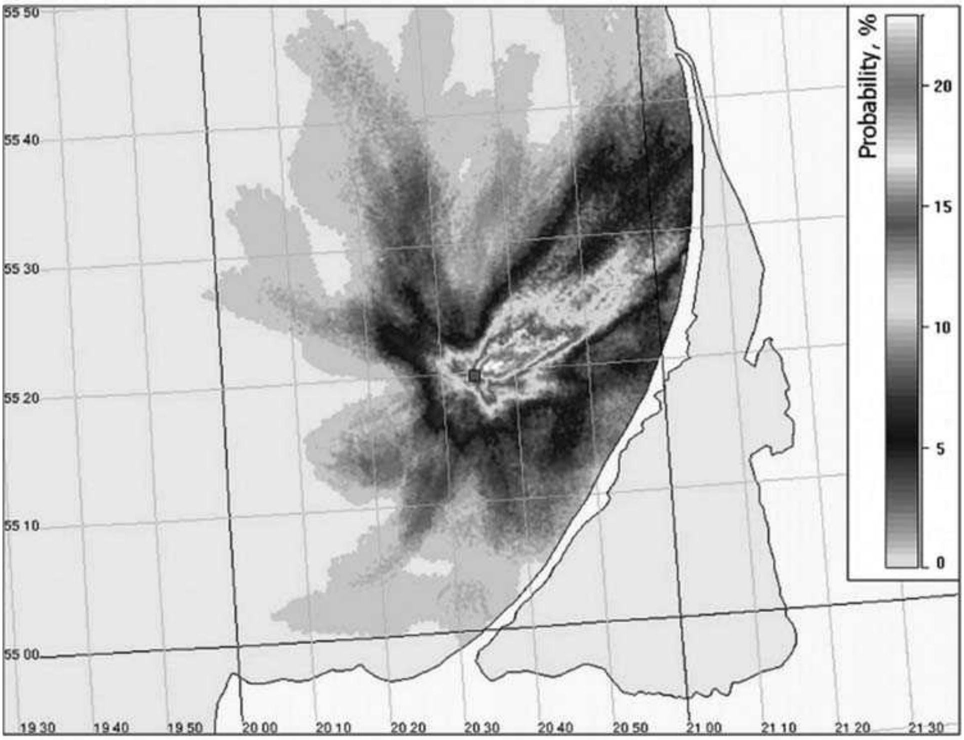

FIGURE 5 Probability of observation of potential oil pollution from the D-6 platform during the first 48 hours after an accidental release of 10 m^3 of oil (based on 6 months daily release of oil spill from the oil platform).

was released on July 23, 2007, at a specific point (red square) of the ship route passing through the Gulf of Finland. The same numerical experiment was performed daily from July 1 to August 31, 2007. Thus, based on the compilation of 62 maps of oil spill drifts, we could construct Figure 6b and calculate a probability of oil spill drift. Figure 6b shows that for this time period, there is no impact of possible oil spill drift on the surrounding BSPAs along the coasts of Finland and Estonia, which are marked by blue and rose colors. This is explained by low wind speed and weak currents observed during July and August 2007. These weather conditions differ from those observed from July 26 to August 15, 2006, when a virtual oil spill could drift 33.5 nautical miles during 2 days with a velocity up to 50 cm/s (Figure 6c). Thus, potential releases of oil spills from the ships may represent a threat to seven protected areas located along the coasts of Finland and Estonia, as well as to the islands and coasts of these Baltic countries. The same dot lies on the trajectory of the Nord Stream gas pipeline (upper line in Figure 6c), which was under construction in the Gulf of Finland since May 2010. Risk assessment for the construction of the gas pipeline was performed using the same methodology in 2006 for seven key points of the pipeline.[32]

Figure 7a shows a simultaneous release of oil from a long part of the ship route located southward of Gotland Island. Figure 7b shows a significant impact of oil pollution produced by this virtual oil release. Both BSPAs were subjected to oil pollution, but at different degrees, so that a quantitative estimation was possible with the help of the Seatrack Web model (Figure 7c and d). For instance, about 60% of the first BSPA and 95% of the second one will be polluted with the indicated probability. In this case, even the coastal zone of Gotland Island was potentially threatened by oil pollution with a clearly calculated probability.[32]

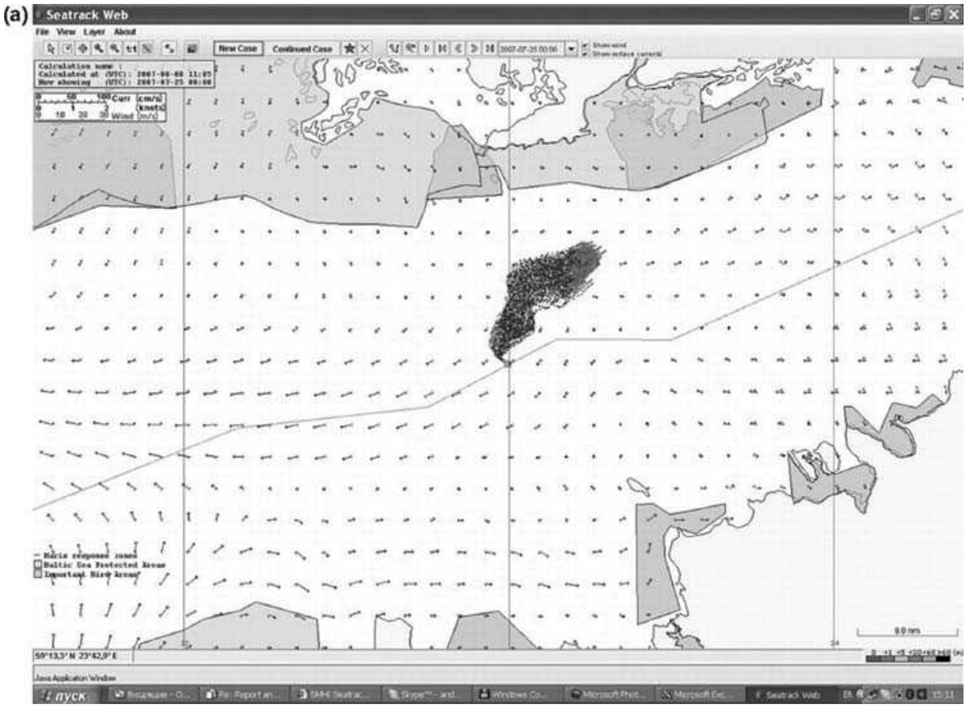

FIGURE 6 Modeling of oil spill drift in the Gulf of Finland. Panel (a) shows oil spill drift on July 23, 2007. Panel (b) shows probability (%) of oil spill drift calculated on the basis of daily modeling at this point for real wind and current conditions in July–August 2007. Panel (c) shows probability (%) of oil spill drift calculated for July 16 to August 15, 2006. BSPAs along the coastlines are shown in light grey color; important bird areas are in grey colors. The lines in panel (a) and (b) show MARIS response zones. The upper line in panel (c) shows approximate position of the Nord Stream gas pipeline, while the lower line is the MARIS response zones.

Problems and Solutions

The main challenge is that the real degree of oil pollution in the Baltic Sea is unknown, because the number of observed oil spills and estimates differ significantly. Partially, this is explained by known differences in aerial surveillance and satellite monitoring. Both methods have their own advantages and limitations and should complement each other. It is clear that statistics on oil spills is not complete and not comparable in different parts of the sea due to different efforts and methods applied for oil pollution monitoring (different number of oil patrol ships, aircraft, and helicopters per country and per unit of the sea area; the number of flight hours per country and unit of the sea area; use of satellites; a number of ASAR/SAR images acquired and analyzed yearly; application of complex satellite monitoring based on the multisensor and multiplatform approach along with the analysis of metocean data; local peculiarities of the water area; and numerical modeling).

For example, since 1993, Russia does not carry out aerial surveillance in the Gulf of Finland and the Southeastern Baltic Sea. The existing satellite monitoring is performed on a regular basis only in the Southeastern Baltic Sea and by a private company, Lukoil-Kaliningradmorneft. According to HELCOM data, since 1994 and 2005, respectively, Lithuania and Latvia seem to have had no regular aerial surveillance of oil pollution. Well-equipped regular aerial surveillance is very expensive, and it is clear that countries in economic recession reduce their aerial and in situ monitoring. Satellite monitoring may partially solve this problem, because satellites cover simultaneously very large areas of the Baltic Sea.

Organization of the Baltic International Satellite Monitoring Center in HELCOM could solve many problems in the operational monitoring of oil pollution in the Baltic Sea.[33] It will:

1. Ensure full and uniform coverage of the Baltic Sea area by remote-sensing control
2. Reinforce aerial surveillance and improve the oil pollution monitoring
3. Establish satellite monitoring for the countries where it is not yet applied

4. Remove duplication of satellite monitoring for the same area performed by neighboring countries
5. Significantly reduce the total cost of operational satellite monitoring for all countries
6. Provide data to all the Baltic Sea States in the same format
7. Solve the problem regarding different technologies, methods, and algorithms used for the analysis of satellite data in different countries
8. Solve the problem of the "night" oil spill pollution that is getting more and more acute
9. Stimulate exchange of data and cooperation between countries
10. Contribute to early warning in case of transboundary oil spill drift
11. Improve the ecological state of the Baltic Sea, coastal zones, and shores of the Baltic Sea States
12. Stimulate organization of analogous operational monitoring centers for the seas with a high density of shipping and/or oil/gas exploration/production industry, i.e., the North Sea, the Mediterranean Sea, the Black Sea, the Caspian Sea, the Gulf of Mexico, etc.

Wide usage of the SMHI Seatrack Web model for oil spill drift forecast is required. Originally, the model was not devoted to the ecological risk assessment, but we found it very useful for this purpose as well.[31] The ecological risk assessment for all ports, oil terminals and platforms, subsurface oil pipelines, ship routes, the Baltic Sea Protected Areas, and any part of the 8000 km long coastline of the Baltic Sea can be performed based on the methodology we elaborated in 2004 and successfully used for Lukoil D-6 oil platform and Nord Stream gas pipeline construction.[18,20,24,31,32] This will quantitatively and precisely reveal the hot spots in the marine area, islands, and coastline of the Baltic Sea that are vulnerable to the impact of the shipping oil pollution. Such a general map of the Baltic Sea with calculated probability for any point of the sea and the coastline to be polluted may serve as a guideline for the Baltic Sea States to improve their monitoring systems.

Conclusions

Oil is a major threat to the Baltic Sea ecosystems. In the last decade, maritime transportation in the Baltic Sea region has been growing steadily, reflecting the intensified trade and oil export. An increase in the number of ships also means that we can expect a larger number of illegal oil discharges. Both oil tankers and all types of ships are responsible for oil pollution of the Baltic Sea. Any discharge into the Baltic Sea of oil, or diluted mixtures containing oil in any form including crude oil, fuel oil, oil sludge, or refined products, is prohibited. This applies to oily water from the machinery spaces of any ship, as well as from ballast or cargo tanks from oil tankers. Every ship entering the Baltic Sea must comply with the antipollution regulations of the Helsinki Convention and MARPOL Convention. Even though strict controls over ships' discharges were established by the Baltic Sea countries, illegal spills and discharges still happen. The number of illegal oil spills has been reduced significantly over the last 30 years, from 763 spills in 1989 to 52 spills in 2017, and this is an evident and positive tendency, resulted from the long-term efforts of HELCOM.[16]

However, the actual total number of oil spills and their volume seem to be unknown because these values contradict significantly (10–20 times) with estimates of different organizations[3,4,6,8] and with the results of complex operational satellite monitoring performed in 2004–2017 in the Southeastern Baltic Sea.[8,21–28] Although the number of observations of illegal oil discharges shows a decreasing trend over the years, it should be kept in mind that for some areas and countries, aerial and satellite surveillance is not evenly and regularly carried out and, therefore there are no reliable figures. We have to add to the uncertainties in the oil pollution statistics considerable seasonal variability in observations of oil spills on the sea surface and predominance of the "night" discharge of oil spills from the ships used to avoid any direct visible evidence of pollution and responsibility for this fact.

So far, as the Baltic Sea ecosystem undergoes increasing human-induced impacts, especially associated with intensifying oil transport and production, further research on the link between physical, chemical, and biological parameters of the ecosystem; the complex monitoring of the Baltic Sea States;

and, especially, oil spill monitoring are of great importance. Oil spill behavior, modeling, prevention, effects, control, and cleanup techniques require supplementary information about a large number of complex physical, chemical, and biological processes and phenomena.

ASAR/SAR satellite imagery provides effective opportunities to monitor oil spills, particularly in the Baltic Sea, as well as in other European seas.[8–11] Combined with satellite remote sensing (AVHRR NOAA, MODIS-*Terra* and -*Aqua*, QuikSCAT, *Jason-1*, etc.), of the SST, sea level, chlorophyll and suspended matter concentration, meso- and small-scale dynamics, and wind and waves, this observational system represents a powerful method for long-term monitoring of the ecological state of semi-enclosed seas especially vulnerable to oil pollution. Our experience in the operational oil pollution monitoring in the Baltic Sea could be easily applied to the Caspian, Black, Mediterranean, and other European seas.

Since 2004, we have elaborated several operational satellite monitoring systems for oil and gas companies in Russia and performed complex satellite monitoring of the ecological state of coastal waters in the Baltic, Black, Caspian, and Mediterranean seas.[24,34] The accident on the BP oil platform "Deepwater Horizon" on April 20, 2010, in the Gulf of Mexico showed that the absence of such a permanent complex satellite monitoring system makes all efforts related to cleaning operations at sea and on the shore during the first weeks after the accident less effective.[35]

A large number of discharges of hydrocarbons that annually take place in European waters, the vast quantity of waste generated by the sea traffic in Europe, the lack of adequate port installations for waste management, and the toxicity of compounds thrown into the sea make solving the chronic hydrocarbon pollution problem a priority for improving the environmental quality of European seas. The growing availability of satellite and sea observation data should encourage interest, involvement, and investment into the complex operational monitoring systems from the side of the state authorities responsible for the environment, pollution control, meteorology, coastal protection, transport, fisheries, and hazard management, as well as from the side of private companies operating in the sea and coastal zone.

Status of Groundwater Arsenic Contamination in the GMB Plain

Abhijit Das, Antara Das, Meenakshi Mukherjee, Bhaskar Das, Subhas Chandra Mukherjee, Shyamapada Pati, Rathindra Nath Dutta, Quazi Quamruzzaman, Khitish Chandra Saha, Mohammad Mahmudur Rahman, Dipankar Chakraborti, and Tarit Roychowdhury

Introduction

During the past few decades with the discovery of newer arsenic sites around the world, high arsenic contamination in drinking water has emerged as a major public health problem. Asian countries, especially the Ganga–Meghna–Brahmaputra (GMB) plain of India and Bangladesh, are the worst affected among the world arsenic scenario. This chapter gives a brief update of the global arsenic contamination situation with a detailed update of arsenic contamination in the GMB plain. It appears that a good portion of all states and countries in the GMB plain, comprising an area of more than 569,749 km^2 and a population of more than 500 million, may be at risk from groundwater arsenic contamination

Background

The natural arsenic content in soil is found at an average value of 5 mg/kg in the range of 1–40 mg/kg.[1,2] Agricultural soils have been detected to contain mean As concentrations in the range of 50–60 mg/kg.[3] Large variations of arsenic content can be found in sediments of lakes, rivers, and streams.[4] In surface water and groundwater not polluted by arsenic, its concentration is 10 μg/L, and in open ocean water, its concentration is typically 1–2 μg/L.[5] Arsenic can be found in inorganic forms of As (III) and As (V). Arsenite [As (III)] is the dominant form under reducing conditions, while arsenate [As (V)] is generally

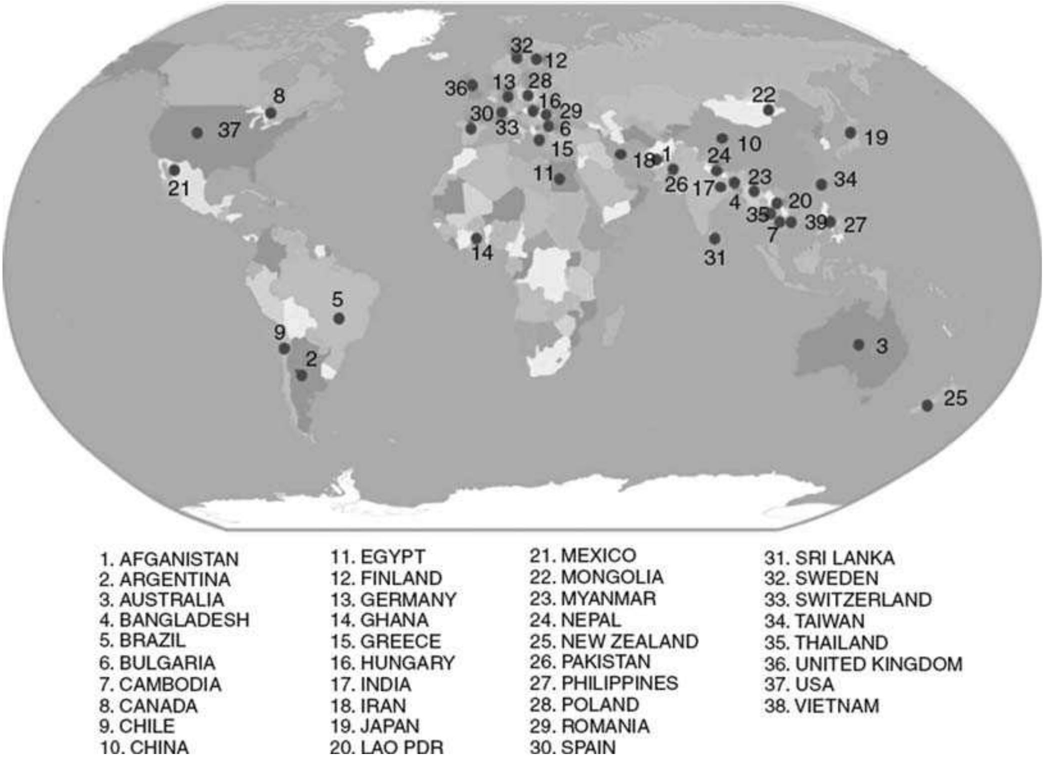

FIGURE 1 Current arsenic contamination scenario around the world.

the stable form of arsenic in oxygenated environments. Presently, there have been 42 incidents of arsenic contamination reported from 38 countries in the world. Figure 1 illustrates the update of these incidents.

However, the magnitude of arsenic contamination is considered highest in the following four Asian countries: Bangladesh, India, China, and Taiwan. Based on the survey carried out over the last 23 years, it can be said that the groundwater of some parts of all the states (Uttar Pradesh, Bihar, Jharkhand, West Bengal, Arunachal Pradesh, and Assam) in GMB plain in India and six out of seven of the northeastern states (all except Mizoram) will be arsenic affected. By the year 2014, the number of states in the pockets of GMB plain where groundwater is reported to be As polluted has increased from seven to ten; Haryana, Punjab, and Karnataka have been added to the abovementioned list of states.[6] Figure 2 shows the arsenic-affected states and countries in the GMB plain. The scenario of groundwater As contamination in the affected states in India is given in detail in Table 1.

Groundwater Arsenic Contamination in West Bengal, India

The severity of Arsenic pollution in groundwater of the districts was categorized into severely affected (>300 μg/L), mildly affected (10–50 μg/L) and unaffected (<10 μg/L).[6] The districts of Maldah, Murshidabad, Nadia, North 24 Parganas, South 24 Parganas, Bardhaman, Howrah, Hugli, and Kolkata are the nine affected districts. During the last 20 years, SOES analyzed 140,150 hand tube-well water samples for the presence of arsenic above the WHO's recommended level from the aforementioned nine districts of West Bengal.[7] From the findings, it was observed that 49.7% of these tube wells had arsenic >10 μg/L, 24.7% had arsenic >50 μg/L, and 3.4% of the analyzed tube wells had arsenic concentrations >300 μg/L (the concentration predicting overt arsenical skin lesions).[8] A maximum arsenic concentration of 3700 μg/L was found in the Ramnagar village of Gram Panchayat (GP) Ramnagar II,

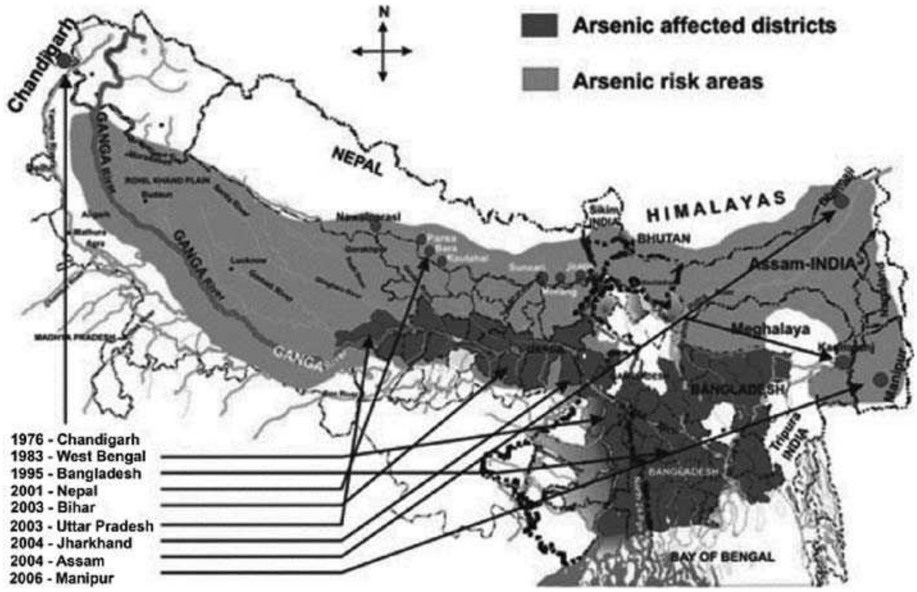

FIGURE 2 Groundwater arsenic contamination situation in India and Bangladesh in the GMB plain.

TABLE 1 Groundwater Arsenic Contamination in India[24,25]

S. No.	Name of the States	Name of the Districts	Level of As Contamination (μg/L)
1	West Bengal	Maldah, Murshidabad, Nadia, North 24 Parganas, South 24 Parganas, Bardhaman, Howrah, Hugli, and Kolkata	50–3700
2	Bihar	Darbhanga, Katihar, Khagaria, Kishanganj, Lakhisarai, Munger, Patna, Purnea, Samastipur, Saran, Vaishali, Begusarai, Bhagalpur, Bhojpur, Buxar	>50
3	Uttar Pradesh	Bahraich, Balia, Balrampur, Bareilly, Basti, Bijnor, Chandauli, Ghazipur, Gonda, Gorakhpur, Lakhimpur Kheri, Meerut, Mirzapur, Moradabad, Raebareli, Sant Kabir Nagar, Shahjahanpur, Siddharthnagar, Sant Ravidas Nagar, Unnao	>50
4	Jharkhand	Sahibgunj	>50
5	Assam	Sivasagar, Jorhat, Golaghat, Sonitpur, Lakhimpur, Dhemaji, Hailakandi, Karimganj, Cachar, Barpeta, Bongaigaon, Goalpara, Dhubri, Nalbari, Nagaon, Morigaon, Darrang, and Baksha	50–657
6	Chhattisgarh	Rajnandgaon	52–88
7	Haryana	Ambala, Bhiwani, Faridabad, Fatehabad, Hissar, Jhajjar, Jind, Karnal, Panipat, Rohtak, Sirsa, Sonepat, Yamunanagar	>50
8	Karnataka	Raichur and Yadgir	>50
9	Punjab	Mansa, Amritsar, Gurdaspur, Hoshiarpur, Kapurthala, Ropar etc.	>50
10	Manipur	Bishnupur and Thoubal	798–986
11	Tripura	North Tripura, Dhalai, West Tripura	65–444
12	Nagaland	Mokokchung and Mon	>50

Baruipur block in South 24 Parganas district. Groundwater arsenic contamination in all the districts of West Bengal is shown in Figure 3. The United Nations Children's Fund (UNICEF) collaborated with the Public Health Engineering Department (PHED), Government of West Bengal. They tested 132,262 government-installed hand tube wells and private tube wells for arsenic from eight arsenic-affected districts of West Bengal.[9] Those tube wells that have water with an arsenic concentration >10 μg/L account for 57.9% of the tested hand tube wells; similarly, 25.5% of the tested hand tube wells contained water that has arsenic concentration >50 μg/L. It is estimated that about 9.5 million people could be drinking water contaminated with an arsenic level of 10 μg/L. A recent study on Nadia, West Bengal reported that all the 17 blocks are affected with arsenic in groundwater. It has been found that about 51.4% and 17.3% of the tube wells had As >10 and 50 μg/L, respectively. The maximum observed level of arsenic in

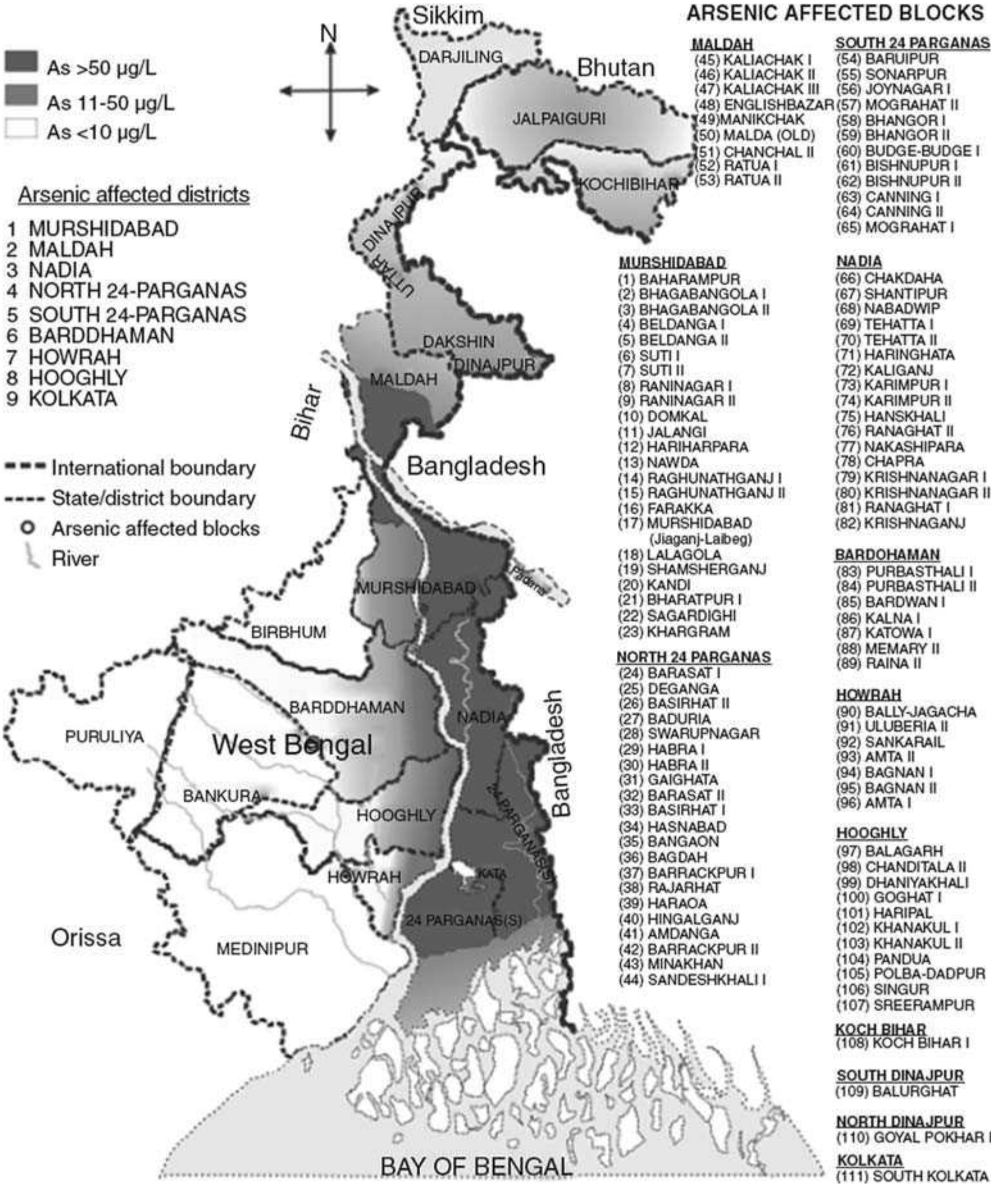

FIGURE 3 Present groundwater arsenic contamination situation in the state of West Bengal in India.

groundwater is found to be 3200 μg/L.[10] Chakdah is one of the worst affected blocks in Nadia where the shallow aquifers as well as the agricultural land show a high magnitude of arsenic content. According to a survey carried out in the nine districts, out of 135,555 samples of groundwater pumped up by tube well, As concentration of above 10 μg/L was reported in 67,306 (49.7%) samples and above 50 μg/L in 33,470 (24.7%) samples. In affected areas, the demographic survey showed that 13.85 million people were under the threat of As concentration above 10 μg/L of which 6.96 million people are exposed to a concentration above 50 μg/L.[11]

Groundwater Arsenic Contamination in Kolkata, India

The present demand of drinking water in Kolkata per day is around 1262 million liters per day (MLD) which is supplied through the pipelines laid down by Metropolitan authority. Out of that, 1096 MLD is treated surface water and the rest is groundwater. A total of 3626 samples of hand tube-well water was collected from 100 out of 141 administrative wards in Kolkata. Tube wells in 65 wards in Kolkata have arsenic concentration levels >10 μg/L, and in another 30 wards, arsenic concentration was found to be >50 μg/L. Based on water samples from 1057 wells, dug deeper than 100 m, 220 samples (20.8%) have shown arsenic concentrations >10 μg/L, 113 samples (10.7%) have arsenic concentrations >50 μg/L, and 72 samples (6.8%) have arsenic concentrations >100 μg/L. Water samples were collected from 977 wells that were 91–100 m deep. Of 977 samples, 149 (15.3%) have arsenic concentrations >10 μg/L and 13 (1.3%) have arsenic concentrations >100 μg/L. However, the tube wells that were deeper than 300 m have been detected with arsenic concentrations >50 μg/L. Maximum arsenic concentration in this region was found to be at 800 μg/L at a depth of 20 m. An analysis of water from these Kolkata Municipal Corporation (KMC) wells shows that out of 734 wells, 121 (16.5%) have arsenic concentrations >10 μg/L, 26 (3.6%) have arsenic concentrations of 50 μg/L, and only 2 (0.2%) have arsenic concentrations >300 μg/L. It has also been found that the southern part of the city is more contaminated by arsenic than the northern and central parts (Figure 4).

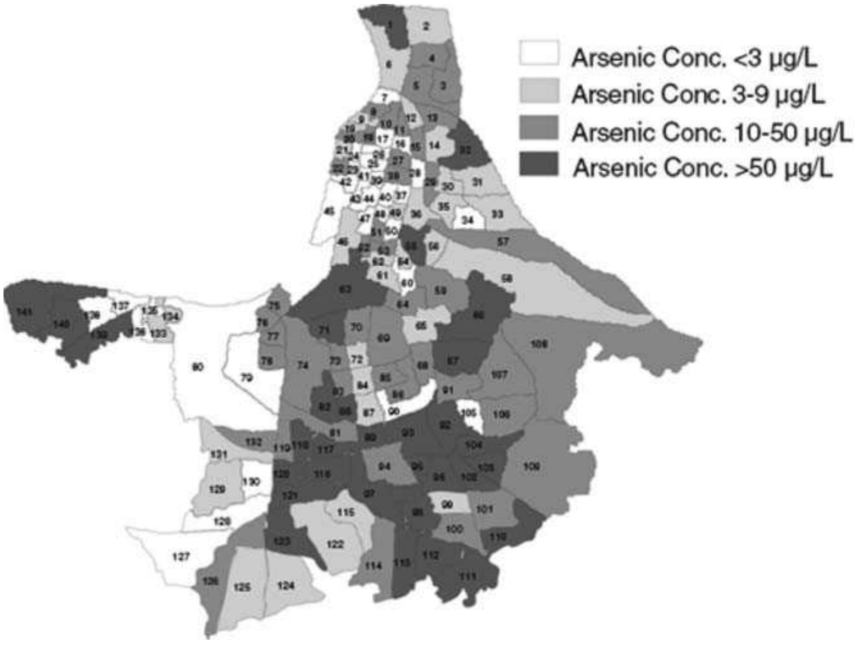

FIGURE 4 Present groundwater arsenic contamination situation in all the 141 wards of KMC, West Bengal.

At present in Kolkata, 70% of KMC area, i.e., 100 out of 144 wards, has been reported with As concentration above permissible limit in shallow unconfined aquifers with 51 wards (i.e. 35.4%) having As concentration >50 μg/L and remaining 49 wards having As concentration between 11 and 50 μg/L.[12] During the past 23 years, 14.2% of samples throughout 77 wards in KMC, exceeded the permissible limit of As in drinking water and around 5.2% samples in 37 wards showed five times higher value of the permissible limit of As in drinking water.[13]

Groundwater Arsenic Contamination in Bihar, India

Water samples from 19,961 tube wells were analyzed, and arsenic content in water samples was found to be >50 μg/L in 12 districts of Bihar. SOES's analysis of water samples from these tube wells revealed that 313 villages have water containing arsenic concentrations >10 μg/L and 240 villages have water containing arsenic concentrations >50 μg/L. Analytical results show that 32.7% of tube wells in that region have concentrations >10 μg/L, 17.75% tube wells have arsenic concentrations >50 μg/L, and 4.55% have arsenic concentrations >300 μg/L. The maximum arsenic concentration was found in the Chakani village of Brahampur GP belonging to the Barahara block of Buxar district. The level of arsenic concentration in its tube well's water is 2182 μg/L. In the two districts of Bihar, Vaishali, and Bhagalpur were reported to have arsenic contamination in groundwater where the maximum arsenic concentration was found to be 20 and 143 μg/L, respectively; 73% of the groundwater samples showed As (III)-dominant species whereas 27% showed As (V). Katihar being the most vulnerable district because of the socioeconomic and biophysical conditions needs a serious concern followed by Vaishali, Samastipur, Khagaria, and Purnia. They investigated 17 districts out of 37 and a total of 87 of 532 community blocks for groundwater arsenic contamination where 72 community blocks are reported with arsenic beyond permissible limit in drinking water.[14] On a further analysis by SOES, Jadavpur, it has been observed that on analysis of 4704 tube-well water samples from all 88 villages of Shahpur block of the district Bhojpur of Bihar, India, 21.1% of water samples is contaminated with arsenic >50 μg/L according to BIS, 2009, whereas nearly 40.3% of water samples is found containing arsenic >10 μg/L (WHO, 2004). The mean and maximum arsenic concentration is found to be 43.5 and 1805 μg/L, respectively.

Groundwater Arsenic Contamination in Uttar Pradesh, India

It was perceived in 2003 that UP is arsenic contaminated.[15] The rural population of the Allahabad district and the urban population of Shuklaganj-Kanpur of the Unnao district in the Allahabad-Kanpur track of the upper Ganga plain first reported cases of arsenic contamination in 49 districts in January 2009.[16] A recent report[11] showed that in a survey done in 2003 in 25 villages of Ballia district, Ghazipur, and Varanasi were added making a total of 20 districts affected by As where the people mostly depended on water from hand pumps which pumped the groundwater from shallow aquifers (20 m deep). Furthermore, it was reported[17] that only 3 out of 72 samples had As concentration <10 μg/L, while 95.83% had As concentration above the permissible limit. The maximum As concentration in the samples collected during pre-monsoon and monsoon was reported to be 75.6 and 74.46 μg/L, respectively. A total of 136 groundwater samples were collected and analyzed from 12 villages on the floodplain of the Rapti River. About 42% of 103 samples collected from nine villages situated on the left bank were reported to have As concentration >10 μg/L with maximum concentration of 399 μg/L while none of the samples collected from the three villages situated on the right bank had As concentration above the permissible limit.[18] On analyzing 5044 water samples from five districts of UP, SOES found 43.1% of those samples to have arsenic concentrations >10 μg/L and 27.5% to have arsenic concentrations >50 μg/L.

Groundwater Arsenic Contamination in Jharkhand, India

In this state, there are only three districts affected by arsenic concentration.[19] It was observed that the groundwater As concentration in Sahibganj district during three seasons was highest in post-monsoon ranging between 1 and 133 μg/L compared to (2–98 μg/L) in monsoon and (7–115 μg/L) in pre-monsoon with the trend of As concentration increasing with depth.[20] SOES has conducted several surveys in the nine blocks of the Sahibganj district (in the middle of Ganga plain) from December 2003 till now, where they have analyzed 3832 hand tube-well water samples for arsenic concentration. The findings suggest that 32.28% of the water samples had arsenic concentrations >10 μg/L, 13.44% contained arsenic concentrations >50 μg/L, and 2.61% had arsenic concentrations >300 μg/L. The highest arsenic concentration in water has been detected in the Hajipur Vitta village of Hajipur Porsun GP, Sahibganj block, in the Sahibganj district of Jharkhand. The amount of arsenic concentration found in the water sample from that region is 1018 μg/L.

Groundwater Arsenic Contamination in Assam, India

Dhemaji and Karimganj in Assam have been surveyed for groundwater arsenic contamination, and both have been found arsenic contaminated in January 2004. So far, water samples from 241 hand tube wells have been analyzed for arsenic contamination from these two districts, and it has been found that 42.3% of these samples have arsenic concentrations >10 μg/L and 19.1% of these samples have arsenic concentrations >50 μg/L.

A total of 27 villages have been identified from these two districts where groundwater arsenic concentrations are above 50 μg/L. Initially, As concentration >50 μg/L was found in a few samples of groundwater collected from Karimganj, Dhubri, and Dhemaji districts. Eighteen out of twenty three districts covering 76 blocks, and a population of 603 are reported to be affected by As toxicity according to a new report by UNICEF.[11] A work in 2014 reported that the mean As concentration in the groundwater of Titabor, Jorhat, Assam is 210 μg/L.[21] It was also noticed that among the six blocks of Golaghat district, Assam, the most severely affected area was Gamariguri block, where 100% of the samples had an As concentration >10 μg/L. The other blocks were also badly affected showing arsenic contamination in groundwater by 87.5%, 71.9%, 42.4%, 42.1%, and 36.4% in the blocks Podumoni, Kathalguri, Dergaon, Morangi, and Kakodonga, respectively.[22]

Groundwater Arsenic Contamination in Manipur, India

Since the preliminary study in Manipur in May 2006, SOES confirmed groundwater arsenic contamination in two districts of Manipur. They are the districts of Thoubal and Imphal. Findings suggest that 41.27% of the collected and analyzed samples have arsenic concentrations >50 μg/L and 64.72% of the samples have arsenic concentrations >10 μg/L. After the preliminary study by SOES in 2006, again 628 water samples of tube wells were analyzed in the Manipur valley which consists of four districts, where 63.3% sample holds arsenic concentration in groundwater >10 μg/L. Among the four districts, Thoubal is the most affected one where 77.6% groundwater contains arsenic >10 μg/L.[23]

Apart from Assam and Manipur, the other north-eastern states like Arunachal Pradesh, Nagaland, and Tripura are also reported with high range of arsenic contamination in groundwater (50–986 μg/L).

Groundwater Arsenic Contamination in Haryana, India

The districts on the banks of Yamuna, originating from Himalaya, and its tributaries are covered by alluvial aquifers resulting in groundwater contamination due to mobilization of As from As-containing minerals. The alluvial sediments are the main source of As in the sporadic region. Under Aquifer Mapping Project, 2013, groundwater As concentration >50 μg/L has been reported in Chandigarh.[11]

Groundwater Arsenic Contamination in Punjab, India

In 2004, 261 shallow groundwater samples were analyzed to find As concentration more than 10 μg/L in 12 districts including Ropar, Amritsar, Hoshiarpur, Gurdaspur, and Kapurthala. In July 2010, out of 105 samples collected from the district of Mansa at a depth ranging from 13 to 35 m, six locations were reported with As concentration more than 10 μg/L.[11]

Groundwater Arsenic Contamination in Bangladesh

In International Conference on Arsenic, Dhaka, held in 1998, it was reported that 66% of water from hand tube wells from Bangladesh contain arsenic concentrations >10 μg/L and 51% have arsenic concentration levels >50 μg/L. The researchers also said that the arsenic detected in the groundwater of 52 districts is >10 μg/L and that in 41 districts is >50 μg/L.[26] In surveys carried out by the British Geological Survey (BGS) along with the Department of Public Health Engineering (DPHE), it was further reported that water samples from 46% of 3534 analyzed tube wells exceeded arsenic concentrations of 10 μg/L and 27% of the samples exceeded arsenic concentration levels of 50 μg/L. This survey had taken samples from tube wells from all over Bangladesh, leaving out the Chittagong Hill tract. Based on their study, BGS-DPHE reported that 57 million and 35 million people could be drinking As-contaminated water >10 μg/L and 50 μg/L, respectively.[27] Between 2000 and 2001, half of 6500 tube wells were sampled for testing by Van Geen in the Araihazar Police Station, which is known as Thana/Upazila. It was found that half of these water samples contain arsenic with concentrations >10 μg/L and one-quarter of these samples contain arsenic concentrations >50 μg/L.[28] It can be found from this database that 1.4 million out of 4.8 million water samples, which is 30% of the water samples in Bangladesh, contain arsenic concentrations >50 μg/L.[29]

The important incidents related to groundwater arsenic contamination in the GMB plain are shown in Table 2.

Bangladesh can be divided into four existing geomorphological regions of which the hill tract and the tableland are free from arsenic contamination. The highly contaminated regions of Bangladesh fall within the deltaic region (Figure 5).

Arsenic content in water in the tableland area (detected in 17 out of 9755 analyzed hand tube wells, which is 0.2%) is >50 μg/L. In another 204 out of the total of 9755, which is 2.1%, arsenic concentration was found between 10 and 50 μg/L. In the floodplain region of Bangladesh, there are 229 thanas in total. Out of these, 19,845 water samples were collected from 158 thanas and were analyzed which suggest that 50.8% of these samples have arsenic concentrations greater than 10 μg/L and another 34.9% of the samples have arsenic concentrations >50 μg/L. Another survey by BGS-DPHE in 1999 has brought out data that indicate that 4587 out of 16,513 (27.8%) of the water samples analyzed have shown concentrations of arsenic >50 μg/L. This survey was also held in the same region. A total of 22,113 water samples from hand tube wells in the deltaic region including the coastal belt were taken for analysis. These samples were collected from 97 of the 139 thanas in that region. On analysis, it was found that 54.7% of the samples have arsenic concentrations >10 μg/L and 32.8% >50 μg/L. In 1999, BGS-DPHE also reported about 12,245 water samples from 126 thanas of this region. A total of 3344 samples (27.5%) have arsenic concentrations >50 μg/L. The study had only collected samples from Chittagong and Cox's Bazar districts. The percentage of samples that have arsenic concentrations >1000 μg/L in the floodplains is 1.14% (227 samples), which is greater than % found in the deltaic region, which is 0.33% (74 samples). Shallow tube wells varying in depth from 10 to 70 m are highly contaminated compared to deep aquifers leading to Arsenic contamination in 61 out of 65 districts of Bangladesh.[30] The maximum arsenic concentration found in the three regions are 134, 4730, and 2190 μg/L, respectively ($n = 9755$, 19,845 and 22,113, respectively). Groundwater As contamination in different areas of Bangladesh reported so far has been given in Table 3.

TABLE 2 Groundwater Arsenic Contamination in India and Bangladesh (September 2010)

Parameters	West Bengal	Bihar	UP	Jharkhand (Sahibganj)	Assam	Manipur	Chhattisgarh (Rajnandgaon)	Bangladesh
Area (km^2)	88,750	94,163	238,000	1,600	78,438	22,327	6,396	147,570
Population (in millions)	80.2	83	166	1	26.6	2.29	1.5	124.3
Arsenic-affected area (km^2)	38,861	21,271	17,919	725	8,822	2,238	6,396	
Total arsenic-affected districts (As > 50 μg/L)	12	12	5	1	3	4	1	50
Total arsenic-affected blocks/PS (As >50 μg/L)	111	36	9	3	9	–	–	197
No. of villages where groundwater arsenic >50 μg/L	3417	235	70	68	–	–	–	–
Total hand tube-well water samples analyzed	140,231	19,961	5,044	3,354	1,448	628	146	52,202
% of samples having arsenic >10 μg/L	48.1	32.70	46.1	36.1	39.0	63.3	25.34	43.0
% of samples having arsenic >50 μg/L	23.8	17.75	26.9	15.4	13.81	23.2	8.22	27.2
Total number of biological samples analyzed (hair, nail, urine)	39,624	1,833	258	367		57 (urine)		11,298
Total people screened by SOES-JU	96,000	3,012	989	522	–	–	a	18,991
People registered with arsenical skin lesions	9,356	457	154	71	–	–	80	3,762
People drinking arsenic-contaminated water >10 μg/L (in millions)	9.5	3.1	1.1	0.15				36.6
People drinking arsenic-contaminated water >50 μg/L (in millions)	4.6	1.7	0.6	0.06				22.7
Population potentially at risk from arsenic contamination >10 μg/L (in millions)	26	9	3	0.4	1.2	1		

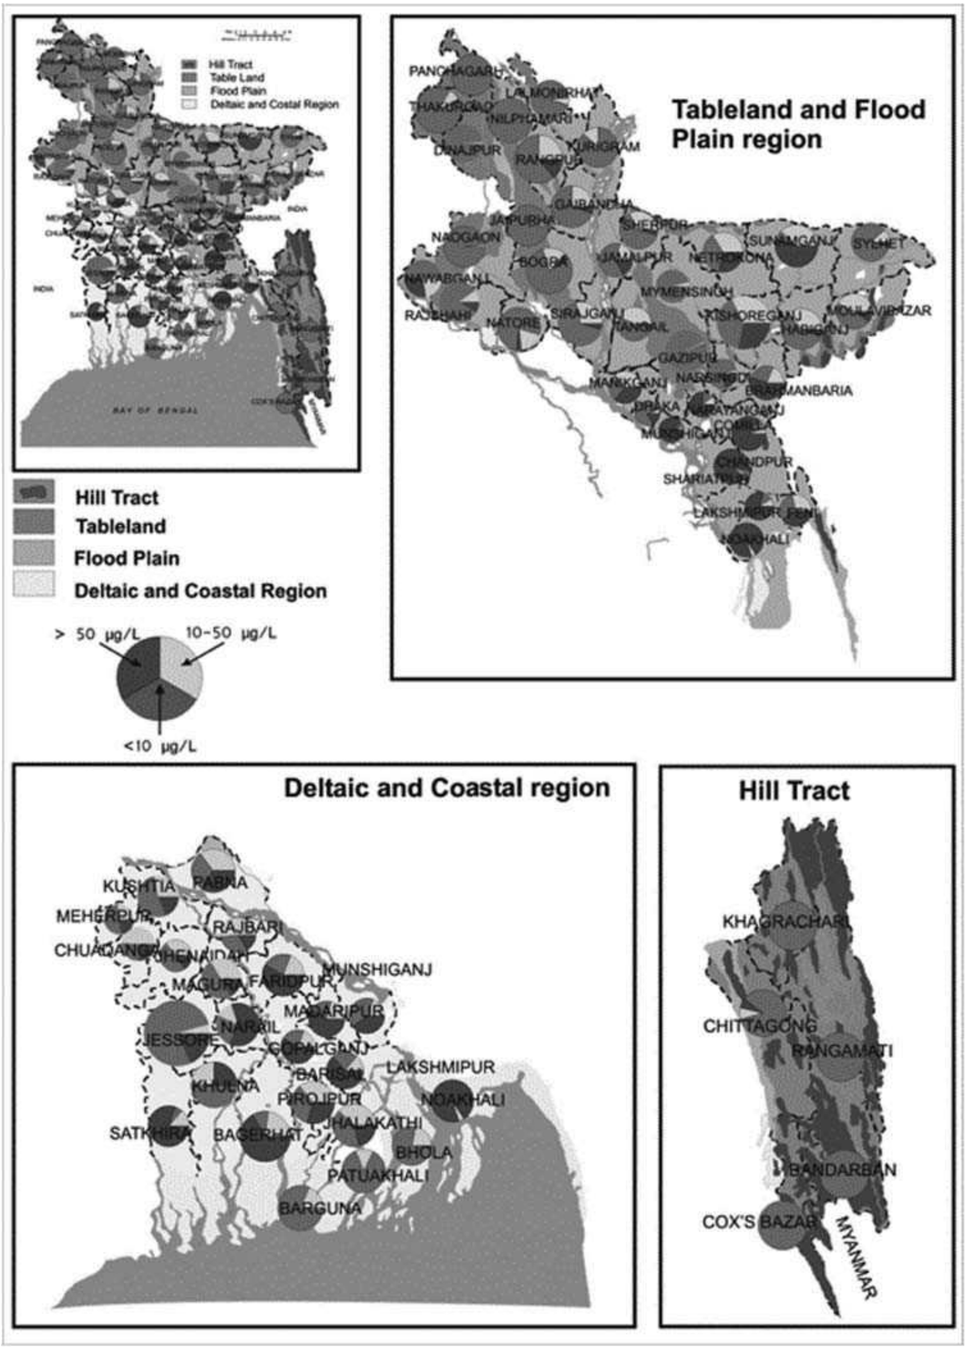

FIGURE 5 Status of As contamination in groundwater in Bangladesh.[26]

Bangladesh and West Bengal are considered the two worst arsenic-affected areas in the world. In Bangladesh, 42.1%, 27.2%, and 7.5% of the hand tube wells had As 10, 50, and 300 μg/L, respectively, whereas in West Bengal, the corresponding values were 48.1%, 23.8%, and 3.3%. SOES has detected 301—(0.6%) hand tube-well water samples with arsenic concentrations >1000 μg/L in Bangladesh, whereas 187 (0.1%) water samples had arsenic concentrations >1000 μg/L in West Bengal.

TABLE 3 Arsenic Contamination Scenario in Groundwater of Bangladesh

S. No.	Cases of As Contamination Reported	Reference
1	Groundwater of 47 districts was reported to be As contaminated on the basis of 22,003 tube-well water samples collected over 64 districts and 6000 samples which were collected over 25 km^2 area and reported to have As concentration exceeding the Bangladesh drinking water standard of 50 μg/L	[31]
2	1,00,000 tube wells in Chandpur	[32]
3	Groundwater As concentration varies from 6 to 934 μg/L with an average of 347 μg/L in Meghna river delta	[33]
4	As concentration >50 μg/L found in 27.2% of 5202 water samples collected from 64 districts	[34]
5	60% tube wells are severely affected in southern and eastern Bangladesh with a maximum concentration of 1000 μg/L	[35–37]

Conclusion

The situation of As contamination has been deteriorating ever since the first evidence of As in Asian countries such as India, Bangladesh, China, Nepal, Taiwan, and Vietnam as well as Mexico, Argentina, etc. Besides the geogenic cause, excessive withdrawal of groundwater to satisfy the increasing demand of the growing population has played an important role in groundwater As pollution. In spite of several mitigation strategies already undertaken, the global situation is even worse than before due to lack of awareness and insufficient steps taken to deal with the problem in domestic level. Since the toxicity of As is directly dependent on the nutritional status as well as economic condition of the people, efforts should be made to improve the condition at ground level.

Yellow River

Zixi Zhu, Ynuzhang Wang, and Yifei Zhu

Introduction

Since 1949, China has made unremitting efforts to harness the Yellow River. A number of water control projects were undertaken, hydropower stations had been built, and the dykes in the lower reaches had been strengthened and heightened. The eroded land on the Loess Plateau had been harnessed and water and soil loss was restricted. Soil and water conservation improved both agricultural production conditions and the ecological environment. Since 1949, the Yellow River has never been breached, thus ensuring the safety of its people and property and promoting the development of economy and society.

Discussion

The Yellow River originates from the Yueguzonglie Basin, which has an elevation of 4500 m and is located at the northern slope of the Bayankera Mountain in the Qinghai–Tibet Plateau. From west to east, it flows through nine provinces/autonomous regions: Qinghai, Sichuan, Gansu, Ningxia, Inner Mongolia, Shanxi, Shaanxi, Henan, and Shandong, and empties into the Bohai Sea in Kenli County, Shandong Province. The trunk is 5464 km in length and the basin area is 795,000 km^2. Within the river basin, the population is 110.08 million, accounting for 8.7% of the total population in China; the cultivated land is 13.1 million ha.[1] The Yellow River basin is the cradle of Chinese nationality and the birthplace of ancient Chinese civilization. As early as 1 million years ago, the "Lantian Man" had been living in the Yellow River Basin. In this very long historical period, the basin was the center of politics, economy, and culture in China.

The terrain of the Yellow River basin is high in the west and low in the east, thus showing great disparity. The west section of the basin belongs to the Qinghai–Tibet Plateau with an elevation of 3000–5000 m. The middle section is mostly located in the Loess Plateau and reaches the east side of Taihang Mountain, with an elevation of 1000–2000 m. The east section starts from east of Taihang Mountain and ends at the Bohai Sea, lying in the Huanghuaihai Plain, with an elevation of lower than 100 m.[1] Based on the geographical position and the feature of the river, the trunk stream of the Yellow River can be divided into upper, middle, and lower reaches. The upper reaches are from the source of the river to Hekouzhen (Tuoketuo county) in Inner Mongolia, with length of 3472 km and area of 428,000 km^2. The middle reaches are from Hekouzhen, then extend to Taohuayu (Zhengzhou) of Henan province, comprising 1206 km in length and 344,000 km^2 in area. Starting from Taohuayu, the lower reaches run through nearly 800 km, occupy 23,000 km^2 of area, and end at the mouth of the river.[1] Because of the height difference, the climate in the Yellow River basin is very distinct, ranging from arid climate in the west through semiarid to semihumid climate in the east. Average annual temperature is −4°C at the source, 1–8°C in the upper reaches, 8–12°C in the middle reaches, and 12–14°C in the lower reaches. The average annual precipitation of the basin is 452 mm. The maximum is in the southeast part of the basin, reaching 800–1000 mm; whereas the minimum annual precipitation is less than 200 mm in the northwest part of the basin, including Ningxia and Inner Mongolia, which features the inland climate.[1] The Yellow River basin is rich in mineral and energy resources that are of great importance in China. Out of the 45 proved major mineral resources in China, 37 are found in the Yellow River basin.[1] The water energy in the upper-middle reaches of Yellow River, the coal in the middle reaches, and the oil and natural gas in the middle-lower reaches are all quite rich in deposits. Thus the Yellow River basin is called the "energy resources basin," playing an important role in China.[1]

The Yellow River provides the major water resource for northwest and north China, but the amount is comparatively poor. The average annual runoff in the basin is 58 billion m^3, making up only 2% of that in China, whereas the area of the Yellow River basin accounts for 8.3% of the land area of the country.[1] The distributions of runoff in different areas are different. Annual runoff in the upper, middle, and lower reaches contributes 55.6%, 40.8%, and 4.6% of the total annual runoff, respectively. It also varies with seasons. More than 60% of the annual runoff happens during the period from July to October, while less than 40% occurs from November to June.[1] The Yellow River basin is an important production area in agriculture. The main crops are wheat, cotton, oil-bearing plants, tobacco, etc. The irrigation area along the Yellow River basin is about 7.3 million ha,[2] most of which is in the Ningxia–Inner Mongolia Plain at the upper reaches, Fen-Wei basin at the middle reaches, and the irrigation area drawing water from the Yellow River at the lower reaches. Agricultural irrigation consumes 28.4 billion m^3 of water from the Yellow River annually, accounting for 92% of the overall annual water consumption of the river.[2] With high-speed development of the economy and continued population growth, water consumption has increased rapidly and the competition between water supply and demand has become more acute. As a result, zero flow in the lower reaches has resulted in recent years. From 1972 through 1998, zero flow occurred in 21years with accumulated duration of 1051 days. The worst was in 1997, when Lijin, near the river mouth, had zero flow for 226 days; the zero-flow section extended upstream even to Kaifeng of Henan Province.[2]

The Yellow River flows through the Loess Plateau, where the surface is characterized by loose soil and sparse vegetation, and the climate is dominated by dry weather and heavy storms concentrated mostly in the summer. Therefore, it is the largest area affected by water and soil loss and the strongest intensity in erosion in China. Based on the data collected by remote sensor in 1990, the area experiencing water loss and soil erosion is up to 454,000 km^2, which makes up 70.9% of the Loess Plateau's area. The area of water erosion with the annual erosion mean exceeding 8000 Mg/km^2 is 85,000 km^2, accounting for 64% of the congener area in China. The severe water degradation area with annual erosion mean exceeding 15,000 Mg/km^2 is 36,700 km^2, about 89% of the congener area.[1] Average annual amount of sediment and sand washed into the river is about 1.6 billion Mg with sand content of 35 kg/m^3. The maximum sand content is 933 kg/m^3, which was measured at Longmen on July 18, 1966.[3] In the lower reaches of the Yellow River, a large amount of sediment is left behind to raise the riverbed. Nearly 9.2 billion Mg of sediment were deposited in the lower reaches of the Yellow River from 1950 through 1998. Thus, the riverbed is 4–6 m higher than the ground outside the river on an average. At some places, this number could even reach 10 m or more.[2] For this reason, the lower reaches of the Yellow River are called the "suspended river." Because of rainstorms occurring in the middle reaches and the channel in the lower reaches being wider in the upper part and narrower in the lower part, the lower reach area frequently suffers from heavy floods. Records indicated that from 602 BC to 1949 AD, the Yellow River was breached 1590 times and changed its route 26 times, i.e., on the average, "breach twice every three years and changing its route every century."[4] Heavy floods affected a large area from Tianjin City in the north to Huaihe River in the south, crossing 250,000 km^2. On the other hand, drought is another disaster that occurs frequently in the Yellow River basin. In 582 years from 1368 to 1949, severe drought occurred in 107 years, once every 5.4 years.[5] Records show that an extraordinarily serious drought lasted 4 years, from 1875 to 1878, through the whole basin of the Yellow River.

Harnessing of the Yellow River has always been a major issue concerning China's prosperity and the people's peaceful life. Since 1949, China has made unremitting efforts to harness the Yellow River and, therefore, ensured the safety of its people and property, promoted the development of economy and society, and improved the ecological environment. On the trunk of the Yellow River, 15 key water control projects and hydropower stations have been built or are being built, providing a total water capacity of 56.6 billion m^3, a total installed capacity of 11.13 million kW, and an average annual power supply of 40.1 billion kWh.[2] By the end of 2000, 1400 km of dykes along the lower reaches had been strengthened and heightened four times. Large-scale channel improvement had been performed. Reservoirs exceeding 10,000 in number and in different sizes have been built, with a total storage capacity of 72 billion m^3. Among them, 22 of the largest reservoirs are able to hold 61.7 billion m^3 of water.[2] Other projects for irrigation and water supply had also been accomplished and the groundwater had begun to be developed. As a result, the irrigation area has increased from 0.8 million ha in 1950 to 7.3 million ha now, including 2.4 million ha that are located outside of the basin.[2] Until 2000, the area of 180,000 km^2 of eroded land on the Loess Plateau, which is one-third of the land with soil erosion, had been harnessed. To some extent, water and soil loss and desertification have been restricted. The amount of sediment and sand being washed into the Yellow River each year had decreased by about 300 million Mg.[2] Soil and water conservation improved the agricultural production condition and ecological environment. By taking these measures, the average annual grain yield has increased by more than 5 billion kg, which can provide enough food and clothing for more than 10 million people.[2] Since 1949, the Yellow River has never been breached, even when heavy flood with flow of 22,300 m^3/sec occurred in July of 1958.[3]

Conclusion

Compared with other rivers in China, the Yellow River is characterized by shortage of water, high content of sand, and serious loss of water and soil. Average annual runoff is only 58 billion m^3, taking up only 2% of that in China, and annual amount of sediment and sand washed into the river is about 1.6 billion Mg with sand content of 35 kg/m^3. The riverbed in lower reaches is 4–6 m higher than the ground outside the river on average. Floods and droughts are two major disasters in the Yellow River basin. Breach occurred frequently in its history. The Chinese government has made great efforts to harness the river. A number of water control projects have been undertaken, hydropower stations have been built, and dykes in the lower reaches had been strengthened and heightened. To a certain extent, the eroded land on the Loess Plateau had been harnessed and water and soil loss was restricted. The implementation of the great-development-of-the-west strategy of China will further prompt the harnessing and exploitation of the Yellow River along with the development of economy and society.

Groundwater: Modeling

Jesus Carrera

Introduction

A model is an entity built to reproduce some aspect of the behavior of a natural system. In the context of groundwater, aspects to be reproduced may include: groundwater flow (heads, water velocities, etc.); solute transport (concentrations, solute fluxes, etc.); reactive transport (concentrations of chemical species reacting among themselves and with the solid matrix, minerals dissolving or precipitating, etc.); multiphase flow (fractions of water, air, non-aqueous phase liquids, etc.); energy (soil temperature, surface radiation, etc.); and so forth.

Depending on the type of description of reality that one is seeking (qualitative or quantitative), models can be classified as conceptual or mathematical. A conceptual model is a qualitative description of "some aspect of the behavior of a natural system." This description is usually verbal, but may also be accompanied by figures and graphs. In the groundwater flow context, a conceptual model involves defining the origin of water (areas and processes of recharge) and the way it flows through and exits the aquifer. In contrast, a mathematical model is an abstract description (abstract in the sense that it is based on variables, equations, and the like) of "some aspect of the behavior of a natural system." However, the motivation of mathematical models is not abstraction, but rather quantification. For example, a groundwater flow mathematical model should yield the time evolution of heads and fluxes (water movements) at every point in the aquifer.

Both conceptual and mathematical models seek understanding. Some would argue that understanding is not possible without quantification. In the reverse, one cannot even think of writing equations without some sort of qualitative understanding. The methods of conceptual modeling are those of conventional hydrogeology (study geology, measure heads and hydraulic parameters, hydrochemistry, etc.). On the other hand, the methods of mathematical modeling (discretization, calibration, etc.) are more specific. Yet, it should be clear from the outset that conceptualization is the first step in modeling and that mathematical modeling helps in building firm conceptual models.

Depending on the manner in which equations are solved, models can be classified as analog, analytical, and numerical. Analog models are based on a physical simulation of a phenomenon governed by the same equation(s) as that of our natural system. For example, because of the equivalence between electrostatics and steady state flow, one may use conductive paper subject to an electrical current to solve the flow equation (a parallelism can be established between electric potential and hydraulic head). This kind of application, however, is restricted mainly to teaching. Boxes of resistances and condensators were used in the 1950s and 1960s as analog aquifer models, but they have become inefficient compared to computers. As a result, analog models are no longer used in practice.

Analytical models are based on closed-form solutions to the groundwater flow and transport equations. They are convenient in the sense that they are easy to evaluate and intuitive (visual inspection of the equation may yield an idea of the phenomenon). As a result, they are used very frequently. Examples include solutions of problems in well hydraulics, tracer movement, etc.

Numerical models are based on discretizing the partial differential equations governing flow and transport. This leads to linear systems of equations that can only be solved with the aid of computers. The advantage of numerical models lies in their generality. Analytical models are constrained to homogeneous domains and very simple geometry and boundary conditions. Numerical models, on the other hand, can handle spatially and temporally variable properties, arbitrary geometry and boundary conditions, and complex processes. The price to pay is methodological singularity. Analytical models are easy to use. Numerical models can be complex and, often, difficult.

Because of the methodological singularity mentioned above, this entry concentrates on mathematical numerical models. Analytical solutions are not discussed. In addition, conceptual modeling will be discussed as the first step in modeling, but not by itself.

What Can Be Modeled and What For?

Modeled Phenomena

The most basic phenomenon is groundwater flow (Figure 1) because of its intrinsic importance and because it is needed for subsequent processes. In essence, the flow equation expresses two things. First, groundwater moves according to Darcy's law. Second, a mass balance must be satisfied in the whole aquifer and in each of its parts. Therefore, the main output from flow models is a mass balance: classified inflows, outflows, and storage variations. The output also includes where water flows through the aquifer (water fluxes) and heads (water levels in the aquifer). In essence, input data are a thorough description of hydraulic conductivity (and/or transmissivity), storativity, recharge/discharge throughout the model domain, as well as conditions at the model boundaries. Obviously, these data are never available, and the modeler has to use a good deal of ingenuity to generate them. This is where the conceptual model becomes important.

Specific cases of flow phenomena are unsaturated and multiphase flow. In the first case, one models water flow in the vadose zone or, in general, in areas where water does not fill all the pores.[1] Therefore, besides heads and fluxes, one must work with water contents (volume of water per unit volume of aquifer), capillary pressures and suctions (difference between water and air pressure). From the input viewpoint, the main singularity of unsaturated flow is the need to specify the retention curve (water content vs. suction) and relative permeability (permeability vs. water content). The multiphase flow case is similar, but includes several fluids (phases). It is used to represent the flow of air or mixtures of liquids, singularly non-aqueous phase liquids (NAPLs), which have been the subject of much research in recent years.[2]

Conservative transport refers to the movement of inert substances dissolved in water. Solutes are affected by advection (displacement of the solute as linked to flowing water) and dispersion (dilution of contaminated water with clean water, which causes the size of the contaminated area to grow while reducing peak concentrations). The main input to a solute transport model is the output of a flow model (water fluxes). Additionally, porosity and dispersivity need to be specified (Figure 1). The output is the time evolution and spatial distribution of concentrations. While the amount of data needed for solute

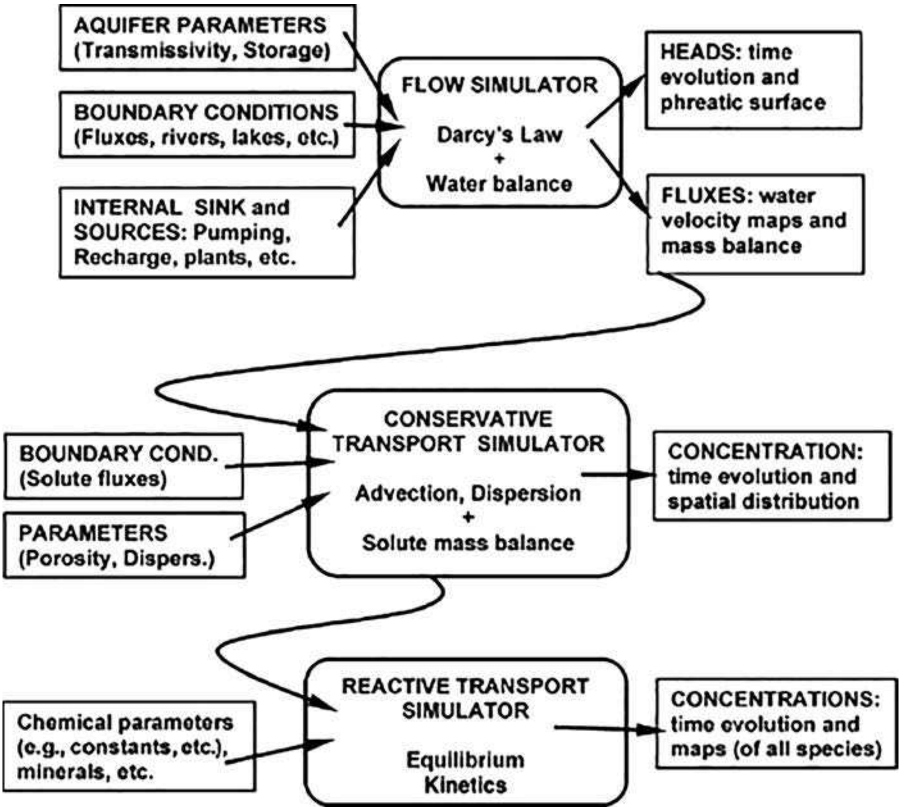

FIGURE 1 A groundwater flow model involves using a flow simulator to take aquifer parameters, boundary conditions, and internal sink and sources as inputs and obtain heads and water fluxes as output. Water fluxes are used in conservative transport models, together with porosity, diffusivity, and solute mass inflows, to yield time evolution and spatial distribution of inert tracers.

transport modeling is relatively small, it must be stressed that solute transport is extremely sensitive to variability and errors in water fluxes. A flow model may be good enough for flow results (heads and water balances) but insufficiently detailed to yield water fluxes good enough for solute transport. Therefore, modeling solute transport ends up being rather difficult.

Reactive transport refers to the movement of solutes that react among themselves and with the soil phase. Reactions can be of many kinds, ranging from sorption of a contaminant onto a solid surface to redox phenomena controlling the degradation of an organic pollutant. Input for reactive transport modeling includes not only the output of flow and conservative transport models but also the equilibrium constants of the reactions (usually available from chemistry databases) and the parameters controlling reaction kinetics. However, the most difficult input is the proper identification of relevant chemical processes. Model output includes the concentrations of all chemical species, the reaction rates, etc.

Coupled models refer to models in which different phenomena are affected reciprocally. Density dependent flow is a typical example. Variations in density affect groundwater flow (e.g., dense sea water sinks under light fresh water), which in turn affects solute transport and, hence, density distribution. Other coupled phenomena are the non-isothermal flow of water (coupling flow and energy transport) and the mechanically driven flow of water (coupling flow and mechanical deformation equations).

What Are Models Built For?

While discussing the usage of models, it is convenient to distinguish between site-specific models and generic models. The former are aimed at describing a specific aquifer while the latter emphasize processes, regardless of where they take place.

Groundwater management is the ideal use of site- specific models. Management involves deciding where to extract and/or inject water to satisfy water needs while ensuring water quality and other constraints. In this context, it is important to point out that a model is essentially a system for accounting water fluxes and stores (Figure 2) in the same way that the accounting system of a company keeps track of money fluxes and reserves. No one would imagine a well-managed company without a proper accounting system. Aquifers will not be managed accurately until they have a model running on real time. Unfortunately, at present, this is still a dream. Because of the difficulties in building and maintaining models and because of legal and practical difficulties to manage aquifers in real time, models are rarely, if ever, used in this fashion.

Instead, models are often used as decision support tools. Building an accurate model is very difficult and time consuming. As a result, one can rarely expect models to yield exact predictions. However, approximate models are much easier to build. These do not result in precise forecasts but normally allow reasonable assessments of the outcome of different management alternatives, i.e., the relative advantages and disadvantages of each alternative can be evaluated and the options ranked. This is usually all one needs for decision making.

This type of use is very frequent in aquifer rehabilitation, where one has to choose among several alternatives, including the option of doing nothing.[3] Models are also used for supporting aquifer exploration policies, i.e., for answering questions such as “how much water can be extracted?,” “where should one pump to minimize environmental impact?,” etc. In fact, a large body of literature is devoted to this kind of questions in an optimal fashion.[4]

Site-specific models are most frequently used, however, as a tool to support aquifer characterization efforts. This is somewhat ironic because a model is an essentially quantitative tool while site characterization is rather qualitative. Yet, experience dictates that modeling is the only way to consistently integrate the kind of data available in site characterization. These data are very diverse and range from geologic maps to isotope concentrations. One can use vastly different models to verbally explain all observations. Quantitative consistency is not so easy to check and requires the use of a model. Because of the difficulties in fully describing all data, this kind of model use is rarely described in the scientific literature.

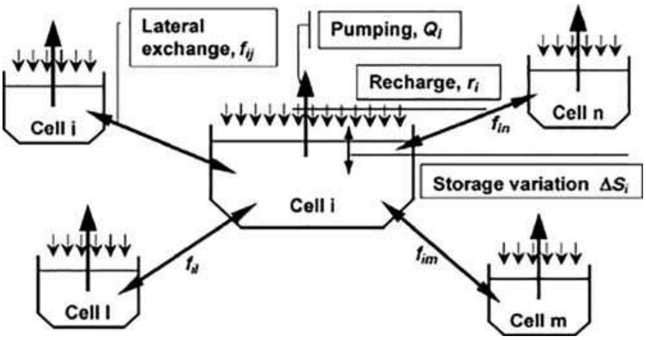

FIGURE 2 A groundwater model is the accounting system of an aquifer. It keeps track of the balance of each section (cells or compartments in the groundwater language) by evaluating exchanges with the outside (pumping Q_i, recharge, r_i, etc.) and with the adjacent sections (f_{ij}). The difference between inflow and outflow is equal to the variation in reserves (storage variation, ΔS_i,). A well-managed company needs an accounting system, and so does an aquifer.

Models can also be used in generic fashion as teaching or research tools to gain understanding on physicochemical phenomena. In these cases, they do not aim at representing a specific aquifer, but at evaluating the role of some processes under idealized conditions. A classical example of this type of use is the analysis of flow on regional basins.[5] Models are used in this fashion to explain geological processes.[6,7] Much emphasis has been placed in recent years on the evaluation of the effects of spatial variability. This involves issues such as upscaling, i.e., finding the relationship between large-scale effective parameters and small-scale measurements;[8] or analysis of hydraulic tests.[9]

How Are Models Built: The Modeling Process

The procedure to build a model is outlined in Figure 3. First, one defines a conceptual model (i.e., zones of recharge, boundaries of aquifers, etc.). Second, one discretizes the model domain into a finite element or finite difference grid. This can be entered as input data for a simulation code. Unfortunately, output data will rarely fit the observed aquifer heads and concentrations. This is what motivates calibration, i.e., the modification of model parameters to ensure that model output is indeed similar to what has been observed in reality. The model thus calibrated can be considered a "representation of the natural system" and can be used for management or simulation purposes.

The above procedure is formally described in Figure 4. This section is devoted to discussing in detail the modeling steps as previously described.[10–12] In practice, the effort behind each of these tasks may be very sensitive to the objectives of the studies and model. For the time being, we will assume that one is building a model aimed at describing reality in detail for the purpose making predictions.

Conceptualization

Modeling starts by defining which processes are important and how they are represented in the model. Definition of the relevant processes is termed "process identification" and it is needed for several reasons. First, the number of processes that may affect flow and transport is very large. For practical reasons, the modeler is forced to select those that affect the phenomenon under study, most significantly. Second, not all processes are well understood and they have to be treated in a simplified manner. In short, process identification involves simplifications, both in the choice of the processes and in the way they are implemented in the model.

Model structure identification refers to the definition of parameter variability, boundary conditions, etc. In a somewhat narrower but more systematic sense, model structure identification implies expressing the model in terms of a finite number of unknowns called model parameters. Parameters controlling the above processes are variable in space. In some cases, they also vary in time or depend on heads and/or concentrations. As discussed earlier, data are scarce so that such variability cannot be expressed accurately. Therefore, the modeler is also forced to make numerous simplifications to express the patterns of parameter variations, boundary conditions, etc. These assumptions are reflected on what is denoted as model structure.

The conceptualization step of any modeling effort is somewhat subjective and dependent on the modeler's ingenuity, experience, scientific background, and way of looking at the data. Selection of the physicochemical processes to be included in the model is only rarely the most difficult issue. The most important processes affecting the movement of water and solutes underground (advection, dispersion, sorption, etc.) are relatively well known. Ignoring a relevant process will only be caused by misjudgments and should be pointed out by reviewers, which illustrates why reviewing by others is important. Difficulties arise when trying to characterize those processes and, more specifically, the spatial variability of controlling parameters.
