In spite of the large amount of data usually available, their qualitative nature prevents a detailed definition of the conceptual model. Thus, more than one description of the system may result from the conceptualization step. Selecting one conceptual model among several alternatives is sometimes performed during calibration, as discussed later.

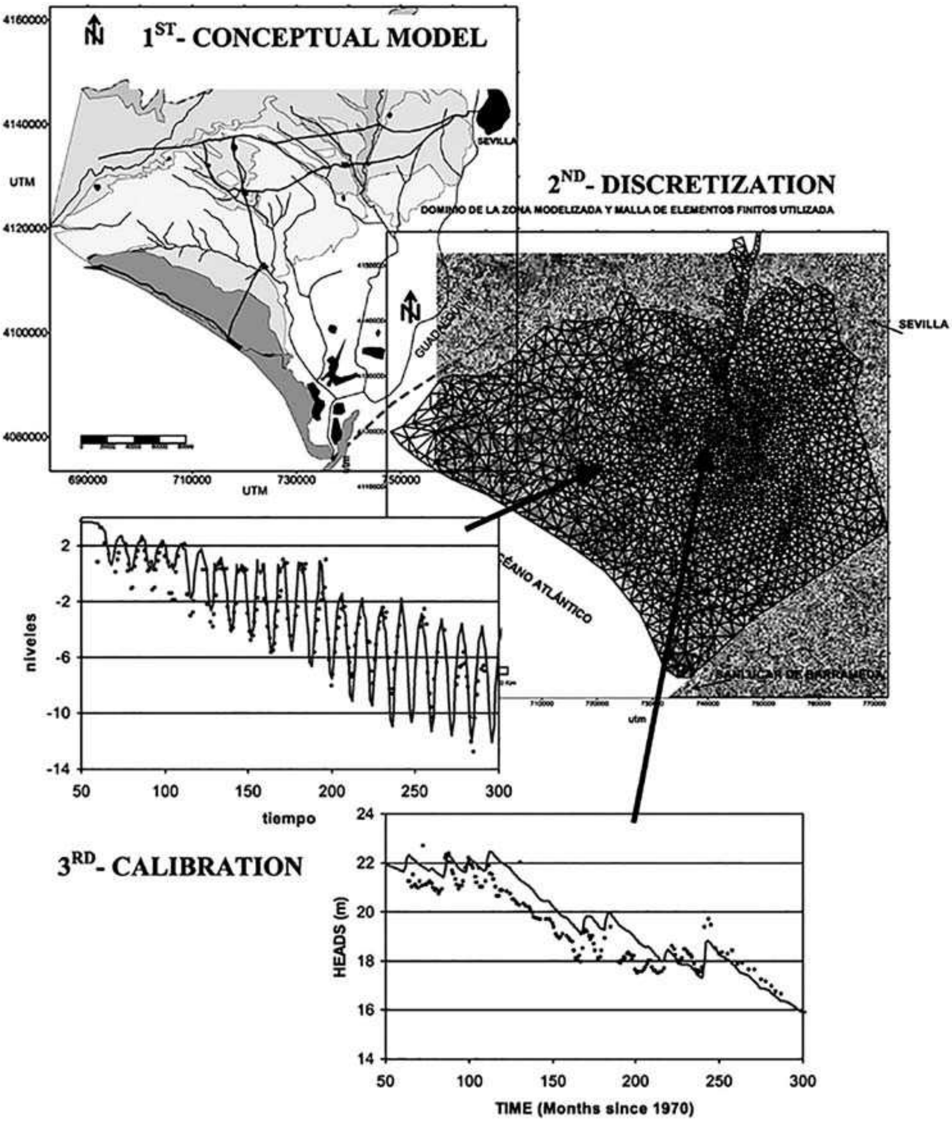

FIGURE 3 Building a model involves three basic steps: conceptualization, discretization, and calibration. Example from the Almonte-Marismas aquifer.

Discretization

Strictly speaking, discretization consists of substituting a continuum by a discrete system. However, we are extending this term here to describe the whole process of going from mathematical equations, derived from the conceptual model, to numerical expressions that can be solved by a computer. Closely related is the issue of verification, which refers to ensuring that a code accurately solves the equations that it is claimed to solve. As such, verification is a code-dependent concept. However, using a verified code is not sufficient for mathematical correctness. One should also make sure that time and space discretization is adequate for the problem being addressed. Moreover, numerical implementation of a conceptual model is not always straightforward international code comparison projects; INTRANCOIN

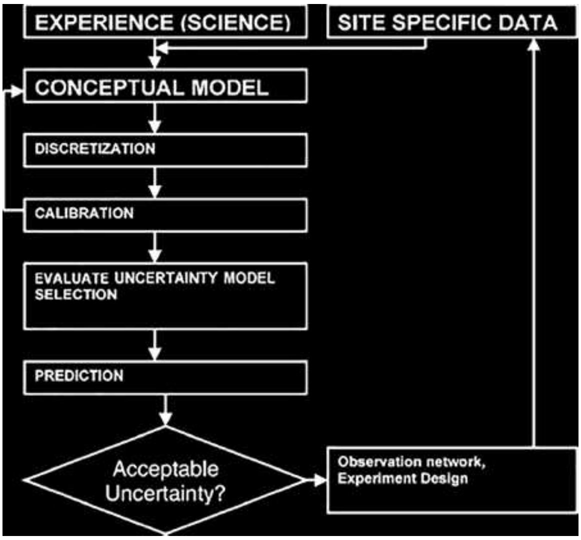

FIGURE 4 A formal description of the modeling process. Modeling starts with an understanding of the natural system (conceptual model), which is based on experience about such kind of systems (science) and on data from the site. Writing the conceptual model in a manner adequate for computer solution requires discretization. The resulting model is still dependent on many parameters that are uncertain. During calibration, these parameters are adjusted so that model outputs are close to measurements (recall Figure 3). Model predictions may be uncertain because so are the fitted parameters or because different models are consistent with observations. If uncertainty is unacceptably high, one should perform additional measurements or experiments and redo the whole process.

and HYDROCOIN have shown the need for sound conceptual models and independent checks of calculation results. Even well-posed mathematical problems lead to widely different solutions when solved by different people, because of slight variations in the solution methodology or misinterpretations in the formulation.[13] The reasons behind these differences and ways to solve them only become apparent after discussions among them.

The main concern during discretization is accuracy. In this sense, it is not conceptually difficult, although it can be complex. Accuracy is not only restricted to numerical errors (differences between numerical and exact solutions of the involved equations) but also refers to the precision with which the structure of spatial variability reproduces the natural system.

Calibration and Error Analysis

The choice of numerical values for model parameters is made during calibration, which consists of finding those values that grant a good reproduction of head and concentration data (Figure 3) and are consistent with prior independent information.

Calibration is rarely straightforward. Data come from various sources, with varying degrees of accuracy and levels of representativeness. Some parameters can be measured directly in the field, but such measurements are usually scarce and prone to error. Furthermore, since measurements are most often performed on scales and under conditions different from those required for modeling purposes, they tend to be both numerically and conceptually different from model parameters. The most dramatic example of this is dispersivity, whose representative value increases with the scale of measurement so that dispersivities derived from tracer tests cannot be used directly in a large-scale model. As a result, model parameters are calibrated by ensuring that simulated heads and concentrations are close to the corresponding field measurements.

Calibration can be tedious and time consuming because many combinations of parameters have to be evaluated, which also makes it prone to be incomplete. This, coupled to difficulties in taking into account the reliability of different pieces of information, makes it very hard to evaluate the quality of results. Therefore, it is not surprising that significant efforts have been devoted to the development of automatic calibration methods.[14–16]

Model Selection

The first step in any modeling effort involves constructing a conceptual model, describing it by means of appropriate governing equations, and translating the latter into a computer code. Model selection involves the process of choosing between alternative model forms. Methods for model selection can be classified into three broad categories. The first category is based on a comparative analysis of residuals (differences between measured and computed system responses) using objective as well as subjective criteria. The second category is denoted parameter assessment and involves evaluating whether or not computed parameters can be considered as "reasonable." The third category relies on theoretical measures of model validity known as "identification criteria." In practice, all three categories will be needed: residual analysis and parameter assessment suggest ways to modify an existing model and the resulting improvement in model performance is evaluated on the basis of identification criteria. If the modified model is judged an improvement over the previous model, the former is accepted and the latter discarded.

The most widely used tool of model identification is residual analysis. In the groundwater context, the spatial and frequency distributions of head and concentration residuals are very useful in pointing towards aspects of the model that need to be modified. For example, a long tail in the breakthrough curve not properly simulated by a single porosity model may point to a need for incorporating matrix diffusion or a similar mechanism. These modifications should, whenever possible, be guided by independent information. Qualitative data such as lithology, geological structure, geomorphology, and hydrochemistry are often useful for this purpose. A particular behavioral pattern of the residuals may be the result of varied causes that are often difficult to isolate. Spatial and/or temporal correlation among residuals may be a consequence of not only improper conceptualization, but also measurement or numerical errors. Simplifications in simulating the stresses exerted over the system are always made and they lead to correlation among residuals. Distinguishing between correlations caused by improper conceptualization and measurement errors is not an easy matter. This makes analysis of residuals a limited tool for model selection.

An expedite way of evaluating a model concept is based on assessing whether or not the parameters representing physicochemical properties can be considered "reasonable;" i.e., whether or not their values make sense and/or are consistent with those obtained elsewhere. Meaningless parameters can be a consequence of either poor conceptualization or instability. If a relevant process is ignored during conceptualization, the effect of such process may be reproduced by some other parameter. For example, the effect of sorption is to keep part of the solute attached to the solid phase, hence retarding the movement of the solute mass; in linear instantaneous sorption, this effect cannot be distinguished from standard storage in the pores. Therefore, if one needs an absent porosity (e.g., larger than one) to fit observation, one should consider the possibility of including sorption in the model. However, despite this example, parameter assessment tends to be more useful for ruling out some model concepts than for giving a hint on how to modify an inadequate model. Residual analysis is usually more helpful for this purpose.

Instability may also lead to unreasonable parameter estimates during automatic calibration, despite the validity of the conceptual model. When the number of data or their information content is low, small perturbations in the measurement or deviations in the model may lead to drastically different parameter estimates. When this happens, the model may obtain equally good fits with widely different parameter sets. Thus, one may converge to a senseless parameter set while missing other perfectly meaningful sets. This type of behavior can be easily identified by means of a thorough error analysis and corrected by fixing the values of one or several parameters.[14]

Predictions and Uncertainty

Formulation of predictions involves a conceptualization of its own. Quite often, the stresses, whose response is to be predicted, lead to significant changes in the natural system, so that the structure used for calibration is no longer valid for prediction. Changes in the hydrochemical conditions or in the flow geometry may have to be incorporated into the model. While numerical models can be used for network design or as investigation tools, most models are built in order to study the response of the medium to various scenario alternatives. Therefore, uncertainties on future natural and man-induced stresses also cause model predictions to be uncertain. Finally, even if future conditions and conceptual model are exactly known, errors in model parameters will still cause errors in the predictions. In summary, three types of prediction uncertainties can be identified: conceptual model uncertainties; stresses uncertainties; and parameters uncertainties.

The first group includes two types of problems. One is related to model selection during calibration. That is, more than one conceptual model may have been properly calibrated and data may not suffice to distinguish which one is the closest to reality. It is clear that such indetermination should be carried into the prediction stage because both models may lead to widely different results under future conditions. The second type of problems arises from improper extension of calibration to prediction conditions, i.e., from not taking into account changes in the natural system or in the scale of the problem. The only way we think about dealing with this problem consists of evaluating carefully whether or not the assumptions in which the calibration was based are still valid under future conditions. Indeed, model uncertainties can be very large.

We do not think that, strictly speaking, the second type of uncertainties, those associated with future stresses, falls in the realm of modeling. While future stresses may affect the validity of the model, they are external to it. In any case, this type of uncertainty is evaluated by carrying out simulations under a number of alternative scenarios, whose definition is an important subject in itself.

The last set of prediction uncertainties is the one associated with parameter uncertainties, which can be quantified quite well.

Conclusion

Groundwater modeling involves so many subjective decisions that it can be considered as an art. This is somewhat contrary to the widely accepted perception of models as something objective. The fact is that numerous assumptions need to be made both about the selection of relevant processes and about the manner of representing them in the computer. All these assumptions are specified in the conceptual model.

The result relies so heavily on conceptualization that models ought to be viewed as theories about the behavior of natural systems. Model predictions should rarely be viewed as firm statements about the future evolution of aquifers. Rather, they should be considered references against which actual data has to be compared. Codes do exist for modeling most processes affecting groundwater (flow, transport, reactions, thermomechanics, etc.). It is lack of understanding and lack of data what limits the actual application of those codes.

Having specified a conceptual model, the remaining steps (discretization, calibration, uncertainty analysis, prediction) are relatively objective, in the sense that systematic procedures can be followed. This explains why conceptualization is so important. It also explains why modeling is the best way of integrating widely different data. Uncertain as it is, it may represent unambiguously the overall knowledge of the aquifer.

Models represent the water balance (or solute balance, or energy balance) at the overall aquifer and at each of its parts. Therefore, they can also be viewed as accounting systems. It is argued that well-managed aquifers need real time models to help decision making, the same way that well managed companies need financial accounting systems. This is the challenge modelers must meet in the near future.

Groundwater: Numerical Method Modeling

Jesus Carrera

A Generic Numerical Method for Solving Groundwater Flow

As mentioned earlier, all methods require, first, discretizing and, second, approximating the physical phenomenon. For the generic method we are going to present here, discretization will be performed as shown in Figure 1. That is, the continuum aquifer domain will be substituted by a discrete number of cells. Furthermore, the continuum aquifer heads, $h(x,y)$, are substituted by a discrete number of model heads, h_i.

The second step, approximation, can be made in different manners. For the purpose of this section, it is sufficient to bear in mind that the flow equation is nothing but a mass balance. Therefore, we will express the mass balance in cell i as change in storage equals inflows minus outflows.

$$\Delta S_i = f_{ij} + f_{il} + f_{im} + f_{in} + g_i \tag{1}$$

where ΔS_i is the rate of change in storage during one time step (say, between time t^k and time t^{k+1}); f_{ij} is the inflow into cell i from cell j (and the same for f_{il}, f_{im}, and f_{in}); and g_i are external inflows into cell i (for example, recharge, minus pumping, minus evaporation, minus river outflow, etc.). Each of the terms in Eq. 1 is relatively easy to approximate. Storage variation can be derived from the definition of storage coefficient, (S is the change in volume of water stored per unit surface area of aquifer and per unit change in head):

$$\Delta S_i = SA_i \frac{\left(h_i^{k+1} - h_i^k\right)}{\Delta t} \tag{2}$$

where A_i is the surface area of cell i, h_i^k is the head in node i at time k and $\Delta t = t^{k+1} - t^k$ is the time step. Darcy's law gives lateral inflows

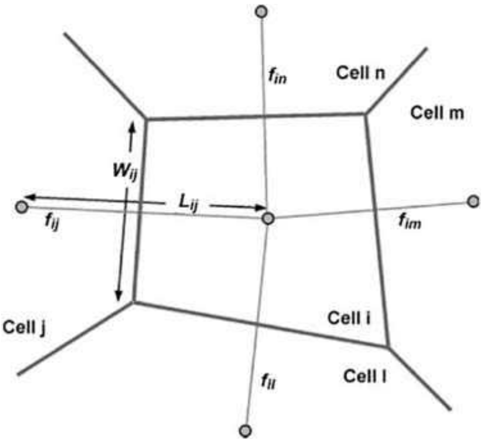

FIGURE 1 The system of equations for a generic groundwater model is obtained by establishing a water balance (inputs minus outputs equal storage variations) at each cell. Inputs and outputs include water exchanges with the outside (pumping Q_i, recharge, r_i, etc.) and with adjacent cells f_{ij}). The latter are expressed, using Darcy's law, as $f_{ij} = T_{ij} w_{ij} (h_j - h_i)/L_{ij}$.

$$f_{ij} = -Tw_{ij}\frac{h_i - h_j}{L_{ji}} = a_{ij}\left(h_i - h_j\right) \tag{3}$$

where T is transmissivity; w_{ij} is the width of the connection between nodes i and j; L_{ji} is the length of such connection; and a_{ij} is implicitly defined as $-Tw_{ij}/L_{ij.}$ The remaining inflow terms, f_{il}, f_{im}, and f_{in} are defined likewise. Changing these terms to the left-hand side of Eq. 1 and rearranging terms yield:

$$SA_i\frac{\left(h_i^{k+1} - h_i^k\right)}{\Delta t} + a_{ii}h_i + a_{ij}h_j + a_{il}h_l + a_{im}h_m + a_{in}h_n = g_i \tag{4}$$

where $a_{ii} = -a_{ij} - a_{il} - a_{im} - a_{in}$. If an equation like Eq. 4 is written for all cells from $i = 1$ through N, N being the number of cells (nodes), the resulting system of equations can be rewritten in matrix form as:

$$\mathbf{D}\frac{\left(\boldsymbol{h}^{k+1} - \boldsymbol{h}^k\right)}{\Delta \boldsymbol{t}} + \mathbf{Ah} = \mathbf{g} \tag{5}$$

where **D** is a diagonal matrix whose i-th diagonal term is precisely SA_i. This matrix is often called storage matrix. **A** is the conductance matrix, a square symmetric matrix whose components are a_{ij}. Finally, **g** is the source vector.

All the numerical methods to be outlined in subsequent sections lead to equations analogous to Eq. 5. Moreover, the meaning of the terms in such equations is always similar to that in Eq. 5. Namely, the system represents the mass balance at each of the N nodes (cells); specifically the i-th equation represents the mass balance at the i-th node. The first term, $\mathbf{D}(\mathbf{h}^{k+1} - \mathbf{h}^k)/\Delta t$, always represents storage variations. The second term, **Ah**, represents outflows from minus inflows into the i-th cell from the adjacent cells. Finally, term **g** represents external inflows minus outflows (recharge, pumping, etc.) at all i.

Equation 5 needs to be integrated in time. For this purpose, let us assume that **Ah** is evaluated at time $k + 1$ ($\mathbf{Ah}^{k+1}$). Then, Eq. 5 can be rewritten as:

$$\left(\boldsymbol{A} + \frac{\boldsymbol{D}}{\Delta t}\right)\boldsymbol{h}^{k+1} = \mathrm{g} + \frac{\boldsymbol{D}}{\Delta t}\boldsymbol{h}^k \tag{6}$$

This is simply a linear system, which can be solved using conventional methods.

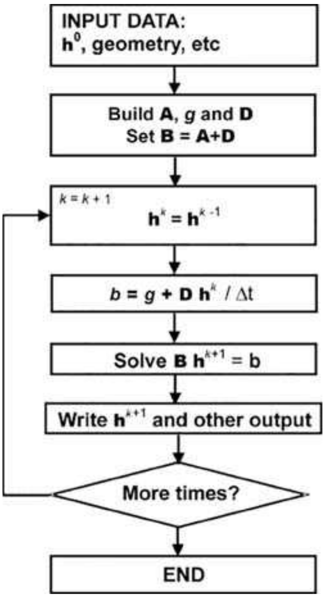

FIGURE 2 Basic steps involved in simulating groundwater flow. Heads $\mathbf{h}^{k+1}$ are computed by solving equation $\mathbf{Bh}^{k+1} = \mathbf{b}$. They may be written for later drawings. They are used as initial head for the next time increment. These steps (time loop) are repeated sequentially until the last time is reached.

$$\boldsymbol{Bh}^{k+1} = \mathbf{b} \tag{7}$$

where $\mathbf{B} = \mathbf{A} + \mathbf{D}/\Delta t$ and $\mathbf{b} = \mathbf{g} + \mathbf{D}\mathbf{h}^k/\Delta t$. This system is solved sequentially in time.

That is, most codes solve Eq. 7 using the following steps (Figure 2):

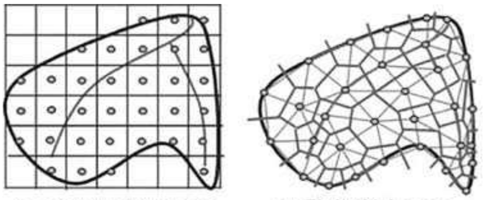
1. Input all data. Set $k = 0$
2. Compute **g**, **A** (Eq. 3); **D** (Eq. 5) and **B** (Eq. 7)
3. Set $k = k + 1$
4. Build **b** (Eq. 7)
5. Solve $\mathbf{Bh}^{k+1} = \mathbf{b}$
6. If $k = k_{\max}$ (maximum number of time steps), end. Otherwise, return to step 3

Most codes follow a structure such as this, although each method displays specific features. Some of these are outlined below.

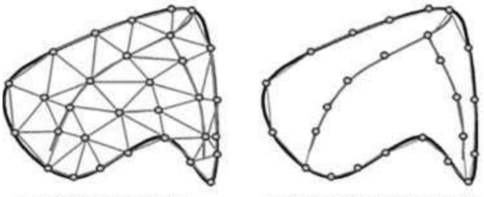
Finite Differences (FD)

As mentioned at the beginning, numerical methods differ in the way in which the domain is discretized and in the way in which the partial differential equation is transformed into a linear system of equations. In finite differences, the problem domain is discretized in a regular grid (Figure 3a), usually rectangular (equilateral triangles or hexagons are possible, but very rare). The grid may be centered at the corners (nodes are located at the vertices of the squares) or at the cells (nodes are located at the center of the squares, such as in Figure 3a).

Regarding the approximation of the partial differential equations, several alternatives are possible. The most intuitive consists of substituting all derivates by an incremental ratio. That is, the derivative between adjacent nodes *i* and *j* is approximated as:



(a) Finite Differences (b) Finite Volumes



(c) Finite Elements (d) Boundary Elements

FIGURE 3 The most widely spread methods of discretization are Finite Differences, which consists of subdividing the model domain into regular rectangles, and Finite Elements, which is based on dividing the aquifer region into elements of arbitrary shape (often triangles). Finite Volumes, also called Integrated Finite Differences, divides the region into polygons. The Boundary Element Method is very convenient, when applicable, because it only requires discretizing boundaries (both internal and external).

$$\frac{\partial h}{\partial x} = \frac{h_i - h_i}{\Delta x} \tag{8}$$

where h_i and h_j are heads at nodes i and j, respectively, and Δx is the distance between them. Approximating all derivatives by means of equations analogous to Eq. 8 leads to a system identical to Eq. 5. In fact, the finite differences method is often introduced using a mass balance approach such as the one in the section "A Generic Numerical Method for Solving Groundwater Flow," only using a regular instead of a generic grid. This is the method used in MOD- FLOW,[1] HST3D,[2] and their children.

Integrated Finite Differences (IFD)

The basic philosophy of this method is very similar to that of the generic method introduced in the generic numerical section. Basically, the domain is discretized in a number of cells centered around arbitrarily located nodes. Frequently, the cells are the Thiessen polygons of the set of nodes. This allows adapting the node density to the problem (e.g., increasing nodes density where accuracy is needed most).

Model equations can be derived using a mass balance approach, such as in the generic method section. Integrating the flow equation over each cell and applying Green's identity to transform volume integrals in boundary fluxes can also yield model equations. This type of approach is the basis of the finite volume method, which is widely used nowadays.

Finite Element Method

Finite element method (FEM) discretization consists of elements and nodes. Elements are generalized polygons (normally triangles or curvilinear quadrilaterals). Nodes are points located at the vertices and, sometimes, at the sides or the middle of the element. Unlike FD or IFD, cells around the nodes are not defined. Still, in many cases, one may write the equations in such a way that the mass balance formulation of the generic method section is still valid. However, the most singular feature of the FEM is the way the solution is interpolated, so that it becomes defined at every point. That is, head (or concentrations) is approximated as:

$$h(x) \cong \hat{h}(x) = \sum_{i} h_i N_i(x) \tag{9}$$

where h_i are nodal heads and N_i are interpolation functions. Since is not the exact solution, it would yield a residual if substituted in the flow equation. Minimizing this residual, which requires somewhat sophisticated maths, leads to a system similar to Eq. 5.

Boundary Element Method

The idea behind the boundary element method (BEM) is similar to that of the FEM. The main difference stems from the choice of interpolation functions, which are taken as the fundamental solutions of the flow equation (or whatever equation is to be solved). As a result, when the corresponding $\hat{h}$ is substituted in the flow equation, the residuals are zero. Since the equation is satisfied exactly in the model domain, one is only left with boundary conditions. In fact, as shown in Figure 3d, discretization is only required at the boundaries, where boundary heads are defined so as to satisfy approximately the boundary conditions. This method is extremely accurate, but its applicability is limited by the need of finding the fundamental solutions. This constrains the BEM to flow problems in relatively homogeneous domains.

Simulating Solute Transport

All the methods discussed above can be used for simulating solute transport. They are called Eulerian methods because they are based on a fixed (as opposed to moving) grid and all derivatives are based on a fixed coordinate system. They work fine when dispersion is dominant. Otherwise, they may lead to numerical problems (Figure 4). Two dimensionless numbers are used to anticipate numerical difficulties. Specifically, discretization must satisfy the following conditions.

Peclet number

$$Pe = \frac{v\Delta x}{D} \cong \frac{\Delta x}{\alpha} < \frac{1}{2} \tag{10}$$

Courant number

$$Co = \frac{v\Delta t}{\Delta x} < 1 \tag{11}$$

where v is the solute velocity, α is dispersivity, Δx is the distance between nodes and we have assumed that $D \cong \alpha v$. The condition on the Courant number implies that the solute at one node will not move

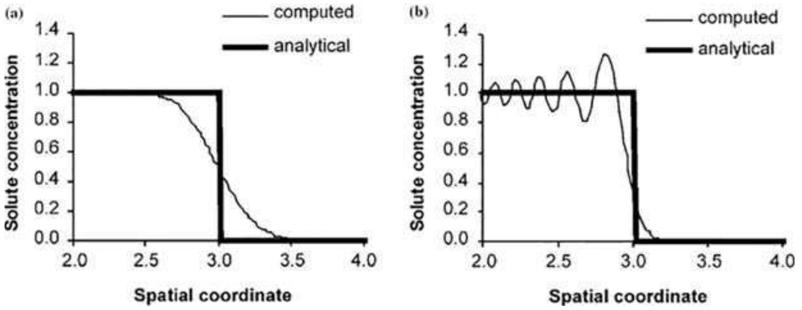


FIGURE 4 Difficulties typically associated to numerical simulation of solute transport: a) front smearing: the concentration front is more dispersed than it should; b) instability oscillations: too high and/or too low (even negative) concentrations.

beyond the following node downstream during one time step. This condition is easy to meet because usually groundwater moves slowly and also reducing Δt to satisfy Eq. 11 is not difficult. The condition on the Peclet number, Eq. 10, implies that Δx is smaller than $\alpha/2$, which may require very small elements, leading to a huge computational burden. Because of this, conventional Eulerian methods are not applicable to many groundwater problems, which have motivated the search of alternative methods.

Alternative methods can be Eulerian or Lagrangian. Among the former, the most popular is upstream weighting, introduced by Heinrich et al.[3] in the FEM, but with a huge number of papers thereafter. It consists of slightly modifying Eulerian equations so as to ensure stability. The problem is that, in doing so, it introduces numerical dispersion. As a result, the wiggles at the solute front in Figure 4 are substituted by an artificially smeared front. However, the vast majority of alternative formulations for solute transport are Lagrangian in the sense that time variations are written in terms of the material derivative, which expresses the rate of change in concentration of a particle that moves with the water. In this way, the advective term, which is the cause of problems in Eulerian formulations, disappears.

The number of Lagrangian methods is very large and many researchers have devoted much effort to find one, which is universal. The fact that so many methods have survived to date suggests that the effort has not been fully successful. Still, in practical problems, one can usually find a suitable method. Following is an outline of some of the most popular methods, with a discussion of their advantages and disadvantages and early references. The interested reader should seek further.

The most natural Lagrangian method is to write the equations on a moving grid, that is on a grid whose nodes move with water. This method is highly accurate, but expensive because the grid has to be updated every time step. Moreover, the grid can become highly deformed over time.

To avoid problems with moving grids it is frequent to work with particles. Displacing the particles with the moving water represents advection, while dispersion can be represented with a variety of methods. One such possibility is to add a random component to each particle basis displacement. This is statistically equivalent to each particle basis dispersion and is the basis of the “random walk” method.[4] The method requires careful implementation, but its main drawback is the fact that the solution is given in terms of number of particles per cell. If one is interested in spatial distributions of the solute, a huge number of particles may be needed.

The method of characteristics (MOC) overcomes the above difficulty by assigning concentrations to particles and interpolating them onto a fixed grid, where dispersion and, possibly, other transport processes are modeled. Concentrations are then interpolated back onto the particles. The method has become very popular in groundwater because of the USGS MOC Code.[5] The method is very practical, but the interpolation back-and-forth between particles and grid may introduce numerical dispersion and mass balance errors.

The modified method of characteristics[6] tries to overcome the problems associated to interpolating particle concentrations by redefining them in each time interval so that at the end of the time step they coincide with a node location. The method is very accurate, although some interpolation errors still occur when the front is abrupt. Some of these problems are overcome by the Eulerian–Lagrangian Localized Adjoint Method,[7] which looks as the most promising method.

Conclusion

Computer codes are available for simulating all phenomena affecting groundwater. In essence, they represent the balance of water (or salt, contaminants, or energy) in a manner that can be solved by the computer. This is achieved by, first, discretizing the problem and, second, rewriting it as a system of equations. This type of approach has been successful for flow problems. Solute transport, on the other hand, remains elusive. No single method is universally successful. Instead, one must seek the appropriate code in each case.

Nitrogen (Nitrate Leaching) Index

Jorge A. Delgado

Introduction: Importance of Nitrogen

The United Nations recently reported that a changing climate will be one of the biggest challenges that humanity will be confronting this century, especially with respect to the potential impacts of climate change on food security.[1] One of the problems of climate change is the potential increase in extreme events.[2] Adapting to the occurrence of these extreme events will be critical since the potential for higher soil erosion is also significant.[3] Increased precipitation or higher amounts of irrigation increase the potential for nitrate leaching losses.[4–9] However, there is potential to use conservation management practices to reduce losses of nitrate leaching and adapt to a changing climate.[10] Humanity will need to implement the best management policies for soil and water conservation, including nutrient management, if it is to be able to adapt to a changing climate to help ensure that agricultural production is increased over the next decades and food security is achieved.[10,11]

With the projected global population increase of over two billion by 2050 and the challenges humanity faces as far as a changing climate, reduction of water resources, and more frequent occurrence of extreme events, there is a need to continue developing new management practices that help to increase nitrogen use efficiencies. This is because increases in grain and other agricultural products will require additional inputs of nitrogen, yet we do not want to increase the pressure in the metaphorical nitrogen pipes of these intensive agricultural systems, which could then potentially increase nitrogen leakages from these systems. Conservationists and nutrient managers across the world will be asking themselves questions about how to increase yields and nitrogen inputs while simultaneously minimizing the losses of reactive nitrogen to the environment, especially leaching losses of nitrate nitrogen, which can quickly move to water bodies in cases of shallow aquifers, tile systems, and surface water bodies. Increases in agricultural production will be necessary to supply grain for a larger world population, and larger quantities of grain and forage will be needed to meet the additional demand for meat and dairy products as large populations in growing economies such as China, and other regions increase in affluence.

Nitrogen management, including management of inorganic fertilizer inputs, management of animal manure and other by-products, and management of nitrogen across the environment from agricultural fields to non-agricultural areas across the watershed, will certainly be at the center of the world's emerging sustainability challenges in the coming decades. Independent of what policies are implemented, nitrogen management will be at the core of agricultural systems since most of the world's systems depend on agricultural inputs to maximize agricultural productivity.[10] As we move closer to the middle of the 21st century and we have more limited soil and water resources, we will need a global agricultural system that is both more productive and more sustainable. Best nitrogen management practices will be an essential component of efforts to increase productivity and sustainability.

Nitrogen Leaching Contributes to Environmental Problems

Although agricultural production has increased with the use of nitrogen fertilizer, nitrogen inputs also have contributed to increased losses of reactive nitrogen from agricultural systems that have contributed to global environmental impacts.[12–16] The US Environmental Protection Agency (EPA) has reported that drinking water with nitrate concentrations above 10 mg NO_3–N L^{-1} can negatively impact humans, and is thus unfit for human consumption.[17] It is important that we reduce the transport of reactive nitrogen from agricultural systems to reduce the negative impacts of reactive nitrogen on the environment and human health.[18,19] Several scientists have reported that nitrogen contributes to the hypoxic zone in the Gulf of Mexico.[20–25] There are hypoxic zones across the USA and around the world, and another example of an area impacted is Lake Erie, with its hypoxic zone and high microcystin levels.[26] Microcystin-LR concentrations above 1.0 μg/L in treated drinking water have been reported to be unsafe by the World Health Organization,[27] while the USEPA reported a much lower concentration of 0.3 μg/L to be unsafe for children less than six years old.[28] Microcystin concentrations above 0.3 μg/L can negatively impact children less than six years old.[28] Health effects from exposure could include gastroenteritis, and liver and kidney damage.[28]

It has been widely reported across the scientific literature that nitrogen losses could impact surface and groundwater quality.[29,30] Nitrate leaching is a major pathway for nitrogen loss that contributes to poorer water quality of aquifers across the world; examples of affected areas include regions of the North China Plain,[31] Europe,[15,32] South America,[33] and the USA.[29,30,34] The Midwest region of the USA has been reported to contribute large amounts of nitrate which is transported to the Gulf of Mexico, and tile systems have been reported as a major pathway for this nitrate mass that moves from agricultural fields to coastal systems.[20–23,34,25] Domestic wells that are sources of drinkable water across the USA have also been impacted by nitrate leaching as reported by Dubrovsky et al.[25] in his extensive study that found the nitrate levels were higher than the 10 mg NO_3–N L^{-1} safe limit established by the USEPA for a significant percentage of the wells.

Applying higher-than-needed N rates does not necessarily mean that all the pathways for nitrogen losses will be affected at the same magnitude, since site-specific properties affect the main mechanism for nitrogen losses. For example, in our adaptation of the metaphorical pipe concept, a higher-than-needed N rate for a coarser-textured soil or a soil system with tile drainage will have a bigger metaphorical pipe for nitrate leaching losses since coarser soils or tile drainage systems will have higher nitrate leaching potential. In other words, applying more nitrogen than needed to a coarser-textured soil or a tile system will most likely increase the pressure in the nitrate leaching pipe and the potential for NO_3–N leaching losses in this system. Another point to consider is that leaching is driven by water movement, so arid systems are less susceptible to leaching than humid systems with higher precipitation. Similarly, irrigated systems are also more susceptible to leaching, and water management practices (e.g., management of type of irrigation) can be used to reduce the leaching potential in irrigated systems. An example of a very sensitive system would be shallow-rooted crops grown in coarse-textured soils in flood-irrigated systems, which results in high potential for nitrate leaching. The good news is that we could use management practices (e.g., the inclusion of cover crops in a rotation with irrigated, shallow-rooted crops grown in coarse-textured soils) to try to reduce the pressure on the NO_3–N leaching pipe and the losses of nitrogen from the system. Randall et al., Delgado et al., and Delgado and Follett discussed in detail how best management practices could be used to reduce nitrate leaching to the environment.[5,35,36]

As previously discussed, nitrogen application rates that are higher than needed increase the flow through the metaphorical pipes to the environment, increasing the potential for nitrogen losses that will potentially impact air and water quality. However, best nitrogen management practices can be used to reduce the pressure in the pipes and minimize the leakage. Practices that will increase denitrification, contributing to conversion of NO_3–N as it is transported across water bodies to N_2 (e.g., wood chips, wetlands), will minimize the environmental impact of reactive nitrogen on the environment. Although this is a beneficial approach environmentally, there is still an economic loss due to the losses of NO_3–N from field applications, and increasing nitrogen use efficiencies at a field level while reducing NO_3–N leaching losses from the field will be a way to reduce the environmental impact and reduce field-level economic losses. Aside from this consideration, best management practices such as denitrification traps will be good practices to reduce the transport of NO_3–N to the environment.

For global sustainability, we could use many different management practices to increase nitrogen use efficiencies and yields while reducing losses of reactive nitrogen to the environment across global agricultural systems. Quick nitrogen tools that can use some general principles of soil hydrology and soil chemical and physical properties while accounting for irrigation and precipitation balances can be used to assess practices for different cropping systems on an annual basis. New, advanced tools such as the Nitrogen Index are among the new ecotechnologies that can be applied.[35–37]

New Ecotechnology: Quick Tools/Indicators

There are a variety of indexes that have been used to assess the risk of nitrate leaching.[38] Shaffer and Delgado[39] proposed a nitrate leaching index that considers the effects of management (e.g., manure, crops, fertilizer, irrigation), soils, climate, and off-site factors; that is easy to use; and that can conduct a quick but strong assessment of the risk of nitrate leaching. They discussed the different indexes that have been developed in the past to assess the risk of nitrate leaching and the advantages and disadvantages of these indexes. Delgado et al. [35,40–44] developed such an index considering hydrological and ecological factors. This new ecotechnology has been used for about the last decade by different US agencies and other national and international institutions to assess the risk of nitrate leaching for a given set of management practices under a given set of weather, soil, and off-site conditions. The tool is available for download at the website of the National Agricultural Library, and the code of the Nitrogen Index is available to download as well (https://data.nal.usda.gov/dataset/cce-nitrogen-index-tool/resource/ec68e0b2-f3e6-4adc-88f4-aee430f6603d).

In addition to the Nitrogen Index, there are other indexes that have been used to assess nitrogen use efficiencies. Shaffer and Delgado[39] and Buczko et al.[38,45] discussed the advantages and disadvantages of several nitrogen indexes approaches. Assessment of the risk of nitrate leaching potential has been conducted in New York with the New York Nitrate Leaching Index[46] and in California with the Nitrate Leaching Hazard Index.[47] However, none of these indexes conduct a quick assessment of the mass of nitrate leaching at different root depths, and the new California Nitrogen Index and new generic Nitrogen Index can be used to conduct a quick assessment of the mass of nitrate leaching at different root depths.[35,40] One of the indexes used to assess nitrate leaching is the water Leaching Index (LI) by Williams and Kissel[48] that assesses the potential for water leaching and extrapolates that risk to nitrate leaching. However, since there is no assessment of the mass of nitrate leaching or the risk of nitrate leaching, this water leaching index is at a disadvantage in assessing the risk since it does not consider N inputs and N dynamics.[39]

Delgado[49–51] studied the movement of nitrate across the soil profile to assess the nitrate leaching potential of cropping systems with different root depths and found a significant correlation between the root depths of cropping systems and nitrate leaching, with a higher nitrate leaching potential for crops with more shallow root systems. Similarly, he assessed the nitrate leaching potential across different soil textures and nitrate leaching spatially across fields and found a significant correlation between soil texture and nitrate leaching potential when fields were managed similarly, with a higher nitrate leaching potential for the areas of the field with coarser-textured soils.[52]

Sharpley et al.[53–55] and Lemunyon and Gilbert et al.[56] reported about the need to join the Phosphorus Index with a nitrogen index to conduct a multi-nutrient assessment of the risk of losses of nitrogen and phosphorus to the environment. Heathwaite et al.[57] developed a joint nitrogen and phosphorus index. OMAFRA[58] also proposed a joint index. Similarly, Delgado et al.[35] proposed to join the new Nitrogen Index to currently available P indexes. Bolster et al.[59] developed a nitrogen and a phosphorus index analysis for USDA-NRCS in Kentucky.

De Paz[15] tested the new Nitrogen Index approach joined with GIS capabilities across one of the regions of Europe most impacted by nitrate leaching.[15,32] De Paz et al.[15] found a correlation between the nitrate leaching and water leaching predicted by the Nitrogen Index, and measured nitrate leaching and water leaching. They also found that the nitrate leaching predicted by the Nitrogen Index was significantly correlated with the measured nitrate leaching across this Mediterranean region and that the areas with higher groundwater nitrate concentrations were correlated with the areas estimated to have higher nitrate leaching potential by the Nitrogen Index.

These results from De Paz et al. are another example indicating that the hole-in-the-pipe model proposed by Firestone and Davidson[60] describing the losses via emissions of greenhouse gases from the soil in the nitrogen cycle can be applied to the whole nitrogen cycle in agricultural systems, as described in the present work, and that the application of higher nitrogen rates than needed increases the pressure in the system, resulting in increased leaking from the system, and thus higher concentrations of nitrate, impacting groundwater quality.

Figueroa et al.[61] found that in intensive manure systems in Mexico that received large manure applications, the risk of nitrate leaching was higher. The tool was used to assess the effects of manure management practices on residual soil nitrate in the profile.[61] The Instituto Nacional de Investigaciones Forestales Agricolas y Pecuaris (INIFAP), a research institution in Mexico, conducted studies in Mexico and reported that the Nitrogen Index was a tool that can be used to assess the nitrate leaching risk in forage systems in this country.[42] Saynes et al.[16] were also able to use the Nitrogen Index to assess the effects of management practices in Mexico on emissions of N_2O from these fertilized systems. This is another example that this simple tool can be used to validate the hole-in-the-pipe model proposed by Firestone and Davidson[60] as adapted in the present work in international systems since the emissions of N_2O increased with higher fertilizer rates.[16]

Conclusion

The Nitrogen Index has been tested and calibrated using data from North America,[4,35,43,44,59,62] different regions in Mexico,[16,41,42,61,63,64] the Caribbean[65] region, different regions of South America[35,66,67] (Andean region and Pampas region), a Mediterranean region,[15] and the North China Plain,[35] where personnel from various national and international agencies, universities, and/or research centers have used the tool. Results of these efforts show that the Nitrogen Index is able to evaluate the effect of management on residual soil nitrate, water leaching, nitrate leaching, emissions of nitrous oxide, crop nitrogen use efficiencies, and crop nitrogen uptake. Additionally, measured groundwater nitrate concentrations have also been correlated with nitrate leaching predicted by the Nitrogen Index, validating the potential of using the tool to assess the risk of nitrate leaching to the environment.

Although it is recommended that users get familiar with the capabilities and limitations of the Nitrogen Index, the correlation between predicted and observed values for these different losses of reactive nitrogen suggests that this is a robust tool capable of being used to assess the risk of management practices on potential nitrate leaching and losses via other pathways. These results also support using the Nitrogen Index as part of an ecological engineering approach to soil and water conservation planning.[35,43] There is potential to use this tool to assess the effects of nitrogen inputs from manure, fertilizer and other organic sources, and management practices, and to rank the risk of losses of reactive nitrogen, including the nitrate leaching pathways, as very low, low, medium, high, or very high risk.

The Nitrogen Index can potentially be used as an indicator to assess the risk of nitrate leaching to the environment, helping conservation practitioners and nutrient managers implement best management practices to increase nutrient use efficiencies while reducing the nitrate leaching risk and losses of reactive nitrogen through different pathways. This tool is a new approach and is available for download, along with the code for the tool. The Nitrogen Index shows promise for being used as a quick and effective assessment tool for global sustainability.

Nitrogen (Nutrient) Trading Tool

Jorge A. Delgado

Importance of Nitrogen

Nitrogen is an essential nutrient with very important functions for life; it is a component of nucleic acids, the building blocks of genetic information encoded in DNA, and protein, the building blocks of biological tissues such as muscles or hair. As evidenced by its contribution to increased yields of cropping systems during the 20th century, nitrogen is also important for food security and therefore global stability and peace. Almost all global cropping systems respond to nitrogen inputs with higher yields and economic returns. When its management is combined with conservation practices, the results are very positive; for example, just recently Delgado et al. reported that in systems implementing conservation agriculture in the Andean region of South America, nitrogen inputs increased profits for farmers by 22%, and that these improved best management practices of fertilizer application and conservation agriculture could increase the profits for 200,000 small farmers.[1]

The ever-increasing global population creates additional pressure to increase agricultural intensification to achieve the needed increase in agricultural production needed to feed 2 billion additional people by 2050. The success of the green revolution has contributed to increased global production of grains and other crops such as potatoes, as well as increased yields per area during the last 100 years. [2] Similarly, the total use of nitrogen and nutrients worldwide has also been increasing as the human population and fertilizer needed to increase total global production also increase.[3] It is expected that the use of nitrogen and other nutrients will continue to increase during the 21st century; thus, management of nitrogen and other nutrients will be key to reducing the environmental impacts of adding additional nutrients to intensive agricultural systems to avoid repeating the errors of the 20th century that contributed to losses of reactive nitrogen to the environment in large quantities.

Environmental systems around the world are under pressure due to different factors such as severe droughts, extreme events, reduction of water sources, deforestation, erosion, and impacts of nutrients on aquatic and other natural systems, among others. The projected additional use of nitrogen and other nutrients at a global scale will continue to put additional pressure on these already impacted environmental systems. Nitrogen will continue to be key during the 21st century and important for food security, global stability and peace. The projected increase in the use of nutrients, the effects of extreme events and a changing climate will all put additional pressure on agricultural systems and increase the potential for losses of nutrients such as nitrogen. Adding more reactive nitrogen to the global nitrogen cycle will also increase pressure on these systems since nitrogen cycles through the environment in a phenomenon known as the nitrogen cascade,[4,5] creating a cascade of effects that accompanies this cycling.

Ribaudo et al. discussed the effects of reactive nitrogen from agricultural sources across the environment and concluded that removing nitrate from drinking water costs about 1.7 billion dollars annually in the United States.[6] Follett et al. reported on the effects of reactive nitrogen on human health and the importance of reducing losses of nitrogen to the environment.[7] In a recent paper, Temkin et al. calculated that exposure to nitrate could be connected to close to 3,000 cases of low birth weight and about 2,300–12,500 cancer cases annually in the United States, with annual economic impacts ranging from 250 million to 1.5 billion US dollars, as well as potentially 1.3–6.5 billion US dollars in lost productivity.[8] These impacts will be much higher on a global scale.[8,9] In addition to the impact of nitrate on groundwater and surface water (which will need to be removed for safety if the concentration is above 10 ppm NO_3–N),[10] surface water with hypoxic zones and algae blooms around the world could potentially develop high microcystin levels.[11] Microcystin-LR concentrations above 1.0 µg/L have been reported to be unsafe by the World Health Organization,[12] while the US Environmental Protection Agency (USEPA) reports that safe concentration limits of microcystin are 0.3 µg/L for children less than 6 years old[13] and that microcystin could contribute to gastroenteritis, and liver and kidney damage.[13] Since current projections suggest that use of nitrogen and other nutrients will continue to increase around the world to produce the additional food needed to feed the growing population, the use of conservation practices and management to reduce losses of nutrients will be of great importance.[14,15] Use of nitrogen trading tools that could assess the positive effects of best management practices will be needed so that savings (reductions in nitrogen loss) could be traded in ecosystem markets during the 21st century. Nitrogen is important for global food security, sustainability and peace; the question is how to manage it in the 21st century in the face of a changing climate, which could contribute to higher losses and make management of nitrogen more complex, and how to avoid the errors that were made in the 20th century, which contributed to a stable food supply but resulted in greater losses of nitrogen to the atmosphere, groundwater and surface water.

Need for Nitrogen Loss Measurements

As climate change continues, the occurrence of extreme events such as droughts and floods, desertification, shrinking water resources and other challenges are beginning to put additional stress on agricultural systems throughout the world. These challenges increase the pressure on these systems to maintain productivity and keep up with the growth in food demand that follows human population growth. Humans are significantly impacting the global nitrogen cycle; these impacts are reflected in, for example, increased concentrations of N_2O in the atmosphere, increased nitrate (NO_3) levels in groundwater or surface water resources and increased ammonia (NH_3) deposition in natural areas. Not only can these reactive nitrogen losses impact human health, as has been previously reported, they can also impact ecosystem health and ecosystem balances.[7–9] Over 20 years ago, the USEPA established that the safe limit for drinking water was 10 mg NO_3–N/L[10]; however, a recent paper has reported a positive correlation of NO_3–N in drinking water as low as 0.14 mg/L nitrate with a colorectal cancer risk of one in a million and greater risk at higher concentrations.[8]

The correlation of food security with nitrogen application is strong, and there is a delicate balancing act to be made: on the one hand, nitrogen applications provide food production benefits, but on the other hand, there are environmental impacts from nitrogen applications. This presents a quandary for humanity as far as how to continue to maximize productivity across agricultural systems, which requires nitrogen inputs, while minimizing nitrogen losses to the environment. Nitrogen trading tools and quantification of savings in nitrogen losses that could be traded in water and air quality markets can help provide some answers to this quandary since farmers that improve management of nitrogen could be compensated by trading these savings in air and water quality markets.[6,16,17] Users of the NTT should look at the effects of improved management in the context of the nitrogen cycle; this will help make it possible to sort out the effects of the practices on losses of reactive nitrogen via emissions of N_2O to the atmosphere (i.e., direct emissions of N_2O) and the losses of nitrogen (e.g. NO_3) through surface transport or leaching, which could impact groundwater or surface waters. How management practices interact with crop rotations depends on the previous and current crops, previous history at the site due to previous manure applications, and the site-specific factors (weather, crops, hydrology and landscape) of a given field, and this can be assessed by these types of tools to reduce nitrogen losses.[6,16,18]

Water Quality Trading Programs

Several researchers have proposed the concept of using payments as part of an ecosystem services payment system in an environmental trading/water quality trading program to reduce the negative effects of reactive nitrogen in the environment.[19–23] Hey and Hey et al.[19,21] recommended the strategic placement of wetlands across the Mississippi watershed that could be used as filters to remove nitrate as it enters these wetlands to reduce the transport of nitrogen to the Gulf of Mexico and have farmers receive environmental payments for developing wetlands for their farms to remove the nitrate. This approach is one of a series of precision conservation approaches that could be used with other conservation practices that could be set up strategically in fields and the landscape to increase the efficiency of conservation practices such as sediment traps, riparian buffers and denitrification traps to remove nitrate, phosphorus and sediment from water traveling to the Mississippi River and water bodies.[24–28] These precision conservation approaches together with precision regulation can contribute to increased adoption of conservation practices that will reduce losses of nitrogen and other nutrients to the environment. These practices can be among the key tools in the 21st-century toolbox to adapt to a changing climate and avoid some of the errors made in the 20th century.[26,28] The concept of Sustainable Precision Agriculture and Environment (SPAE)[29] is similar to the 7 R's approach to reduce the transport of nitrogen to the environment and the transport of other nutrients and sediment.[26,28] There are tools such as the Nutrient Tracking Tool and COMET-VR that can be used to assess the effect of management practices and quantify the reductions of nitrogen losses, nutrient losses and sediment transport across the environment so these reductions can potentially be traded in water quality and air quality markets.[30,31]

A review of potential trading markets by Lal et al.[32] found that precision conservation approaches have been considered by the Connecticut Department of Environmental Protection (DEP), Pennsylvania, Ohio and Oregon, and that these markets could benefit from the use of an NTT approach. The state of Pennsylvania's DEP has a nutrient trading program and additional information could be found at the program's website (https://www.dep.pa.gov/Business/Water/CleanWater/NutrientTrading/Pages/default.aspx). The nutrient trading program in Pennsylvania has developed Excel files used in calculations to assess practices such as cover crops, wetlands restoration, riparian buffers and grass buffers (https://www.dep.pa.gov/Business/Water/CleanWater/NutrientTrading/Pages/TradingResources.aspx) and their reduction of nitrogen losses.

The World Resources Institute (WRI) and the Chesapeake Bay Foundation have reported that these nutrient trading approaches in the states that are part of the Chesapeake Bay area can contribute to reduced environmental impact and could provide income for a farmer that installs a grass buffer along a stream to filter out fertilizer runoff and trades these credits with municipal wastewater treatment plants or stormwater management units that are having trouble reducing their pollution (https://www.wri.org/blog/2017/03/podcast-how-we-can-clean-chesapeake-and-save-money-process).

The concept of nutrient trading for water quality has been supported by the USEPA (https://www.epa.gov/nutrient-policy-data/collaborative-approaches-reducing-excess-nutrients#creating) with policies and regulations. Figure 1 shows nutrient trading for water quality efforts in the United States up to 2016. These nutrient trading efforts have contributed to localities and regions achieving compliance with the regulatory requirements of the Clean Water Act. The USEPA has implemented efforts to leverage

FIGURE 1 A map of water quality trading in the United States in 2016 (USEPA webpage).

emerging technologies and facilitate broader adoption of market-based programs. Customers of the water quality trading effort under the Clean Water Act can use this option for compliance with water quality-based effluent limitations with a National Pollutant Discharge Elimination System (NPDES) permit. Ribaudo and Gottlie[33] and Ribaudo et al.[34,35] reviewed different trading markets that can be used to reduce environmental effects from agriculture and reported that tools like the NTT could be used to reduce the uncertainty and provide information that could be used for these market systems.

Payments for Environmental Services Programs

Various reviews have been conducted about worldwide water quality trading programs or other types of trading programs. Selman et al. reported in 2009 that water quality trading programs were gaining traction and that there were 57 water quality trading programs worldwide, with 26 active programs, 21 under consideration for development and 10 inactive, with the majority of the programs in the United States and others in Australia, New Zealand and Canada. Stanton et al.[36] reported that there were 288 watershed payment programs. They reported that in 2008 there were 14 active water quality trading programs and 113 payments for watershed service programs with a value of transactions of 9.3 billion dollars, protecting 50.1 billion hectares.[36] They reported that in 2008 there were programs across 24 different countries including the United States, Brazil, Canada, France, China and New Zealand.

Forest Trends has a map of current active ecosystem markets that displays current watershed projects worldwide (https://www.forest-trends.org/project-list/#s). These projects have been identified as projects where people or organizations pay for conservation practices. They identified 466 watershed projects worldwide covering over 330,000,000 hectares. The water quality trading in the United States in 2016 can be found at the USEPA website (https://www.epa.gov/nutrient-policy-data/collaborative-approaches-reducing-excess-nutrients#creating), with a large number of programs concentrated around the north-east and in the Midwest. At this webpage, the user could click on each identified point on the map and find specific information about the program (Figure 2).

The Nature Conservancy identified 391 carbon sequestration projects worldwide covering over 52,000,000 hectares. These carbon projects can be used to produce carbon offsets (reductions in CO_2 emissions) that are sold in carbon markets. These sold offsets in CO_2 can be used to offset greenhouse gas emissions elsewhere. The Environmental Defense Fund has a website describing 19 multinational, national,

regional and local emissions trading systems (https://www.edf.org/worlds-carbon-markets). They reported that there are over 50 jurisdictions around the world with emission trading programs (or carbon markets).

The NTT has been reported as a potential tool that could be used to assess the effects of management practices on reductions of greenhouse gases (GHG).[6,16,30,31] Delgado et al. reported that since nitrogen fertilizers increase N_2O emissions and we could use the NTT to assess the effects of practices that reduce emissions of N_2O and that reduce NH_3 volatilization and NO_3 leaching losses that contribute to indirect emissions of N_2O, the NTT could be used to trade reductions of direct and indirect N_2O emissions.[6,16] Recent advances with tools such as the Nutrient Tracking Tool and COMET-VR also put these tools in a strong position to be used to assess the effects of management practices on carbon sequestration and reductions of direct and indirect N_2O emissions.[30,31] Both of these tools are being used by NRCS.[30,31]

The Nutrient Tracking Tool (NTT) is a tool being used by NRCS and is a free, online, user-friendly tool that quantitatively calculates the nitrogen, phosphorus and sediment losses from crop and pasture lands, and these savings could potentially be used for trade in water and air quality markets. The COMET-Farm tool is the official greenhouse gas quantification tool of USDA, and it could be used to the assess effects of management practices on reductions of GHG (https://www.nrcs.usda.gov/wps/portal/nrcs/detail/national/programs/?cid=stelprdb1261363).

The American Carbon Registry is a nonprofit carbon market in the United States that is a voluntary greenhouse gas registry (https://americancarbonregistry.org/). Among the different factors that this voluntary registry can keep track of is carbon sequestration in soils as well as potential reductions in N_2O emissions from agricultural fields. This registry lists accepted methodologies for quantifying reductions in greenhouse gas emissions resulting from changes in fertilizer management, such as improvement in nitrogen fertilizer management practices, which could contribute to reductions in N_2O emissions (https://americancarbonregistry.org/carbon-accounting/standards-methodologies/emissions-reductions-through-changes-in-fertilizer-management). Examples like this show that water and air (carbon) quality markets are connected, in that improved nitrogen management practices that increase nitrogen use efficiencies and reduce losses of nitrate, generate savings that can be traded in water quality markets, and increase efficiency, simultaneously reducing emissions of N_2O and generating savings that can be traded in air (carbon) trading markets. The 21st century will continue to bring opportunities to farmers to improve their nitrogen management practices and trade these savings in nitrate leaching losses and direct and indirect emissions of N_2O in water and air (carbon) trading markets.

Conclusion

There are new ecotechnologies such as the Nitrogen Trading Tool (NTT) that could be used to quickly assess how best management practices may reduce the losses of reactive nitrogen via several pathways, including nitrate leaching and direct and indirect N_2O emissions. The first NTT was developed by ARS in cooperation with NRCS.[6,16,37] The concept and capabilities of the original Nitrogen Trading Tool (NTT) were expanded in the Nutrient Tracking Tool (NTT), which can assess the effects of management practices on reductions of nitrogen and phosphorus losses and reductions in erosion.[18,30] Additionally, the new COMET-VR model can also assess the effects of conservation practices on reductions of greenhouse gas emissions and assess carbon sequestration in farms. There is potential to use the Nutrient Tracking Tool (NTT) and COMET-VR tools, which are both robust and have a strong scientific background, across the United States and internationally. Both the NTT and COMET-VR are currently being used by USDA as their tools to assess the effects of conservation practices on potential reductions in greenhouse gases and protection of water quality.

There is also potential to use other tools and approaches that could quantify the effects of management practices on reduction of nitrogen losses to the environment. For example, various water quality trading markets have developed coefficients and Excel files to quantify the reductions in nitrogen losses when a given conservation practice is applied (www.dep.pa.gov/Business/Water/CleanWater/NutrientTrading/Pages/default.aspx; https://www.wri.org/blog/2017/03/podcast-how-we-can-clean-chesapeake-and-save-money-process). Webpages developed by the EPA and Forest Trends are examples of online tools that track the development of active water and air quality markets where there are opportunities for tools like the NTT be to applied (https://www.epa.gov/nutrient-policy-data/collaborative-approaches-reducing-excess-nutrients#creating; https://www.forest-trends.org/project-list/#s). Independent of what tools are being used to assess the benefits of management practices in reducing losses of reactive nitrogen to the environment, application of conservation practices across watersheds will provide opportunities to reduce losses of nitrogen that can potentially impact water quality and air (carbon) quality. The use of new technologies and tools like the Nutrient Tracking Tool and COMET-VR that can assess temporal and spatial variability will allow us to assess hot-spot sources of nitrate leaching and greenhouse gas emissions across the environment and effectively apply conservation practices by considering spatial and temporal variability with precision conservation management and precision regulation.[27–31] The concept of the NTT and new ecotechnologies such as COMET-VR and the Nutrient Tracking Tool will help nutrient managers, conservation practitioners, farmers and other users quickly identify conservation practices that maximize nitrogen use efficiency while reducing nitrogen losses to the environment, providing an opportunity to trade the saved nitrogen in water and air (carbon) markets and contributing to conservation of the biosphere.[6,16,18,17,29–31]

The Accounting Framework of Energy–Water Nexus in Socioeconomic Systems

Saige Wang and
Bin Chen

Introduction

Water use and energy consumption are highly interwoven in economic networks due to their interconnections in both the production and consumption of primary, intermediate, and final goods and services (Chen 2016; Chen and Lu 2015). At all stages of the production chain, water and energy resources are used and "embodied" in the products. Nexus analysis highlights the interconnections and interdependencies for all kinds of economic activities (Dai et al. 2018; Hoff 2011). The tracking of energy and water flows among regions and the quantification of their interdependencies are fundamental for coordinated management of regional resources (Liu et al. 2018).

Most of the recent research on energy–water nexus has explored the energy or water sector alone or impacts of specific technologies on sectors with energy minimization and water use options (Kenway et al. 2011; Wang and Chen 2016; Wang et al. 2017a). However, there are few works published that conceptualize the role of the nexus in reconfiguring the interactions between energy- and water-related sectors in a socioeconomic system (Chen et al. 2018; Owen et al. 2018). Some studies have explored the direct and indirect interdependencies between energy and water in socioeconomic systems (Duan and Chen 2016; Fang and Chen 2017; Liu et al. 2019). By tracking sectoral economic flows through a supply chain, input–output analysis (IOA) can be used to investigate these interdependencies, which are a common focus in nexus studies (Wang et al. 2019; Wang and Chen 2016). Based on these sectoral interactions and exchanges with other economies through the supply chain, IOA-based approaches can assess both the direct and indirect energy (or water) consumption required to produce goods and services in a region (Wang et al. 2017b; Wang and Chen 2018). Compared with conventional nexus studies, which prioritize specific interdependencies (e.g., by defining that specific processes require certain resources), the system-wide approach of IOA presents a more comprehensive picture that includes direct and indirect use profiles and hotspots. Pioneering works have used IOA case studies to focus on the interplay involved in the water–energy nexus (Cao et al. 2018; Chen and Chen 2016; Wang et al. 2019). For example, Wang et al. (2017b) proposed a modified IOA that provided a unified framework to analyze the tradeoffs between urban energy and water systems. Fang and Chen (2017) used IOA and linkage analysis to detect synergetic effects of water and energy consumption and their interactions among economic sectors. Marsh suggested various IOA techniques to address multiple dimensions of the nexus (linkage, dependency, multiplier, and scenario analyses) (Marsh 2008). Kahrl and Roland-Holst built relevant metrics to quantify the nexus from physical, monetary, and distributive perspectives (Kahrl and Roland-Holst 2008).

Ecological network analysis (ENA), a system-based approach, has its unique strength in examining the structure and function of system from a system perspective (Fath 2007, 2015). The control and dependence analysis of ENA may also provide insights into the interwoven relationships among nodes due to the direct and indirect flows, which can be used to identify the regulating pathways for the system. Also, Wang and Chen (2016) established a multiregional nexus network based on multiregional IOA and ENA to explore the structural properties and sectoral interactions within urban agglomerations. However, nexus issues in energy and water policy are rarely studied from a systems perspective, an area that urgently requires investigation. Particularly in energy development planning, the role of water stress issues is insufficiently considered as a part of nexus management (Font et al. 2017; Williams et al. 2014).

Water is directly or indirectly required in all types of power generation technologies for cooling purposes, steam generation, and infrastructure manufacturing. There is a great diversity of water intensities among different energy types. The water intensity gap among different electricity types provides us the opportunity to reduce the power generation's vulnerability to water shortages. In this study, we will propose an accounting framework to extend the energy development scenarios into nexus to study interwoven connections of energy consumption and water use in economic supply chain based on IOA and ENA.

Accounting Framework

In our accounting framework, we will first quantify the energy-related water and water-related energy from consumption and production perspectives combining a bottom-up method and a life cycle analysis. Then, energy and water flows among regions and sectors will be calculated based on IOA. The direct and indirect energy and water-related energy were then combined as embodied energy to build the nexus network model. By merging the energy-related water and direct water, we will build a regional energy–water nexus network to investigate its system properties. The nexus point is built to form the energy and water flows in the same nexus network. The tools from ENA were used to explore the energy and water control and dependence relationship among sectors under the nexus impact background. Flow analysis was used to identify critical pathways for nexus management. We investigated the sectoral nexus impact for energy system by comparing energy and water-related energy network to identify critical sectors for energy-side nexus management. The sectoral nexus impact under different scenarios was compared and analyzed based on ENA. Finally, network impact through direct and indirect pathways is used to reveal the effect of energy–water nexus on all sectors in a more explicit and predictable way and the tradeoffs among energy, water, and carbon using nexus accounting and the scenario features can be discussed.

Thus, we can capture both intensities and structures of regional nexus and how they alter the local consumption. Integrated analysis and modeling of the water–energy nexus require the simulation of many human and natural systems and their complex interactions and dynamics (Wang et al. 2018, 2019). By doing this, we are trying to reveal energy–water nexus impacts of pathways and sectors on the system and track energy and water flows among sectors. System properties, such as cycling index and system robustness, can help us to identify the risks in the energy–water nexus and leverage points to promote sustainable regional energy and water management.

Water Quality: Modeling

Richard Lowrance

Introduction

Water quality models are based on some representation of hydrology and may include movement of surface water, groundwater, and mixing of water in lakes and water bodies. Based on the hydrology, water quality models then simulate some combination of sediment, nutrients, heavy metals, and xenobiotics such as pesticides. Some water quality models, especially those that deal with nutrients, may contain substantial detail related to biological processes including algal growth, nutrient transformations, and respiration. Most water quality models that portray the movement of water within a landscape or landscape components (e.g., fields, forests, streams) portray the interaction of water with soil in a variety of ways. Newer water quality models and add-ons to older water quality models are able to portray the effects of water quality parameters on the biota of lakes and streams or incorporate stream bank, riparian zone, and/or channel functions to understand the effects of these areas on chemical and sediment transport. Other water quality models are used to simulate the effects of critical inputs on the biological communities of lakes and rivers. These aquatic ecosystem models may or may not be tied to watershed models that provide simulated loading to the aquatic ecosystem under varying land use and management.

Classification of Water Quality Models

Water quality models are either built on hydrologic models, are used in conjunction with hydrologic models, or use empirical hydrologic data. Although water quality models can be physical representations of the real world such as channels and ditches built to scale, mathematical or formal models are more common.[1] Mathematical water quality models are quantitative expressions of processes or phenomena that are known to occur in the real-world. The expressions are simplifications of real-world systems through a series of equations governed by conservation of mass. Mathematical water quality models are often a combination of theoretical and empirical representations of the real-world system. Empirical models use water quality observations to provide estimates of water quality parameters through regression analysis. Process based or theoretical representations use physical, chemical, and biological causal relationships to describe the workings of a conceptual system.

Although the real world is subject to random occurrences of weather and management that drive hydrology and water quality, many models ignore the randomness of inputs and spatially distributed attributes and assume that there is a known value for all model parameters. Conversely, stochastic (or random) models use probability distributions of parameters in time or space and can provide outputs based on the distribution. Most water quality models are deterministic models in the sense that one set of inputs will provide only one set of outputs. The difference in a stochastic and deterministic model can be illustrated by how models deal with something simple like how fast water moves in a soil. A deterministic model would use one value for each soil while a stochastic model would vary the movement rate based on the range and distribution of measured water movement rates. Deterministic models are often used with a range of key parameters in order to produce a range of outputs that would better represent real world conditions. Another critical distinction among water quality models is whether they provide continuous or event-based simulations. Continuous simulation models generally provide at least some representation of groundwater/surface water interactions, while event-based models are more likely to provide only representations of hydrologic processes that take place during rainfall events.

A final distinction among models is whether they are lumped or distributed parameter models. A lumped parameter model contains little or no spatial realism and represents landscape units as homogeneous with respect to the parameters and inputs that drive the model. A distributed parameter model represents certain aspects of the landscape structure, typically by representing areas that are homogeneous with respect to soils, vegetation, and/or land use. Each of these discrete areas is modeled separately and then outputs from all the discrete areas are put together and routed through the system. Because most water quality models are tied to hydrologic models, the water quality outputs from source areas in the model are typically routed through either surface flow pathways, subsurface flow pathways, or both. Models that deal only with events are typically routed through surface flow pathways. Models that simulate continuous or daily water quality in a watershed or field generally must deal with both subsurface or groundwater routing and surface water routing.[2]

Uses of Water Quality Models

Risk Assessment of Pesticides

Knowledge of fate and transport of pesticides in the environment is essential to the assessment of risk due to dietary and drinking water exposure. The passage of the Food Quality Protection Act (FQPA) lead to a pressing need to quantitatively predict ranges and magnitudes of expected environmental pesticide concentrations in drinking water. Health-based safety standards mandated by FQPA require USEPA to consider drinking water exposures of humans to pesticides during the risk assessment process. Some state agencies and USEPA use screening models to estimate pesticide concentrations in groundwater and surface water to identify those food-use pesticides that are not expected to contribute enough exposure via drinking water to result in unacceptable levels of aggregate risk.[3] The models are used to guide regulatory agencies such as USEPA to identify where more detailed field data are needed.

Evaluation of Best Management Practices (BMPs)

Water quality improvement from extensive land uses such as agriculture and forestry depends largely on the use of BMPs. Agricultural water quality modeling attempts to adequately represent the differences among various management practices in order to compare and choose which BMPs lead to the least transport of pollutants. These models are typically structured to represent homogeneous landscape units such as fields or portions of fields in order to compare management features such as tillage, fertilizer sources, manure use, and pesticide use and predict the relative impacts on local transport of pollutants such as sediment, nitrogen, phosphorus, and pesticides. Existing models may be used to test the application of BMPs to areas for which no water quality data are available or to determine the effects of BMPs that are similar to those for which water quality effects have been quantified.

Evaluation of Sources and/or Impacts of Pollutants

Both process based and empirical models have been used successfully to examine the sources of pollutants in watersheds and the impact of pollutants or non-pollutants on aquatic ecosystems. The need to quantify the non-point source contributions for watersheds and small basins is largely driven by total maximum daily load (TMDL) assessments and implementation plans mandated by the federal Clean Water Act.[4] The TMDL assessments are done with a water quality accounting approach that typically uses water quality models to estimate non-point source pollution. The non-point and point sources of a pollutant that are causing the water quality impairment are then combined and compared to observations in the water body. If the water quality is impaired due to the direct presence of a pollutant, then the model estimates of non-point source pollution are used to design a plan for reducing non-point sources or trading point sources for non-point. If pollutants are tied indirectly to the impairment, for instance nutrient enrichment that causes low dissolved oxygen, then the behavior of the pollutant in the waterbody is modeled in order to determine the necessary pollutant load reduction.

Explanation of Large-Scale Systems Behavior

As the behavior of large-scale systems becomes more of an issue and as water quality monitoring data become more available, attempts have been made to combine monitoring and modeling to predict the transport of water-borne pollutants on large scales—river basins and continents. Regression models are used to relate measured pollutant transport in streams to spatially referenced descriptors of pollutant sources, land surface characteristics, and stream channel characteristics.[5] Although mechanisms of pollutant transport are not modeled directly, coefficients that serve as surrogates for processes are used to achieve substantial explanatory power for observed water quality data.

Drainage: Hydrological Impacts Downstream

Mark Robinson
and D.W. Rycroft

Introduction

Land drainage is the practice of removing excess water from the land, and it is one of the most important land management tools for improving crop production in many parts of the world. Drainage systems may be broadly divided into surface drainage (comprising land grading and open ditches), shallow drainage (such as subsoiling to mechanically loosen the upper layer of soil), subsurface or groundwater drainage (buried perforated pipes or deep ditches), and the main drainage systems (commonly open channels) used to convey the drain water away.[1] Drainage will inevitably affect the pattern of water flows from the land and into the receiving watercourses. It is these downstream impacts of farmland drainage on the timing and magnitude of peak flows that are considered here, using the results of experimental studies and computer simulations, to present a coherent picture, and to answer most of the apparent anomalies and conflicts.

Hydrologic Impacts

Concern about the possible downstream effects of drainage is shown by many published papers worldwide, in North America,[2,3] Great Britain,[4,5] and continental Europe, including France,[6] Netherlands,[7] Ireland,[8,9] Fin- land,[10] and Germany.[11] The role of drainage has often been highlighted by serious flood events—for example, in the Midwest of the United States in 1993, and across Europe in 1997—which reawakened concerns that drainage could aggravate flooding downstream.

There has been a debate about the effects of drainage on streamflow for well over a century, but until recently, due to the lack of appropriate data, the debate has been largely speculation. Too often, the absence of evidence has erroneously been taken as evidence of an absence of effect. The earliest published account[12] was a report of a 4-day meeting held at the Institution of Civil Engineers in London in 1861. Many of the arguments and opinions expressed have resonance today, but due to the absence of objective measurements, the participants were unable to reach any conclusions and the meeting was inconclusive.

These conflicting opinions resulted from differences in the emphasis given to the two processes of water storage and routing. Considering the former, it may be argued that because drainage lowers the water table, the available storage capacity in the soil is enlarged and able to absorb more storm rainfall, thereby reducing peak flow rates. In contrast, according to the routing argument, the purpose of drainage is to "remove water from the land more quickly" than under natural conditions, so peak outflows must necessarily increase.

Probably more work has been carried out in Britain upon the effects of agricultural drainage upon streamflow than in any other country. Britain was the originator of modern field drainage[13] and so became the first country where concern arose about its downstream effects; it is also one of the most extensively drained countries in the world.

It is only in the last few years that it has been possible to obtain a coherent picture based on observations of field processes and supported and extended by computer modeling. This has shown that general statements that drainage "causes" or "reduces" flood risk downstream are oversimplifications of the complex processes involved, and that any consideration of the impact of drainage on streamflow must identify the point of interest, whether at the outfall from the field, along the main channel, or a combination of both at the catchment scale.

Experimental studies indicate that the provision of surface drainage will result in higher peak flows downstream. This was shown by a long-term experiment at Sandusky in Northern Ohio[14] and is a result of the reduction/ elimination of surface storage capacity, as well as the provision of more efficient faster flow routes. This has been demonstrated conclusively both by experimental studies and by computer simulations.

In contrast, there seems to be general agreement from experimental studies that subsurface drainage of waterlogged, poorly permeable clay soils reduces peak out- flows.[15–17] Since this is one of the most common situations where artificial drainage is used, it might be considered to represent the most general result of field drainage.

There are, however, instances where even on heavy soils this result may not apply. Due to their low hydraulic conductivity, most water movement in clay soils is confined to flow through macropores, such as cracks. As a result of clay shrinkage and cracking in warm, dry summers, rapid macropore flow can result in larger peak flows from the drained land than from the undrained land. The role of macropores on the seasonality of peak flows from drained land was demonstrated in detail.[18]

More permeable, drier soils may also be drained where there is an economic justification—for example, drainage of land producing high-value crops. In contrast to clay soils, relatively few scientific field studies have investigated the impact of draining lighter, more permeable soils. This may be partly due to the emphasis on draining clay soils, but also, no doubt, results from the greater practical difficulty encountered in plot definition where the soils are more permeable. Nevertheless, data from several drainage experiments on permeable soils are available. At Withernwick,[19] flow peaks were increased in the first year after drainage and there was then a reduction in the following years due to the progressive deterioration of the secondary system of subsoiling designed to improve the soil structure. Supporting evidence of increased peak flows following the drainage of more permeable soils also comes from studies at Cockle Park in northern Britain[20] and Ellingen in Central Germany.[21]

To identify factors influencing drainage response, the results of field drainage experiments under temperate northern European climates were analyzed in terms of their site characteristics.[22,23] This included topography, precipitation, drainage depth and spacing, natural (i.e., pre-drainage) soil water regime, and the soil properties. The only characteristic distinguishing sites, where drainage increased peak flows from those where they were reduced, were those relating to the soil water regime before drainage. The experimental sites all had similar land practices on the drained and the undrained land.

Drainage reduced peak flows on sites that had wetter soils and with poor natural drainage, and significant amounts of storm runoff were generated as overland flow and near-surface flow in the thin upper layers of the soil. These sites had higher topsoil clay contents and shallower depths to a poorly permeable subsoil horizon. When artificially drained, the surface saturation was largely eliminated, greatly increasing the soil water storage capacity.

In contrast, at sites with more permeable, loamy soils that were not routinely saturated before drainage, natural storm flow occurred predominantly by slower subsurface flow, and the artificial drainage pipes provided more rapid flow routes leading to increases in peak outflows.

The findings are summarized in Figure 1. This shows the topsoil texture, together with the effect of drainage on peak flows, and provides the engineer or conservationist with an initial guide to predict the effect on flows of the drainage of a site, based on knowledge of the predrainage site characteristics.

Further insights into the factors controlling the impact of drainage may be obtained by the application of modeling techniques to investigate the important interaction between soil properties and climate in determining soil water regimes. DRAINMOD[24] was applied to two of the field sites with similar climates: a heavy clay soil at Grendon and a more permeable loam at Withernwick. The model was applied to each site using actual field values of drain and soil parameters, and the simulated peak flows from drained and undrained land were compared for similar rainfall inputs. The results showed a 70% lower median peak flow after drainage of clay soil and an increase of 40% in the median peak flow from the more permeable land.[23]

The modeled fluxes and water stores confirmed that the reduction in peaks from the clay soil after drainage was achieved by a change in storm runoff generation from overland flow (caused by soil saturation) to subsurface drainflow. For the loamy soil, the model indicates that the increase in peak subsurface flow rates was due to the steeper hydraulic gradients created by the closer-spaced artificial drains.

The model also demonstrated the effect of different climatic conditions. If the loam soil site at Withernwick had double the normal rainfall (1200 mm yr^{-1} instead of 600 mm yr^{-1}), the resulting increase in ground wetness would be sufficient to generate substantial amounts of overland flow on the undrained land. Artificial drainage in this case would then reduce peak flows—exactly as happens for a clay soil (where, in contrast, the ground wetness is caused by the low soil permeability). Using the model in this way enables these effects of site characteristics to be explored in an objective manner. The overall dominant criterion—the amount and frequency of surface runoff from undrained land—can be assessed in terms of both soil properties and climatic characteristics.

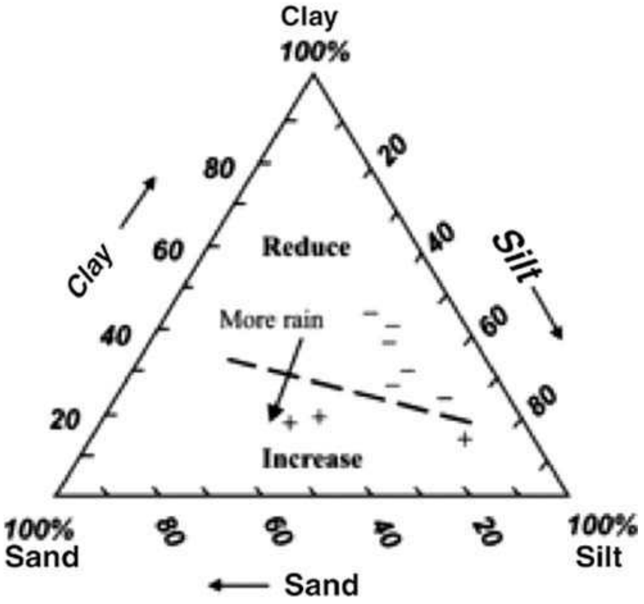

FIGURE 1 Observed impact of pipe drainage on downstream peak flows (increase/reduce), showing the importance of soil texture. Model simulations of climate changes indicate that higher rainfall and wetter ground conditions will shift the balance towards drainage schemes reducing peak flows. See text for details.

Conclusions

The effect of subsurface drainage on peak flows depends upon site wetness. If the water table is close to the surface (due to high rainfall or poor permeability), natural flows occur either over the surface or through the upper, more permeable layers of the soil. Drainage will increase soil water storage capacity and hence the amount of water that can infiltrate, thereby reducing surface runoff and peak storm flows. If the water table is deeper, due to a dry climate or due to more permeable soils, natural flows will occur through the body of the soil. In this case, artificial drainage will increase peak flows as a result of the shorter flow paths and steeper hydraulic gradients.

It must be noted that these conclusions depend upon the scale of the drainage considered. At the river catchment scale, main channel improvements will undoubtedly increase the speed of flow routing, and the timing of arrival of flows from different subcatchments will influence the peak discharge at the point of interest. The relative importance of field drainage and main drainage channels will vary with storm size: field drainage being dominant for small and medium storms, but main channel improvements becoming dominant for large events. In extreme situations where the rainfall intensity exceeds the infiltration capacity of the soil, the effects of the subsurface drains will be minimal, but the associated improved watercourses will rapidly carry away the surface runoff.

Overall, it seems likely that in large catchments, drainage schemes with substantial associated surface drainage and main channel improvements will lead to higher flow peaks downstream, even though locally, the effect of drainage may be to lower the peak flows.

Drainage: Soil Salinity Management

Glenn J. Hoffman

Introduction

Soil water must drain through the crop root zone when salinity is a hazard to prevent salts from increasing to levels detrimental to crop production. Drainage occurs whenever irrigation and rainfall provide soil water in excess of the soil's storage capacity. In humid regions, rainfall normally satisfies crop water requirements and precipitation infiltrating into the soil in excess of this requirement leaches (drains) salts present below the crop root zone. In subhumid areas, rainfall is often inadequate in amount or temporal distribution to satisfy crop needs and irrigation is implemented. For arid regions, rainfall is never abundant and the preponderance of the crop water requirement must be provided by irrigation. Regardless of the climate, if soluble salts are present, water in excess of that needed to satisfy the crop water requirement must be provided to leach excess salts. Leaching may be accomplished continuously or at intervals, depending on the degree of salinity control required. It may take decades or as little as one season, depending on the hydrogeology of the area, but without drainage, agricultural productivity cannot be sustained where salinity is a threat. For a more complete discussion on drainage design for salinity control, the reader is referred to Hoffman and Durnford.[1]

Drainage Conditions

All soils have an inherent ability to transmit soil water provided a hydraulic gradient exists. If the hydraulic gradient is positive downward, drainage occurs. Soils with compacted layers, fine texture, or layers of low hydraulic conductivity may be so restrictive to downward water movement that drainage is insufficient to remove excess salts. In some areas, the hydrogeology may be such that the hydraulic gradients are predominantly upward. This leads to water logging and salination.

Before designing a man-made drainage system, the natural drainage rate should be determined. If the natural hydraulic gradient causes soil water to drain out of the crop root zone, the capacity of the artificial system can be reduced, thereby decreasing the cost for drainage. In some situations, upward flow into the crop root zone from a shallow aquifer can significantly increase the drainage requirement.

The upward movement of groundwater leads to salination as the water evaporates at the soil surface, leaving salts behind. If upward flow is ignored, the drainage system may be inadequate. Regardless of the source, an artificial drainage system will not function unless it is below the surface of the water table.

Drainage Requirement

Saline Soils

The amount of drainage required to maintain a viable irrigated agriculture depends on the salt content of the irrigation water, soil, and groundwater; crop salt tolerance; climate; soil properties; and management. At present, the only economical means of controlling soil salinity is to ensure an adequate net downward flow of water through the crop root zone to a suitable disposal site. If drainage is inadequate, harmful amounts of salt can accumulate.

In irrigated agriculture, water is supplied to the crop from irrigation, rainfall, snow melt, and upward flow from groundwater. Water is lost through evaporation, transpiration, and drainage. The difference between water inflows and outflows is the change in soil water storage. A water balance, expressed in terms of equivalent depths (D) of water, can be written as

$$D_s = D_i + D_r + D_g - D_e - D_t - D_d \tag{1}$$

where the subscripts s, i, r, g, e, t, and d designate storage, irrigation, rainfall and snow melt, groundwater, evaporation, transpiration, and drainage, respectively. The corresponding salt balance, where S is the amount of salt and C is salt concentration, can be expressed as

$$S_s = D_iC_i + D_rC_r + D_gC_g + S_m + S_F - D_dC_d - S_p - S_c \tag{2}$$

with S_s being salt storage, S_m is the salt dissolved from minerals in the soil, S_f indicates salt added as fertilizer or amendment, S_p is precipitated salts, and S_c is the salt removed in the harvested crop.

Rarely do conditions prevail long enough for steady state to exist in the crop root zone. However, it is instructive to assume steady state to understand the relationship between drainage and salinity. If upward movement of salt, the term ($S_m+S_f-S_p-S_c$), and the change in salt storage are all essentially zero, then the salt balance Eq. (2) can be reduced to

$$D_dC_d = D_iC_i + D_rC_r \tag{3}$$

The leaching fraction, L, is the ratio of the amount of water draining below the crop root zone, D_d, and the amount applied, D_i+D_r. The ratio of the salt concentration entering and leaving the root zone can also be used to estimate L. Since C_r is essentially zero.

$$L = C_i/C_d = D_d/D_i + D_r \tag{4}$$

The concept in Eq. (4) is important because it illustrates the relationship between leaching fraction and salinity.

The minimum leaching fraction that a crop can endure without yield reduction is termed the leaching requirement, L_r. The leaching requirement is the minimum amount of drainage required to prevent excess accumulations of salt that result in loss of crop yield. Several models have been proposed to estimate the drainage (leaching) requirement. Of the four models tested,[2] the one presented in Figure 1 agrees well with measured values of the drainage requirement through the range of agricultural interest. The drainage requirement given in Figure 1 is the fraction of the volume of applied water that must pass through the crop root zone as a function of the salinity of the applied water and the salt tolerance of the crop.

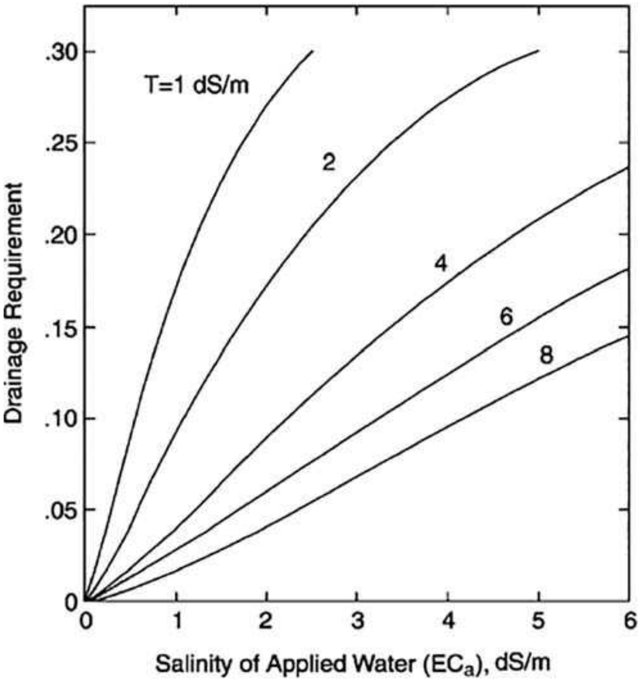

FIGURE 1 Drainage requirement as a function of the salinity of the applied water (reported as the volume weighted electrical conductivity) and the salt tolerance threshold value for the crop (T).
Source: Adapted from Hoffman and Van Genuchten.[15]

Sodic Soils

A soil is said to be sodic if an excessive concentration of sodium causes a deterioration of soil structure. The impact of excess sodium is a reduction in hydraulic conductivity and crust formation. Sodic conditions decrease the rate of drainage. Before a sodic soil can be restored to full productivity the excess sodium in the soil must be replaced with calcium or magnesium. This process frequently requires copious amounts of leaching to reclaim the soil. The design of an artificial drainage system that may be required, however, is based upon the long-term requirement for drainage as estimated in Figure 1 rather than the anticipated high drainage requirements for reclaiming a sodic soil.

Drainage System Design

There are three types of subsurface systems used to control soil salinity: relief drains, shallow wells, and interceptor drains. Relief drains, usually consisting of perforated corrugated plastic tubes buried in a regularly spaced pattern, is the most common subsurface system. Laterals for relief drains are typically placed 2.0–3.5 m deep and are spaced horizontally ten to hundreds of meters apart where salinity is a hazard. Shallow wells, called tube wells in some regions, can also be used to lower the water table by allowing pumping from shallow, unconfined aquifers. Tube wells are spaced at distances of a few hundred meters to several kilometers and may be a few meters to a hundred meters deep. Interceptor drains are used to remove excess soil water from saline seeps. Frequently, one subsurface drain, properly located at the upslope side of the seep, is sufficient. Regardless of the type of drainage system, the depth of the water table must be maintained low enough that (1), salts in the soil profile move to the water table (2), the rate of water movement by capillary flow to the soil surface because of evaporation is minimal, and (3), upflow of saline groundwater into the root zone is prevented.

Relief Drains

A relief drainage system consists of a main drain, collector drains, and field drains (laterals). The main drain is frequently a surface stream or an open drainage canal. Collectors and laterals are usually buried in a regular parallel pattern. Either open ditches or perforated pipes can serve as collectors and laterals. Open ditches are not normally installed now because they occupy land, are difficult to maintain, and are only capable of shallow drainage. Laterals are up to 300 m long and terminate in a collector drain. Both single- and double-sided entries by laterals into a collector are common.

Drain Depth

Subsurface drains are installed much deeper for salinity control in arid regions than drains for water table control in humid regions. The goal for salinity control is to place the drains deep to limit salination of the root zone by capillary upflow. Drains are placed at depths of 2.0–3.5 m in arid regions.[3] The appropriate drain depth depends upon the depth capacity of the installation machinery, the location of a shallow soil layer that impedes water movement, and anticipated benefits compared to additional costs of deeper installation.

Drain Spacing

The spacing between laterals is often estimated using simple drainage design equations. Drain spacing determinations can be based on criteria of steady-state, falling- water-table, or fluctuating-water-table conditions.[4] For large drainage projects or where more accurate values are desired, computerized drainage design models are available. An early computer model developed by Skaggs[5] has been altered by several for irrigated conditions.[6,7] Other models present drainage designs for irrigated areas based on optimization,[8] decision support systems,[9] or reuse of drainage water.[10]

Drainage Wells

Shallow or tube wells offer a viable alternative to relief drains when the aquifer has sufficient transmissivity to provide a significant yield of drain water and the vertical permeability between the crop root zone and the aquifer is adequate. Under these conditions, tube wells have the advantages of being able to lower the water table to greater depths than relief drains and also provide supplemental water for irrigation if the quality is appropriate.

Because drainage wells can be installed at convenient locations within the area to be drained and can be operated either continuously or intermittently, the management of a system of drainage wells is more versatile than relief drains. Relief drains are typically a passive drainage system relying on gravity and designed to operate continuously.

Economic comparisons between the costs of drainage wells and relief drains vary. It is generally found that relief drains have lower construction and operation costs.[11] However, Mohtadullah[12] showed tube wells were a better economic choice than relief drains for the Indus Basin.

Saline Seeps

The occurrence of saline water at the soil surface downslope from a recharge area is referred to as a saline seep. Saline seeps can occur because of the reduction of evapotranspiration that occurs when grasses or forests are converted to cropland in the upland (recharge) areas of a watershed. Dryland farming practices that include fallow periods tend to aggravate the seepage problem. Salination occurs as water infiltrating in the upper elevations of the watershed moves through salt-laden substrate on its path to a discharge site at a lower elevation. In the discharge area of the seep, crop growth is reduced or the plants killed by an intolerable level of salinity. Saline seeps can be distinguished from other saline soil conditions by their recent origin, relatively local extent, saturated soil profile, and sensitivity to precipitation and cropping systems.[13] Saline seeps occur throughout the Great Plains of North American and in Australia, India, Iran, Turkey, and Latin America.[14]

Planting crops in the recharge area that consume soil water before it percolates below the crop root zone will prevent saline seeps. Failing this, improved drainage may provide a solution. Installing an interceptor subsurface drain immediately upslope from the saline seep is frequently a successful solution. Interceptor drains to control seepage should be installed as deep as practical. If the layer restricting soil water flow is not too deep, placing the interceptor drain just above this layer is the most effective location.

Lakes: Restoration

Anna Rabajczyk

Introduction

The 21st century is anticipated as the century of the environment. In this regard, it is crucial to remedy pollution and conserve resources, particular with respect to aqueous ecology, for fostering a healthy environment. Water reservoirs, whether natural or artificial, differ in methods of lake basin formation. The former exist as a result of physical and physicochemical processes occurring in nature; the latter appear due to human interference. Natural water reservoirs of relatively slow exchange of the liquid found therein are defined as lakes.[1,2]

Artificial reservoirs, in turn, also referred to as barrier lakes, are formed by closing river valleys with water dams or drops as damming structures. Several of these reservoirs may also be natural barrier lakes with regulated outflows.[3]

According to their functions, three main types of water reservoirs may be distinguished:[2]

- Dry reservoirs: periodical storage of water during the passage of flood peaks
- Flow-through reservoirs: maintenance of steady retention levels
- Retention reservoirs: storage of water at times of surplus in order to utilize it at other times (subtypes include flood control, navigation, power engineering, water equalization, municipal, industrial, agricultural, or rock waste control reservoirs)

Another classification, which takes into account land configuration, includes mountain, submountain, and lowland reservoirs. The first of these are usually the deepest, with short and high dams. The lowland ones occupy the largest areas and are less deep.[2]

Such considerable diversification of both formation methods and localities causes lakes to be characterized by varying parameters of lake basin morphometry, water transfer speed and routes, water quality therein, etc. Lake shape and dimensions condition lake susceptibility to degradation. Wind speed is higher over large lakes than over small ones, which results in stronger waving and better water oxygenation. Waters in lakes whose elongation follows the most frequent wind directions are also better mixed than in those with transverse orientation.[4]

Low values of the mean-to-maximum depth ratio suggest that large depths are found in a small part of the lake; hence, they may not be of considerable importance for lake functioning. The occurrence of thermal stratification and the size of the littoral zone that uses the biogenes found in the water are both dependent on lake depth.

Each lake, together with the surrounding land and watercourses, forms a catchment characterized by parameters such as topographic features, plant cover, basal complex, and climate conditions, which determine the volume of water resources in a given area. A catchment shaped by low atmospheric precipitation and lowland topographic features provides less water than one with high precipitation and mountainous topographic features, facilitating surface wash. The direction of precipitation waters, accompanied by a variety of compounds, is determined by the basal complex that conditions the river network density and, thus, inflow and outflow volumes. The vegetation found in a particular area stores the water and then gives it off to the atmosphere via the process of transpiration.[2]

At moderate latitudes, water exchange in reservoirs occurs twice yearly: in spring and in autumn. During spring circulation, winter-specific temperature distribution changes when bottom temperatures reach 4°C and upper layers of the reservoir become cooler. As a result of more intensive solar radiation and air warming, surface water temperatures rise. As they reach 4°C, the temperatures of the vertical section equalize because water temperature at the reservoir bottom is 4°C.[5]

As a consequence of wind-induced circulation currents, the entire water mass is mixed (spring homothermy). Further warming of surface waters causes near-surface waters to become lighter than the near-bottom waters whose temperature reaches 4°C (summer stagnation), and an upper warm layer called the epilimnion is formed. The lower layer of cold water is called the hypolimnion. In the metalimnion, i.e., the lake middle or transition water layer, a sharp temperature drop occurs at that time.[6]

In autumn, surface waters cool until they reach a state in which, upon reaching the temperature of 4°C, they attain density identical to that of near-bottom waters. In a way analogous to spring, waters are mixed by wind-induced motion (autumn homothermy). Further cooling of surface waters makes them obtain temperature that approximates 0°C, as well as lesser density than that of near-bottom waters. Subsequently, on the surface, the ice cover is formed (winter stagnation).[5]

Thermal stratification is related to oxygen content stratification in reservoir waters, thus affecting organic life growth. Because the epilimnion is a layer of intensive wind-induced water mixing as well as easy solar radiation access, it displays better oxygenation than deeper layers. As a result of intensive photosynthesis, in summer, water may become supersaturated with oxygen. Spring and autumn circulations cause oxygen to be distributed over the entire water mass.[5,7]

Temperature also conditions other processes that occur in the lake, including the rates of all chemical, biological, and physical reactions.[5] Higher temperature, for example, intensifies the processes of phosphorus release from bottom sediments (Figure 1).

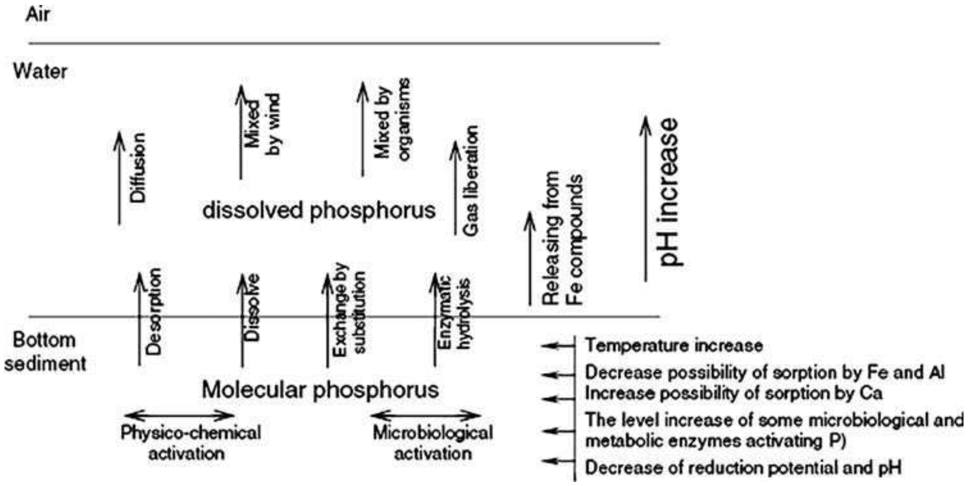

FIGURE 1 Phosphorus release from bottom sediments affected by temperature.
Source: Bajtkiewicz-Grabowska and Zdanowski.[8]

Water temperature increase in the reservoir decreases water viscosity and density. This is particularly significant for plankton organisms as it accelerates the sedimentation speed and changes locomotive conditions. Consequently, the rates of chemical and biochemical reactions increase, and solubility of most substances is enhanced as well, while gas solubility is reduced. The intensification of the processes occurring in the reservoir results in increased use of oxygen. Photosynthetic processes are accelerated, which may lead to cyclical supersaturation of upper water layers. A sudden water temperature rise by 10°C may lead to thermal shock or even death of organisms.[9]

Temperature increase may cause spontaneous discharge of bottom sediments and intensify gas liberation to the extent that the material collected at the bottom is loosened and discharged into water.

Access to solar radiation conditions the growth of autotrophs in the water, as well as that of the organisms situated behind them in the food chain, because the fluctuations in producer numbers affect level 1 (and further) consumer numbers. The propagation of solar radiation in the lake is affected by lake size and shape, i.e., morphometry. For instance, it determines thermal stratification of lake waters as well as chemical, physical, and biological processes that occur in reservoirs.[10]

Natural water reservoirs are efficiently operating ecosystems, capable of maintaining internal homeostasis despite the operation of adverse factors. Yet, human proximity and in particular the effects of human existence have far-reaching consequences (frequently negative) for the environment. Human activity takes forms against which a lake cannot defend naturally. Pollutants rich in biogenic elements from a variety of sources (including municipal waste, agricultural fertilizers, degraded woodland and communication routes) are discharged into lakes and rivers, causing considerable increase in the fertility of lake waters and rivers that serve as lake outflows. In raw municipal waste, for instance, nitrogen concentrations are contained in the 25–50 mgdm^{-3} range, while total phosphorus concentrations are in the range 4.0–12 mgdm^{-3}.[3] According to Vollenweider,[11] limiting concentrations of phosphorus and nitrogen compounds in waters, in excess of which mass algal growth may occur, amount to 0.01 mg Pdm^{-3} and 0.3 mg Ndm^{-3}, respectively.

For the assessment of external factors affecting a particular lake, an assessment of the catchment in terms of yearly delivery of biogenic (N and P) compounds into lake waters must be performed. The calculations are based on the formulas:[3,11]

$$L = I/P_j \left(g \cdot yr^{-1} \cdot m^{-2} \right) \tag{1}$$

$$I = I_{pr} + I_{pl} + I_{pz} + I_o + I_k + I_w + I_l \left(kg \cdot yr^{-1} \right) \tag{2}$$

where P_j is lake area (m^2), I is total load, I_{pr} is grassland load, I_{pl} is woodland load, I_{pz} is built-up area load, I_o is atmospheric precipitation load, I_k is bathers load, I_w is anglers load, and I_l is linear source load.

The values of external nitrogen and phosphorus loading in a particular lake are then compared with Vollenweider's criteria,[11] which define permissible and hazardous nitrogen and phosphorus loadings to a lake:

$$L_{d(\mathrm{N})} = 15 \left(25\ z^{0.6} \right)$$

$$L_{\mathrm{n(N)}} = 15 \left(50\ z^{0.6} \right)$$

$$L_{\mathrm{d(P)}} = 25\ z^{0.6}$$

$$L_{\mathrm{n(P)}} = 50\ z^{0.6}$$

where z is mean lake depth, $L_{\mathrm{d(N)}}$ is permissible reservoir N loading ($\mathrm{mg \cdot yr^{-1} \cdot m^{-2}}$), $L_{\mathrm{d(P)}}$ is permissible reservoir P loading ($\mathrm{mg \cdot yr^{-1} \cdot m^{-2}}$), $L_{\mathrm{n(N)}}$ is hazardous reservoir N loading ($\mathrm{mg \cdot yr^{-1} \cdot m^{-2}}$), $L_{\mathrm{n(P)}}$ is hazardous reservoir P loading ($mg \cdot yr^{-1} \cdot m^{-2}$), 25 is the limiting loading rate for oligo- and mesotrophic reservoirs, and 50 is the limiting loading rate for meso- and eutrophic reservoirs.

External loading of a reservoir with biogenic compounds per area unit is a major indicator specifying the reservoir's trophy. Trophy increase is based primarily on increased concentrations of biogenic compounds such as nitrogen and phosphorus, and this phenomenon is referred to as eutrophication. It is worth noting that the process of eutrophication is a most natural phenomenon. Organic substances are delivered to the lake starting from the moment of its formation and deposited at the bottom in the form of bottom sediments. Yet, due to intensified pollutant inflow, the phenomenon of eutrophication begins to intensify until it becomes a major threat to lakes.

Recultivation Methods

The growing eutrophication rate of water reservoirs and the increasing number of degraded reservoirs create the demand for effective prevention methods. In the 1960s, attempts at recultivation of degraded lakes were made. However, adequate know-how resulting from experience in this field was lacking, particularly because each water reservoir operates under different internal and external conditions. The current know-how and further developments in other fields of science, not only in natural sciences, have made it possible to explore theoretical issues related to water reservoir recultivation on the basis of the practical experience obtained.

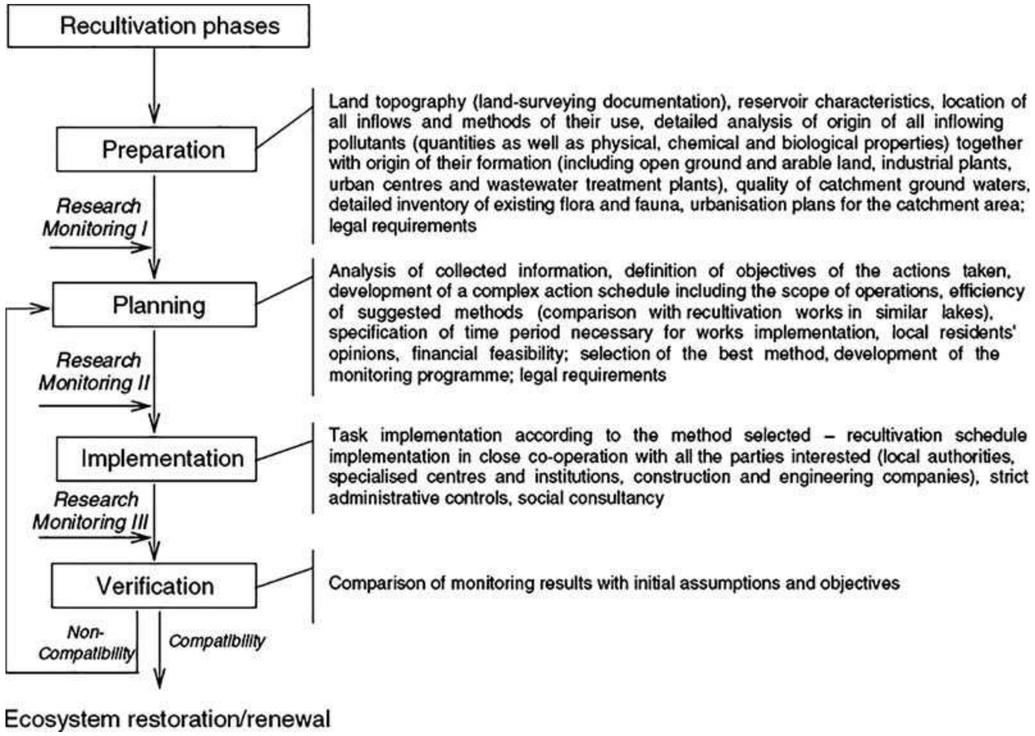
As water ecosystems, lakes are located in land depressions; hence, they provide natural receiving water for the pollutants that come from the catchment area. Due to the functions that they perform in human environment and economy, it is crucial to take appropriate steps in order to improve the quality of degraded waters or protect those in better condition. To this end, scientific, organizational, and technological actions are undertaken jointly, known as recultivation. This process consists in elimination of possible chemical contamination of waters and sediments, improvement of oxygen and nutrient balance, maintenance of flora and fauna at a level appropriate for a given water ecosystem, and provision of engineering elements of flow regulation in the form of desired depths, erosion control, and speeds.[12–15]

The idea of lake recultivation is to restore the previous functions of lakes (e.g., water storage, recreation, household, and agriculture), as well as physical, chemical, and biological features approximating as closely as possible the natural ones. The selection of an appropriate method is determined by the diversity of individual lakes, differences in the ways and scopes of pollution, together with their location in a catchment. The type of the recultivation method used depends on the reservoir size, the nature of the fauna and flora resident therein, connection with watercourses, and proximity to clean water reservoirs in the vicinity of the reservoir under recultivation.[12,14]

Recultivation of water reservoirs is a four-phase process, including the phases of preparation, planning, implementation, and verification monitoring (Figure 2). The duration of actions aimed at restoration of utility values to a particular area, from the initial phase to the final stage of implementation, is typically measured in years.

The first stage is the collection of information as well as the development of a detailed inventory of the immediate catchment. The following may also be helpful: soil maps; maps of localities with erosion-susceptible land and soils, utility or arable lands adjacent to rivers and reservoirs, and critical terrain (with its specific problems); maps of areas where surface waters supply groundwaters; and urbanization plans for the building in catchment areas and industrial development trends.

In view of the above, an individualized approach to each reservoir and planning a complete ecosystem restoration process are necessary. While taking any recultivation actions, it should be remembered that physical, chemical, external, and internal environmental factors may cause profound changes, destabilize the water ecosystem, and push it into one of the two alternative stable states. It must also



Land topography (land-surveying documentation), reservoir characteristics, location of all inflows and methods of their use, detailed analysis of origin of all inflowing pollutants (quantities as well as physical, chemical and biological properties) together with origin of their formation (including open ground and arable land, industrial plants, urban centres and wastewater treatment plants), quality of catchment ground waters, detailed inventory of existing flora and fauna, urbanisation plans for the catchment area; legal requirements

Analysis of collected information, definition of objectives of the actions taken, development of a complex action schedule including the scope of operations, efficiency of suggested methods (comparison with recultivation works in similar lakes), specification of time period necessary for works implementation, local residents' opinions, financial feasibility; selection of the best method, development of the monitoring programme; legal requirements

Task implementation according to the method selected – recultivation schedule implementation in close co-operation with all the parties interested (local authorities, specialised centres and institutions, construction and engineering companies), strict administrative controls, social consultancy

Comparison of monitoring results with initial assumptions and objectives

FIGURE 2 Recultivation phases.

be borne in mind that biological elements and processes conditioned thereby, which occur in a water ecosystem, stabilize and perpetuate its status quo.

A significant element of recultivation is the specification of a monitoring program, i.e., catchment control at critical points as well as in terms of registration of environmental quality indicators important for the recultivation process. This program assumes the establishment of observation sites, equipped with control and measurement apparatus. After a set monitoring time, all data from field observation sites are covered in a technical study that enables developing a representation of a catchment demonstrating the origin of possible pollutants and the problems to be tackled. Following from an extensive data base, including input from various sources, and complete with monitoring program results, it becomes possible to enter the definition phase for particular elements and actions necessary to achieve recultivation effect for a particular reservoir.

Nevertheless, it must be stressed that Research Monitoring I usually differs from the subsequent phases of monitoring, which results from task implementation at individual stages. During the inventorying process, maximum quantities of data concerning pollutant sources and migration routes, as well as the quantity and quality of substances delivered, ought to be collected. In contrast, the objective of Monitoring II is to obtain information on whether the selected recultivation method is well adjusted to the lake's individual characteristics.

To improve the situation in a degraded lake, it is not enough to restore its condition to that from before the disturbance: much feedback in the lake perpetuates the postchange status, and lakes tend to demonstrate resilience, i.e., immunity to recultivation actions. Very often, the condition for the application of any recultivation method is prior reduction of phosphorus concentration in the water to the 0.050–0.100 mg $PO_4 \cdot dm^{-3}$ level and phosphorus removal/ inactivation in sediments (internal import inhibition).[12–14]

TABLE 1 Most Commonly Used Lake Recultivation Methods and Techniques with Their Characteristics

Method/Technique	Characteristics	Model Application	Literature
Dredging	Bottom sediment removal from the entire lake, deepest waters and inflow (in flow-through lakes); complete sediment removal to reach mother rock guarantees radical improvement in water quality; necessity of thorough physico-chemical tests to determine the chemical composition of the sediments, their thickness and distribution in the reservoir (specification which sediment layer and in which lake parts ought to be removed); a sensitive issue is to find sites for storage and management of extracted sediments treated as hazardous	Mission Lake, Kansas; Lake Elkhorn, Columbia; Saluda Lake, South Carolina; Chain Lake, British Columbia	[16–19]
Macrophyte reintroduction	Bentonite is a good macrophyte substratum, which enables macrophyte layer reconstruction as well as restoration of destroyed trophy web structures	Alderfen, Barton, Belaugh and Cockshoot Broads, Norfolk;	[20]
Flushing, rewashing	Provision of clean, nutrient-deficient water, removal of strongly eutrophicated hypolimnion waters and replacing them with well-oxygenated waters from outside the lake; requires a source of clean water in the vicinity of the lake; lake water exchange ought to be performed a couple of times a year	Lake Veluwe, the Netherlands; Willow Lake, Arizona	[21,22]
Macrophyte removal	Comprises artificial lowering of lake water level, lake icing in winter, in-freezing of plant stalks into ice, raising the river level and plant uprooting, collection of floating plant remains and removal from the lake; the quantities of phosphorus thus removed are much lower than the loads introduced to the reservoir; effective in the case of lakes which are strongly polluted with biogenes, accumulated mostly in littoral vegetation	Lakes: Mary, Ida and Bass, Minnesota; Boreal Lake, Ontario	[23,24]
Hypolimnion water removal	Procedure possible in flow-through reservoirs; consists in liquid removal from the profundal layer via a hose; a disadvantage of this method is the pollution of the watercourse discharged from the lake; during near-bottom water removal, the sediments which remain in chemical balance with them become depleted; the process may cause reservoir pollution with H_2S, accumulated in the sediments and temperature increase near the bottom, which leads to hypolimnion oxygen depletion	Bled, Yugoslavia; Lake Kortowo, Olsztyn	[14,25]
Sparging, oxygenation (aeration)	Introduction of a duct into the water through which air is pumped, without disturbance (near-bottom liquid temperature is low: slow rate of organic matter decomposition) or with disturbance of natural lake stratification (entire water mass mixing and water oxygenation: near-bottom layer temperature increase, intensification of chemical and biological processes, including enhanced mineralization and internal supply); enhances hypolimnion oxygen conditions as well as enforcing lake water circulation	Canyon Lake, Teksas; Lake Commabbio, Lombardy; Kieleckie Bay, Kielce	[26–28]

(*Continued*)

TABLE 1 (*Continued*) Most Commonly Used Lake Recultivation Methods and Techniques with Their Characteristics

Method/Technique	Characteristics	Model Application	Literature
Artificial destratification	Destruction or prevention of the lake's thermal stratification, stimulating mass algal growth in the top (warmed and lighted) water layer; very often linked to sparging	Canyon Lake, California; Lake Catherine, Arkansas; Lake Starodworskie, Olsztyn	[29–31]
Nutrient deposition and deactivation in water and sediments	Possible in small reservoirs; does not guarantee permanent phosphorus removal from water; enduring results depend on coagulant properties ($FeCl_3$, $Al_2(SO_4)_3$, $FeSO_4$); optimum water pH 6–8 and high Redox potential level; phosphorus inactivation in sediments is possible due to application of a mixture of bentonite clay with lanthanum, which becomes a phosphorus bonding element upon adsorption on bentonite	Kielecki Bay, Kielce; Jessie Lake, Alberta; Lake Głęboczek, Tuchola; Lake Sønderby, Sønderby	[28,32–34]
Sediment isolation (capping)	Possible in small reservoirs where water transfer is low and does not cause mobility of the introduced layer; used in order to counter chemical exchange in the sediments-water system; physical isolation: sand and foil; chemical isolation: $+Al^{+3}$ diatomite, bentonite or other clayey minerals	Great Lakes, North America; Onondaga Lake, Central New York; Venice Lagoon, Porto Marghera	[35–37]
Precipitation (chemical methods)	Use of herbicides, including algaecides (e.g. barley straw, tree leaves) to fight algae; short-lasting procedure results due to appearance of other algae in place of the removed blooms; causes introduction of large amount of hazardous substances into water	Shoecraft Lake, Washington; Eight lakes located in the eastern and western portions of southern Michigan; Joliet Junior College Lake (JJC Lake), Illinois	[38–40]
Biomanipulation	Change in living conditions of organisms or quantitative ratios in a given ecosystem by means of several food chain dependencies: limiting the populations or complete elimination of individual groups of organisms (e.g. increase in the amount of zooplankton and introduction of selected fish species in order to reduce algal population, introduction of silver carp to the lake to limit the growth of phytoplankton; introduction of white amur to eliminate excess of macrophysical vegetation; introduction of predators such as pike, pike perch or perch in order to limit plankton-eating fish populations); use of biomanipulation requires thorough analysis of dependencies occurring in a given ecosystem	Lake Terra Nova, Loosdrecht Lakes ; Lake Eymir, Ankara	[41–43]
Fish catch	Regular catch of fast-growing fish (important is good cooperation with the lake management) enables reducing lake fertility (so-called trophy) and systemic enhancement of water quality; effective in the case of lakes which are strongly polluted with biogenes, accumulated mostly in the ichtiofauna	Lake Fure, Copenhagen; Lake Ringsjön, Skåne County	[44,45]
Seston removal/ catch	Pumping out water at sites richest in seston, its subsequent filtration in appropriate apparatus; in barrier lakes, zooplankton removal may be accomplished by water inflowing through bottom culverts when zooplankton density is highest at the bottom	Lake Jussi, Pikkjärv	[46]

Source: Cooke,[12] Klapper,[13] Sengupta and Dalwani,[14] and Gupta et al.[15]

As a rule, each catchment and its environment are distinct, but from a practical viewpoint, it is possible to distinguish several actions, techniques, and methods enabling renewal or protection of the status quo of the lake at issue (Table 1).

The most popular methods that provide significant effects in biogene removal are those based on sparging and dredging. Reservoir water sparging enables reduction of excessive algal and waterweed growth. Aeration is performed with the use of either mechanical apparatus or compressed air. Water sparging by means of mechanical apparatus may be performed by water spraying or direct penetration of air into the reservoir.[26,27]

Spraying occurs when water passes along a perforated hose through which it is catapulted into the air in the form of fine droplets. This effect can also be achieved by directing water to purpose-made diffusers. The most important element of this technique is the generation of adequately sized water droplets. The finer the water droplets that penetrate into the atmosphere, the larger the area of gas exchange between the droplet and the air, thanks to which better aeration effects are obtained—more oxygen is transferred into the water.[12–14]

The apparatus used for direct transfer of oxygen into a reservoir includes, for example, aerators with horizontal and vertical rotation axes, including surface, turbine- driven subsurface, and combination aerators. Aerators may also be classified according to paddle-wheel shapes: some may be straight, whereas others have single- or multisided curvatures.

The simplest is the surface aerator. Its operation relies on a turbine or rotor pumping the water upwards and then downwards, thus causing turbulence and splashing on water surface. Oxygen is delivered through water droplets in contact with atmospheric air. This type of aerator is used in ponds, water reservoirs, and rivers.

Combination aerators, which display features of both surface and turbine-driven aerators, are characterized by high capacity for oxygen transfer and provide good sparging results in deep reservoirs. In this type of devices, the surface rotor and the turbine are usually powered by the same aggregator, which causes high power demand, high noise levels, and possible icing during operation.[13,14]

The other types of aeration devices have vertical axes, which enables operation in both open and closed setups. In open aerators, the liquid is centrifugally catapulted, which causes the occurrence of the suction force that sucks the air into the so-called hopper and inter-paddle-wheel space. At the outlet of this space, a mixture of air and liquid appears and is then splashed on the surface of the aerating chamber. This construction provides for the mixing of the liquid and the air in the entire volume. In closed aerators, the liquid is propelled onto paddle-wheels by means of a pump. The air is thus sucked from the atmosphere by means of suction resulting from the flowing liquid at set sites in the inter-paddle-wheel channel.[47]

The compressed air aerator consists of a blower or a fan, sources of compressed air, and distribution ducts and sparging devices. In order to obtain the largest possible contact area between the two phases, a variety of porous elements are used for air dispersion. They are made of ceramic or artificial materials, and are pipe or plate shaped.[47]

In the process of selection of lake aeration systems and methods, the following factors ought to be taken into consideration:

- Oxygen concentration in the water and at the bottom of water reservoirs, which depends on water reservoir eutrophication degree, oxygen deficit volume in bottom sediments, with allowances being made for sediment resuspension, temperature, spring and autumn circulation intensity, and possible waving effects.
- Nominal result of aerator operation, which depends on total nominal hydraulic efficiency, reservoir depth at installation site, reservoir area, air volume fed into the aerator, and aerator construction type, such as the following:
  - Pump and surface dispersion
  - Pump and reversal-to-bottom with surface dispersion (with a thin water jacket)

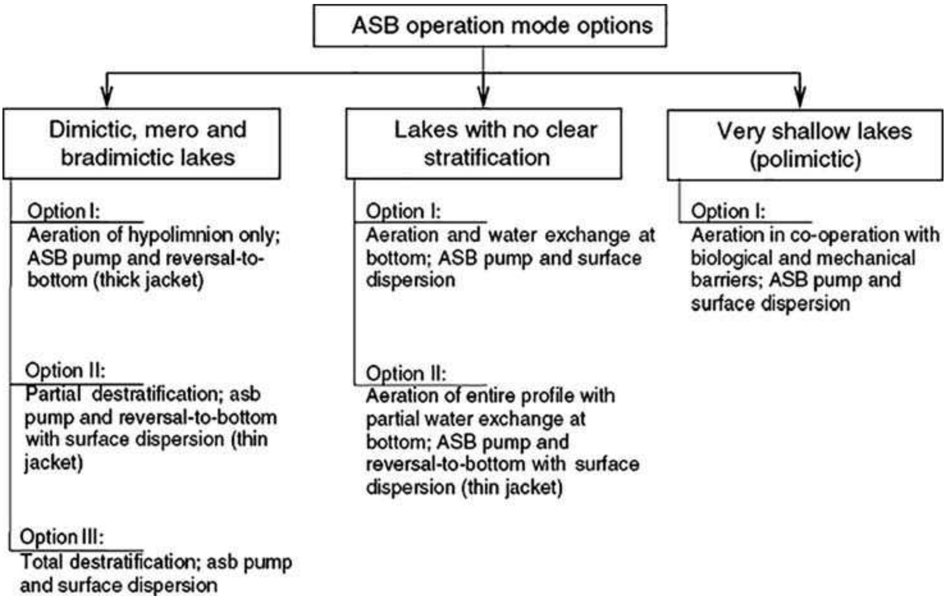


FIGURE 3 ASB operation mode options depending on lake type.

- Pump and reversal-to-bottom (with a thick water jacket)
- Pump with deep suction—in all the above types[48–50]

Overall change to oxygen and dynamic conditions at aerator installation site, i.e., genuine efficiency, depends on lake type and operation mode selected, i.e., aerator construction, as exemplified by the air-stream bottom aerator (ASB) (Figure 3).

During the method selection process, it is also necessary to answer the question of what immediate effect is expected from aeration since the procedure of aeration alone can bring positive results only in few cases.

An equally popular method of lake recultivation is dredging. During sediment removal, it is necessary to construct single or multiple thick-structure islands. Scarps, or island shores, should be equipped with bottom baffle piers that will constitute initial base for the benthos. At the early stage of island construction, the circumference wall should not be closed completely. Through the gap, waters overlying the sediment will be discharged. The gap ought to be secured with sedimentation barriers as well as a set of directional ASBs operating in the countercurrent to the outlet from the closed area. The applied cofferdam will only be temporary. At the end of island filling, the outlet gap ought to be closed with a cofferdam. Upon completion of sediment dredging, the whole ought to be covered with stable material.[48–50]

Upon completion of engineering work, red osier (for instance) needs to be planted. This type of islands can be used for recreation as well as natural purposes. Appropriate, separated parts of the islands can become nesting areas for many bird species. Sediments remaining at the bottom, whose thickness should not exceed 20 cm, may be immobilized by means of a baffle pier grid.

In the course of recultivation procedures, supply points ought to be perpetually monitored. If biogenes are found to be introduced via these routes, it is necessary to place biological barriers, possibly active (with aeration) at inflow inlets.[51,52]

The negative influence of surface wash can also be limited by barriers of appropriate plantings parallel to the shoreline. When forming the islands, it would be advisable to dredge a couple of local deepest waters (ca. 5–6 m). At those sites, an aerator is placed to disable the occurrence of oxygen deficits at windless periods. Artificial sparging enhancement ought to be sustained until balance is obtained between food and consumers, as well as between producers and reducers. Hence, in order to reduce power costs, in near-shore island zones and non-developed shore segments, installation of artificial reef as initial base for benthos is recommended. The ichtiopopulation status and composition also need to be considered.[48–50]

Another method aimed at restoration of good water quality is chemical bonding and inactivation of nitrogen and phosphorus. This system, used in Scandinavia, has been adapted to Polish conditions and tested at several sites, e.g., Lake Dlugie in Olsztyn. The phosphorus inactivation method is recommended for those lakes in which, despite cutoff of external sources of biogenic compounds, high fertility is sustained through deposition of these compounds from bottom sediments. Used primarily in shallow lakes, this method relies on removal of excess phosphorus from the pelagic zone and trapping it in bottom sediments. It also increases sorption capacity of degraded lake bottom sediments. Strongly eutrophicated lakes are characterized by high biogenic compound content, which causes blooms (increased phytoplankton population). At this degree of degradation, the lake no longer fulfills its recreational or economic functions. Chemical deposition of phosphorus by means of aluminum (PAX) and ferric (PIX) coagulants reduces the quantity of biogenic (nutrient) compounds, thus limiting algal growth intensity, which results in improvement of water quality and transparency.[53,54]

In the case of shallow reservoir recultivation, it is necessary to mitigate the deoxygenated layer of benthic water, the so-called oxicline. The oxicline generally occurs in the summer, appearing as a result of oxygen depletion in the course of chemical reactions. These reactions occur at the contact zone between bottom sediment and water, depending, among others, on ambient temperature: the warmer the water, the faster the reactions proceed. Under the circumstances, more and more frequently, actions are taken to place aerators equipped with a phosphorus inactivation system in reservoirs. This method has also been used in the Kielce Lake, where a pulverizing aerator was installed in May 2008. It is powered with wind energy and has a built- in installation dosage system for iron sulfate, which bonds phosphorus.[28]

Most efforts to alleviate the detrimental and undesirable effects of eutrophication on aquatic systems address the problem of P reduction in the inflows. Despite many cases of success in the reduction of nutrient loads of lakes in recent years, the expected corresponding reduction of phytoplankton abundances has often been delayed by many years. Sometimes, lakes have been reported to be resistant in their response to loading reductions. Recycling of P from the sediments becomes more important if the P in inflows is reduced.[55]

Phosphate inactivation in bottom sediments enables the elimination of internal transport in the reservoir (release of biogenes accumulated in bottom sediments into the pelagic zone), which is the cause of self-maintenance of high trophy levels—a feature of overfertile lakes, conditioning the occurrence of blue-green algae blooms. This means that as a result of the application of this method, the cause is removed, rather than the effects of excess of biogenes in the water. This testifies to greater efficiency of the above technique.[56]

The only alternative for application of the phosphorus inactivation method in bottom sediments is lake dredging. This is a technique that is equally effective, but very expensive, long-lasting, and accompanied by the problem of storage and further treatment of the removed sediments. It must be stressed that the storage site must not be located in the lake catchment area so that effluent waters together with their biogene load cannot find their way back to the reservoir. Similarly, treatment of the sediments is connected with the need for a recipient, transportation, etc. The phosphorus inactivation method in bottom sediments is far less costly, is incomparably faster at application, and provides enduring results of reduced phosphorus concentration in the water.[56,57]

The oldest method of phosphate inactivation in sediments, with simultaneous mineralization of organic matter, is the Riplox method, which yields good results. The required labor intensity and technical complexity make it extremely unpopular. Other techniques are its modifications, the Prote method being a case in point. The similarity lies in the fact that in both cases, air and the flocculant are simultaneously supplied to bottom sediments. A major difference is prior induction of intense sediment resuspension and flocculant application to a very carefully delineated sediment layer. The responsibility for the success of lake recultivation with this method lies with an effective device, providing precision dosage of flocculants to lake bottom sediments.[56,58]

To that end, several purpose-made mixes, containing a variety of substances as well as enzyme complexes, selected bacteria, biological activators, complete with extended-surface mineral carriers and stabilizers, have been developed. A preparation introduced into a water reservoir strongly activates the detritus food chain and increases the participation of autotrophic bacteria in matter circulation.[56,58]

The effects are so enduring that the following results are observed over 2 years:[56,58]

- Acceleration of organic matter decomposition in the sediments: quantitative reduction of accumulated bottom sediments and deceleration of natural reservoir shallowing
- Elimination of anaerobic zones in the hypolimnion and acceleration of sediment surface oxidation
- Enhanced elimination of biogenic compounds from matter circulation
- Blue-green algae bloom intensity control
- Boosting the growth of submerged water vegetation.
- Increased fish biomass[56,58]

Achieving enduring improvement of reservoir condition takes time and efficient implementation of the stages aimed at reduction of external supply, internal supply (elimination of anaerobic zones), and the quantity of biogenes in circulation (trophy reduction).

The experience in terms of external supply reduction has shown that the main condition that determines the efficiency of this technique is possibly the fastest reduction of external biogene supply. If this requires improvement of wastewater management in the reservoir catchment, the issue may seem problematic and distant in time due to the need for a wastewater treatment plant to be modernized or constructed. In contrast, the application of the Trigger-1 and Trigger-2 biopreparations in already-existing household, municipal, or industrial treatment plants enables limitation of pollutant inflow into the lake. Because the elimination of 1 kg of phosphorus and nitrogen in the process of wastewater treatment, even at plants with inadequate technical equipment, is far easier and cheaper than in the water environment, it is not advisable to wait for the construction to be completed, instead using all the methods to enable the reduction of external supply.[59]

In reservoirs where storage of large internal loads at stagnation periods has already occurred, the occurrence of anaerobic zones above the bottom is observed in the water. This triggers the mechanism of internal supply, i.e., releasing the previously accumulated biogenes from bottom sediments. This leads to accelerated degradation of the reservoir, although initially, only increased reservoir productivity is noted (primary and secondary productivity). Natural processes that occur in the reservoir are accelerated several times and result in rapid expansion of anaerobic zones. The methods applied to check this phenomenon, such as aeration, are expensive and carry a high risk of failure. A less costly method that does not require complex technical procedures is the application of a biopreparation, such as Trig- ger-3max, which, without changing water stratification, eliminates anaerobic zones in the hypolimnion, reducing the internal supply and eliminating anaerobic zones.

Recently, many biopreparations containing saprophytic microorganisms are commercially available and commonly offered for use in ponds, lakes, and reservoirs. These preparations usually consist of selected bacterial strains immobilized on a mineral carrier. Sometimes, the preparations are also enriched by bacterial enzymes such as biocatalyzators. Some preparations are even enriched by nutrients as growth stimulants at the beginning of growth after addition into the water. However, in most cases, parallel aeration or sediment oxidation by adding another electron acceptor such as nitrate will be necessary to support the growth and activity of added microbes. Otherwise, the method hardly brings any effects. With regard to many bacterial extracellular exudates that have been reported to inhibit the growth of cyanobacteria, a direct effect on cyanobacterial development may be possible as well.

However, no scientific proof of such an effect in the case of application of these commercially available biopreparation is available.[56,60]

All biogenes that occur in a water reservoir ecosystem are in circulation, the major stages of which are transformations of the dissolved phase into the solid phase and back into the dissolved phase. The main mechanisms of this change are the initial placement of elements in the biomass (solid and molecular phase), and their subsequent release from mortified organisms and fecal matter (dissolved phase). Phosphorus is the quickest to be released, and consequently, it circulates in the epilimnion, passing many times from the dissolved phase to the solid before falling onto the sediments. The application of a biopreparation will thus enable a reduction of the quantity of biogenes in circulation, thus limiting lake trophy.[48]

More and more frequently, attempts are made to develop and apply sustainable methods of water reservoir qualitative enhancement, based on "bio" structures. A case in point is the bio-hydro structure (biofilter filling), as well as active biological and mechanical filters, which may be used in open water reservoirs, thanks to which the processes of mineralization and biomass growth are induced.[48,61]

Components of biofilter filling are manufactured as standard panels. They are five-layer grids, made of wide strips, with single net-mesh dimensions. Each subsequent layer is shifted in relation to the previous layer in two directions, by half a net-mesh module.[48]

When this packet is placed vertically, the vertical strip plane is perpendicular to the panel plane. The horizontal strip plane is differently inclined to the panel plane. This geometric arrangement enables directing the stream upward or downward, depending on flow direction. Consequently, this structure may be used as, for instance, a sedimentation element, a lift component, or a resuspension barrier and initial base for the complex of plant (phytobenthos) and animal (zoobenthos) organisms, which occupy the water reservoir bottom.[61]

Strip surface is rough (knurled) and made of chemically neutral plastic, which enables occupancy by a variety of sedentary species. Despite the fact that the extended surface of such filters amounts to 122 $m^2 \cdot m^{-3}$, the filter displays a low degree of flow suppression and relatively large vacant internal space. Due to this, upon placement in the pelagic zone, it very soon becomes the habitat of a very wide range of periphyton. By being an ecological niche in its own right, it also acts as an attractant to many sedentary species as well as fish fry. Above the pelagic zone, autonomously, on the top elements of the panels, a wide variety of hydrophilous plants settle.[48]

In the 1980s, at Biotechnika Company, the occupancy extent of these filters was studied in Lakes Karczemne and Klasztorne. On average, one standard panel came to be occupied by biomass in the amount of ca. 70 kg. If such an occupied filter is removed from the reservoir at the right moment, then, together with the biomass, the built-in biogenic compound load will also be removed. The certainty of the effect achieved, in contrast to chemical methods for example, consists in the fact that the application of chemical deposition does not guarantee that, under certain conditions (pH, redox potential), the sorption capacity of metals in the coagulants applied will not be destroyed. As data demonstrate, this is a very frequent occurrence and then, apart from the still unsolved problem of phosphorus removal, the additional "foreign" load in the form of metal compounds is found in the water. Then, the phenomenon of system adjustment to new conditions, which can moreover take a completely unknown direction, arises.[48]

Sparging, in connection with bio-hydro barriers, also offers several options, including passive biological barriers as well as active biological and mechanical filters. If a lake receives a strongly polluted watercourse, the inlet of the watercourse may be separated from the remaining area with a barrier (consisting of several layers to make it most advantageous) made of bio-hydro structures placed jointly, streamwise—first downwards and then upwards. Mechanically, this setup will function as a sedimentation barrier, which will, due to autonomous occupancy, after a short period of time, also and perhaps primarily become a biological barrier.

On account of its structure, despite initial passivity, as occupancy progresses, it becomes an attractant for an increasing variety of species, in most cases beneficial to further development of reservoir biocenosis and further recultivation procedures. During the observation of this type of barrier placed in Lake Rybnickie, it was noted that it had become a "refuge," initiating changes in both animal and plant populations. A double-positive effect was thus achieved: the inflowing pollutant load that degraded the lake has been set to work towards beneficial renewal of the reservoir.

In Lake Rybnickie, the positive result of barrier operation was visible as soon as after 1 year of working. Positive results of water quality tests restored the recreational value of the reservoir, and after many years, the State Sanitary and Epidemiological Board ultimately permitted bathing.[48]

Conclusions

Fertility or abundance of a water reservoir with biogenic mineral substances gradually increases in time, and may be either a natural process or one resulting from human activity. Natural eutrophication proceeds slowly, whereas anthropogenic eutrophication is characterized by a rapid change rate. At the initial stage, an increase of primary and secondary productivity is observed, but as eutrophication progresses, the efficiency of secondary productivity decreases and algal biomass gradually accumulates. The reservoir basin gradually fills with sediments and the water volume decreases, which, even at no biogenic inflow, simultaneously accelerates eutrophication. Further succession leads to the reservoir being turned into land.

In order to preserve a lake, human intervention becomes necessary. All recultivation strategies require sensible planning, time, and, frequently, considerable financial outlay. Their results are not always certain, but the current know-how concerning the subject enables appropriate selection and implementation of an effective recultivation process in a particular lake. The type of the method and technique used depends on the size of the reservoir, the nature of fauna and flora resident therein, the character of the catchment, and the type of adjacent land development. Effectiveness and efficiency of the work performed depend on accurate assessment of the reservoir status and adoption of an appropriate action plan.

While analyzing the efficiency of various procedures carried out in the world's lakes, it must be stated that before embarking on recultivation, it is necessary to

- Define the current trophic status of the lake as well as causes and sources of its degradation basing on physicochemical and biological tests of lake waters, inflows and outflows, complete with an analysis of sediment chemical composition, considering exchange processes between sediments and water.
- Specify the feasibility of the water reservoir recultivation in view of its natural, recreational, and economic value.
- Design and perform protective procedures consisting of the elimination, or at least limitation, of individual pollution sources.
- Develop the most advantageous concept of a recultivation method that ought to make allowances for the trophic status as well as morphometric and hydrological conditions of the reservoir, together with possible uses of margin land, its development, ownership status, access to the shore and a power supply, duration of the process, and financial outlay required.
- Ensure that recultivation will be performed by an expert team under the supervision of an experienced limnologist at all times.
- Document the course of recultivation and its effects through the results of monitoring carried out at particular stages.
- Deem recultivation unfeasible in view of its failing to offer an opportunity for water quality enhancement, if it is found that excess loading of the lake is impossible to eliminate.
- Have a close connection with appropriate regulations, enabling the protection of a lake subject to recultivation procedures from further degradation processes.

Wastewater Use in Agriculture: Policy Issues

Dennis Wichelns

Introduction

Treated and untreated wastewaters have been used for many years to irrigate farms, landscapes, and golf courses in both developed and developing countries. Public officials in arid countries have promoted wastewater use primarily to extend their limited national water supplies. Officials in other countries have promoted the benefits of using treated wastewater in agriculture or landscape maintenance as an alternative to discharging the wastewater into a stream or ocean. Their rationale is based partly on cost and partly on environmental implications. Treating wastewater is expensive, and a portion of the cost can be recovered by using the wastewater in a productive endeavor. From an environmental perspective, applying the treated wastewater to a farm field provides another layer of quality improvement before the water is finally returned to a stream or ocean.

Many farmers in developing countries use untreated wastewater for irrigation, often because it is the only source of water available. Many small-scale farmers obtain irrigation water from streams or ditches that are polluted with effluent from a nearby city, industry, or housing development. The farmers likely would prefer higher-quality water, but in most cases, they have no alternative source for irrigation. There can be agronomic value in the nutrients in the untreated wastewater (the nitrogen, phosphorus, and potassium), but there are also pathogens and chemicals that threaten the health of farmers, food vendors, and consumers. Irrigating with untreated wastewater is risky business in developing countries, yet it generates household income for families with limited livelihood alternatives. Most farmers using untreated wastewater for irrigation likely would vote to continue using the wastewater, even if they understood all the risks, in the absence of an alternative, higher-quality water supply.

In a sense, farmers using untreated wastewater provide a public service by removing effluent from polluted streams and applying it to soils, thus reducing the pollutant load in downstream locations. Soils filter some of the undesirable constituents, and plants consume some of the nutrients. However, wastewater irrigation also generates risk for farm communities and consumers of farm products. Polluted canals and ditches and wastewater-irrigated fields create hazards in which children and other residents are exposed to harmful pathogens and chemicals. Consumers of farm produce also are at risk of illness when they handle and ingest contaminated vegetables, particularly when the food is eaten raw or prepared with inadequate care toward reducing contamination risk.

The goal of this entry in the encyclopedia is to describe policy issues pertaining to wastewater use in agriculture. The issues in developed countries are somewhat straightforward and mature. Public agencies have largely determined appropriate water quality criteria and implemented treatment protocols to support wastewater use in irrigation. Future issues will include refining those standards and protocols and continually evaluating the costs and benefits of alternative levels of wastewater treatment and use in agriculture and other activities. There will also be discussions of who should pay for wastewater treatment and who should have priority in receiving limited supplies. These issues involve costs, returns, and the division of economic rents, but they generally do not involve decisions that can support or destroy livelihood opportunities, whether intentionally or as the unintended consequences of seemingly beneficial policy choices.

Policy issues are more challenging in developing countries, where most of the wastewater used for irrigation is untreated and much of the use is informal and unintentional. Farmers, communities, and consumers are at risk from harmful constituents in the untreated wastewater, yet each group also obtains critically important benefits. Farmers generate financial returns that enhance their livelihoods and improve the economic status of farm communities. Consumers gain nutritional value by having affordable access to locally grown fresh vegetables. The public, more generally, benefits also when farmers divert effluent for use in irrigation, rather than allowing it to continue flowing downstream.

There are no easy—and affordable—policy choices regarding the use of untreated wastewater in developing countries. Public funding for treating all wastewater will not be available in many countries within the foreseeable future. Lacking the treatment alternative, public agencies must identify measures that will reduce the risks of using untreated wastewater, while still maintaining a notable portion of the benefits that accrue to farmers, consumers, and the larger community. In this review of policy issues pertaining to wastewater use in irrigation, we focus largely on issues involving the informal use of untreated wastewater in developing countries. The issues in such countries are more challenging, and the potential rewards of identifying and implementing successful risk reduction measures are substantial.

Wastewater Is a Resource in Waterscarce Settings

With increasing demands on water resources in arid and humid regions, the role of wastewater as a resource in municipal, industrial, and agricultural applications will continue to gain importance in many countries. Large numbers of farmers irrigate with wastewater in developed and developing countries, yet we do not have good statistics on the areal extent or the value of output generated through wastewater irrigation. This is due partly to the difficulty of identifying and measuring farm areas irrigated fully or partially with treated or untreated wastewater. In most countries, wastewater is used to irrigate vegetables, fruits, cereals, cotton, and fodder crops (Table 1). Fruits and vegetables are often consumed without cooking and thus pose a higher risk of illness due to pathogens or chemicals in wastewater.

TABLE 1 Examples of Wastewater Reuse in Selected Countries

Region and Country	Examples of Use
Africa	
Tunisia	Citrus, fodder
Morocco	Vegetables, fodder
Americas	
Argentina	Vegetables, fodder
Chile	Vegetables, grapes
Mexico	Vegetables, cotton, fodder, parks, and greenbelts
Peru	Vegetables, cotton, fodder
United States	Vegetables, cereals, fodder, greenbelts, golf courses
Middle East	
Israel	Cotton
Kuwait	Vegetables, orchards, fodder
Saudi Arabia	Cereals, fodder, greenbelts
Asia	
India	Vegetables, cereals

Wastewater Use in Developed Countries

Farmers and landscape managers have been using treated wastewater for many years in Australia, Israel, Spain, the United Arab Emirates, the United States, and other developed countries.[2–5] Treated wastewater is used directly in some applications and indirectly in others, often following storage in an aquifer or discharge to a drain or stream from which farmers obtain irrigation water at some distance from a water treatment facility.[6,7] Over the years, scientists and practitioners have improved their understanding of the impacts of using treated wastewater for irrigation, and public officials have implemented policies and regulations consistent with current knowledge and experience.[8–11]

Persistent water scarcity in the Middle East and North Africa has led many governments to advance the state of knowledge regarding irrigation with wastewater and desalinized water. Wastewater is a key irrigation resource in Israel, Jordan, Kuwait, Iran, Oman, and Saudi Arabia.[12,13] In Israel, where 73% of treated municipal sewage is recycled[10] the government has supported the construction of pipelines to deliver wastewater to agricultural areas where many farmers use drip irrigation systems to minimize potential harm from contact with the wastewater.[14] Treated effluent also is stored in aquifers before recovery and delivery to farmers.[10] In Jordan, 95% of the treated wastewater volume is used each year, primarily for irrigation in the Jordan Valley.[15] In Saudi Arabia and the United Arab Emirates, many farmers and municipal landscape agencies irrigate with secondary and tertiary treated wastewater.[16–18] Tunisia, Egypt, and Morocco also have notable programs in which farmers are provided with treated wastewater for use in irrigation.[13]

Treated wastewater is used extensively for irrigation also in Australia and in the arid southwest and the humid southeast of the United States. In Australia, as in Israel, treated municipal effluent is infiltrated into aquifers, and farmers later retrieve the water for irrigating horticultural crops.[19] Most of the irrigation with wastewater in the United States is found in California and Florida, where strict water quality standards are enforced to protect consumer health and to sustain positive market acceptance of crops produced in these heavily agricultural states.[13]

Wastewater Use in Developing Countries

Perhaps the greater challenge regarding wastewater use in agriculture in the future pertains to developing countries in which there is inadequate capacity to collect, treat, and distribute wastewater in ways that minimize potential harm to public health.[20] Millions of farmers in developing countries rely on untreated, partially treated, or haphazardly blended wastewater as a source of irrigation supply. They produce grains, vegetables, and fruits with the low-quality water, often for sale at attractive prices in urban markets.[21,22] The farmers and their family members who have contact with the untreated and partially treated wastewater are at risk of health damage due to biological and pathogenic constituents.[23] The consumers of leafy vegetables also are at risk if they do not take adequate precautions in preparing the vegetables prior to consumption.[24,25] In many cases, some consumers are unaware that vegetables have been produced using wastewater, and they have no experience of becoming ill after eating raw vegetables. Hence, they are not inclined to implement the necessary precautions.[26]

Worldwide, an estimated 800 million farmers are engaged in urban agriculture. One-fourth of these farmers produce crops for sale in local markets on small plots of land of which they might or might not have ownership, using low-quality irrigation water that often contains untreated wastewater.[27] Market demand for irrigated vegetables in tropical areas is strong, and those produced locally are particularly important in warm regions where modern transportation and storage facilities are largely unavailable. Farmers in urban and periurban areas can bring their highly perishable vegetables to market quickly, thus generating household income and providing an important source of vitamins for consumers.[24]

Many farmers in sub-Saharan Africa and south Asia rely on untreated wastewater for a portion of their irrigation supply. Some farmers utilize wastewater taken directly from tanker trucks or sewage lines, while others divert irrigation water from streams and ditches polluted with untreated municipal wastewater.[20,28] In many areas, farmers irrigate crops and sell them in local markets (Figure 1), with few precautions taken to minimize risks in production or consumption.[23]

More than 60% of the vegetables consumed in many West African cities are produced locally in urban and periurban areas.[29] In Kumasi, the second largest city in Ghana, urban farmers produce 90% of the

FIGURE 1 Selling wastewater-irrigated leafy vegetables in local markets generates revenue for small-scale farmers, while creating a risk of contamination for consumers.
Source: Sanjini de Silva, IWMI, Hyderabad.

lettuce and spring onions consumed in the city. With irrigation, urban farmers can harvest 9 to 11 crops per year on their small plots (0.1 hectare), thus generating annual incomes of $400 to $800 per year.[24] Farmers place substantial value on the availability and reliability of their irrigation supply, even though it contains wastewater from the city.

Farmers along the Musi River, downstream of Hyderabad, India, irrigate rice and fodder grass with untreated wastewater discharged into the largely dry riverbed from many locations in the city. Farmers rely on the wastewater as their only source of irrigation water.[30] While reporting negative health effects due to wastewater exposure, farmers also report that the availability of wastewater in the Musi River enhances their livelihoods.[31,32] Farmers irrigating with wastewater report greater occurrence of fever, headaches, and skin and stomach problems than farmers who do not use wastewater.[31] Although irrigation enhances incomes, substantial costs are imposed on households by illnesses that might be caused by exposure to wastewater. It is in such settings that effective policies are needed to enhance farm family health and to protect consumers from the potentially negative impacts of consuming wastewater-irrigated vegetables.

Farmers in periurban areas of Calcutta, India, irrigate about 5000 hectares of rice using untreated wastewater from the city's sewage collection system. Many farmers use wastewater for aquaculture as well, thus enabling them to generate a steady annual income and provide employment opportunities for local workers.[1] The sustainability of the system is uncertain, as much of the wastewater contains heavy metals that accumulate in soils and can be taken up by vegetables.

Untreated wastewater is used also by farmers in periurban areas of Addis Ababa, Ethiopia, where only 3% of the residents are served by a centralized sewer system.[33] The farmers appreciate the nutrient content of the wastewater in a region where the price of imported fertilizer has been increasing by as much as 20% per year. Controlled experiments on urine-irrigated plots in Ethiopia, and in trials on farm fields, have demonstrated the agronomic value of the nitrogen and phosphorus contained in untreated wastewater.[33]

Policies Are Needed to Ensure Wise Use

From a policy perspective, the use of wastewater in agriculture provides both opportunities and challenges that require public intervention. In one sense, wastewater is an effluent requiring treatment or disposal, subject to regulations that protect public health. In the absence of regulations, private generators of wastewater would have little incentive to reduce volume or to manage the flow of wastewater beyond their property line. Because wastewater generation is a negative externality in most settings, regulations and incentives are needed to minimize the potential harm from wastewater in the environment.

Wastewater management has public-good characteristics in that once it is provided, many members of society benefit. At the same time, it is difficult to exclude individuals from enjoying the benefits of a cleaner, healthier environment once the decision has been made to collect and treat all wastewater in a community. The non-rival nature of the benefits and the difficulty of exclusion provide the basis for managing wastewater treatment within the public sector.

The public-goods perspective is appropriate when viewing wastewater as an effluent requiring treatment or disposal. However, when viewing wastewater as a resource, there are notable private benefits for which individuals will be willing to invest time, effort, and funding to enhance their opportunities. The private-goods perspective pertains to both treated and untreated wastewater. Several water agencies in Australia, Israel, and the United States sell treated wastewater (directly or through an aquifer recharge program) to farmers and golf course owners who obtain private benefits through irrigation.[34,35] Often there is a price differential between treated wastewater and fresh water, thus providing a financial incentive for irrigators to select the treated wastewater.[36,37]

Farmers in developing countries also obtain private benefits, but the distribution of wastewater among them is much less formal, and the wastewater generally has not been treated. An estimated 80% of the sewage generated in developing countries is discharged untreated into the environment, and half the population is exposed to polluted water sources.[38,39] Many farmers acquire untreated wastewater when they divert irrigation water from a stream or ditch that carries effluent from a nearby city or from households in an urban, periurban, or rural area. Water diversions and the use of wastewater in such settings generate private benefits for the farmers. The public gains also as the farmers remove the low-quality water from streams and ditches. However, the primary motivation for farmers is to boost their productivity and increase their net returns in agriculture. By doing so, they risk the health of their families through exposure to untreated wastewater, and they create situations in which consumers also are at risk of eating harmful produce. Public policies are needed to reduce these risks and to optimize the management of wastewater from the public's perspective.

Policy Issues in Developed Countries

Current policy issues regarding wastewater use for irrigation are best described separately for developed and developing countries. In developed countries, the primary policy issues involve economics and finance. The public generally has already determined that protective water quality guidelines must be followed when using wastewater for irrigation. The technology for treating wastewater is well understood, and advances in technology that lower the costs and increase the benefits will be forthcoming in response to market demands and in accordance with government-sponsored research programs. The question will not be whether wastewater will be treated but who will pay for treatment and how much of the cost will be passed along to the users. In some areas, public officials also will seek to determine the economically optimal level of wastewater treatment, as a function of its intended uses.[40]

Key policy questions will also involve the appropriate levels of government involvement in wastewater treatment and reuse programs. Where the private, farm-level benefits of wastewater use are notable, farmers should be financially motivated to invest in production methods and develop market outlets that support irrigation with wastewater. Farmers should also be able and willing to pay for treated wastewater delivered by a public agency or water user association. Using contingent valuation methods in a survey of Greek farmers, Bakopoulou et al.[41] determined that 58% of the participants would be willing to pay half the fresh water price to purchase treated wastewater for irrigation. Small-scale farmers on the island of Crete expressed a greater willingness to pay for treated wastewater after attending a session in which they learned of the private and social benefits of wastewater irrigation.[42]

Farmers should also have incentive to invest in communal facilities for collecting, treating, and delivering wastewater to farms, as the price and availability of wastewater improve over time, relative to the price and availability of fresh water. Public agencies can hasten a farm-level switch from fresh water to wastewater with water pricing and investment incentives and also by informing farmers and consumers of the safety and benefits of irrigating with treated wastewater.

Policy Issues in Developing Countries

The primary policy questions in developing countries are more challenging, in part, because financial resources are limited and there are many competing demands on public funds. In addition, much of the wastewater irrigation takes place in decentralized, informal settings in which individual farmers gain access to wastewater very simply by diverting polluted water from a stream or ditch. Property rights to the water are not defined, and there is no communal agency or water user association that coordinates irrigation activities. Millions of individual farmers will be very reluctant to stop diverting polluted water for use in irrigation, given that their livelihoods currently depend on the sale of irrigated farm produce.

Public officials in developing countries must address the following question: How do we minimize the risks to farmers and consumers, while not destroying or severely diminishing the livelihoods of those farmers who currently irrigate with wastewater? This is not an easy question to answer. Public officials will be mindful of the benefits that farmers provide by diverting and using polluted water for irrigation. If not for that activity, larger volumes of wastewater would continue flowing downstream in

TABLE 2 Average Nutrient Availability in Human Excreta per Person, per Year

	Amount of Nutrient Available (kgs)			
	In Urine	In Feces		Amount of Nutrient Required to Produce
Nutrient	(500 liters)	(50 liters)	Sum	250 kg of Cereal (kgs)
Nitrogen	4.0	0.5	4.5	5.6
Phosphorus	0.4	0.2	0.6	0.7
Potassium	0.9	0.3	1.5	1.2

many watercourses, creating greater risk for downstream residents and causing environmental harm over a larger area. Farmers who irrigate with wastewater generate one set of risks for their families and consumers while reducing another set of risks to residents downstream.

Public officials also will note that some of the pollutants in municipal wastewater (such as nitrogen, phosphorous, and potassium) are plant nutrients. In areas where inorganic fertilizer is costly and difficult for small-scale farmers to obtain, those nutrients have substantial agronomic value. The nutrients contained in the average amount of urine and feces generated by one person each year are sufficient to produce enough grain to sustain that person. Urine is a particularly good source of nitrogen, phosphorus, and potassium (Table 2). Efforts to collect and transport urine directly to farms, rather than discharging it to waterways, would allow farmers to manage their nutrient applications with greater care and accuracy.

In summary, farmers generate both private and public benefits when they divert polluted water from streams and ditches to irrigate crops in urban areas. The nutrient content of wastewater is sufficient to increase crop yields, provided that farmers do not apply excessive amounts of some nutrients, such as nitrogen.[1,43] Public officials in developing countries must determine how to sustain these beneficial aspects of wastewater irrigation and the livelihoods of farm families, while minimizing risks to those same families and the consumers of their produce.

Policy Options Include Treatment and Non-Treatment Alternatives

The policy options available to public officials for reducing the risks associated with wastewater irrigation in developing countries, while sustaining livelihood benefits, might be placed into four categories:

1. Improve and extend centralized wastewater treatment
2. Improve and extend decentralized wastewater treatment
3. Regulate (with enforcement) the use of untreated wastewater in agriculture
4. Complement existing wastewater use patterns with risk reduction interventions to protect farm families, communities, and consumers

The first category is likely the most costly and the least likely to be implemented along a reasonable timeline. There might be affordable opportunities in some settings within developing countries, in which new, large-scale wastewater treatment plants can be constructed to improve the quality of water available for agriculture. Yet it seems that if such opportunities were affordable, if they compared favorably with alternative public investments, and if an affordable source of finance were available, then such efforts would already be underway. It is difficult to imagine that the pace of investments in large, centralized wastewater treatment plants will be sufficient to improve water quality for many of the farmers who currently use wastewater for irrigation in developing countries.

The second category includes options that should be more affordable than building large, centralized wastewater treatment plants. The goal within this category is to identify opportunities for enhancing irrigation water quality at an appropriate scale and within a meaningful distance from the point of wastewater use. Small-scale wastewater treatment plants might be designed with the expressed purpose of making higher-quality water available for irrigation. The construction costs and operating criteria for such plants might be different—and less expensive—than those pertaining to centralized wastewater treatment plants that discharge water intended for uses outside agriculture.[44] For example, it is important to remove solids, salts, and pathogens from water intended for use in irrigation, but farmers can accommodate higher nutrient levels than wastewater users in municipal and industrial settings.

The third option likely will be challenging in many developing-country settings, given the decentralized, informal nature of wastewater use and the strong dependency of farm households on wastewater. Regulations will be politically unpopular, and enforcement will be difficult to achieve. In Syria, for example, the government disallows the irrigation of vegetables with wastewater, but compliance with the restriction is not complete. Syrian officials resort to destroying vegetable crops irrigated with wastewater when they find such situations. As a result, less than 7% of the area irrigated with wastewater near the city of Aleppo is in vegetable production.[27] The opportunity costs involved in planting and cultivating crops, only to have them destroyed by the government, can be substantial for farm households with limited sources of income.

The financial burden of treating wastewater in developing countries and the challenge of regulating wastewater use by farmers will remain substantial for the foreseeable future. Hence, many farmers will continue using wastewater, and their workers and families will remain at risk of infection while applying irrigation water. Consumers will remain susceptible to sickness caused by handling and consuming the irrigated produce. Given this near-term outlook, public agencies in developing countries should seek opportunities to reduce the risks of infection and sickness by intervening at selected stages of the process, which includes wastewater generation, capture, irrigation, crop production, harvest and handling, and food preparation and consumption. Thus, we focus on the fourth category of policy options—reducing risk to farm households, communities, and consumers.

Policy Interventions Should Focus on Reducing Risk

Conventional wastewater treatment might be viewed as the ultimate risk reduction measure when considering the use of wastewater in irrigation.[45] Establishing and enforcing water quality standards, in conjunction with a wastewater treatment program, can be effective in removing potentially harmful constituents. However, the cost of treating wastewater and enforcing water quality standards will exceed affordability in many developing countries. Recognizing this challenge, the World Health Organization (WHO) recommends shifting the policy focus from reliance on wastewater treatment and water quality standards to establishing health-based targets that might be achieved by implementing a range of risk-reducing interventions.[11,45]

The WHO[46] describes three sets of health protection measures pertaining to the three groups most susceptible to health impacts of wastewater irrigation: 1) farmers and their families; 2) consumers of farm products; and 3) agricultural communities. We consider each group in turn.

Farmers and Their Families

When delivering irrigation water or working in fields irrigated with wastewater, farmers, family members, and other farm workers can be exposed to microbial pathogens, including viruses, bacteria, helminths (nematodes and tapeworms), and protozoa.[47] Wastewater also can contain endocrine-disrupting chemicals, pharmaceutically active compounds, and residuals of personal care products.[48–51] Exposure to wastewater can result in skin irritation and diseases related to pathogens in human waste products. The WHO[46] recommends the following protective measures to be considered when designing public policies and intervention strategies:

1. Treating wastewater
2. Supporting the use of personal protective equipment.
3. Providing access to safe drinking water and sanitation on farms
4. Promoting good health and hygiene practices
5. Providing chemotherapy and immunization
6. Controlling disease vectors and intermediate hosts
7. Reducing contact with disease vectors

One or more of these measures would be helpful in breaking or disrupting the pathway of contamination from wastewater to farm family members and farm workers. However, success will be determined by how effectively the benefits of these measures are communicated to farmers and how aggressively farm workers adopt them. The farm-level cost of any measure also will be a key determinant of its successful adoption.

Agricultural Communities

In a sense, many residents of agricultural communities are susceptible to the same types of risks as farmers and their families, particularly if they utilize water in irrigation canals or ditches or if they have access to farm fields. In many irrigated areas, community residents use water from irrigation canals or ditches for cleaning clothes, washing livestock, and watering kitchen gardens (Figure 2).[52] Young children often swim or play in irrigation ditches, while some residents rely on irrigation canals as a source of household drinking water.[53] The lack of knowledge regarding the potential health risks in many rural and periurban settings and the scarcity of fresh water supplies create situations in which many residents are at substantial risk. The WHO[46] recommends the following measures to protect members of agricultural communities:

1. Treating wastewater
2. Restricting access to irrigated fields and canals and ditches

FIGURE 2 Community members are at risk of contamination from wastewater carried in local stream, as they withdraw water for cooking, cleaning, and other purposes.
Source: Ben Keraita, IWMI, Ghana.

3. Providing safe recreational water, particularly for adolescents
4. Providing safe drinking water and sanitation facilities to communities
5. Promoting good health and hygiene practices
6. Providing chemotherapy and immunization
7. Controlling disease vectors and intermediate hosts
8. Reducing contact with disease vectors

Several of these measures are similar to those recommended to protect farm families and farm workers, given the similarity in exposure opportunities on farms and in the larger community. Many of the challenges involved in implementing the measures and encouraging sustainable adoption also would be similar.

Consumers of Farm Products

In many settings, in the absence of policy intervention, consumers might be the least informed group regarding the potential health risks due to wastewater irrigation. They might be unaware that farmers using wastewater have produced some of the fruits and vegetables for sale in local markets. They might also be unaware that some of the farm produce carries harmful pathogens and chemicals or that cooking the produce might reduce the likelihood of damage from infectious pathogens. Given these considerations, the WHO[46] recommends the following measures to reduce the risk to consumers:

1. Treating wastewater
2. Restricting the crops that are irrigated with wastewater
3. Promoting irrigation practices that minimize contamination of plants
4. Implementing withholding periods that allow pathogens to die between the last irrigation and harvest
5. Promoting hygienic practices at food markets and during food preparation
6. Promoting good health and hygiene practices
7. Promoting produce washing, disinfection, and cooking
8. Providing chemotherapy and immunization

Although enforcement will be difficult, public agencies might consider disallowing wastewater irrigation of vegetables and other crops that consumers often eat without cooking. Leafy vegetables, such as lettuce and spinach, are particularly prone to accumulating pathogens on edible portions of the plant when wastewater is applied directly over the plants and when irrigators splash contaminated soil particles on the leaves (Figure 3).[54] Modifying the spouts of watering cans will reduce contamination by reducing the splashing of soil particles (Figure 4).[54] Drip irrigation on the soil surface or below ground will minimize contamination,[55] but many poor farmers will not have the funds to invest in such systems (Figure 5).

Withholding periods between the date of last irrigation and harvest are sensible approaches as well, but monitoring and enforcement might be problematic in areas where wastewater irrigation is prevalent. Some farmers report that irrigating lettuce on the morning of the day of harvest freshens the crop and enhances its appearance in local markets.[54] Encouraging farmers to change such practices will be challenging, particularly given the perishable nature of leafy vegetable crops. Farmers generally want to obtain the highest price possible and to sell their produce quickly, before its appearance and quality begin to fade.

Public efforts to improve hygienic practices and food preparation at homes and in the marketplace also will be challenging. In areas where small-scale farmers sell produce to small-scale vendors who resell the produce in a restaurant or fast-food outlet, individuals have little incentive to assume the extra cost of enhanced food treatment. This situation in which information is limited and asymmetric can be described also an externality involving producers and consumers. The benefits of a cleaner, safer food

FIGURE 3 Leafy vegetables are susceptible to contamination by pathogens in wastewater used for irrigation, particularly when watered with sprinklers or cans, as in this photograph from Ghana.

Source: Frank Rijsberman, IWMI.

supply accrue to consumers and communities, rather than to the farmers and food shop owners who will incur higher costs if they implement improved production, washing, and handling practices. Public policy is needed to ensure that farmers and vendors internalize the external costs of their activities.

Motivating Safe Practices along the Wastewater Exposure Pathway

From a policy perspective, it is helpful to view the use of wastewater in irrigation as an activity along a pathway on which many individuals and communities are exposed to potential contamination. The pathway begins with wastewater generation in households, companies, and industries. Farmers, fishers, and members of urban and rural communities who utilize water in streams or drains carrying wastewater are exposed to contamination as they conduct their activities. Farmers and laborers applying irrigation water or working in farm fields are exposed, as are community members who spend time in fields irrigated with wastewater. The exposure pathway continues from the farm to food processors, vendors, and consumers.

Along the wastewater exposure pathway, farmers and food vendors generate value as they produce and market crops that are desired by consumers. That value provides motivation for reducing risk, while maintaining irrigation opportunities. The value also can provide a partial source of finance for implementing measures to reduce risk. Both farmers and food vendors have a financial stake in sustaining their activities, and they should be able and willing to pay some portion of the cost of achieving acceptable risk levels. Given this perspective, cost-sharing programs in which farmers pay a portion of the cost of adopting safer irrigation methods might be helpful in promoting rapid adoption. Food vendors also might be offered cost-sharing programs for adopting measures that will improve hygiene and preparation of irrigated produce.

Local officials might also consider ways to motivate farmers and food vendors to participate actively in the study and enhancement of crop production and food preparation methods in areas where wastewater is used for irrigation. At present, it is likely that many farmers and vendors prefer to operate with minimal visibility, to reduce the probability that a public agency or consumer organization might endeavor to end the practice of wastewater irrigation. The public will gain value by encouraging farmers and vendors to explain their practices, maintain production records, gather information regarding water quality and food safety, and participate in training programs on irrigation and food preparation. Public officials might offer farmers greater security of land tenure or access to affordable credit, in exchange for active participation. Food vendors also might respond positively to the offer of affordable credit or the opportunity to obtain a license that enables them to sell food products in a desirable location for several years.

Consumers also can be expected to contribute some portion of the cost of reducing risk along the wastewater exposure pathway. Consumer willingness to pay market prices for fresh produce reflects the value generated by farmers and food vendors in making the produce available. Fresh fruits and vegetables enhance dietary intake in important ways, provided the produce is free of pathogens and chemicals. The net value consumers actually obtain from wastewater-irrigated produce will be diminished if they become ill due to interaction with pathogens or chemicals. Hence, they should be willing to pay a premium for produce that is certified free from potentially harmful constituents.

Local governments might consider implementing food safety assurance programs, in which trained professionals monitor and certify the production of farm produce in areas where wastewater is used for irrigation. The programs might be started on a voluntary basis, with the goal of eventually including all farmers using wastewater to produce vegetables for sale in local markets. Funds for the program could be generated through an assessment on the sale of farm products to food vendors, or at the point of sale from vendors to consumers. In either case, consumers would pay a portion of the cost of assuring food safety.

In summary, a key question for policy makers is how to enhance the values generated along the wastewater exposure pathway, while also encouraging farmers and food vendors to use a portion of those values to improve food safety and reduce farm-level and community risks. Poor farmers might initially be resistant to changing irrigation practices in ways that reduce contamination of their produce, but they should be encouraged to consider their financial situation with and without access to wastewater. To the extent that wastewater irrigation enhances farm-level net income, there should be some farm-level willingness and ability to invest in safe irrigation practices. Public officials might consider implementing cost-sharing programs to encourage farmers to invest in drip irrigation systems or other watering methods that reduce the risks associated with wastewater irrigation.

The same perspective applies with regard to food vendors. To the extent that their sales are enhanced through access to crops irrigated with wastewater, food vendors should be able and willing to invest some portion of their net returns in efforts to improve food safety. They might be encouraged to purchase vegetable washing devices and to clean all produce carefully before it is sold to consumers. A successful campaign of improving food safety might enhance food sales, as consumers learn of the campaign and as they suffer fewer health effects from consuming vegetables produced by local farmers.

Public officials also might consider implementing farm produce certification programs in which farmers who agree to improve their cultural practices in ways that reduce contamination are given special recognition. For example, one can envision a “consumer-safe” labeling program in which vegetables produced using risk-minimizing irrigation methods are given a label denoting that status. If implemented along with an innovative marketing campaign, consumers might be willing to pay a premium price for consumer-safe produce, thus rewarding farmers for investing in safe irrigation practices.

A similar program could be implemented for food vendors who purchase consumer-safe produce from farmers and then prepare the food for sale using safe handling and preparation practices. One can envision a consumer- safe label affixed to the storefronts of participating food vendors. Over time, if the program is successful, market forces might guide both farmers and food vendors to join the consumer-safe program, as the demand for non-labeled produce and food diminishes.

Examples of Public Policies

Helpful examples of public policies regarding wastewater use in irrigation are found in the Middle East and North Africa and other regions where farmers have been using treated and untreated wastewater for many years. In some countries, such as Egypt, the volume of municipal wastewater exceeds the treatment capacity, and large volumes of untreated wastewater enter agricultural drains.[56] The government attempts to manage the blending of treated and untreated wastewater with agricultural drainage water and the use of blended water by farmers, but success is limited by the scale of the problem and the strong demand for supplemental water supplies in the Nile Delta. Irrigation with treated wastewater will increase over time, with the expansion of wastewater treatment capacity. Egypt has developed a code of practice for using treated wastewater in agriculture (Table 3).

Several countries in the region, including Algeria, Cyprus, and Tunisia, do not allow the irrigation of vegetables with treated wastewater. Cyprus also disallows the irrigation of ornamental plants destined for sale in international markets.[57] Wastewater policies are well developed in Cyprus and Tunisia, where the governments actively support and regulate wastewater treatment and reuse. In Cyprus, the government pays for large portions of the cost of water treatment plants in cities and villages, while also paying for the distribution of wastewater to farmers (Table 4). Tunisia requires that industries comply with wastewater discharge standards designed to support reuse on farms, golf courses, and landscapes, and also for aquifer recharge (Table 4). Saudi Arabia plans to use all of its treated wastewater, primarily in agriculture. The city of Muscat in Oman has installed an extensive drip irrigation system for irrigating landscapes with treated municipal wastewater.[60]

In other regions, Italy has established water quality criteria regarding the use of treated wastewater on vegetables and grazing crops, while several autonomous provinces in Spain have developed legal prescriptions or recommendations regarding wastewater reuse.[61] Wastewater accounts for an estimated 41% of the irrigation water used on Spanish golf courses.[62]

The government of Botswana encourages greater reuse of wastewater in irrigation and mining, in part, by ending its policy of providing fresh water supplies at subsidized prices.[63] Botswana also is considering how to account for wastewater volumes within its national water accounting framework.[64]

Public officials in countries with little experience in regulating the use of wastewater in irrigation can gain value by reviewing the examples presented here and by considering ways to engage producers and consumers in active discussion of wastewater issues. As in many regulatory settings, the prospect of new rules and procedures regarding wastewater irrigation and food preparation will be viewed initially as a cost-increasing outcome that will harm the financial performance of individual farmers and food vendors. Hence, the rational strategy from an individual's perspective involves a combination of maintaining a low profile and quietly lobbying against the adoption of any new programs. Yet, in aggregate, net social welfare is decreased if the sum of damages from using wastewater in irrigation exceeds the sum of the benefits.

TABLE 3 The Cairo East Bank Effluent Re-use Project

Goal

Examine the potential for reusing in agriculture the treated wastewater from three sewage treatment plants that serve Cairo communities on the east bank of the Nile River.

Key Issues

1. What is the best way to distribute and allocate the treated wastewater?
2. What are the safest and most efficient ways to supply and use the wastewater?

Outcomes

1. A draft code of practice, which addresses irrigation requirements, legislative needs, water quality standards, health issues, and monitoring programs.
2. An institutional framework to ensure the design of safe and efficient water reuse projects.

Source: Angelakis et al.[58]

TABLE 4 Examples of Wastewater Policies in the Middle East

Cyprus
The government pays for 75% of the cost of water treatment plants in villages. In cities, the government pays the full costs of construction and operation of tertiary treatment plants. In addition, the government pays the cost of distributing wastewater to farmers.
Egypt
The Ministry of Agriculture supports the restricted reuse of treated wastewater for irrigation of nonfood crops, including trees for timber and green belts designed to stabilize sand dunes. Large volumes of untreated wastewater flow into agricultural drains, where farmers withdraw water for irrigation.
Jordan
Wastewater treatment standards were introduced in 1982, and they have been modified in recent years. Vegetables may not be irrigated directly with treated wastewater.
Kuwait
Treated wastewater may not be used for landscape irrigation. It may be used only to irrigate "safe crops."
Saudi Arabia
The Kingdom plans to use all of its treated wastewater, primarily in agriculture. Other uses include landscape irrigation and aquifer recharge. Guidelines requiring secondary and tertiary treatment have been developed to support the unrestricted use of wastewater for irrigation.
Syria
Wastewater irrigation is restricted to fodder crops, industrial crops, and fruit trees, but enforcement is not complete.
Tunisia
Industries must comply with discharge standards to support intensive development of wastewater reuse on farms, golf courses, and landscapes, and also for aquifer recharge.

Source: Bakir.[59]

Perhaps the key to starting policy discussions is to demonstrate the potential gains in aggregate net benefits. Farmers, food vendors, and consumers can gain value together as they work with public officials to develop safe practices in crop production and food preparation. Individual farmers and food vendors will not be disadvantaged if everyone agrees to adopt safe practices and if consumers are willing to pay higher prices in return for safety assurances. Details regarding policy parameters and effective monitoring and enforcement programs can be developed over time, once all parties appreciate the potential gains in net benefits made possible through the safe and efficient use of wastewater in agriculture and the preparation of healthful food products.

Conclusions

Policy issues regarding the use of wastewater in irrigation are quite different in developed and developing countries. In developed countries, most municipal and industrial wastewater is treated, and thus, most of the wastewater used in agriculture is treated. Protective guidelines regarding the quality of wastewater used for irrigation have been in place for many years. Policy issues in developed countries pertain largely to financial and economic considerations regarding the improvement and expansion of wastewater treatment facilities. Public officials and water management agencies motivate greater use of wastewater by providing financial incentives and increasing public awareness of the safety and benefits of using treated wastewater on farms, golf courses, and urban landscapes.

Policy issues in developing countries also include financial and economic questions regarding investments in wastewater treatment. However, in many countries, the pace of such investments will not be sufficient to meet demand. Much of the wastewater generated in cities and rural areas will remain untreated for many years. As a result, farmers will continue to use untreated wastewater for irrigation, and its use will be largely unintentional and informal. Public officials must therefore implement risk reduction programs that protect farm families, communities, food vendors, and consumers from the potentially harmful effects of exposure to the pathogens and chemicals in untreated wastewater.

Policy options in developing countries will reflect a range of interventions along the pathway that includes wastewater generation, irrigation water capture and use, crop production and harvest, food preparation, and consumption. Public officials can implement risk-reducing guidelines and programs at each stage along the wastewater exposure pathway. For example, public officials can support improvements in wastewater treatment at the point of generation, when funds for such improvements are available. Officials also can call for changes in household and industrial production practices that would reduce the loads of harmful constituents in wastewater, thus reducing concentrations of those constituents in the irrigation water diverted from streams and ditches by farmers.

At the farm level, public agencies can provide technical assistance regarding water diversion and irrigation methods that would reduce potential exposure of farm workers to harmful pathogens and chemicals. Technical assistance regarding irrigation methods that reduce contamination of leafy vegetables and other produce consumed without cooking is essential for reducing risks to food vendors and consumers. Although difficult to enforce, regulations that establish a minimum time period between the dates of last irrigation and harvest would be helpful in reducing the risk of contamination from agricultural products.

Public officials in developing countries might also consider implementing certification programs for consumer-safe farm produce, particularly in markets where local farmers sell their irrigated vegetables. Public agencies can begin such programs, with support from farmers and food vendors, but eventually, market forces must arise to sustain them. Consumers must find value in certified produce, and they must be willing to pay a small premium that compensates farmers and vendors for their costs in providing the safer produce. Educational and marketing campaigns can be helpful in boosting demand for safe produce among consumers.

The policy issues we describe in this entry pertain largely to near-term strategies for minimizing the risk of negative health effects, while also enabling farmers to gain the potential benefits of using untreated and partially treated wastewater in agriculture. This approach is appropriate for countries that presently cannot afford to build, operate, and maintain a full complement of modern wastewater treatment facilities. Over time, as the demand for water in agriculture and other uses continues to increase, public officials in all countries should endeavor to provide wastewater treatment that matches end uses, including the irrigation of crops, landscapes, and golf courses. In developing countries, it will be necessary also to ensure that small-scale farmers retain access to a reliable source of irrigation water when the untreated and commingled wastewater they once relied on becomes unavailable, with the expansion of wastewater treatment programs.

Water: Total Maximum Daily Load

Robin Kundis Craig

Introduction

This entry explains what a "total maximum daily load" (TMDL) is and how TMDLs help regulators to achieve the ultimate goals of the Federal Water Pollution Control Act (FWPCA), more commonly known (since the 1977 amendments) as the Clean Water Act.[1] A TMDL is both a regulatory and an informational tool that helps regulators to "restore and maintain the chemical, physical, and biological integrity of the Nation's waters"[2] by ensuring that each water body in the United States meets its water quality standards. As such, the Act's TMDL provisions also force regulators to take a broader look at water body integrity, and hence, the TMDL requirements could prompt state water quality managers in particular to move water quality regulation beyond individual source requirements to a more systemic and watershed-based pollution control program.

Congress first enacted the FWPCA in 1948.[1] However, early versions of the FWPCA left water quality regulation almost entirely to the states, providing almost nothing that qualifies as a true regulatory program, although the 1965 Water Quality Act unsuccessfully tried to prompt states to adopt water quality standards programs.[1] In 1972, however, Congress significantly amended the Act in order to better protect water quality, significantly expanding the federal role in water quality regulation and creating mandatory regulatory requirements.[1] Specifically, Congress relied upon three main mechanisms to improve the quality and integrity of the Nation's waters: two federal permit programs that regulate the discharges of pollutants from point sources and state nonpoint source control programs that are supposed to manage more diffuse sources of water pollution, such as agricultural runoff.[1]

The Act's two permit programs and the state nonpoint source control programs are source-focused mechanisms for improving water quality—that is, they control water pollution by regulating or managing

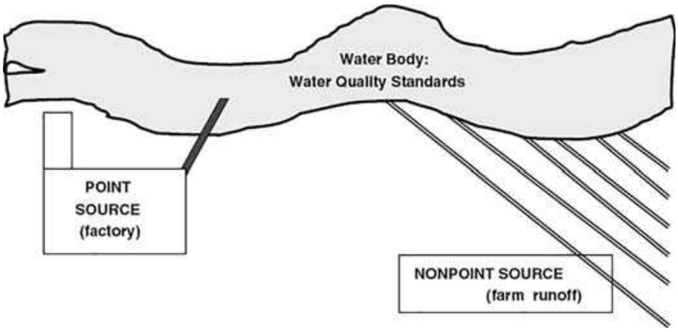

FIGURE 1 Clean Water Act overview.

the sources of that pollution.[3] Point sources—that is, "discernible, confined, and discrete conveyances," like pipes[4]—receive one of two kinds of permits. National Pollutant Discharge Elimination System (NPDES) permits dictate limits on how much of what kinds of pollutants the source can discharge into the water, predominantly based on technology-based effluent limitations.[1] Section 404 "dredge and fill" permits limit both how much dredged or fill material a source can discharge into waters and the broader impacts of construction projects in waters.[1] Similarly, when states manage nonpoint sources, they generally dictate how those nonpoint sources should manage water pollution, such as through best management practices (BMPs).[1]

However, neither the permit programs nor the state nonpoint source management programs dictate specific goals for water quality regulation—that is, nothing in the permit limitations or in BMPs specifies the ultimate water quality goals that their regulatory mechanisms are intended to achieve. Moreover, a single set of national water quality goals would not suffice, because water bodies naturally differ in their water quality characteristics. A headwater stream in the Rocky Mountains is not the Mississippi River, and Lake Erie is not Crater Lake.

Instead, the Clean Water Act uses water quality standards to determine the individual water quality goals for specific water bodies[1] (see Figure 1). The regulatory issue then becomes the following: how do regulators connect the Clean Water Act's two regulatory programs and the state nonpoint source management programs to these water quality standards? Although other mechanisms also exist,[1] the TMDL is the ultimate calculation that the Clean Water Act prescribes to connect water quality standards—the water quality goals for particular water bodies—and the Act's source-based regulatory mechanisms.

A TMDL is, literally, the "total maximum daily load"—that is, the maximum amount of a given pollutant that can be added to a particular water body on a daily basis while still having that water body meets its water quality standards. Individual states and the federal EPA use TMDLs when the national technology-based effluent limitations in NPDES permits, the water quality requirements in Section 404 dredge and fill permits, and the standard state nonpoint source control requirements are not stringent enough to allow a particular water body to achieve its water quality standards. Proper employment of a TMDL can require adjustments to the discharge permits, adjustments to the nonpoint source control requirements, or both.

Regulation of Point Sources

Statutory Trigger: A "Discharge of a Pollutant"

Total maximum daily loads cannot be understood without understanding the Clean Water Act's overall regulatory structure. As a starting point, the Act's regulatory provisions prohibit any "discharge of a pollutant" except as in compliance with the Act.[5] The Act defines "discharge of a pollutant" to be

"(A) any addition of any pollutant to navigable waters from any point source, (B) any addition of any pollutant to the waters of the contiguous zone or the ocean from any point source other than a vessel or other floating craft." [4] The Act does not define "addition," but case law has defined that term to mean any human-controlled contribution of pollutants to regulated waters.[1] The Act defines "pollutant" broadly to mean "dredged spoil, solid waste, incinerator residue, sewage, garbage, sewage sludge, munitions, chemical wastes, biological materials, radioactive materials, heat, wrecked or discarded equipment, rock, sand, cellar dirt and industrial, municipal, and agricultural waste discharged into water."[4] Case law has made clear that the Act does not apply to small, isolated waters.[6] By regulation, the "navigable waters," the "contiguous zone," and the "oceans" are defined so as to include almost everything else,[4] but in 2006, the U.S. Supreme Court issued an indecisive opinion regarding the test that the agencies and the courts should use to determine whether other smaller waters should qualify as "navigable waters" under the Act.[7] Finally, a "point source" is "any discernible, confined and discrete conveyance," like a pipe.[4]

NPDES Permit Program

In order to comply with the Clean Water Act, point sources that discharge pollutants must get a permit. The Act's most generally applicable permit program is the NPDES permit program, which applies to any "discharges of a pollutant" except discharges of dredged or fill material.[8,9] At the federal level, the EPA has the primary authority to implement the NPDES permit program,[8] although it has delegated much of its permitting authority to the individual states.[10] Even where states issue the NPDES permit, however, the EPA retains supervisory authority and can override state authority to issue individual permits.[8,11]

When a point source gets an NPDES permit, most of the requirements governing its discharge will be based on national effluent limitations[1] (see Figure 2). Effluent limitations are "end of the pipe," numerical limitations on the concentrations of pollutants that a discharger can discharge.[4] The EPA generally sets effluent limitations on an industry-wide basis.[5] Moreover, the effluent limitations are technology based. For example, the EPA currently sets most effluent limitations for most industries on the basis of the "best available technology economically achievable" for each category of industry.[5] In contrast, effluent limitations for publicly owned treatment works (or sewage treatment plants) are based on secondary treatment of the sewage. Where the EPA has not issued national technology-based effluent limitations, states write equivalent limits into individual permits.

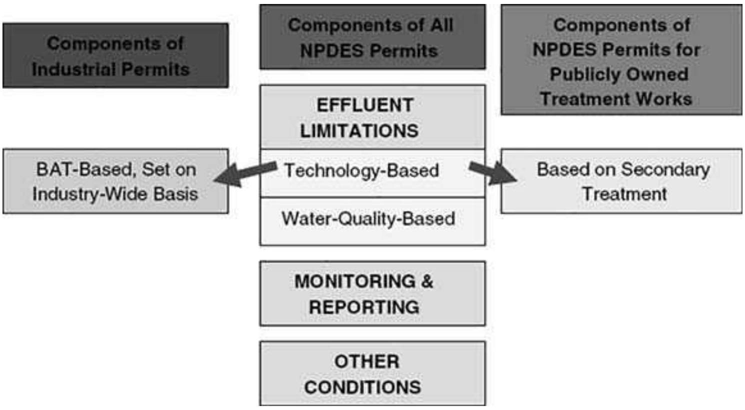

FIGURE 2 Components of an NPDES Permit.
Source: Adopted from U.S. EPA.[32]

Section 404 Dredge and Fill Permit Program

The Clean Water Act's second permit program, the Section 404 dredge and fill permit program, applies only to discharges of dredged or fill material.[9] At the federal level, the U.S. Army Corps of Engineers received the primary authority to implement this permit program, although the EPA retains oversight authority and can veto Section 404 permits.[9] States can also acquire authority to issue some Section 404 permits,[9] but to date, only two states—Michigan and New Jersey—have chosen to do so.[12] As a result, the Army Corps issues most Section 404 permits.

Under the Army Corps' regulations, "the term discharge of dredged material means any addition of dredged material into, including redeposit of dredged material other than incidental fallback within, the waters of the United States"[13]; "dredged material" is "material that is excavated or dredged from waters of the United States."[13] In turn, "[t]he term discharge of fill material means the addition of fill material into waters of the United States,"[13] where "fill material" is "material placed in waters of the United States where the material has the effect of: (1) Replacing any portion of a water of the United States with dry land; or (2) Changing the bottom elevation of any portion of a water of the United States."[13] Thus, Section 404 permits most often regulate construction in or filling of waters of the United States, especially wetlands.

In issuing an individual Section 404 permit (general permits are available for several kinds of smaller activities with limited impact on the environment), the Army Corps reviews the proposed activity against two sets of permitting criteria: the EPA's Section 404(b) Guidelines[9,14] and the Corps' public interest review requirements.[15] Both sets of criteria provide the Army Corps and, in its oversight capacity, the EPA with means to deny individual Section 404 permits to activities that are too damaging to the environment. However, the more common result of the agencies' review of projects in light of the Guidelines and the public interest criteria is that the permit applicant will have to modify the project's design, engage in mitigation, or both in order to receive the Section 404 permit.

Role of Water Quality Standards in Point Source Permitting, before the TMDL Process

The states received the primary authority to set water quality standards.[16] As noted, water quality standards establish the ultimate goals of water pollution regulation for individual water bodies. Specifically, water quality standards "consist of the *designated uses* of the navigable waters involved and the *water quality criteria* for such waters based upon such uses" (emphasis added).[16]

As far as designated uses are concerned, Congress directed states to consider waters' uses for public water supply, fish and wildlife support, recreation, agriculture, industry, and navigation.[16] However, states are free to designate other uses, as well (see Figure 3).

Water quality criteria, in turn, can be either numeric or narrative. State water quality criteria for toxic pollutants, for instance, have often been narrative in form—typically, "no toxic pollutants in toxic amounts." However, the EPA is strongly encouraging states to move to numeric water quality criteria for all pollutants of concern, and states setting numeric water quality criteria often borrow the EPA's water quality criteria guidelines.[17]

Whether numeric or narrative, however, the water quality criteria are supposed to specify the water quality, along multiple parameters (temperature, salinity, turbidity, toxicity, oxygen content, and so forth), that is necessary to achieve the waterway's designated uses.[16] For example, waters designated for salmon populations generally require cold, clear water, whereas waters designated for industrial use need not be so pristine.

In choosing the designated uses of particular water bodies and then establishing the associated water quality criteria necessary to achieve and support those uses, states particularize the meaning of the Clean Water Act's general goal of "chemical, physical, and biological integrity"[2] for specific water bodies. In theory, a state could create different water quality standards for every single water body in the

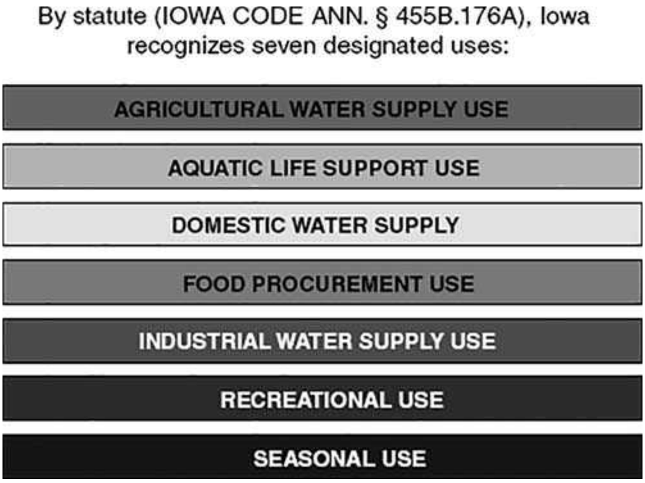

FIGURE 3 An example of Designated Uses: IOWA.

state. In practice, however, states tend to create categories of water bodies and then set water quality standards on that categorical basis.

Although the states received the primary authority to set water quality standards, the EPA retains the authority to set those standards for states that refuse to do so.[16] For example, in 2010, the EPA proposed numeric water quality criteria for nutrients (nitrogen and phosphorus) for the state of Florida.[18] The EPA also has the authority to disapprove state water quality standards that are inconsistent with the Act's requirements.[16]

Besides setting the water quality goals for individual water bodies, water quality standards also directly influence the two point source permitting programs. For example, in NPDES permitting, if the industry-wide technology-based effluent limitations are insufficient to achieve the water quality standards for a particular water body, the state or the EPA should instead use water quality–based effluent limitations in the permits of point sources discharging into that water body[19] (see Figure 2). The Army Corps, in turn, must ensure that projects requiring a Section 404 dredge and fill permit will not violate state water quality standards, and states can ensure that the project will comply with state water quality standards through their Section 401 certification authority.[20–22]

State Management of Nonpoint Sources

State Nonpoint Source Management Plans

The federal permit programs apply only to point sources—that is, "discernible, confined, and discrete conveyances"[4]—of water pollution. In contrast, a nonpoint source of water pollution is any source that is not a point source. Common nonpoint sources are uncontrolled and contaminated runoff or snowmelt or deposition onto water of air pollution.[23]

The Clean Water Act leaves the states in charge of managing nonpoint source water pollution. Initially, states were supposed to address nonpoint source pollution through their Section 208 area-wide waste treatment management programs.[24] These plans emphasized the construction of treatment works.[24] However, they were also supposed to do the following: 1) "identify, if appropriate, agriculturally and silviculturally related nonpoint sources of pollution" and establish controls for them; 2) identify and control "mine related sources of pollution"; 3) identify and control "construction activity related sources of pollution"; and 4) identify and control salt water intrusion problems.[24]

Dissatisfied with states' progress in controlling nonpoint source pollution under Section 208, Congress in 1987 added Section 319 to the Clean Water Act, which encouraged states to enact more specific and detailed nonpoint source management programs.[25] Section 319 nonpoint source management plans are supposed to include BMPs for all relevant nonpoint sources in the state, enforcement and assistance programs, and annual milestones against which to judge the state's progress in reducing nonpoint source pollution.[25]

Role of Water Quality Standards in Nonpoint Source Management before the TMDL Process

The ultimate goal of nonpoint source management, as in the regulatory provisions of the Clean Water Act generally, is to achieve the "chemical, physical, and biological integrity" of the Nation's waters,[2] which, as noted, is defined as a practical matter through the states' water quality standards. Thus, state nonpoint source management programs are often keyed to state water quality standards. Idaho, for example, explicitly requires that the designated BMPs for nonpoint sources ensure compliance with state water quality standards.[26]

As a more elaborate example, Washington explicitly ties its forest practice rules, which prescribe BMPs for forest activities that cause nonpoint source pollution, to its water quality standards, requiring the forest practice rules to be protective of water quality standards in waters affected by forestry-related nonpoint source pollution.[27] Once that connection is made, however, a forestry activity that complies with the forest practice rules is deemed to be in compliance with the state's water quality requirements.[27]

Role of TMDLs in Achieving Water Quality Standards

Introduction

As noted, Congress intended the regulatory mechanisms in the Clean Water Act "to restore and maintain the chemical, physical, and biological integrity of the Nation's waters."[2] The state-set water quality standards define such integrity for particular water bodies, and hence, water quality standards are the measure of whether the Act's goals have been achieved for an individual water body.

The Act's TMDL process provides a means for adjusting both permit requirements and the nonpoint source management requirements for the particular sources that contribute pollution to a water body that cannot achieve its water quality standards through the application of "normal" source-based requirements. The TMDL thus provides the information necessary to "ratchet down" the Clean Water Act's regulatory requirements to meet the water quality needs of specific water bodies.

Section 303 Impaired Waters List

The first step in the Clean Water Act's TMDL process is the state's creation of a Section 303(d) impaired waters list.[17] Specifically, the Act requires each state to identify water bodies or segments within its boundaries for which the effluent limitations "are not stringent enough to implement any water quality standard applicable to such waters."[17] States vary considerably in how many impaired waters they have.

Impaired waters are also known as "water-quality-limited water bodies." It is important to remember, however, that the designations of impairment depend on the following: 1) the exact water quality standards that each state has decided to apply to a particular water body; and 2) how the state decides to segment its water bodies in general. Given these particularities of state law, the number of impaired water bodies is actually a poor basis for attempting to compare actual water quality across state lines. For example, the fact that Pennsylvania has thousands of impaired water bodies may mean that most waters in Pennsylvania have poor water quality—but it could also mean that Pennsylvania has chosen very stringent water quality standards, applied water quality standards to very small segments of rivers and streams, and/or monitors water quality quite comprehensively. On the other hand, the fact that Alaska has identified less than 100 impaired waters might mean that water bodies in Alaska are generally pristine—but it could also mean that Alaska applies its water quality standards to entire rivers and lakes (creating fewer regulatory "water bodies"), has less stringent water quality standards than Pennsylvania, and/or monitors water quality less comprehensively than Pennsylvania.

Once a state identifies water bodies within its borders that do not meet their applicable water quality standards, it must rank those impaired water bodies for the purpose of establishing TMDLs for them.[16] The priority ranking must "tak[e] into account the severity of the pollution and the uses to be made of such waters." [16] States have considerable discretion in ranking their impaired water bodies. At the same time, the state must also "identify those waters or parts thereof within its boundaries for which controls on thermal discharges … are not stringent enough to assure protection and propagation of a balanced indigenous population of shellfish, fish, and wildlife."[16] States submit their lists of impaired waters to the EPA biennially,[28] and these lists—known as the Section 303(d) lists—are subject to the EPA's approval.[16]

Setting the TMDL and State Water Planning

Once a state has identified water-quality-impaired water bodies within its borders, establishing a TMDL is mandatory, and the EPA must establish the required TMDLs if the state fails to do so.[16] In establishing a TMDL, the state estimates, "in accordance with the priority ranking, the total maximum daily load" of all pollutants contributing to the violation of the relevant water quality standards that the EPA has determined can be subject to such a numeric calculation.[16] The state must establish the TMDL "at a level necessary to implement the applicable water quality standards with seasonal variations and a margin of safety which takes into account any lack of knowledge concerning the relationship between effluent limitations and water quality."[16] Thus, the TMDL should be somewhat conservative, allowing for both scientific uncertainty and natural variations in water quality.

Under the EPA's regulations, "TMDLs may be established using a pollutant-by-pollutant or biomonitoring approach. In many cases both techniques may be needed. Site-specific information should be used wherever possible."[28] Moreover, the state must establish TMDLs for "all pollutants preventing or expected to prevent attainment of water quality standards."[28]

Similarly, for thermally impaired waters, the state must estimate "the total maximum daily thermal load required to assure protection and propagation of a balanced, indigenous population of shellfish, fish, and wildlife."[16] Statutory factors for setting a thermal TMDL include "normal water temperatures, flow rates, seasonal variations, existing sources of heat input, and the dissipative capacity of the identified waters or parts thereof."[15] Moreover, like other TMDLs, thermal TMDLs are set conservatively, because they must include a margin of safety to account for scientific uncertainty.[16]

Once a state has established its TMDLs, it submits them to the EPA. The EPA must approve or disapprove the TMDLs within 30 days of submission.[16] If the EPA disapproves of the TMDLs, it has 30 days to establish its own TMDLs.[16]

For each TMDL established, the state must allocate the total daily load of the relevant pollutant among the sources that contribute that pollutant to the impaired water. The EPA recognizes that the TMDL's total pollutant load must be allocated among three sources (see Figure 4): background or "natural" sources of the pollutant; nonpoint sources of the pollutant (the "load allocation," or LA); and point sources of the pollutant (the "waste load allocation," or WLA).[29]

These allocations then provide the basis for strengthening the regulation of the relevant sources so that the water body can achieve its water quality standards. For example, the WLA provides the total amount of the relevant pollutant that the point sources can discharge. As a result, it becomes the basis for calculating water quality–based effluent limitations that should then be incorporated into the point sources' NPDES permits.[29] Moreover, the Clean Water Act limits the states' abilities to amend these

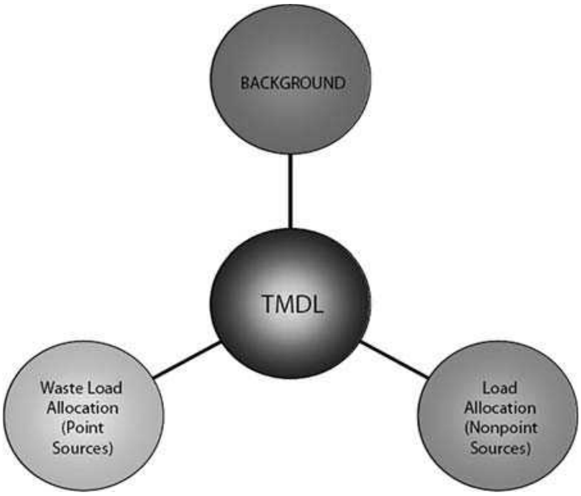

FIGURE 4 Allocation of the TMDL.

TMDL-based effluent limitations so long as the water body remains impaired: such standards "may be revised only if (i) the cumulative effect of all such revised effluent limitations based on such total maximum daily load or waste load allocation will assure the attainment of such water quality standard, or (ii) the designated use which is not being attained is removed. …"[16] Removing designated uses is difficult, however, because the Act incorporates an antidegradation policy.[16,30]

The LA, in turn, allows for the possibility that the state will also amend its nonpoint source management requirements—especially for waters impaired entirely or predominantly as a result of nonpoint source pollution. As the EPA recognizes in its regulations, "[i]f Best Management Practices (BMPs) or other nonpoint source pollution controls make more stringent load allocations practicable, then wasteload allocations can be made less stringent. Thus, the TMDL process provides for nonpoint source control tradeoffs." [29]

If the EPA approves the state's TMDLs, or if the EPA establishes TMDLs for the state, the state also incorporates those TMDLs into its continuing planning process for water quality.[16] The state's continuing planning process includes the following: 1) effluent limitations and schedules of compliance, including effluent limitations stringent enough to meet water quality standards; 2) the applicable Section 208 area-wide waste management plans; 3) the TMDLs; 4) procedures for revision; 5) authority for intergovernmental cooperation; 6) mechanisms to implement new and revised water quality standards, including schedules of compliance; 7) controls for the disposal of residual wastes from wastewater treatment; and 8) an inventory and priority ranking of treatment works.[16]

Two Examples: Applying a TMDL

The potential impacts of a TMDL, and the potential tradeoffs between point source regulation and nonpoint source regulation, are best illustrated by example (see Table 1). Suppose that, in its Section 303 water quality standards, State A has designated both the Blue River and the Green River as cold-water rivers to support native trout populations. To support this designated use, State A establishes water quality criteria for sediment. Moreover, it includes standard effluent limitations for sediment in the NPDES permits that it issues to point sources. State A's nonpoint source management program includes extensive BMPs for farming, which has been a traditional source of water pollution in the state. However, forestry is a relatively new industry in State A, and the state has not amended its nonpoint source management program to account for water pollution from those activities.

TABLE 1 Sources of Sediment in the Blue River and Green River in State A

Source	Blue River	Green River
Background/natural	5 kg/day from cliff erosion	10 kg/day from upstream erosion
Point sources	500 kg/day from 4 confined animal feeding operations, each of which has an NPDES permit	None
Nonpoint sources	10 kg/day from runoff over a small farm	600 kg/day from 3 large timber operations along the river

During its most recent biennial Section 303(d) review of impaired waters, State A discovers that both the Blue River and the Green River are violating their water quality standards for sediment, causing harm to the native trout populations. Through the TMDL process, State A estimates that 100 kg of sediment can be added to each river each day without violating the sediment water quality standard for trout, leaving an ample margin of safety and allowing for seasonal variations, such as increased sediment runoff during the rainy season.

State A then identifies the sources contributing sediment to each river (Table 1).

Given these sources, State A should take a different approach to implementing the sediment TMDL on the Blue River than it does to implementing the sediment TMDL on the Green River. To ensure that the Blue River will meet its water quality standards, State A will need to adjust the point sources' *WLA*. As a result, to ensure compliance with the Blue River's water quality standards, State A will need to amend each of the point sources' NPDES permits to incorporate more stringent water quality–based effluent limitations for sediment.

In contrast, to ensure that the Green River will meet its water quality standards, State A will have to address the nonpoint sources' *LA*. Most obviously, State A should amend its nonpoint source management plan to impose nonpoint source control requirements, such as BMPs, on the timber companies. Such BMPs may, for example, require the use of buffer zones, require selective logging instead of clear-cutting, or limit the amount of road building and land clearing allowed.

Conclusion

Congress designed the TMDL process to ensure that every "water of the United States" would eventually enjoy chemical, physical, and biological integrity, as defined by the states in water quality standards. While TMDLs have been part of the Act since 1972, states ignored the TMDL process for many years.[31] Instead, citizen litigation drove the establishment and implementation of TMDLs, and many states are still working their way through court orders that require them to set TMDLs.[31]

Given that litigation context, TMDL implementation focused initially on adjusting the effluent limitations in point sources' Clean Water Act permits. However, as it becomes clear that nonpoint source pollution is the most significant remaining source of water quality impairment, TMDLs are increasingly becoming the mechanism that encourages states to adequately control those nonpoint sources of water pollution, as well.

Watershed Management: Remote Sensing and GIS

A.V. Shanwal
and S.P. Singh

Introduction

The need for natural resource conservation must be considered in any agricultural development plans involving conversion of new land use to increase production. An action plan to minimize natural resources degradation must be based on the principles of sustainability so that soil can be handed over to the future generation under better conditions than received from the previous generation. Thus, management practices must be ecologically sound, economically feasible, and socially and politically acceptable.

Natural resources degradation can be contained by adopting the watershed as a hydrological unit for development and management. This approach is multidisciplinary, broad based, and intensive vis-a-vis the simple “Seed and Fertilizer Approach.” Despite the investment, it is an economic approach in the long run.[1]

The degradation of improperly used watersheds happens because of increase in soil erosion, decline in soil productivity, reduction in livestock-carrying capacity, decline in forest cover and perturbation in ecological equilibrium, and reduction in biodiversity. The problem requires a hightech solution with back-up policy decisions.

Remote sensing (RS) and geographic information system (GIS) are important technologies for addressing challenges in sustainable management of natural resources. Remotely sensed data (e.g., aerial photographs and satellite imagery) can be used to obtain information on soils, land use, vegetation, slope gradient, runoff, erosion, etc. However, recent developments in multispectral scanner, radar system, and a multitude of quantitative techniques for analyzing and processing such data provide opportunities for data acquisition through RS and array of techniques for data analyses.

GIS is an important tool for tracking spatial data. GIS draws the composite map by superimposing the data and image files obtained from traditional methods and satellite imageries, allows us to develop, analyze, and display spatially explicit information, and gives us the ability to deal with the larger spatial scales in process such as soil erosion and drainage (500 acres) and regional landscape (several million acres).

Inventorying and Monitoring

Despite efforts at inventorying and monitoring, conventional techniques provide only sketchy information on resources in a watershed, their location, and spatial and dynamic distribution. Of inventorying and monitoring, the latter is probably the major new thrust for resource managers and scientists.

Improved management practices are not thought of spontaneously prior to testing and implementation. Such practices have evolved over time through experimentation, experience, and trial and error. A case in point is the Bunga watershed in Ambala, Haryana, India.[10] As was expected, numerous components did not work properly. Neither the rate of runoff nor the outflow from the reservoir was in harmony in the initial stage. High rate of siltation of Sukhana Lake near Chandigarh, Haryana, India, due to severe soil erosion in the catchment area is another example of dire need for inventorying of data prior to starting any project.[11] Because of high siltation, the ponded area of Sukhana Lake decreased by about 30ha between 1980 and 2000. During this period, the courses of Sukhana and Kansal streams feeding the lake also changed considerably. The siltation of Sukhana Lake is the result of poor vegetation cover and heavy runoff in the catchment within the Shiwalik Hills.[11]

It is thus important that RS and GIS specialist and the resource managers must work together to determine the specific information needed (e.g., the nature of earth surface cover and their characteristics; the location, size, terrain, and other characteristics of the watershed area involved). Relevant information needed includes the format (e.g., maps, tables, scales, etc.); time frame for both collecting and processing the data; level of accuracy and reliability; costs of obtaining and interpreting/processing the data.

Research and Development

Using watershed, landscape or ecosystem approaches have broad support as a means in achieving sustainable use of natural resources and integrating objectives on a practical scale. Yet, addressing watershed management issues on large scales requires enhanced technical capabilities and modern set of tools and facilities.

Landsat-1 was launched in 1972 and the Landsat Thematic Mapper (TM) type of data has been in existence only since 1984. Thus, a tremendous progress has been made over short time in developing effective methods of processing and analyzing such data. The last decade of 20th century witnessed rapid advances and significant increase in the operational use of remotely sensed data.[3]

Landsat-7 launched in 1998 carries Enhanced Thematic Mappers (ETM) and pointable sensor with improved spatial resolution and signal-to-noise ratio (Table 1). The Earth Observing System consists of a morning (AM) and an afternoon (PM) components and carries five separate sensors including MODIS, a 36-narrow band imager with 1-km spatial resolution.[2] These sensors are significantly improved in their capability to map watershed information classes. These advanced sensors and computational capability have new requirements for satellite data processing algorithms. Added to the image analysis system, there is also a need for RS algorithms for estimating biophysical parameters necessary to drive and validate the watershed process models.[5]

ETM: enhanced thematic mapper; HRVIR: high resolution visible and middle infrared; LISS: linear imaging self scanner system; SAR: synthetic aperture radar; VIRS: visible infrared scanner; TMI: TRMM microwave imager; CERES: clouds earth's radiation energy system; AVHRR: advanced very high resolution radiometer; OCTS: ocean color and temperature scanner; AVNIR: advanced visible and near infrared radiometer; ASTER: advanced space borne thermal emission and reflectance radiometer; MODIS: moderate resolution imaging spectrometer-nadir; PAN: panchromatic; MS: multi spectral; IFOV: instantaneous field of view.[5]

During the 1980s, advances in computer hardware, particularly speed and data storage, catalyzed the development of software for handling spatial data. One of the most significant products of this period of rapid technological change was the development of GIS (Table 2). It has made a tremendous impact in identifying strategies of watershed development by manipulating and analyzing individual "layers"

TABLE 1 Recent RS Satellites with Advanced Sensors

		Sensor		
Satellite	Country	Name	Spectrum	IFOV
Landsat-7	U.S.A.	ETM⁺	0.45 µm ~ 12.50 µm (8 bands)	30 m
SPOT-4	France	HRVIR	0.50 µm ~ 1.75 µm (5 bands)	10 m
IRS-1D	India	PAN	0.50 ~ 0.75	5.8 m
		LISS-III	0.45 ~ 0.86 1.55 ~ 1.70 (5 bands)	24.0 m
		WIFS	0.67 ~ 0.86	188 m
RADARSAT	Canada	SAR	5.3 GHz	25 m × 28 m
TRMN	Japan	VIRS	0.63 ~ 10.7 (5 bands)	2km
		TMI	10.65 GHz ~ 85.5 GHz	5.6 km × 3.8 km

of spatial data and providing tools for analyzing and modeling the interrelationship among layers. The GIS also provides a means of displaying complex watershed information in a comprehensible manner.

The GIS also provides a means of predicting the outcomes of alternative courses of action, from both spatial and temporal perspective and in a timely and cost-effective manner. However, it does not preclude the need for monitoring the ground truth as a guide to development of future management practices.

The last decade of the 20th century witnessed rapid advances and a significant increase in the operational use of RS and GIS in watershed management.[8] Much of this increase in operational use is due to the continued integration of RS, GIS, GPS (global positioning system), and Crop Model (CM) techniques.[4] These four technologies form a powerful, interrelated combination (Figure 1). In watershed management, there has been a continuous increase in the use of RS data to provide input to new GIS database, upgrade existing database, and monitor land use changes.

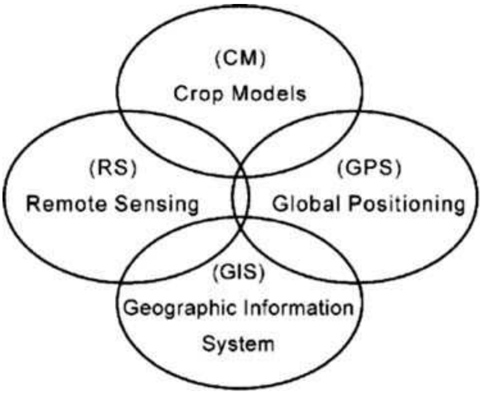

FIGURE 1 Relationship between RS, GIS, GPS, and CM.

In addition to providing input to GIS database, the RS data enables significant improvements in classification accuracies. Further, GPS capabilities provide effective cartographic control to the GIS database, and will enable field plots to be located efficiently and accurately in the data set.

The integration of GIS and CMs has proven very successful for alternative land use planning in the watershed. The important ones are DSSAT (Decision Support System for Agro-technology Transfer), AEGIS/WIN (Agricultural and Environmental Information System for Windows), IDSS (Intelligent Decision Support System), and DSSE (Decision Support System Engine). These simulation models are capable of predicting the potential yields of crops (rice, cassava, potato, sugarcane, sunflower, maize, wheat, barley, millet, sorghum, soybean, peanut, drybeans, tomato, and chickpea) in different physiographic units of a particular watershed. In addition, several GIS-based simulation models have been developed for natural resources management and are used in watershed management.[9] The important ones are SNAP (Scheduling and Network Analysis Program), LUCAS (Land Use Analysis System), and LANDSIM and LANDIS (Land Information System). All these models involve database (nonspatial), GIS, model base (simulation analysis), and a GUI (Graphic User Interface).

Challenges and Opportunities Ahead

Rapid advances in RS and GIS technologies can bring about quantum leap in watershed management. Yet the challenge lies in assuring that RS and GIS technologies continue to serve the practitioners and users, but not vice versa.

However, GIS and RS are both a panacea and a Pandora's box. These are panacea because of the promise to meet the challenges of resource inventory and monitoring, and planning and policy analysis. These are Pandora's box because of the numerous pitfalls of using the tools wrongly, capturing the data poorly, miscommunicating information, conveying incorrect results, and overselling the capabilities.

The dilemma can be addressed by a careful integration of RS, GIS, and other simulation models in watershed management and with due consideration of the following:

- Designing the classification system as totally exhaustive, mutually exclusive, and hierarchical
- Determining the temporal and spatial scale of the watershed by accommodating GIS and RS at multiple scales without compromising flexibility and quality of a project
- Identifying the appropriate data sources (video, aerial photography, satellite imagery, airborne scanner, etc.), for different land cover
- Assessing and reporting the accuracy of the data needs
- Limiting the scope of the project according to the budget and schedule
- Standardizing the formats needed for the exchange of information across projects and eliminating duplication

Future changes may include the following:

1. Developing effective techniques of integration and analysis of data from various sources such as AVHRR and Landsat TM or SPOT data or Landsat TM plus satellite radar data.
2. Converting research into operational applications in watershed management.
3. Developing effective expert system to assist the analyst.
4. Educating and training the user community in principles and theory of these technologies so that they can use these powerful tools wisely, appropriately, and effectively.

Anticipated developments and opportunities in these technologies comprise the following:

- Economic availability of satellite optical sensor data with improved spatial, spectral, radiometric, and temporal resolutions
- Availability of operational multifrequency, multipolarization synthetic aperture radar data from satellite altitudes
- Improvement in computer storage and processing capabilities
- Better understanding and use of combined data from optical, microwave, and other remote sensors
- Integration of RS, GIS, GPS, and CM technologies
- Increased use of expert systems for data analysis

These developments will improve the quality and characteristics of the data and analytical capabilities in the area of watershed management. A combination of knowledgeable resource managers and practical farmers with the technological tools and data available to them holds great promise for identifying effective watershed management technologies.

Conclusions

A variety of information about the characteristics and condition of the area is needed for judicious management of watershed. Aerial photography has been used since the 1950s for obtaining information on soils, land use, vegetation, slope, runoff, erosion, etc. The advent of space research through satellite, multispectral scanner, and radar data, and quantitative analytical techniques of processing such data has increased the array of data, analysis procedure, and results that can be obtained using RS capabilities.

During the 1980s, advances in computer hardware for processing and data storage catalyzed the development of software for handling spatial and image digital data. These technologies played an important role in the development of GIS for natural resource management, especially in preparing composite map superimposing the data and image files.

During the 1990s, significant development in GIS technology and integration of RS, GIS, GPS, and Crop Simulation Model techniques have created additional complexity and opportunities of using various data sources and analysis techniques for obtaining the information needed by the resource managers. Yet, there are some critical issues that need to be addressed for integration of RS, GIS, and other technologies to obtain information needed for sustainable natural resource management through watershed development.

Wetlands: Conservation Policy

Clayton Rubec

Introduction

Meeting the challenge of conserving wetlands requires comprehensive national policies to provide a foundation for domestic action and a framework for international and national cooperation. Such policy is valuable as countries seek to address the management and habitat requirements for wildlife and other natural resources, such as soil and water, as well as human needs. Implementation of a national wetland policy is a key feature of the wise use principles of the Convention on Wetlands of International Importance (the Ramsar convention). However, such policy remains an elusive goal for many of the 145 nations that today (May 2005) are contracting parties to this global environmental treaty.

Responding to recommendations by the Convention, in 1998–1999 the author led a team of writers in preparing guidelines for developing and implementing national wetland policies.[1] These Policy Guidelines complement the convention's guidance on wetland legislation.[2] The following entry provides highlights of the guidelines and reports on the status of wetland policy development around the world, effective mid-1999.

Relationship between Policy and Wise Use

The wise use principles are a hallmark of the Ramsar convention. "Wise use" applies not only to sites listed as wetlands of international importance (as of May 2005 covering over 125 million hectares at 1429 sites), but also to all wetlands in the territory of contracting parties. These *principles* help contracting parties improve institutional and organizational arrangements, address legislative and policy needs, increase knowledge and awareness of wetland values, inventory and monitor the status of wetlands, identify program priorities, and develop action plans for specific sites as components of a national wetland policy.

The formulation of national wetland policies sometimes involves a lengthy and complex process. Political, jurisdictional, institutional legal, and financial constraints affect policy formulation in addition to social and economic factors that continue to contribute to wetland loss while the policy process is under way.

What Are Wetland Policies, and Are They Needed?

A policy can simply be a document. However, making is also a process involving consensus building, encapsulation of ideas and commitments, implementation, accountability, and review complemented by legislation, strategies, and operational programs. It is a mechanism for an administration to capture the public will or mandate on an issue, and refine it with its own vision.

A national wetland policy is nationwide in scope but it may be developed at several levels of government. In Australia and Canada, for example, both the federal government and state/provincial governments have developed wetland conservation policies. This reflects the federal nature of these two nations, wherein constitutional authority for natural resources management (including wetlands) is divided between the levels of government.

Wetlands are seldom explicitly covered in other natural resource management policies such as for water, soil, forest, land, or agriculture at a national level. Development of a "stand-alone" wetland policy and/or strategy can be an important step in recognizing and solving wetland problems. A wetland policy recognizes wetlands as ecosystems requiring different approaches not masked under other sectoral management objectives. Articulation of goals and objectives for these ecosystems identifies clear responsibilities of the government and a public expectation that the government will deliver these commitments.

Wetland policy objectives need to focus on a variety of themes as they become the image of the policy. However, practical implementation of the Policy may result in only one or two of these objectives receiving the greatest public attention. For example, Canada's announcement of its federal wetland policy in 1992 contained seven objectives but "no net loss of wetland functions" has proven to be its catch phrase.

Guidelines

The Guidelines review the key steps and issues that may arise in both developing and implementing a National Wetland Policy. These include over 20 detailed sections defining the purpose of such an initiative, organizing a suitable process, deciding how to present the content of the policy document, and developing strategies for implementation and monitoring. The text is complemented by seven wetland policy essays: 1) *defining stakeholders',* 2) *consultations;* 3) *wetland policies within a federal state;* 4) *sectoral policies and legislation;* 5) *compliance strategies;* 6) *role of nongovernment organizations;* and the 7) *development and coordination process.* The guidelines provide a reference against which all nations can review their wetland action plans and strategies at the national level.

A team of contributors with governmental or nongovernmental work experience and expertise in wetland policy development prepared the guidelines. The team included writers from Ramsar national authorities in Australia, Canada, Trinidad and Tobago, Uganda, and the United States of America. Contributors from Bird Life International, University of Massachusetts, IUCN Environmental Law Centre, and Wetlands International were also involved.

Implementation Strategies

A National Wetland Policy includes specific implementation strategies that demonstrate the priorities of the government, but also fosters the cooperation and involvement of other interests. Linkages between these strategies and national water, soil, biodiversity, and sustainable development policy initiatives are explored in the guidelines.

An analysis of the strategies used in selected National Wetland Policies is summarized in Table 1. These include the policies/action plans of Australia, Cambodia, Canada, Columbia, Costa Rica, Finland, France, Jamaica, Malaysia, Peru, Trinidad and Tobago, and Uganda. These initiatives have many common strategic approaches including: a) ensuring public awareness and education; b) developing

TABLE 1 Implementation Strategies in Selected National Wetland Policies

Uganda		X	X		X	X		X	X		X	X

Policy strategies:

1. Management of national wetland networks
2. Integration with other policies such as water, soil and forests
3. Public awareness and education
4. Partnerships
5. Science, monitoring, assessment, and research
6. International commitments
7. Managing special sites
8. Administration and institutions, capacity building
9. Enforcement, regulation, and legislation
10. Financial mechanisms
11. Restoration of degraded sites
12. Sustainable use and conservation

cooperation and partnerships between levels of government from national to local; c) developing and supporting legislation and interrelated land and water use policies and programs; d) implementing wetland site management responsibilities; e) developing a sound basis for the policy through scientific research and expertise; f) developing institutional and financial capacity for policy implementation; and g) meeting international commitments. These strategies have been drafted to evoke a clear vision and acceptance across the nation.

Global Review of the Status of Wetland Policies and Strategies

Significant progress is evident globally in the development of National Wetland Policies since the Ramsar Convention focused attention on this issue in 1987.[1,3,4] Meetings of the contracting parties every three years allow regular review of the status of wetland policies. The Contracting Parties last met in November 2002 when there were 123 Contracting Parties while now (May 2005) there are 145 Contracting Parties.

Policies

As of November 2002, 60 (56%) of the 107 Ramsar Contracting Parties that submitted national reports to the Eighth Meeting of the Contracting Parties to the Convention on wetlands indicated that they were engaged in development or implementation of a National Wetland Policy. Between 1987 and 2002, the number of nations with a National Wetland Policy officially adopted grew from 0 to 41. An additional 19 nations indicated that a National Wetland Policy was in draft or under consideration. However, 47 (44%)

Oceania (Australia and Pacific)	Australia, New Zealand	—

[a] Russia straddles Asia and Europe.

of the Ramsar Contracting Parties did not yet report any actions being taken in support of National Wetland Policy development. A number of nations, particularly those with a commonwealth or federal make-up, reported wetland policies and strategies at the sub-national level also. National Wetland Policies have also been called a "National Wetland Strategy" or "Action Plan."

Table 2 summarizes the status of the development and adoption of National Wetland Policies from 1987 through November 2002. This table was developed by reviewing the reports and conference papers that summarize Convention activities every three years by each country. In 1987, only two nations indicated that they were involved in developing any sort of national wetland policy/strategy. By 2002, this number grew to at least 60 nations. Table 3 summarizes the countries by Ramsar's regions (Africa, Asia, Europe, Neotropics, North America, and Oceania) that have either a *national wetland policy* or *national wetland strategy* adopted, being drafted or considered up to May 2005.

Conclusions

Development and implementation of a national wetland policy in the 145 countries that have acceded to the Ramsar Convention is proceeding throughout the World. The Convention's Wise Use Principles and Guidelines on National Wetland Policy,[1] complemented by guidelines for wetland legislation,[2] are effective tools in fostering the completion and use of National Wetland Policies and Strategies as important cornerstones of this Convention. At least 56% of the Ramsar Convention's Contracting Parties now are implementing or developing national wetland policies/strategies.

One of the most interesting aspects of the Ramsar Convention is its capacity to foster sharing of experience. Interchanges by wetland policy experts are now occurring internationally that involve short-term invited visits or sabbaticals, informal exchange of documents, confidential advice, and review of draft policy. Consultation workshops, working with non-government groups, meeting with senior government officials, exploring funding mechanisms, and assistance in drafting of text have also been involved. Experience gained in one nation's development of these policies can be shared and local expertise enhanced, filling a need among the Ramsar family.

Irrigation Systems: Subsurface Drip Design

Carl R. Camp, Jr.
and Freddie L.
Lamm

Introduction

Subsurface drip irrigation (SDI) is generally defined as the application of water below the soil surface through emitters, with discharge rates in the same range as drip irrigation.[1] While this definition is not specific regarding depth below the soil surface, most SDI laterals are installed at a depth sufficient to prevent interference with surface traffic or tillage implements and to provide a useful life of several years as opposed to annual replacement of surface or near-surface drip laterals.

Development of drip irrigation accelerated with the availability of plastics following World War II, primarily in Great Britain, Israel, and the United States. SDI was part of drip irrigation development in the United States beginning about 1959, especially in Hawaii and California. While early drip irrigation products were relatively crude by modern standards, SDI devices were being installed in both experimental and commercial farms by the 1970s. As drip irrigation products improved during the 1970s and early 1980s, surface drip irrigation grew at a faster rate than SDI, probably because of emitter plugging problems and root intrusion. However, interest in SDI increased during the early 1980s, increased rapidly during the last half of the 1980s, and continues today, especially in areas with declining water supplies, with environmental issues related to irrigation, and where wastewater is used for irrigation. Initially, SDI was used primarily for sugarcane, vegetables, tree crops, and pineapple in Hawaii and California. Later, SDI use was expanded to other geographic areas and to agronomic and vines crops, including cotton, corn, and grapes. Currently in the United States, the major uses of SDI are for cotton, processing tomato, corn, and onions using various installation depths and other design aspects.[2]

SDI has the advantage of multiple-year life, reduced interference with cultural practices, dry plant foliage, and a dry soil surface. Multiple-year life allows amortization of the entire system cost over several years, often more than ten. There are a few systems in the United States that have achieved 20 years are more in longevity.[3] If all system components are installed below tillage depth, surface cultural practices can be accomplished with minimal concern for system damage. Dry soil surfaces can reduce weed growth in arid climates and may reduce evaporation losses of applied water. Because the plant canopy is not irrigated, the foliage remains dry, which may reduce the incidence of disease. SDI is also very adaptable to irregularly shaped fields and low-capacity water supplies that may provide design limitations with other irrigation systems.

The major disadvantages of SDI include system cost, difficulty in locating and repairing system leaks and plugged emitters, and poor soil water manipulation near the soil surface. Most system components are installed below the soil surface and are neither easy to locate nor directly observable. In a properly designed and managed SDI system, the soil surface should seldom be wet. Consequently, seed germination, especially for small seeds, can be very difficult.

SDI systems offer considerable flexibility, both in design and operation. For example, SDI systems can apply small, frequent water applications, often multiple times each day, to very specific sites within the soil profile and plant root zone. Fertilizers, pesticides, and other chemical amendments can be applied via the irrigation system directly into the active root zone, often at a modest increase in equipment cost. In many cases, the operational cost may be less than that for applying these chemicals via conventional surface equipment.

System Design

Site, Water Supply, and Crop

Design of subsurface drip systems is similar to that of surface drip systems, especially with regard to hydraulic characteristics.[3,4] Specific crop and soil characteristics are used in the design process to select emitter spacing and flow rate, lateral depth and spacing, and the required system capacity. Emitter properties and lateral location are influenced by soil properties such as texture, soil compaction, and soil layering because these affect the rate of water movement through the soil profile and the subsequent wetting pattern for each emitter.

The water supply capacity directly affects the design of an SDI system. The size of the irrigated field or zone is often determined by the water supply capacity. For example, in some humid areas, high-capacity wells are not available but multiple low-capacity wells can be distributed throughout a farm. Fortunately, the design of SDI systems can be economically adjusted to correspond to the field size and shape, to the available water supply capacity, and to other factors. Water supply quality should be tested by an approved laboratory before proceeding with system design. This information is needed for the proper design and management of the water filtration and treatment system. Some water supplies require frequent or intermittent injection of acids and/or chlorine. Other saline and/or sodic water supplies may require treatment or special management. As water supplies become more limited, treated wastewater is becoming an increasingly important alternative water supply that can be applied through SDI systems. Camp[5] listed several reports that emphasized water supplies (saline, deficit, and wastewater) for SDI systems.

The SDI system is usually designed to satisfy peak crop water requirements, which vary with specific site, soil, and crop conditions. When properly designed and managed, SDI is one of the most efficient irrigation methods, providing typical application efficiencies exceeding 90%. In comparison with other methods of irrigation, reported yields with SDI were equal to or greater than those with other irrigation methods. Generally, water requirements with SDI are similar or slightly lower than those with other irrigation methods. In some cases, water savings of up to 40% have been reported.[5] However, unless more specific information is available, it is usually best to use standard net water requirements for the location when designing SDI systems.

Lateral Type, Spacing, and Depth

SDI lateral depth for various cropping systems is normally optimized for prevailing site conditions and soil characteristics.[3,5] Where systems are used for multiple years and tillage is a consideration, lateral depths vary from 0.20 to 0.70 m. Where tillage is not a consideration (e.g., turfgrass, alfalfa), depth is sometimes less (0.10–0.40 m). Lateral spacing also varies considerably (0.25–5.0 m), with narrow spacing used primarily for turfgrass and wide spacing used for vegetable, tree, or vine crops. In uniformly spaced row crops, the lateral is usually located under either alternate or every third midrow area (furrow). For crops with alternating row spacing patterns, the lateral is located about 0.8 m from each row, usually in the narrow spacing of the pattern.

The lateral should be installed deep enough to prevent damage by tillage or injection equipment but shallow enough to supply water to the crop root zone without wetting the soil surface. Generally, laterals in SDI systems are placed at depths of 0.1–0.5 m, at shallower depths in coarse-textured soils, and at slightly deeper depths on finer-textured soils. The selection of emitter spacing and flow rate is influenced by crop rooting patterns, lateral depth, and soil characteristics. It is also desirable to select an emitter spacing that provides overlapping subsurface wetted zones along the lateral for most row crops. For wider spaced crops such as trees and vines, emitters are normally located near each plant and may have wider spacings that do not provide overlapping patterns. Lateral spacing is determined primarily by the soil, crop, and cultural practice and should be narrow enough to provide a uniform supply of water to all plants.

Special Requirements

Site topography must be considered in system design and selection of components as with any irrigation system, but SDI is suitable for most sites, ranging from flat to hilly. For sites with considerable elevation change, especially along the lateral, pressure-compensating emitters should be used.

Two special design requirements for SDI systems, which are significantly different from those for surface drip systems, are the needs for flushing manifolds and air entry valves. Flushing manifolds are needed to allow frequent flushing of particulate matter that may accumulate in laterals. Air relief valves are needed to prevent aspiration of soil particles into emitter openings when the system is depressurized. These valves must be located in sufficient number and at the higher elevations for each lateral or zone to prevent negative pressures within the laterals.

Emitter plugging caused by root intrusion is a major problem with some SDI systems but can be minimized by chemicals, emitter design, and irrigation management. Chemical controls include the use of herbicides, either slow-release compounds embedded into emitters and filters or periodic injection of other chemical solutions (concentrated and/or diluted) into the irrigation supply. Periodic injection of acid and chlorine for general system maintenance can also modify the soil solution immediately adjacent to emitters and reduce root intrusion. In some cases, emitters plugged by roots may be cleared via injection of higher concentrations of chemicals, such as acids and chlorine.

Emitter design may also affect root intrusion. Smaller orifices tend to have less root intrusion but are more susceptible to plugging by particulate matter. Some emitters are constructed with physical barriers to root intrusion. Root intrusion appears to be more severe when emitters are located along dripline seams, which can be an area of preferential root growth. However, root intrusion problems appear to be greater for emitters, driplines, and porous tubes that are not chemically treated.

Irrigation management can also be used to influence root intrusion by controlling the environment immediately adjacent to the emitter. High-frequency pulsing that frequently saturates the soil immediately surrounding the emitter can discourage root growth in that area for some crops but not others. Conversely, deficit irrigation sometimes practiced to increase quality or maturity, or to control vegetative growth, can increase root intrusion in lower rainfall areas because of high root concentrations in the soil zone near emitters.

System Components

Pumps, Filtration, and Pressure Regulation

Pump requirements for SDI are similar to those for other drip irrigation systems, meaning water must be supplied at a relatively low pressure (170–275 kPa) and flow rate in comparison to other irrigation methods. Because of the flushing requirement for SDI systems, a flow velocity of about 0.3 m/s must be achievable, either by reducing the zone size while using the same pumping rate or by increasing the pumping rate without changing the zone size.

Water filtration is more critical for SDI systems than for surface drip systems because the consequences of emitter clogging are more severe and more costly. Generally, the better the water quality, the less complex the filtration system required. Surface and recycled or wastewater supplies require the most elaborate filtration systems. However, good filtration is the key to good system performance and long life and should be a major emphasis in system design. Filtration systems range from simple screen filters for relatively clean water to more elaborate and complex disc and sand media filters for poorer quality water.

The pressure regulation requirement in SDI systems is similar to that in surface drip systems. When non-pressure-compensating emitters are used on relatively flat areas, pressure is typically regulated within the system supply lines (main and/or submain) using pressure-regulating valves. When pressure-compensating emitters are used, typically on more hilly terrain, the pressure within the system supply lines is controlled at a higher, but more variable, pressure that is within the recommended input pressure range for the emitters used. Water pressure should be monitored on a regular basis at the pump or supply port and at various locations throughout the SDI system, especially at the both ends of laterals.

Laterals and Emitters

Many types of driplines have been used successfully for SDI and most have emitters installed as an integral part of the dripline. This is accomplished by one of three methods: (1) molded indentions created during the fusing of dripline seams, (2) prefabricated emitters welded inside the dripline, or (3) circular prefabricated in-line emitters installed during extrusion. Regardless of the emitter used, dripline wall thickness and expected longevity must be considered along with other design factors in selecting the lateral depth. Flexible, thin-walled driplines typically are installed at shallow depths and normally have a shorter expected life. Thicker-walled, flexible driplines have been used successfully for several years provided they are installed deep enough to avoid tillage, cultivating, and harvesting machinery but shallow enough to prevent excessive deformation or permanent collapse of the dripline by machinery or soil weight. Rigid tubing with thicker walls can be installed at deeper depths without deformation and is often used on perennial crops or annual crops for longer time periods (>10 years). Some driplines are impregnated with bactericides or other chemicals to reduce the formation of sludge or other material that could plug emitters.

Chemical Injection

Subsurface drip systems offer the potential for precise management of water, nutrients, and pesticides if the system is properly designed and managed. The marginal cost to add chemical injection equipment is generally competitive with other, more conventional application methods. Water and fertilizers can be applied in a variety of modes, varying from multiple continuous or pulsed applications each day to one application in several days. Choice of application frequency depends upon several factors, including soil characteristics, crop requirements, water supply, system design, and management strategies. If labeled for the purpose, some systemic pesticides and soil fumigants can be safely injected via SDI systems. Use of the SDI system for chemical applications has the potential to minimize exposure to workers and the environment, reduce the cost of pesticide rinse water disposal, and improve precision of application to the desired target (root pests). Injection of other chemicals, such as acids and chlorine, is often required to clean and maintain emitters in optimum condition. However, a high level of management with system automation and feedback control is required to minimize chemical movement to the groundwater when chemicals are used.

Air Entry and Flushing

Air entry valves must be installed at higher elevations in SDI systems to prevent the emitter from ingesting soil particles that could plug emitters when the system is depressurized. Typically, air entry valves are located in water supply lines near the head works or control station and in both the supply and flushing manifolds. In some cases, such as turf or pasture, air entry valves may be installed below the soil surface and enclosed within a protective box. Flushing valves installed on the flushing manifold are required to control periodic system flushing.

Operation and Maintenance

Operation

SDI systems can be operated in several modes, varying from manual to fully automated. Overall, SDI systems are probably more easily automated than many other types of irrigation. One reason is that most are controlled from a central point using electrical or pneumatic valves and controllers that vary from a simple clock system to microprocessor systems, which are capable of receiving external inputs to initiate and/or terminate irrigation events.

Irrigation scheduling is as important for SDI systems as for any other type of irrigation. Choosing to initiate an irrigation event and how much water to apply during each event depends on crop, soil, and irrigation system type and design. Factors that affect those decisions include soil water storage volume, sensitivity of the crop to water stress, irrigation application rate, weather conditions, and water supply capacity. Camp[5] discussed several irrigation scheduling methods that have been used successfully with SDI. However, the important point is that a science-based scheduling method can conserve the water supply and increase profit.

If seed germination and seedling establishment and growth are critical, especially in arid climates when initial soil water content is not adequate, either sprinkler or surface irrigation is often used for germination. However, the need for two systems increases cost and decreases economic return. If subsurface drip is used for germination, an excessive amount of irrigation is often required to wet the seed zone for germination, which could result in excessive leaching and off-site environmental effects as well as increased cost. Surface wetting can also occur when the emitter flow rate exceeds the hydraulic conductivity of the soil surrounding the emitter, but wetted areas are often not uniform.

Because salts tend to accumulate above the lateral, high salt concentrations may occur between the lateral and soil surface in arid areas where rainfall is not available to leach the salts downward. Salts may also be moved under the row when laterals are placed under the furrow.[6] Supplemental sprinkler irrigation may be required in some areas to control salinity if precipitation is inadequate for leaching during several consecutive years.

Maintenance

Often, SDI systems must have a long life (>10 years) to be economical for lower value crops. Thus, appropriate management strategies are required to prevent emitter clogging and protect other system components to ensure proper system operation. Locating and repairing/replacing failed components is much more difficult and more expensive with SDI systems than with surface systems because most system components are buried, difficult to locate, and cannot be directly observed by managers. Consequently, operational parameters such as flow rate and pressure must be measured frequently and used as indicators of system performance. Good system performance requires constant attention to maintain good water quality, proper filtration, and periodic system flushing to remove particulate matter that could plug emitters. Periodic evaluation of SDI system performance in relation to design performance can identify problems before they become serious and significantly affect crop yield and quality.

Conclusion

Although there is a general consensus that use of SDI is increasing on a worldwide basis, this growth is difficult to document. In the 10-year period (2003–2013), SDI in the United States increased by 89% from 164,017 to 310,361 ha according to USDA-NASS irrigation surveys.[2] Use of SDI should continue to increase in the future, depending primarily upon the economic and water conservation benefits in comparison to other irrigation methods. As water supplies become more limited, the high application efficiency and water-conserving features of SDI should increase its application. Also, SDI offers potential advantages such as reduced odors and exposure to pathogens when using recycled domestic and animal wastewater. The SDI technology offers the capability to precisely place water, nutrients, and other chemicals in the plant root zone at the time and frequency needed for optimum crop production. With proper design, installation, and management, SDI systems can provide excellent irrigation efficiency and reliable performance with a system life of 10–20 years.

Recent Approaches to Robust Water Resources Management under Hydroclimatic Uncertainty

J. Pablo Ortiz-Partida, Mahesh L. Makey, and Alejandra Virgen-Urcelay

Introduction

Managing water resources under hydroclimatic uncertainty is a primary focus with respect to water resources management (Brown et al. 2015; Poff et al. 2015). There is a scientific consensus that climate change is going to impact current water systems in a variety of ways. For example, expected impacts on California's water resources include increase in evaporation rates and water demands (Hayhoe et al. 2004); reduction in crop yield as a consequence of higher temperatures (Pathak et al. 2018); less precipitation falling as snow and more as rain translating into wetter wet seasons and drier dry seasons (Mallakpour et al. 2018), which may force operators to lower reservoir levels to allow for space and reduce the risk of flood events; increase in water temperatures affecting aquatic and riparian ecosystem (Poff et al. 2012); and sea-level rise, which will increase seawater intrusion into coastal aquifers (Ferguson and Gleeson 2012). Meanwhile, there is, however, uncertainty on their magnitude and extent, which raise the question of how we can develop management strategies that account for the range of possible future alternatives.

Water systems modeling has been crucial to answer such questions because of the advancement of computational power. Water systems modeling was often deterministically developed, considering some variables such as temperatures, precipitation, streamflow, or water demands as known parameters. Despite recognizing their hydrologic variability, the only available data are often treated as a statistical description of hydrologic variables resulting into unreliable forecasts. Deterministic models treat stochastic parameters as known quantities reducing – to some extent – the complexity of the model (Chen et al. 2018). Depending on the application of the model, such assumptions can be sustained. Nevertheless, the simplifications cannot retain all the essential characteristics of the original data and may lead to unsatisfactory results given the complex behavior of a system (Puente et al. 2018). Climate change is bringing extreme hydroclimatic events of low probabilities but high impacts that – as noted – deterministic approaches do not capture well (Farmer and Vogel 2016; Philbrick and Kitanidis 1999). Thus, there is a need for integrating the seemingly random behavior of precipitation, temperature, streamflow, and other sometimes-unknown variables (e.g., soil properties, water quality) for developing water management strategies suitable for a variety of future socioeconomic and climatic alternatives.

This chapter describes recent approaches from the scientific literature that incorporate hydroclimatic uncertainty to develop robust water management strategies. This chapter is divided into three sections. The first section describes the development of robust reservoir operations, a main technical area in water resources. The second section describes an approach to achieve water systems sustainability that goes beyond common performance criteria (e.g., economic, reliability) by integrating stakeholder-defined performance metrics within the modeling framework. The last section outlines how to move forward and incorporate uncertainty into the decision-making process, a crucial component pertaining to real-life activities.

Robust Reservoirs Management

Reservoirs around the world provide storage to supply water for urban, agriculture, and industry sectors; flood protection; hydropower; and support recreational activities. However, in some cases, these benefits came at the cost of environmental and social degradation (WCD 2000). Leaving aside the controversy of building dams, it is important to recognize that most of the current reservoirs will persist despite their contribution to the degradation of river ecosystems. Given the uncertainty and variability of hydroclimatic conditions under climate change, droughts and floods may worsen, turning reservoir management vital to prevent or reduce expected drought and flood events (Cristina and Tullos 2017).

Modifying reservoir operations offers an opportunity for mitigating hydrologic responses to climate change as current operation rules tend to be static and based on historical inflows and outflows observations. Given the new recurrence and magnitude of hydroclimatic events, some reservoir operation rules are no longer suitable for managing drought periods and floods or for reaching the full potential of a reservoir (Howard 1999; Moy et al. 1986). New reservoir operations that incorporate projected hydroclimatic variability may be an effective strategy for reducing the impacts of changes in water supplies and demands (Vonk et al. 2014). Reservoir operations developed with new available tools and information contribute to increased resilience of water management systems and ecosystem restoration.

Alternative approaches to improve long-term reservoir operations have utilized multi-objective genetic programming (Ashofteh et al. 2015), machine learning (Herman and Steinschneider 2018), and stochastic modeling (Ermoliev et al. 2019) to incorporate climate change projections and a broader set of observations and forecasts. Such approaches link hydroclimatic observations and predictions with water resources management decisions to improve tradeoffs among human and environmental water supply and flood management objectives.

Another recently proposed framework presents a two-stage stochastic optimization model that maximizes regional economic benefits as a function of reservoir deliveries to water users (Ortiz-Partida et al. 2019). The first-stage decisions allocate water based on an expected deficit for the whole system, while in the second stage, the now known deficit is allocated in a way that maximizes economic benefits. This framework was applied to the single reservoir system of Luis L. Leon dam in the Rio Conchos, the main tributary to the Rio Grande of North America. The model result is a set of robust monthly reservoir releases that can cover most of the water demands – including the environment – and reduce the frequency and magnitude of flood events under a wide range of hydroclimatic conditions.

Results from these different approaches suggest that robust operations could improve long-term planning by making the water system more reliable and resilient, and less vulnerable to extreme hydroclimatic events. However, these technically complex approaches tend to have bigger scale implications and usually lack stakeholder involvement, making them difficult to implement.

Integrated Framework

Attaining water sustainability needs to go beyond historically used criteria (e.g., economic performance) and integrate socioeconomic, environmental, and climate components. As such, decision makers are seeking for robust decisions with satisfactory performance across a large range of plausible futures. To make plans that are flexible and enhance long-term decision-making, various model-based frameworks have been proposed (Kwakkel et al. 2016). One of the frameworks that distinguishes from others is decision scaling (DS). DS integrates stakeholder-defined performance metrics that allow for inclusion and empowerment to foster collaboration across historically conflicting perspectives (Brown et al. 2011, 2012). In addition, DS attempts to find alternative solutions for multi-objective water resources systems under a variety of nonstationary hydroclimatic conditions and modeling uncertainties. Steinschneider et al. (2015) advanced previous applications of DS to identify long-term planning alternatives with the use of Monte Carlo simulations and by quantifying uncertainty in each stage of the modeling chain. Such a novel approach efficiently selects future climate realizations to assess the effects of hydrologic modeling uncertainty. Its limitation lies on a computational burden and required high-performance computing facilities to handle large multi-reservoir systems.

DS has been further developed by Poff et al. (2015) into the eco-engineering decision-scaling (EEDS) framework that explicitly and quantitatively explores tradeoffs across management actions under hydroclimatic uncertainty and incorporates ecological and engineering performance metrics. EEDS has five main steps that include (1) developing a clear definition of performance criteria, unacceptable thresholds, and management options; (2) building a systems model that relates hydroclimatic variables with the defined performance criteria; (3) performing a vulnerability analysis under a variety of hydroclimatic and social alternatives to discard unacceptable options and identify robust management strategies; (4) evaluating management options on the basis of their ability to satisfy both engineering and ecosystem performance under uncertain future conditions; and lastly, (5) selecting an alternative or developing new performance criteria based on political and institutional feasibility through converting the framework into an iterative process. As a case study around Coralville Dam, Poff et al. (2015) identified the most robust management strategy that would satisfy economic and ecological goals (Figure 1).

In truly achieving robustness and avoiding undesirable consequences, Herman et al. (2015) argue that (1) alternative decisions should be searched and not prespecified, (2) uncertainty should be discovered with sensitivity analysis and not assumed, and (3) stakeholders should carefully select their satisfactory measure of robustness based on their problem-specific performance requirements.

Moving Forward

Robust water management strategies need to go beyond water data and incorporate uncertainty in socioeconomic, environmental, and climate variables to be capable of assessing a broader range of future alternatives. Moreover, other information related to global climate change, population growth, land-use change, globalization, or even political stability makes long-term water resources planning difficult. Projected information of these variables is pertinent to long-term sustainable water resources strategies. A lack of information regarding interactions among these variables often misleads outputs from models entailing uncertainties to be adopted by water managers, planners, and decision makers. A first step towards creating robust water management strategies is to improve data collection and monitoring, which can be costly, suggesting that benefits and tradeoffs between investments in monitoring and development should be considered properly (Wada et al. 2016).

Adequate performance of long-term water resources management highly depends on a modeling chain that links technical, socioeconomic, environmental, and climate components. This is because each stage of the modeling chain is vulnerable to uncertainty. Such uncertainties include nonstationarity in future climate and potential shifts in large-scale synoptic circulation (Sheridan and Lee 2010) as

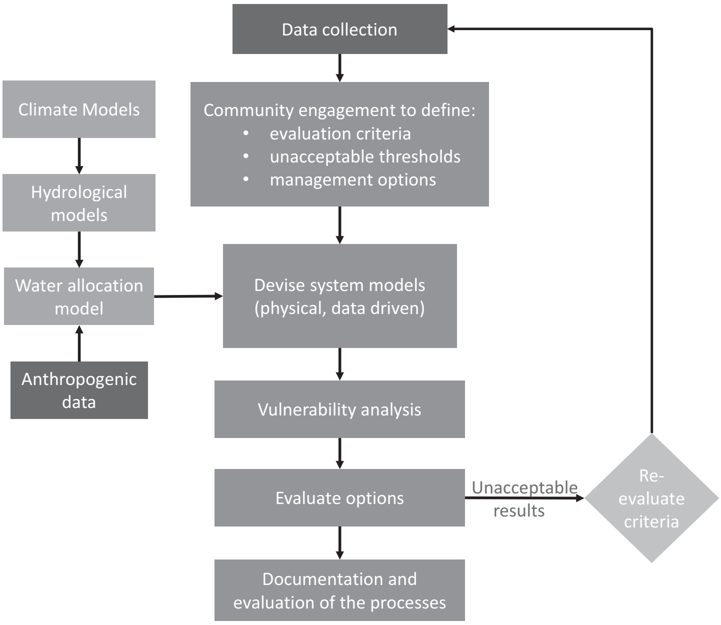

FIGURE 1 Eco-engineering decision scaling (EEDS). (Adapted from Poff et al. (2015).)

well as nonstationarity in water demands (Kang and Lansey 2012). As observed and experienced, it is difficult to propose long-term robust approaches without better prediction of climatic shifts and water demand variability (Korteling et al. 2013; Matrosov et al. 2013; Prudhomme et al. 2010; Turner et al. 2014). In fact, these frameworks attempt to bring the pieces together for decision-making rather than accounting each component individually.

To meet diverse water demands, Groves et al. (2019) recently applied "robust decision making (RDM)" to (a) identify water management strategies to reduce vulnerabilities in the Colorado River Basin and (b) develop robust investment strategies for the Green Climate Fund that reduce greenhouse gas emissions. This work suggests that RDM addresses long-term policy challenges associated with multifaceted, nonlinear, natural, and socioeconomic systems for defining policy pathways in a beneficial way. Existing water system models still need to address issues related to current human impact modeling and associated indicators and their limitations in representing regional water management. In this way, one can integrate land use and climate interaction to integrate human behavior into a large-scale modeling and to fill the gap among human–water management information. Advancing water system models coupled with human–water systems over a wide range of temporal and spatial scales will be beneficial for water science community and for understanding the climate and Earth system science communities.

Conclusions and Future Needs

Current water management strategies and infrastructure were not designed for some of the hydroclimatic changes that we have observed in the last decades. Robust water resources management strategies provide an opportunity to cope and adapt to the changing climate. This chapter presents different approaches to incorporate hydroclimatic uncertainty for developing robust water resources management strategies. Technically complex approaches tend to have bigger scale implications and usually lack stakeholder involvement, which leads to simplified social and environmental components. Long-term planning with stakeholder involvement tends to simplify climate processes. Ultimately, the social, economic, environmental, and climate components must be considered for developing sustainable and resilient water management systems. Despite potential model and data limitations, one important step is to account more realistically for the nature of socioeconomic and environmental components to identify associated uncertainties and data gaps. Such considerations may lead to accurately assess future sustainability of water use under the current envisaged population growth, ecosystems degradation, and climate change.

Rivers: Restoration

Anna Rabajczyk

Introduction

River ecosystems play a significant role in the human environment and economy. They are characterized by a remarkable variety of plant and animal organisms, while simultaneously acting as ecological corridors and exerting considerable landscaping and recreational impact. The riverbed, riparian zones, and the valley support vegetation, whereas the mass of the flowing water, the bottom soil substratum, riverbanks, and riparian land support a rich generic and onthogenic variety of fauna. The occurrence of these organisms is connected with microhabitats formed owing to the river's morphological diversity, resulting from natural processes occurring over the centuries.[1,2] The naturalness of the river course, including its various curvatures, their radiuses and central angles; the diversification of flow volume, directions, and velocity; the fluctuations of the river water level; and the riverbed bottom type all affect the appearance and maintenance of the morphological diversity. All these factors are subject to change in time and along the river course under the influence of human activity, but also of natural phenomena and processes. If natural processes predominate, living organisms adapt to them and the entire natural system remains stable, due to which rivers can create favorable conditions for the development of various organisms and river ecosystems display very high biological diversity.[2,3]

However, over the centuries, humans have been using rivers, regulating and straightening their courses, building water drops, clearing riverside carrs, and draining floodplains in order to enhance river navigability, and expand farming acreage and area allocated to industrial and housing infrastructure. In many cases, this has led to changing natural watercourses into homogeneous channels deprived of natural value, whose function has become limited to water removal. Simultaneously, the rapid progress of land development, together with farming and industrial advances, has become the source of many pollutants, considerably diversified in terms of quantity and quality, and frequently hazardous to the functioning and life of plants, animals, and humans.[1–5]

Widespread environmental degradation has forced the authorities to take appropriate steps aimed at the introduction of principles of sustainable development to provide social welfare, understood as a possibility to satisfy fundamental needs not only by the present-day but also by future generations, with a focus on eco-safety. Appropriate policies and legislative regulations are being introduced to enable the determination of water quality, and guidelines are being developed for actions to be taken to improve it.[5,6]

One of the objectives in water resources management is to restore and maintain good water quality. First and foremost, it is necessary to specify the subject of river maintenance. To specify the types and

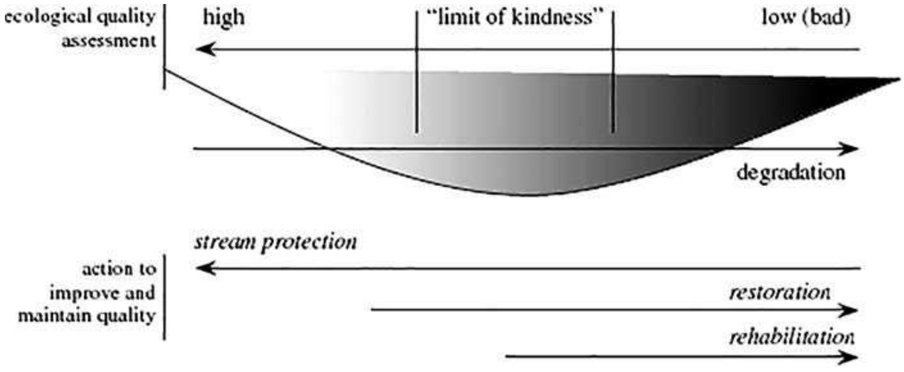

FIGURE 1 Types and scopes of actions geared at river protection and maintenance in terms of quality.
Source: Based on Phillips et al.[7]

scopes of actions geared at river protection and maintenance, it may prove helpful to use a diagram that shows river and stream quality in terms of the so-called limit of kindness (Figure 1).[7]

In the case of very good, good, and moderate quality of water ecosystems, with focus on very good and good quality, only stream protection is justified since actions need to be taken to enable both maintenance and protection of high-quality natural river ecosystems. Another type of action is the recovery of conditions, or restoration, used in the case of rivers characterized by moderate quality, whose "limit of kindness" suggests the hazard of rapid deterioration of the ecosystem's conditions. It is vital to take actions geared at the restoration of natural (primary) characteristics and values from a period taken as a reference point, including, but not limited to

- Natural water quality range
- Natural sedimentation and flow regime (including seasonal fluctuations in a year and multiyear seasons, according to flood patterns)
- Natural riverbed geometry and its stability, determined according to stability ratios, from that period
- Natural riparian vegetation
- Restoration of indigenous aquatic flora and fauna[2,5–9]

Rehabilitation, in turn, pertains to cases of more serious degradation of natural ecosystems and/or when complete restoration of natural features is impossible (e.g., due to technical or economic reasons). Rehabilitation comprises enhancement and improvement of major environmental features of the watercourse so that valuable characteristics thereof are created to define ecological quality.

Another method is to implement remediation, which does not lead to the reconstruction of the primary ecosystem but to the construction of a completely new, different one (Figure 2).[7] This pertains primarily to strongly urbanized (urban) areas, in particular to situations when

- Natural watercourses became degraded in the past and are currently being "brought back to life."
- Ditches were used as storm drains and, partly, as sewage sludges in the past, and are now, upon the introduction of new, closed systems of municipal sewers, often treated as natural.[8–11]

It ought to be stressed that, as a result of adequate actions, it is possible to create new ecosystems, of high biological functionality, yet depleted in terms of biodiversity

River recultivation can only be effective when approached holistically—as an element of comprehensive protection and maintenance of water ecosystems. Consequently, as part of the recultivation process, the planned and implemented actions ought to

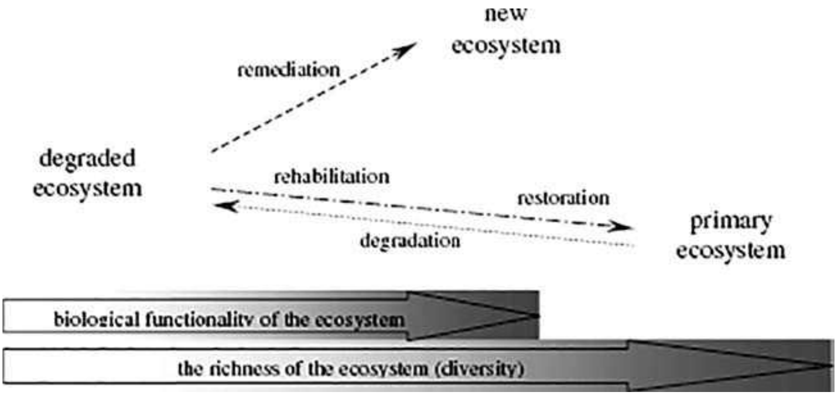

FIGURE 2 Actions aimed at restoration of relevant features of a water ecosystem.
Source: Based on Phillips et al.

- Be integrated, i.e., a particular watercourse (a river segment or the entire river subject to recultivation), together with its appurtenant ecosystem, ought to form one whole, immune to possible environmental impact (seasonal high water, depleted oxygen content, etc.), clearly, up to a limit.
- Reflect the catchment's capacity for natural self-renewal.
- Take into account the physical structure of a given watercourse that fosters the development of desirable flora and fauna (morphological changes, riverbed straightening, or cutoffs from ecosystems may promote degradation).
- Take into account the influence of catchment area users on a particular water body (this is related to the impact of industry, urban areas, or commercial centers).
- Take into account all the reasons for the existing situation, in particular the immediate causes of degradation (including toxic waste discharge, changes to land use, expanded hard road surface in proportion to green areas, and water-logged area elimination).
- Be based on strict guidelines and their methodological implementation, and on adequate monitoring of actions taken to improve the situation.[8–17]

Methods Used in River Recultivation

Adequate implementation of individual actions requires clearly specified methods, techniques, and technical procedures. However, first of all, a conceptual framework ought to be established to specify the principles of operation in terms of

- An assessment of the current status, consistent with legal requirements as well as local/domestic conditions and limitations resulting from both data availability and historical and cultural contexts.
- Principles of operation for the restoration of those features of the ecosystem that determine its capacity for the maintenance of continuity, as well as the major characteristics that constitute the value of ecological quality.
- Following the establishment of the conceptual framework and set of principles, detailed standards are to be developed that will enable the methodological, technical, and technological implementation of appropriate solutions. That is why specialists in a variety of scientific disciplines (such as ecology, water environment biology, hydrology, hydraulics, geomorphology, construction engineering, spatial planning, communications, and sociology) ought to participate in the works.[11,18–26]

Each catchment and its environment are, as a rule, unique, and each case requires an individualized approach, hence the first step is to collect information on the catchment structure and development from a number of sources. This should be complemented with results of research monitoring over a specified period (such as several months or a hydrological year) as well as the catchment area located before the final part of the segment subject to recultivation.[27,28] Only by basing on a wide range of data collected from several sources is it possible to pass on to the phase of specification of individual elements and procedures necessary to obtain recultivation results in a particular watercourse.

The development of criteria for an assessment of a particular watercourse's quality enables standard assessment of current river quality, followed by verification of the actions implemented as part of the recultivation process (Figure 3). These should take into account not only the valid worldwide, European, and domestic regulations, but also the uniqueness resulting from locality, together with environmental and economic functions.[29]

In view of the above, preparatory recultivation works cover watercourse assessment in accordance with adopted criteria, on the basis of which it is possible to describe the status quo and pinpoint shortcomings in relation to an upgraded status. A partial function assessment is based on the lowest rating

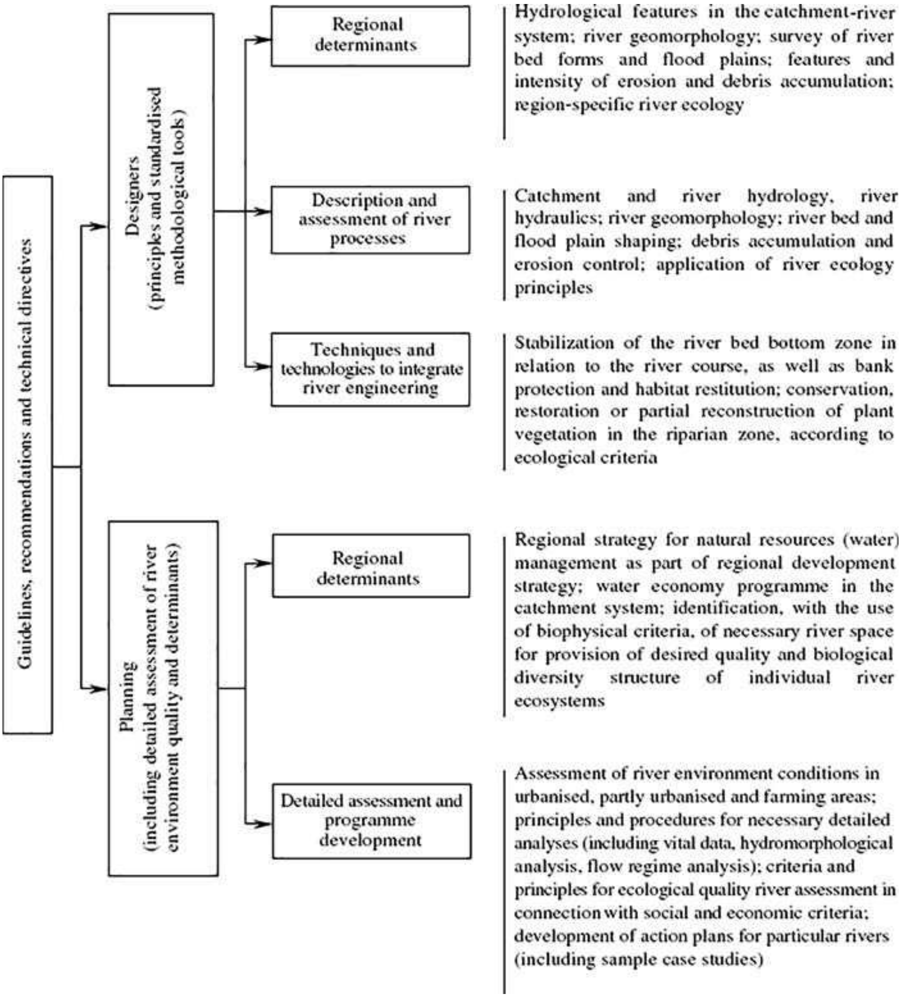

FIGURE 3 Guidelines and recommendations for planning and development of river recultivation programs.

for the criteria appurtenant with that function; the segment rating covers the function's lowest partial rating, with allowances being made for the weakest-link principle. The content of this kind of a document enables fast identification of hotspots whose adjustment will allow for value enhancement of a particular watercourse segment. On this basis, appropriate procedures and diverse actions are selected.

As part of complex works toward river ecosystem renewal, actions are taken to influence various elements of the environment (Figure 4). This course of recultivation allows the objective of river renewal to be achieved. In most cases, single-tasking actions do not yield expected results, or the results take much longer to become visible than they would in the case of a wider spectrum of actions.[29]

Multitasking actions ensure high diversity in the methods and techniques that may be, and are, used in the process of river recultivation. Yet, according to recultivation assumptions, the performed operations ought to enable the intensification of watercourses' natural capacity for cleansing. Consequently, possible works include the following[30–36]

- Construction of aeration-enhancing drops and step falls
- River course regulation
- Elimination of isolated still water pools where oxygen depletion is easy to occur

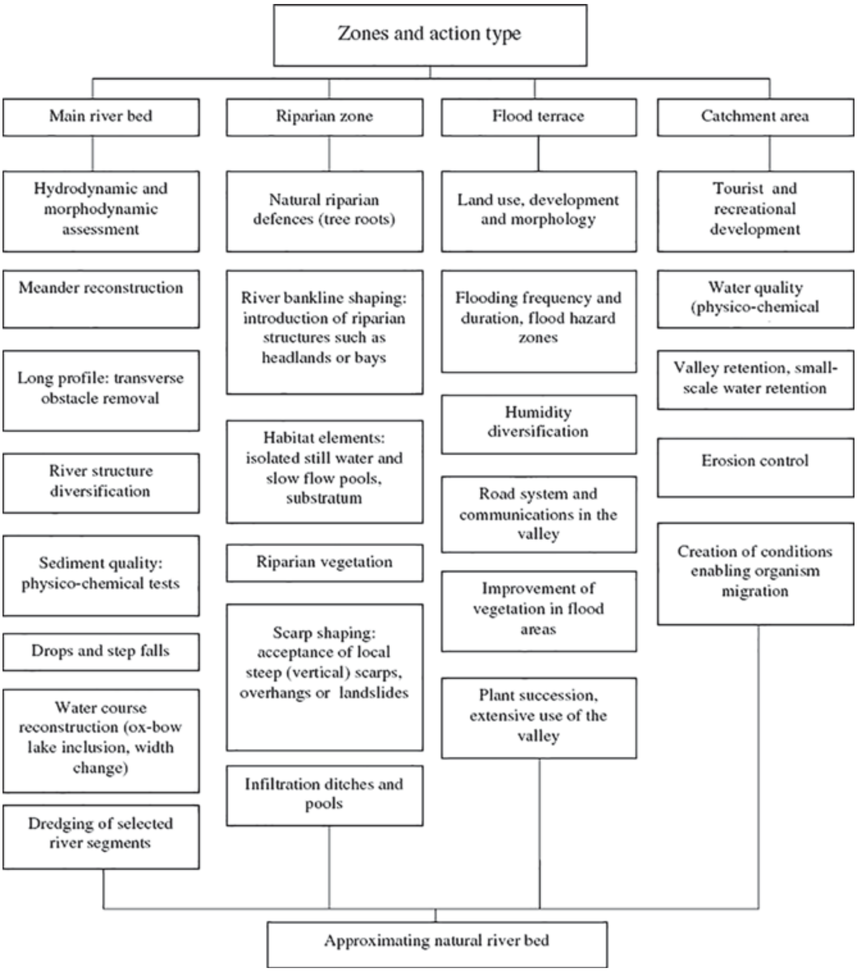

FIGURE 4 Example of multitasking for river recultivation.
Source: Bojarski et al.[30]

- Dredging sediments in selected river segments
- Formation of riparian vegetation strips
- Removal of excess vegetation from the riparian zone
- Formation of infiltration pools and ditches along river- banks to enable both surface runoff limitation and precipitation water pretreatment
- Establishment of small-scale water retention facilities
- Precipitation water management in urban areas
- Groundwater remediation

Not all cases require a full range of actions; it is not always and not everywhere that implementation of all assumptions will be possible. That is why the recultivation process ought to be implemented in stages. First and foremost, the most vital actions need to be taken, i.e., those that will yield optimum natural results, and whose implementation is acceptable to other water users. Of particular importance is, however, the development of strategic action plans that ought to outline both further actions aimed at bringing waters close to nature and result monitoring of the operations performed, complete with reactions adequate to the results obtained.

A complex approach to the problem of river recultivation is renaturization, understood as restoring the river, previously regulated or reshaped in another way, into a state close to the natural (existing before the regulation or found in nature). At times, the notion of river revitalization is used to describe these actions. Yet, it covers a narrower scope of actions than renaturization and is conceived as restoring ecological functions to the river, without technical operations to restore the natural characteristics of the riverbed, riverbank, or valley.[33,34]

One of the major objectives of renaturization is to restore diversified riverbed morphology to regulated rivers, which may be obtained, e.g., through shaping a more curvilinear river course, cross-sections varying in shape and dimensions, or the introduction of diversified vegetation. Most frequently, this is a long-lasting process, comprising a variety of technical undertakings, such as

- Anti-erosion drop replacement with slides enabling communication of water organisms as well as elimination of water-tight defenses.
- Works, which—upon completion—do not produce ready-made elements of renaturized water but foster a natural process that can restore naturalness to waters (e.g., vegetation planting).
- Maintenance works consisting in minor corrections to natural transformations when these are not progressing toward a state close to the natural; replacement of fallen trees and bushes.
- Water maintenance during the renaturization process (maintenance and conservation procedures, water quality protection and enhancement).
- Discontinuation of selected actions concerning water management and leaving them to natural impact only.[33–38]
- A river functionality analysis suggests that a significant role in river naturalness restoration is played by vegetation. As part of renaturization operations, the following are implemented: riparian plant structure, tree planting in riparian zones and flood areas, introduction of vegetation into the existing riparian technical structures (the so-called revitalization of existing structures or replacement with plant defenses).[36]

Conducted recultivation procedures, both technical and biological, constitute a long-lasting and difficult-to-design process whose course requires expert supervision, including result monitoring. Hence, riparian vegetation that improves riverbank stability and carries high natural and landscape importance ought to be distributed in stories comprising trees, bushes, perennial grasses, and gramineous plants already found on the site, which meet the necessary requirements. New replacements and seedings of species from nearby habitats are also needed. Tall vegetation ought to be rarefied so that gramineous plants receive enough light. The interface of the tree-covered area and the river ought to be as long as possible, taking tree thinning into account.[27–29]

It must be stated that, when selecting flora and fauna elements, local species are recommended, as their functioning is conditioned by local hydraulic and hydrological determinants. In the spatial distribution of vegetation, they may fulfill natural functions (e.g., those related to ornithology). The introduction of elements from beyond a given ecological system may cause unwanted disturbance in the environment. Moreover, the plants selected ought not to display antagonisms.[2,5,36]

The elongation of river bankline fosters the dovetailing of the riverbed with the adjacent land strip. Over newly formed water habitats, vegetation plantings accelerate the watercourse's integration with the landscape. This is of particular significance in urban areas. In addition, slides situated in the bottom to break up the watercourse gradient, together with islands and boulders to disturb the flow, serve to diversify the current. Hence, they enable the enrichment of the streambed structure and the formation of various minor biotopes for the animal world.[36–38]

The objective of technical actions is to eliminate obstacles that prevent or limit the course of natural fluvial processes. These works are meant to initiate a return to conditions approximating the natural, and affect both abiotic and biotic conditions.[36]

Upon removal of obstacles to shaping morphological conditions in accordance with natural laws, the second stage of renaturization follows. This is a spontaneous transformation implemented by nature as, due to succession and natural transformation, the environment comes to approximate the natural. Most frequently, this spontaneous process comprises riverbed transformations and shaping hydromorphological conditions, as well as vegetation and animal organism development. It is long lasting and may occasionally take from 10 to 15 years, or even up to 30 years.

Recultivation through renaturization ought to make allowances for the multifunctionality of rivers and valleys.[37,39] The chances for implementation of renaturization procedures in rivers increase when these actions, apart from enhancement of the natural state of the rivers, bring other benefits, including economic, municipal, recreational, etc. A case in point may be the improvement of flood control by restoration of the valley retention function. The municipal aims of renaturization may be, e.g., the enhanced self-cleansing capacity of the waters, as well as upgrading the protection status of particular infrastructure. The objective of renaturization in urban areas may be, in turn, the enhancement of a city's (and its surroundings') landscape value, thanks to the restored naturalness of existing water bodies and through the establishment of new ones. These actions are desirable in many cities; however, at the same time, they encounter much difficulty posed by urbanization.[36,40–43]

The most effective, from the natural viewpoint, are renaturization actions conducted in riverbeds and riparian zones in order to increase the diversity of riverbed morphology. This diversity is among the most significant natural features of rivers. It results from water and debris movement as well as the closely related phenomena of erosion and sedimentation. Increased morphodynamic activity may be achieved through elimination or limitation of factors that restrict the process: changes to the river course, riparian defenses and the long profile, or inducing the removal of obstacles disturbing the river debris movement regime.[36,37]

The recreation of the natural shape of the river course (altered as a result of river regulation) is rarely possible as ox-bow lakes are usually buried or permanently cut off from the regulated river. Due to these reasons, as part of renaturization procedures, reclamation usually comprises only fragments of ox-bow lakes, or provision of organisms with opportunities for mobility between ox-bow lakes and the main riverbed. Another option is that a regulated (straightened) river receives a curvilinear shape, resembling those found in natural rivers.[36,39–45]

However, even this kind of local recovery of the river course is very often impossible and the restoration of naturalness is limited to a reconstruction of structures characteristic of natural rivers, i.e., bays, headlands, islands, and local barriers that affect velocity distribution, leading to enhancement of riverbed morphology. This pertains, in particular, to large regulated rivers in which renaturization operations may only cover segments of the riverbank, elimination or replacement of riparian defenses, clearing lateral river arms, renewal of intergroyne space, or partial reclamation of floodplains.[10,14,30]

A significant element in restoration of good ecological quality to rivers is to increase the diversity of crosssection forms. Under natural conditions, this diversification results from the complex hydraulic structure of a water stream as it runs along a curving route. If the restoration of the curvilinear river system is deemed impossible, in order to diversify bottom topography, facilities that steer the water stream (deflectors, digger logs, or appropriately shaped drops) are introduced. Diversification of cross-section width and placement of barriers in the riverbed to enable changing the flow velocity, thus enhancing the diversity of the riverbed morphology, are also practicable.[35–40]

The diversified river banklines thus obtained enable the expansion of the interface between the substratum and water, causing the appearance of a variety of biotopes: a system of fissures in the watercourse gravel substratum, the water area, the interface between water and land, the water level fluctuation zone, the riparian area, and other humid habitats.

The research conducted suggests that, as a result of riverbed renaturization, in the cases of minor lowland rivers with sandy bottoms, where riparian impact significantly affects flow resistance, flow resistance increases. This changes several parameters characterizing water flow and debris drag transport conditions. If riverbed dimensions and flow regime do not change, the increase in scarp coarseness will cause increased falls of the water plane, riverbed filling, and stream impact on the bottom. At constant flow intensity, the drag rate will increase and cause deep riverbed erosion. In view of the above, in river renaturization projects, it is necessary to check not only the riverbed capacity but also the debris drag conditions.[33–40]

To maintain and enhance the ecological quality of rivers, regardless of renaturization procedures, other actions also ought to be taken. A case in point may be adequately conducted river maintenance and conservation works.

These works ought to take into account major requirements of natural protection. Special attention must be paid to the methods used in technical solutions for river development and use. The principles of environmentally friendly river regulation (natural river regulation) ought to be implemented, basing on the preservation of riverbed morphological diversity, through restricted riverbed transformation. This results in the limitation of adverse effects of planned actions on the natural environment. Natural regulation solutions are based on the following principles[36,38,40–49]:

- The river route ought to remain unchanged, and crosssections ought to preserve their diverse forms and dimensions.
- River rerouting ought to be seen as an exception, which may be justified only by very important arguments and lack of alternative solutions.
- River bed structures, i.e., islands, slower flow areas, river outwash, silts, and other riverbed diversifications, should not be eliminated.
- Riverbanks ought to be reinforced only in those segments where the occurring erosion may cause major hazards.

The application of environmentally friendly river regulation principles enables obtaining a compromise solution that will ensure the protection of the most valuable natural resources as well as the fulfillment of major economic goals.

Yet, if riverbed regulation is needed, the solutions should be based on the following principles[36,38,40–49]:

- Natural riverbed protection: rechanneling is done through initializing the meander pool by imposing a triangular section.
- Smoothing natural riverbed meanders by means of linear structures with cross-beams: dams are replaced with river walls that only reinforce concave banks and are pitched against the existing banks (apart from cases when this solution cannot be used).
- Meandering, including riverbank walls or short structures resembling groyne heads (only for riparian protection, low impact on riverbed flows and the riverbed itself).
- Transverse structures that stabilize the riverbed bottom: made as gentle-sloped erratic riffles (1:10 is the optimum gradient, tested in practice), thus preserving the biological passability of the

watercourse; if possible, the location of the riffle is selected so that it can also act as a cataract and not only as bottom gradient reducer and stabilizer.
- Stone backfill with appropriate scarp inclination from 1:2.5, the recommended ratio being 1:4 and lower (wherever possible): more capacious watercourse bed, accessible to people and animals; regulative structures are more durable.
- Preservation of the riverbed's and the river bottom's morphological form: construction of stone backfill from the meander pool bottom (elimination of the necessity to disturb the natural gravel bottom shield during the formation of partitions from these alluviums; the structures are made without partitions).
- Stone backfill durability and visual appeal enhancement: boulder placement and turfing initialization by soil filling of interboulder space and grass seeding according to pertinent formulas.
- Application of defenses made of stone netting baskets: only for protection of building structures situated in the vicinity of the watercourse bank.
- River bar or island leveling or correction—riverbank reinforcement.

As part of the recultivation process, it is necessary to take action in the field of precipitation water management, which is important in view of the current change in climate, and increasing freshwater use and degradation. The construction of retention and infiltration basins enables establishment of the so-called small-scale water retention facilities at the sites where precipitation occurs.

Enhancement of individual forms of retention may be obtained through a variety of methods. Briefly speaking, technical, planning, and agrotechnical procedures may be distinguished. The group of technical methods includes the majority of hydrotechnology and melioration works, aimed at limitation of surface water runoff, e.g.,[5,37,39]

- Surface water retention through the construction of small water reservoirs; lake damming; and construction of damming structures in watercourses, ditches, and channels.
- Regulation of water runoff from drainage systems and ditch networks.
- Increase in underground water reservoir supply through the construction of infiltration ponds and wells.
- Application of adequate methods for rainwater removal from sealed surfaces (roofs, squares, and streets), enabling water infiltration in adjacent nonsealed areas.
- Limitation of rapid surface water runoff through renaturization of small watercourses and reconstruction of floodplains where possible due to economic (farming) reasons.

A significant role in water management, including water quality protection and enhancement, is played by relevant spatial arrangement in rural areas, particularly in terms of formation of such systems in which precipitation and meltwater runoff does not occur rapidly. The methods used in this respect are defined as planning. These include, but are not limited to the following[26–29,30–39]:

- Development of an appropriate arrangement of arable fields, green areas, and woodland in the catchment.
- Peat land, swamp, and wetland protection and reconstruction.
- Formation of protective vegetation strips (bushes and trees: increased catchment woodiness), reconstruction of as many as possible ecological sites, including aquatic gardens.
- Reconstruction of floodplains in river valleys.
- Establishment of protective areas with appropriate facilities.
- The application of appropriate agrotechnical methods, including observance of the Code of Good Agricultural Practice, may contribute to improvement and reconstruction of natural conditions in rivers. The basic actions in this respect, which form the so-called group of agrotechnical methods, include but are not limited to the following[45,48–50]:
- Soil retention increase through soil structure enhancement and soil humus content increase (correct tillage, agromelioration procedures, fertilizing, and liming).

- Surface runoff limitation through erosion control and aftercrops planting.
- Evapotranspiration decrease through appropriate plant selection and limitation of soil surface evaporation.

The suggested methods for catchment retention capacity enhancement do not introduce any significant change to the natural water regime, but only necessary corrections aimed at improving the water balance structure without disturbing the ecosystem's biological balance. Also in terms of precipitation water management, complex solutions are recommended, which comprise urban area drainage, including roofing, downspouts, and underground pipes, thus providing for rapid and effective rainwater removal to a retention and infiltration box system.[27–29,32,50–54] There are several solutions available in the field of rational rainwater removal:

1. Infiltration: used in permeable and poorly permeable soils, with the maintenance of the minimum 1-m distance from the bottom of the box, which is wrapped with non-woven geotextile to the groundwater level; the water infiltrates to the soil; the most popular solution in rainwater management.
2. Retention: used in firm grounds and at high groundwater levels; the water is stored for subsequent runoff to storm drains or waterways; the box system is wrapped with a geomembrane, which prevents water infiltration into the soil.
3. Storage: an alternative solution for open surface reservoirs; precipitation water is stored in boxes wrapped with geomembrane, and may be used later, e.g., as fire water supply.

The variety of methods and techniques that may be used in the recultivation process enables their adaptation to individual needs and objectives (Table 1).

The works in the field of watercourse restoration are subject to numerous technical, legal, administrative, economic, and natural constraints. Under the circumstances, a compromise is needed between approximating nature and achieving economic results. If a river's naturalness has been lost, for instance, owing to the building of hydrotechnical facilities, it cannot be fully restored without the demolition of these facilities. Consequently, that would mean the community's return to conditions that, in the past, made living difficult (floods or swamping) to the extent that led to decisions being taken to improve the situation. While undertaking recultivation procedures, it is necessary to bear in mind that the scope will be limited in proportion to what might be implemented if there is no need to meet the economic requirements. That means that the recovery of natural values in the scope in which they are found in rivers untampered with by humans will not be achieved.

Serious limitations for river recultivation may also result from lack of space for appropriate actions. "Human nature" conflicts most frequently arise in situations when morphological diversification of the riverbed is intended, including addition of a curve to a straightened river; riverbed diversification through the introduction of changeable bottom widths or scarp gradients; or the introduction of islands, headlands, bays, breaches, precipices, and beach segments. The reason is that these require the taking of land adjacent to the river and disturbing the riverbanks, whose shaping is perceived differently by land owners and by ecologists. There is little chance of reaching a compromise on these issues, so the best solution would be to purchase the strip of riparian land where appropriate actions, such as river bankline diversification or allowing for riverbank erosion, may be taken.

Recultivation actions may also be constrained by technical reasons. The restoration of natural elements to rivers, including cutoff meanders, ox-bow lakes, or connections between the river, land depressions, and marshes, will only become possible if, after the regulation, these structures have not been completely demolished and the land has not been developed. Relatively frequent are cases when the existing, necessary riverbed facilities as well as the ways in which they are used (e.g., the river running across a built-up area, a walled riverbed, a link between the river and the water economics system) render transformation of rivers into more natural ones completely unfeasible or feasible only to a small extent.

TABLE 1 Sample Procedures Geared at River Restoration with Their Characteristics

Method/ Technique	Model Application	Characteristics	Literature
Dredging	Buffalo River	Primarily relies on natural sedimentation processes after dredging to achieve dredge residual performance standards established during detailed design; remediation area was approximately 164 acres, including 138 acres in the Buffalo River and 26 acres in the City Ship Canal	[55]
	Eel River	Excess sand and all peat excavated during site restoration work were placed in the former sand borrow pits around the perimeter of the bogs; insecticide-affected peat was buried beneath a variable layer of sand; once filled—sand borrow pits into the surrounding upland forest; a layer of top soil was imported and placed as a final cap over the former borrow pits, revegetated with native plantings, and monitored over time to ensure growth and survival	[56]
Capping	Buffalo River	Introduced for remediation of the end of the City Ship Canal, beyond the limits of the authorized navigation channel, to isolate underlying sediment contaminants and provide a clean sediment surface; capping depths and cap materials were designed to optimize and enhance habitat restoration plans while providing adequate protection against damage from root penetration; cap placement was performed by either of the following methods: 1) extending a navigational channel to the downstream end; 2) through hydraulic means; or 3) in dry conditions using earth moving equipment, by temporary sheeting and dewatering the proposed cap area and using the adjoining upland areas for material handling	[55]
Renaturization	Izara River	Along a 14-km-long segment, the riverbank structures were removed; there appeared gravel river bars, shoals, main riverbed forks, and stagnant waters; in selected segments, modern fish ladders were built and riparian communities originated	[57]
	Mistelbach Stream	Concrete gutters were removed from stream bottom and banks; so was the irregular stream bank shaping; islands and widenings were installed; stones were introduced into the streambed bottom; slides (ramps) were built and planted with vegetation	[58]
	Enz River	Irregular widenings were formed (at two sites, forking the river by means of islands); the bottom shape was diversified, the scarp inclination of 1:4–1:5 was obtained; the watercourse gradient was increased to 2.7%; dead willow fascine was used; structures were erected with the use of reed beds; plantings of tree shoots were inserted into the substratum, and seedings were made (vegetation was mostly obtained from floodplains and nearby areas)	[59,60]
	Kwacza River	Riparian alders were felled; six bypasses were made for the existing riverbed; in the riverbed, fallen trees were retained, providing valuable natural microhabitats; in the current, artificial structures in the forms of stone piles were placed; wooden and stone deflectors were made, as well as wooden log drops and in-stream digger logs made of tree trunks (deflectors); riverbank defenses were made of tree trunks; the connection between the major riverbed and the ox-bow lake was reconstructed; bays and stagnant water pools were formed; several hundreds of tons of gravel and stones were used to increase bottom material graining so that its composition would approximate the natural salmonid spawning sites	[61]
	Skjern River	Elimination of hydrotechnical structures, restoration of the river's meandering course, and purchase of farming land adjacent to the river	[62]

(*Continued*)

TABLE 1 (*Continued*) Sample Procedures Geared at River Restoration with Their Characteristics

Method/ Technique	Model Application	Characteristics	Literature
Rehabilitation	River Frome	Dig a borrow pit to create a supply of clay; use clay to raise the riverbed level (specific depth to be agreed on site); win gravels from embankments (old river dredgings or borrow pit); return gravel to the river creating riffles and gravel features; spoil created from bank reprofiling used to infill the borrow pit (less material available—in the original pit volume, a small pond or wetland was created), giving varied habitats	[63]
	River Rother	Restore the loop to these dimensions tempering them with uncovered in-channel features (basic river archaeology using remnant channel features as a guide in favor of theoretical section design); fix the channel features at the upstream and downstream end of the system to prevent channel adjustment between the canalized section and the restored naturalized section (headward recession, etc.); restore the effect of the lock gates and system to prevent any passage of flow down the canal and divert all flows through the loop	[64]
Restoration	River Avon	Physical features and geomorphological processes of the watercourse habitat were re-established at six river restoration demonstration sites; approximately 7 km of river and banks was enhanced and woody debris introduced; an estimated 0.36 ha of new spawning area for Atlantic salmon, bullhead, and lamprey was created (Atlantic salmon are already spawning on the new gravel)	[65]
Restoration of native terrestrial plants	Niagara River	Restore extirpated species to gorge; close unauthorized trails; upgrade existing trails with water bars, fencing, signs; initiate trail steward program; selectively remove aggressive nonnative species from the vicinity of gorge and gorge rim; use flow restriction or diffusion devices on outfalls; eliminate perched outfalls; restore water flow to Devil's Hole; reduce acidification; restore original character of cove; exclude birds (removal of nests, egg oiling); reduce soil acidification; reduce direct trampling or pulling of plants by gulls; reduce input of alien seeds in material brought in by gulls	[66]
Remediation	Sumida River	Waterfront amenity improvement coexisted with flood prevention; gently sloping levees and high standard levees were constructed as substitutes for linear levees to increase durability; river edge terraces (promenades) were improved and levees were forested to improve water amenities; improvement of the sewage system and activities of citizens' groups	[67]
Revitalization	River Brent	Restored two sections of this river by remeandering the straightened channel along its original route, creating a backwater channel, and naturalizing the river's banks; linked up with the earlier restoration work to enhance the entire park	[68]
	River Thames	Activities covered by the tributaries were carrying pollutants, e.g., creation of a natural channel in place of a buried culvert; creation of sustainable instream, marginal, wetland, and floodplain habitats; potential for improved biodiversity in the area and increased flood storage capacity; reconnected the two stretches of seminatural channel up- and downstream of Brookmill Park	[69,70]

Conclusion

The recultivation of flowing surface waters may be based on tested case studies from other regions of the country or abroad. Yet, it should be remembered that each environment, while similar in terms of the problems encountered, is unique. The adaptation of solutions must then be carried out with due care.

More and more often, an ideal model of a watercourse is taken as a starting point during the recultivation planning process. The model corresponds to natural conditions of the watercourse, unchanged by humans. It is only on that basis that its current state, and deficits, or degradation rating, are assessed. Subsequently, taking into account socioeconomic boundary conditions, such as the degree of valley occupancy, navigation, fire safety, and environmental protection requirements, development goals are set, i.e., the character of the watercourse after recultivation is determined. The actions taken are based on a variety of methods and techniques, individually adapted to the local situation and the specified objectives. They include technical, engineering, biological, and hydrological procedures. Nonetheless, the scope of the works conducted must demonstrate multitasking and be capable of complex inclusion of selected environmental elements, at the same time stimulating their reconstruction process.

It must be stressed that recultivation procedures do not usually yield direct economic benefits, which constitutes another obstacle. The improvement of a river's natural condition or enhancement of landscape values in themselves are not sufficient arguments in favor of beginning the recultivation.

Such actions, understandable and convincing from the point of view of the natural environment and its needs, tend to breed substantial controversy if local economic expectations are considered. It is then vital to recognize hydrological and hydraulic conditions, and describe the phenomenon of water supply to the land subject to recultivation procedures, together with recognition of farming water needs in the area. Social and sociological surveys that would answer the questions related to the intentions of the farmers themselves, the prospects for local agriculture, possibility of land sale, etc., are also needed.

The chief obstacle is indeed found in the mentality of local communities who expect the proprietor of flowing waters to fulfill the protective obligations. These include deepening and narrowing the riverbed and the streambed so that they no longer flood; reinforcing riverbanks and securing private facilities built nearby; and creating or establishing conditions for recreational river use. Yet, the responsibility to protect the environment as our shared asset remains a shared obligation.

Waste: Stabilization Ponds

Sven Erik Jørgensen

Application of Waste Stabilization Pond Systems

A more detailed review of waste stabilization ponds (WSPs), their kinetics, and design can be found in Kayombo et al.[1]

WSPs are large, shallow basins in which raw sewage is treated entirely by natural processes involving both algae and bacteria.[2] They are used for sewage treatment in temperate and tropical climates and represent one of the most cost-effective, reliable, and easily operated methods for treating domestic and industrial wastewater. WSPs are very effective in the removal of fecal coliform bacteria. Sunlight energy is the only requirement for its operation. Further, it requires minimum supervision for daily operation, by simply cleaning the outlets and inlet works. The temperature and duration of sunlight in tropical countries offer an excellent opportunity for high efficiency and satisfactory performance for this type of water-cleaning system. They are well suited for low-income tropical countries where conventional wastewater treatment cannot be achieved due to the lack of a reliable energy source. Further, the advantage of these systems, in terms of removal of pathogens, is one of the most important reasons for its use.

Types of WSPS and Their Specific Uses

WSP systems comprise a single string of anaerobic, facultative, and maturation ponds in series, or several such series in parallel. In essence, anaerobic and facultative ponds are designed for removal of biochemical oxygen demand (BOD), and maturation ponds are designed for pathogen removal, although some BOD removal also occurs in maturation ponds and some pathogen removal occurs in anaerobic and facultative ponds.[3,4] In most cases, only anaerobic and facultative ponds will be needed for BOD removal when the effluent is to be used for restricted crop irrigation and fishpond fertilization, as well as when weak sewage is to be treated prior to its discharge to surface waters. Maturation ponds are only required when the effluent is to be used for unrestricted irrigation, thereby having to comply with the World Health Organization guideline of >1000 fecal coliform bacteria/100 mL. The WSP does not require mechanical mixing, needing only sunlight to supply most of its oxygenation. Its performance may be measured in terms of its removal of BOD and fecal coliform bacteria.

Processes in WSPS

Anaerobic Ponds

Anaerobic ponds are commonly 2–5 m deep and receive wastewater with high organic loads (i.e., usually greater than 100 g/m^2 24h, equivalent to more than 3000 kg/ha/ day for a depth of 3 m). They normally do not contain dissolved oxygen or algae. In anaerobic ponds, BOD removal is achieved by sedimentation of solids and subsequent anaerobic digestion in the resulting sludge. The process of anaerobic digestion is more intense at temperatures above 15°C. The anaerobic bacteria are usually sensitive to pH <6.2. Thus, acidic wastewater must be neutralized prior to its treatment in anaerobic ponds. A properly designed anaerobic pond will achieve about a 40% removal of BOD at 10°C and more than 60% at 20°C. A retention time of 1.0–1.5 days is commonly used.

Facultative Ponds

Facultative ponds (1–2 m deep) are of two types: Primary facultative ponds that receive raw wastewater, and secondary facultative ponds that receive particle-free wastewater (usually from anaerobic ponds, septic tanks, primary facultative ponds, and shallow sewerage systems). The process of oxidation of organic matter by aerobic bacteria is usually dominant in primary facultative ponds or secondary facultative ponds. The processes in anaerobic and secondary facultative ponds occur simultaneously in primary facultative ponds, as shown in Figure 1. It is estimated that about 30% of the influent BOD leaves the primary facultative pond in the form of methane.[2] A high proportion of the BOD that does not leave the pond as methane ends up in algae. This process requires more time, more land area, and possibly 2–3 weeks water retention time, rather than 2–3 days in the anaerobic pond. In the secondary facultative

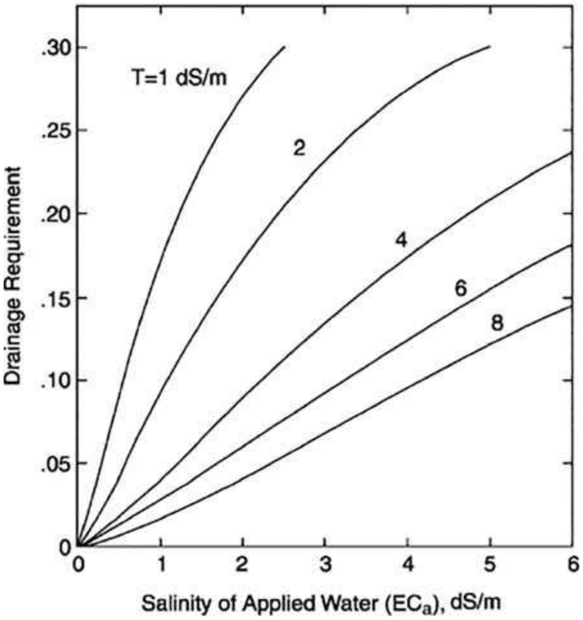

FIGURE 1 Pathways of BOD removal in primary facultative ponds.
Source: After Marais.[2]

pond (and the upper layers of primary facultative ponds), sewage BOD is converted into "algal BOD" and has implications for effluent quality requirements. About 70%–90% of the BOD of the final effluent from a series of well-designed WSPs is related to the algae they contain.

In secondary facultative ponds that receive particle-free sewage (anaerobic effluent), the remaining non-settleable BOD is oxidized by heterotrophic bacteria (*Pseudomonas, Flavobacterium, Achromobacter,* and *Alcaligenes* spp). The oxygen required for oxidation of BOD is obtained from photosynthetic activity of the micro-algae that grow naturally and profusely in facultative ponds. Facultative ponds are designed for BOD removal on the basis of a relatively low surface loading (100–400 kg BOD/ha/day), in order to allow for the development of a healthy algal population, since the oxygen for BOD removal by the pond bacteria is generated primarily via algal photosynthesis. The facultative pond relies on naturally growing algae. The facultative ponds are usually dark green in color because of the algae they contain. Motile algae (*Chlamydomonas* and *Euglena*) tend to predominate the turbid water in facultative ponds, compared to non-motile algae (*Chlorella*).

The algal concentration in the pond depends on nutrient loading, temperature, and sunlight, but is usually in the range of 500–2000 μg chlorophyll-*a* per liter.[3,4] Because of the photosynthetic activities of pond algae, there is a diurnal variation in the dissolved oxygen concentration. The dissolved oxygen concentration in the water gradually rises after sunrise, in response to photosynthetic activity, to a maximum level in the mid-afternoon, after which it falls to a minimum during the night, when photosynthesis ceases and respiratory activities consume oxygen. At peak algal activity, carbonate and bicarbonate ions react to provide more carbon dioxide for the algae, leaving an excess of hydroxyl ions. As a result, the pH of the water can rise to above 9, which will kill fecal coliform. Good water mixing, which is usually facilitated within the upper water layer by strong wind, ensures a uniform distribution of BOD, dissolved oxygen, bacteria, and algae, thereby leading to a better degree of waste stabilization.

Kinetics of the Processes in Facultative Ponds

The growth of the mixed culture was studied at concentrations ranging between 200 and 800 mg COD/L, in a series of batch static reactors. From laboratory data, the specific growth rate (μ) was determined, using the modified Gompertz model.[1,5] There are several growth models in the literature used to evaluate growth parameters, first-order reaction, logistic models, etc. The maximum specific growth rate ($\mu_{\max}$) and half saturation coefficients (K_s) were calculated using the Monod kinetic equation, which is the generally applied expression:

$$\mu = (\mu \text{max})^{*} \, \text{S}/(\text{S} + (\text{K}_\text{s}))$$

S in this equation is the substrate concentration usually expressed as mg/L BOD5 or COD.

The maximum observed growth rate ($\mu_{\max}$) for heterotrophic bacteria was 3.8 L/24 hr, with a K_s of 200 mg/L when COD was applied as unit for *S*.

The $\mu_{\max}$ for algal biomass, based on volatile suspended solids, was 2.7 L/24 hr, with a K_s of 110 mg COD/L. The $\mu_{\max}$ of algae, based on chlorophyll-*a*, was 3.5 L/24 hr with a K_s of 50 mg COD/L. The indicated constants were all found on the basis of literature values that were found from data. The regression coefficients for the constants were all 0.96–0.99 according to the literature.

The observed specific substrate removal by heterotrophic bacteria varied between the concentrations of substrate used, with an average value of 0.82 (mg COD/mg biomass). Thus, the determined Monod kinetic parameters are useful for defining the operation of secondary facultative ponds. The specific substrate utilization rate in the bioreactors was directly proportional to the specific growth rate.

Although the Monod equation was developed for the pure culture of bacteria growing in a single organic substrate, the results may be used correctly also for a mixed culture of algae and heterotrophic bacteria growing in a heterogeneous-mixed organic carbon. The K_s values obtained are the characteristic of the wastewaters containing a complex mixture of organic carbon. The Monod constants for algae depend on the method used in determining the biomass as indicated above.

Knowledge of the effects of the pH on the growth rate of algae and heterotrophic bacteria, and its subsequent impacts on the degradation of organic matter, is useful for better operation and design of secondary facultative ponds. The kinetics of microbial growth and product formations are influenced by diurnal variation in the pH in the pond resulting from diurnal variations in the carbon dioxide.[6] Algae require large quantities of dissolved carbon dioxide during photosynthesis, causing a depletion of carbon dioxide (CO_2) and leading to a shift in the carbonate-bicarbonate ($CO3^{2-}$–$HCO3^{-}$) equilibrium, resulting in an increase in pH due to the formation of hydroxyl (OH^{-}) ions.[7] The effects of pH on the growth rate of heterotrophic bacteria and algae in secondary facultative ponds were investigated, using batch growth at a pH value between 5 and 11. The optimum pH was found to be between 7.0 and 8.0. The results indicate that, for a pH value higher than 8, the chlorophyll-*a* content decreases. However, the specific growth rate of heterotrophic bacteria and algae was high with a pH value between pH 6.5 and 8. At a pH value above 9, the specific growth rates of both biomasses decrease.

Oxygen tension in WSPs is an operational parameter with a great deal of daily and hourly variation. The rate of oxygen production is a function of the algal concentration. Because algal growth is both light and temperature dependent, the rate of oxygen production (photosynthetic) follows the same pattern. Temperature also is a parameter exhibiting marked seasonal and daily variation in WSPs. It influences photosynthesis, the growth of microorganisms, and the bio-decomposition of organic carbon in the system. The fluctuation in pH influences the kinetics of microbial growth, species competition, and product fomations in the pond.[6] Microbial species can grow within a specific pH range, which typically extends over 3 to 4 pH units, with an optimum growth rate near the midpoint of the range. Values of pH up to 11 are not uncommon in WSPs, with the highest levels being reached in the late afternoon. These results lead to the conclusion that the most useful rate that may be used to govern the processes from the WSP should be those determined from the combined influence of the various forcing functions.

Maturation Ponds

The maturation ponds, usually 1–1.5 m deep, receive the effluent from the facultative ponds. Their primary function is to remove excreted pathogens. Although maturation ponds achieve only a small degree of BOD removal, their contribution to nutrient removal can be significant. Maturation ponds usually show less vertical biological and physicochemical stratification, and are well oxygenated throughout the day. The algal population in maturation ponds is much more diverse than in the facultative ponds. The algal diversity generally increases from pond to pond along the series.[3] Although fecal bacteria are partially removed in the facultative ponds, the size and numbers of the maturation ponds especially determine the numbers of fecal bacteria in the final effluent. There is some removal of solids-associated bacteria in anaerobic ponds, principally by sedimentation. The principal mechanisms for fecal bacterial removal in facultative and maturation ponds are now known to be

1. Time and temperature
2. High pH (>9)
3. High light intensity, combined with high dissolved oxygen concentration

Time and temperature are the two principal parameters used in designing maturation ponds. Fecal bacterial die-off in ponds increases with both time and temperature. High pH values (above 9) occur in ponds, due to rapid photosynthesis by pond algae, which consumes CO2 faster than it can be replaced by bacterial respiration. As a result, carbonate and bicarbonate ions dissociate, as follows:

$$2\ HCO_3^- \rightarrow CO_3^{2-} + H_2O + CO_2$$

$$CO_3^{2-} + H_2O \rightarrow 2\ OH^- + CO_2$$

The resulting CO_2 is fixed by the algae, and the hydroxyl ions accumulate, often raising the pH to values even above 10. Fecal bacteria (with the notable exception of *Vibrio cholerae*) die very quickly at pH values higher than 9.[8] The role of high light intensity and high dissolved oxygen concentration has recently been elucidated. Light of wavelengths between 425 and 700 nm can damage fecal bacteria by being absorbed by the humic substances ubiquitous in wastewater. They remain in an excited state sufficiently long to damage the cell. Light-mediated die-off is completely dependent on the presence of oxygen and is enhanced at high pH values. Thus, the sun plays a threefold role in directly promoting fecal bacterial removal in WSP and in increasing the pond temperature, and more indirectly by providing the energy for rapid algal photosynthesis. This not only raises the pond pH value above 9, but also results in high dissolved oxygen concentrations, which are necessary for its third role, namely, promoting photo-oxidative damage.

Nutrient Removal in WSPs

In anaerobic ponds, organic nitrogen is decomposed to ammonia. Thus, the effluent from anaerobic ponds usually has higher concentrations of ammonia than what is found in raw sewage. In facultative and maturation ponds, ammonia is incorporated into algal biomass. At high pH values, ammonia leaves the pond through volatilization. There is little evidence for nitrification (and hence denitrification, unless the wastewater has a high nitrate content).[3] This is due to the fact that the population of the nitrifying bacteria is low because of the lack of physical attachment sites in the aerobic zone. Total nitrogen and ammonia removal from WSP can reach 80% and 95%, respectively.[3] Phosphorus removal in WSP is associated with its uptake by algal biomass, precipitation, and sedimentation. Mara[3] suggested that the best way to remove much of the phosphorus in the wastewater by WSP is to increase the number of maturation ponds. However, both nitrogen and phosphorus must be removed in order to prevent eutrophication in receiving water bodies. The common practice in the design of the WSP is not based on nutrient removal; rather, it is based on BOD and fecal coliform removal.

Design of WSPs

Design Parameters

There are four important design parameters for WSP, including temperature, net evaporation, flow, and BOD. The climate also is important in as much as the processes responsible for BOD5 and fecal bacterial removal are temperature dependent. Further, algal photosynthesis depends on solar insulation, which is a function of latitude and cloud cover. Cloud cover periods are seldom a problem because the solar insulation during the day in tropical and subtropical regions generally greatly exceeds the saturation light intensity of the algae in the ponds. The design temperature usually is the mean air temperature in the coolest month (or quarter). The pond water is usually 2–3°C warmer than the air temperature in the cool season, with the reverse also being true in the warm season.

Because the bacteria responsible for treatment are mesophilic, high temperatures are not a problem. However, low temperatures can be, since they slow down the treatment process. In the case of the methanogenic bacteria (crucial to anaerobic digestion), methane production virtually ceases below temperatures of 15°C. Thus, in areas where the pond temperature remains below 15°C for more than a couple of months of the year, careful consideration should be given to deciding whether or not anaerobic units are needed. Net evaporation (evaporation minus rainfall) must be taken into account during the design of facultative and maturation ponds, but not for anaerobic ponds.[9] Anaerobic ponds generally have a scum layer, which effectively prevents significant evaporation of the water.

Total nitrogen and free ammonia (NH_3, rather than $NH_4^+ + NH_3$) are important in the design of wastewater-fed fish ponds. Typical concentrations of total nitrogen in raw domestic wastewater are 20–70 mg N/L, and total ammonia ($NH_4^+ + NH3$) concentrations are 15–40 mg N/L. Fecal coliform numbers are important if the pond effluent is to be used for unrestricted crop irrigation or for fishpond fertilization. Grab samples of the wastewater may be used to measure the fecal coliform concentration if wastewater exists.

Estimation of Water Flows and BOD Concentrations

The mean water flows should be carefully estimated, since they have direct effects on the size of the ponds and the construction costs. A suitable design is 85% of the in-house water consumption. The BOD may be measured if wastewater exists, based on 24 hr flow weighted data. Alternatively, the BOD may be estimated from the value 30 to 70 g/(capita/24 hr), with rich communities producing more BOD than poor communities. In medium-sized towns, a value of 50 g/(capita/24 hr) is more suit-able.[10,11] A typical design figure for an urban area in a developing country would be 40–50 g BOD_5/(capita/24 hr).[9] Although it is dangerous to generalize, in view of the wide variations that can be expected with differing social customs, religion, etc., a BOD_5 per capita contribution of 40 g/day with a wastewater contribution of about 100 L/(capita/24 hr) is probably a reasonable initial estimate where there is a household water supply; however, flows also could be considerably less. The usual range of fecal coliform in domestic wastewater is 10^7–10^8 fecal coliform/100 mL, with a suitable design value being 5×10^7/100 mL.

Design of Anaerobic Ponds

The anaerobic ponds are designed on the basis of a recommended volumetric loading between 100 and 400 g BOD_5/m^3/24 hr, in order to maintain anaerobic conditions. Once the organic loading is selected, the volume of the pond is then determined and the hydraulic retention time is calculated. A retention time of less than 1 day should not be used for anaerobic ponds. If it occurs, however, a retention time of 1 day should be used, and the volume of the pond should be recalculated accordingly.

Design of Facultative Ponds

Facultative ponds can be designed on the basis of kinetic or empirical models. The rate at which the organic matter is oxidized by bacteria is a fundamental parameter in the rational design of biological wastewater treatment systems. It has been found that BOD removal often approximates first-order kinetics; that is, the rate of BOD removal (rate of oxidation of organic matter) at any time is proportional to the quantity of BOD (organic matter) present in the system at that time. The simple approach to the rational design of facultative ponds assumes that they are completely mixed reactors in which BOD_5 removal follows first-order kinetics[12] with the kinetic constant, k_1 at 20°C to be equal to 0.3/day.[13] For the temperature dependence, the Arrhenius expression is used, with the constant between 1.01 and 1.09—an average value of 1.05 is recommended to be applied generally. A minimum retention time value of 5 days should be adopted for temperatures below 20°C, and 4 days for temperature above 20°C. This is to minimize hydraulic short-circuiting and to give algae sufficient time to multiply (i.e., to prevent algal washout).

Design of Maturation Ponds for Fecal Coliform Removal

The method of Marais[2] is generally used to design a pond series for fecal coliform removal. This assumes that fecal coliform removal can be reasonably well represented by a first-order kinetic model in a completely mixed reactor. The numbers of fecal coliform/100 mL in the effluent and influent are used as unit in the applied first-order equation. k_T, the first-order rate constant for fecal coliform removal, is 2.6 L/24 hr, and it is highly dependent on the temperature. If an Arrhenius expression is used to calculate the influence of the temperature, an Arrhenius constant as high as 1.19 should be applied. Thus, k_T changes by 19% for every change in temperature of 1°C. The first-order equation represents the removal of fecal coliform in a series of ponds as a whole reasonably well. Maturation ponds require careful design to ensure that the fecal coliform removal is sufficient. Marais,[2] and Mara,[13] recommend a value of 3 days as the minimum retention time of the maturation ponds, although at temperatures below 20°C, values of 4–5 days are preferable. The BOD loading on the first maturation pond must be checked and must not be higher than that on the preceding facultative pond; in fact, it is preferable that it be significantly lower. The maximum BOD loading in the first maturation pond should normally be 75% of that on the preceding facultative pond. It is not necessary to check the BOD loadings on subsequent maturation ponds, as the non-algal BOD contribution to the load is very low. The loading on the first maturation pond is calculated on the assumption that 70% of unfiltered BOD has been removed in the preceding anaerobic and facultative ponds (or 80% for temperatures above 20°C). Mara and Pearson[11] and Mare[14] also suggested 90% cumulative removal in anaerobic and facultative ponds, and then 25% in each maturation pond, for temperatures above 25°C (80% and 20%, respectively, for temperatures below 20°C), when the BOD is based on filtered BOD values.

Helminth Egg Removal

Helminth eggs are normally removed by sedimentation, with the process occurring in the anaerobic or primary facultative ponds. If the final effluent is to be used for restricted irrigation, it is necessary to ensure that it contains no more than one egg per liter.

Water Quality and WSPs

By the right design of WSPs, it is possible to obtain close to 90% removal of BOD_5 (i.e., a BOD_5 of about 10–20 mg/L), a phosphorus removal of about 20%–35%, and a total nitrogen removal of at least 25%–50%. Usually, nitrate is removed very effectively. The organic nitrogen is easily oxidized to ammonia but ammonia may be removed by a relatively low efficiency due to insufficient oxygen concentrations in the ponds. By aeration (even rather moderate aeration), for instance, in the last facultative pond, it is possible to increase the nitrogen removal to almost 85% by oxidation of ammonium to nitrate, which, as indicated above, is removed usually with high efficiency. By careful design of the maturation ponds, the removal of coliform bacteria will be satisfactory.

Kayombo et al.[1] present several models that are able to give a fully acceptable design of WSPs. The same reference gives several equations for an empirical design, but as the model can consider interactions of several factors of importance for the design, it is recommendable to apply models for the design of WSPs whenever it is possible.

WSPs are, with very few exceptions, only applied in the tropical region, because the treatment results would not be sufficient during the winter months in the temperate zone, where the industrialized countries are using mostly high-technological treatment methods.

Wastewater Treatment Wetlands: Use in Arctic Regions 5-Year Update

Colin N. Yates,
Brent Wootton, and
Stephen D. Murphy

Introduction

In the last 50 years, conventional and alternative wastewater treatment systems (e.g., lagoons and tundra wetlands) have been used in remote Arctic communities in Canada for wastewater treatment. Current knowledge of the performance of these systems is limited, as little research has been conducted and regulatory monitoring has been poorly documented or not observed at all. Also, in the past, the rational design process of treatment systems in Arctic communities has not acknowledged cultural and socioeconomic aspects, which are important for the long-term management and performance of the treatment facilities in Canadian Arctic communities.

Wastewater treatment in extreme cold climate regions of world, such as the Canadian Arctic, is a comparatively recent exercise in the history of wastewater treatment. The term extreme cold climate wastewater treatment is used in this entry as cold climate wastewater has been coined for treatment in more temperate locations where mean annual ambient air temperatures are above 0°C. In comparison, the regions discussed in this entry all have mean annual ambient air temperatures well below –5°C, and often below –10°C.

Most communities in the far north regions of Canada, as well as other localities globally such as Greenland, have primarily relied on dilution of small volumes of wastewater by the receiving environment. However, with rapid population growth occurring in Arctic regions because of resource extraction and exploration, risk to the receiving environment has become a concern. In communities where wastewater treatment technologies have been employed, performance evaluations of the systems are now required to determine whether they can cope with the growing demand on them. This entry includes an overview of wastewater treatment in the Canadian Arctic with a specific emphasis on the use of tundra wetlands to treat municipal wastewater from the region's remote communities.

The corresponding objectives of this entry are as follows: (1) to provide a detailed description of current wastewater treatment practice in the Canadian Arctic with special consideration on the use of wetland systems; (2) to convey the current knowledge of wastewater treatment performance using natural wetlands in the Canadian Arctic; (3) to explore the potential for the application of ecotechnologies, namely, constructed or engineered wetlands in remote Arctic communities; and (4) to discuss a case study on a natural treatment wetland (Paulatuk, Northwest Territories, Canada) as an example to illustrate performance as well as describe other challenges associated with remote extreme cold climate wastewater treatment.

State of Current Knowledge and Practice

Current knowledge of performance of Canadian Arctic wastewater treatment systems is largely restricted to governmental reports, consultant reports, and other sources of gray literature. Only a few peer-reviewed documents exist to contribute to our current understanding of performance and are confined to the performance of lagoons.

In the Canadian Arctic, wastewater treatment facilities such as lagoons and wetlands are largely designed and managed using southern engineering standards, adopting design models to reflect Arctic temperature.[1–3] Since the 1970s, our knowledge of wastewater treatment in remote Canadian Arctic communities has grown very little despite a half-century of operation. Much of our understanding has been developed from site-specific consultant and government reports[4,5] and only a few peer-reviewed entries, as well as conference proceedings.[6,7]

The entries that have been listed above primarily address the performance of lagoon treatment systems. Only Doku and Heinke discuss the potential for greater use of natural and constructed wetlands (CWs) to treat wastewater in Northern Canada in detail.[8] The work of Dubuc et al. is one of very few papers to investigate long-term performance of treatment wetlands in Northern Canada, with a study on a hydro-construction camp along the 55th parallel in the province of Quebec.[9] To date, no long-term monitoring of treatment wetlands has occurred in the Canadian Arctic, except for research conducted by the authors in several wetland systems between the years 2008 and 2010. Unfortunately, in the past 10 years, additional long-term studies have not continued. Nor has there been any extensive discussion or study of mechanistic functions of tundra wetlands to treat wastewater in peer-reviewed literature except for some sporadic example works conducted since 2013.[10,11] Still, the closest approximation for mechanistic functionality in Arctic treatment wetlands is drawn from cold temperate climate regions of southern Canada, Scandinavia, and northern United States; examples from extensively studied locations being from Minot Wetland in North Dakota and Houghton Lake wetland in Michigan.[12,13] Only an entry by Kadlec and Johnson addresses some mechanistic function in a Canadian Arctic treatment wetland but does not provide significant background data.[1] Furthermore, much of the current knowledge on plant and microbial influence on wastewater treatment in the Arctic derives from smaller-scale fertilizations and carbon cycling studies in different Arctic environments.[14,15]

The authors would also like to note the lack of attention that has been given to the planning practice of wastewater treatment in the Canadian Arctic. In both peer-reviewed and gray literature, evidence of planning practice for wastewater treatment has been minimal. Only Ritter and Johnson directly touch upon the issue of planning and wastewater management in remote Arctic communities in North America.[16,17] More recently, more discussion has been made on public health risks in the Canadian Arctic with respect to wastewater.[18,19] The remainder of current thought on the subject relies on contributions from indirect sources on waste management and contamination in the Arctic.[20,21] Unpublished work by author Yates discusses these issues in great detail and identifies several primary factors that have compounded the problem of sanitation in Arctic communities, including the climate, their remote localities, and in some cases physiographic features. A few experts in sanitation and wastewater treatment have proposed and implemented conventional techniques in the Canadian Arctic with varying degrees of success in terms of (1) performance of the technology and (2) acceptance or understanding by the community.[6,23,24] Despite this, there remains a great deal of uncertainty with regard to which approaches are most suitable for Arctic communities. This uncertainty is because there is limited knowledge of how Arctic environments respond to increased loads of nutrients, other pollutants, and water, and how conventional systems respond to Arctic conditions.[7] Therefore, appropriate loading rates and predictions of expected performance are still largely speculative. Socioeconomic issues are also an ever-present concern, especially in the Canadian Arctic. This is related to a lack of resources and trained personnel as well as other factors.[16] Furthermore, there is distrust caused by a lack of communication and discussion between aboriginal groups in the Canadian Arctic and government agencies over treatment approaches and, more recently, concerns over compliancy to existing and proposed new regulatory standards.[25]

As previously described, there is a paucity of seasonal and long-term performance data of tundra treatment wetlands. Therefore, unsurprisingly, we know even less with respect to treatment mechanisms in tundra treatment wetlands. Attention still needs to be given to testing alternative technologies for wastewater treatment, such as CWs or engineered wetlands in these remote communities as well as emerging technologies that may provide low cost, effective, and socioculturally acceptable. The following discussion presents some evidence on the capability of tundra wetlands' ability to treat municipal wastewater.

A Discussion of Performance

Cold climate treatment wetlands have been identified as a significant area of interest for those studying treatment wetlands in the past three decades.[26] Vymazal also identified the important role that natural wetlands historically have played in our understanding of wetland function for wastewater treatment.[26] However, because of the growing knowledge of the importance of wetland function and values early in the adoption of wetlands to treat wastewater, their use has largely ceased except in controlled conditions[29,30] and in a few other locations around the world.[22] The tundra wetlands in the Canadian Arctic are among those still used to treat wastewater.

During a period over about 5 years (2008–2013), significant effort and funding were made available to characterize wastewater treatment wetlands in the Canadian Arctic for performance and to make recommendations on how to best manage these extreme cold climate systems. This work was largely conducted by CAWT (Fleming College) and Dalhousie. In the following discussion, a case study is used to illustrate the performance of Arctic tundra wetland wastewater treatment the authors conducted during that time. The authors also draw on some preliminary results collected in other tundra treatment wetlands that they have studied throughout the Canadian Arctic (Figure 1) and provide discussion on the potential for CWs.

Case Study of Paulatuk Treatment Wetland

This case study documents unpublished data collected by the authors in 2009 in a remote community of the Canadian Arctic (see summary of water quality data from Paulatuk and other selected wetland sites in Table 1). The Hamlet of Paulatuk is located in the Northwest Territories, Canada (69°N 124°W). The system is composed of a facultative lake and wetland serving approximately 294 residents.[31] Since this time, the population has decreased to 265 residents.[32] Wastewater from households and a small number of businesses is trucked to the facultative lake daily. The community is only accessible by aircraft, as few physical transportation corridors exist between the majority of communities in the Canadian Arctic (Figure 2).

Background Information

In 2007, it was estimated that approximately 11,200 m^3 of wastewater was being discharged into the lake (~31 m^3/day). The lake is estimated to have a volume of 103,000 m^3.[33] Basic estimates of effluent flow rate from a preferential flow channel as measured by Yates and Wootton showed a rate of 1.2 m^3/day.[34]

TABLE 1 Influent and Effluent Concentrations from Selected Tundra Treatment Wetlands in Arctic Canada

	Taloyoak			Paulatuk			Gjoa Haven		
	Influent	Effluent	% Removal	Influent	Effluent %	% Removal	Influent	Effluent	% Removal
Ammonia (NH_3N)	4.58	0.127	97	3.19	0.01	99	102	5.75	94
Total phosphorus	3.86	0.324	91	2.42	0.04	98	12.3	2.08	94
$cBOD_5$	12	3	75	40	2	95	138	3	83
Total suspended solids	–	–	–	35	3	91	22	3	97
E. coli	1.30E+03	2.40E+01	98	2.85E+03	1.00E+00	99	2.42E+03	3.30E+01	86

Note: All values are expressed as milligrams per liter (mg/L) except for *E. coli,* which was recorded as colony-forming units (cfu)/100 mL.

The wetland ranged from 40 to 80 m in width, extending approximately 350 m from the facultative lake to the Arctic Ocean (Figures 3–8). The wetland was characterized as wet-sedge tundra, dominated by *Carex* and *Poa* spp. In drier upland areas along the wetland boundaries, *Salix* spp. were observed to be dominant. The highest daily maximum temperature for the area is 15°C for July; mean annual temperature is approximately −9.2°C.[35] Paulatuk's wetland hydraulic loading rate into the facultative lake was estimated at 31 m^3/day, assuming that the amount of water continuously discharged from the facultative lake is equal to the amount as it receives a Carbonaceous Biochemical Oxygen Demand ($cBOD_5$) areal loading rate of 0.9 kg/ha/day. However, the flow rate into the wetland is much less because of evaporation and some loss into groundwater. Precipitation and runoff from neighboring hillsides may add to the flow through the wetland but only a minimal amount as this region only receives 84 mm of precipitation

from June to October.[35] Background water quality concentrations for $cBOD_5$, NH_3–N, and *Escherichia coli* from a nearby reference wetland were measured to be 2 mg/L, 0.01 mg/L, and 9 colony-forming units (cfu)/100 mL, respectively.

Methods

The authors conducted an extensive characterization analysis on the treatment wetland, collecting surface and subsurface water samples throughout the wetland. A onetime sampling of the site was conducted over a week in early September 2009 with a sample size of $n = 41$. Spatial interpolative analysis was conducted to illustrate concentration changes throughout the wetland. Measurements for $cBOD_5$, NH_3–N, and *E. coli* were taken. Samples were shipped within 24 hours to an ISO 17025 accredited laboratory and processed using *Standard Methods for the Examination of Water and Wastewater.* Tension spline was used to conduct interpolation analyses mapping of water quality parameters.

Results

The interpolation analysis showed that treatment for all parameters was found to be occurring in the first 50–100 m of the wetland. After 150 m, flows of wastewater were difficult to detect, as wastewater appeared to be flowing evenly at low velocities across much of the wetland. With a basic understanding of the rate of flow and loading of the wetlands and interpolation of concentration of specific wastewater parameters, it is possible to discuss the performance of the system. Treatment of wastewater was observed to occur primarily in the upper portions of the wetlands, with concentrations quickly dissipating to background levels (Figure 9).

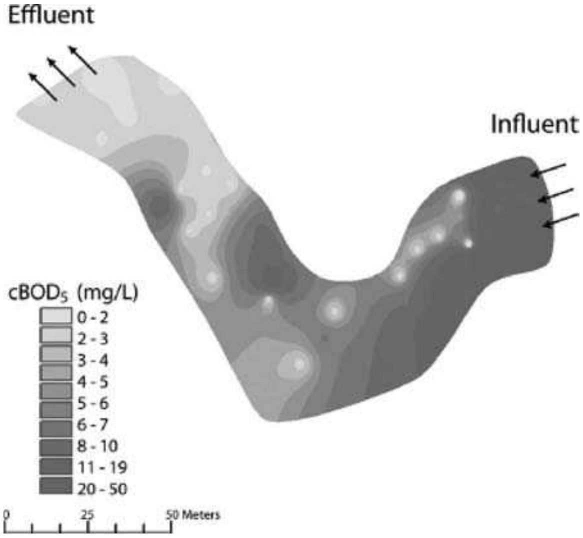

FIGURE 9 Concentration gradients of $cBOD_5$ in the Paulatuk treatment wetland.

Expected effluent concentrations for the identified active portions of the wetlands were calculated using a first-order kinetic model at 10°C. We calculated expected effluent concentrations using P-*k*-C* in order to determine expected effluent values for $cBOD_5$. The van't Hoff–Arrhenius equation as described in Crites and Tchobanoglous was adopted[31]:

$$\frac{\mathrm{d}(\ln k)}{dT} = \frac{\mathrm{E}}{RT^2} \tag{1}$$

The P-*k*-C* model is described in Campbell and Ogden as follows[32]:

$$\mathrm{As} = \frac{Q(\ln \mathrm{Co} - \ln \mathrm{Ce})}{k_\mathrm{t} * d * n} \tag{2}$$

The k_t value for the P-*k*-C* model was determined by using a k_{10} value of 1.0; the θ-factor used was 1.14. A high θ-factor was deemed appropriate for extreme temperature cases as determined for a Minnesota horizontal subsurface flow wetland with a temperature range from 1°C to 17°C, as outlined in Kadlec and Wallace.[30]

Expected $cBOD_5$ effluent values calculated for the Paulatuk wetland were 3 mg/L. In the Paulatuk wetland, $cBOD_5$ levels were actually observed to decrease rapidly (Table 1) within the first 50–100 m. This was likely due to the low influent levels from pretreatment facilities, allowing the top end of the wetland to assimilate or treat remaining organic matter. The influent demand was observed to be 40 mg/L. Effluent demands were observed to be 2 mg/L. However, a level of 2 mg/L was observed to consistently appear less than halfway down the wetland during the study. Effluent oxygen demands were observed to be the same as background conditions measured in the nearby reference sites.

Nutrient parameters, specifically ammonia (NH_3–N), also decreased rapidly down each of the wetlands; concentrations quickly dissipated within the first 50 m of the wetland, again likely due to the low influent concentrations (Figure 10).

Observed NH_3–N concentration in the influent was 3.19 mg/L. Effluent concentration was observed to be 0.01 mg/L. Like $cBOD_5$, NH_3–N concentrations dissipated rapidly, achieving background concentrations in approximately 150 m. Pathogen removal by the wetland was also observed to occur quickly in

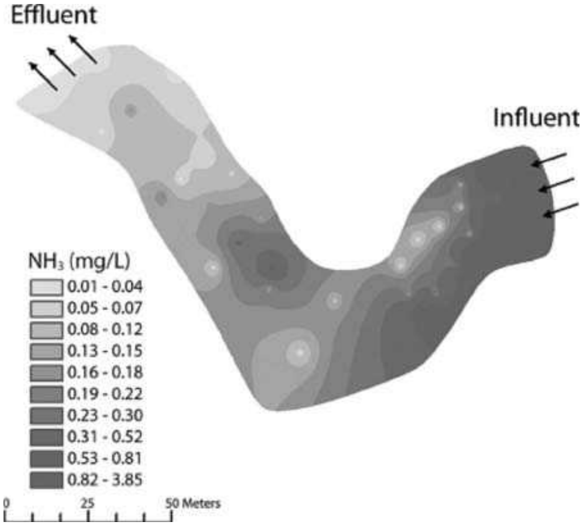

FIGURE 10 Concentration gradients of NH_3–N in the Paulatuk treatment wetland.

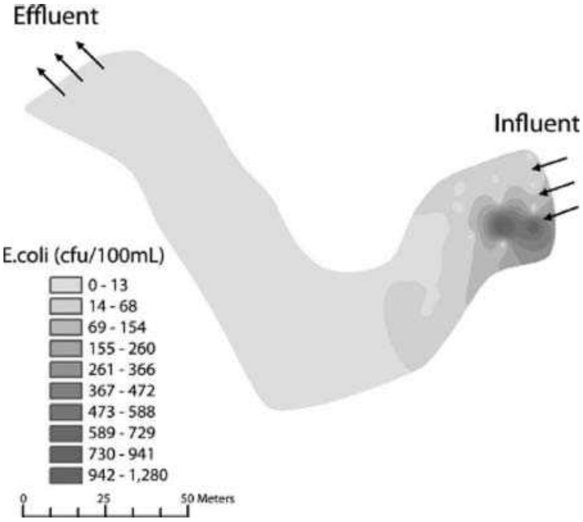

FIGURE 11 Concentration gradients of *E. coli* in the Paulatuk treatment wetland.

the pretreated wastewaters entering the wetlands in Paulatuk. Concentrations of *E. coli* were observed to be low at the influence of the wetland: 2.85E3 cfu/100 mL. *E. coli* was observed to be quickly removed, only observed in trace amounts within a third of the wetland distance. Variation throughout the wetland is likely explained by natural background concentrations from local wildlife (Figure 11).

Discussion

Microbial activity and plant growth influenced by soil temperature are likely the most important mechanisms for the treatment of wastewater in Arctic wetlands.[36] Arctic soil is known to be an excellent sink of organic matter and nutrients, immobilizing nutrients within the frozen matrix and within the microbial community.[37] Phosphorus has been shown to be bound to soils in the Arctic, rendering it unavailable for plant uptake.[38] However, it is unknown how much the soil matrix is responsible for "treatment" by locking nutrients. Fertilization studies in various Arctic habitats, including wet-sedge tundra, have shown that in nutrient-limiting conditions, plant communities respond to increased nutrient input based on small nutrient additions,[39–41] especially when nutrients were added simultaneously,[27] as would be the case with wastewater. Some Arctic plants have even demonstrated the ability to uptake organic forms of N because mineralization of organic material is slow due to low soil temperatures.[39] Plants in tundra treatment wetlands, such as those presented here, may be utilizing the readily available nutrients in such a manner, which may explain low values of inorganic N in a similar study conducted on Arctic treatment wetlands.[28] A study by Yates et al. showed that plants may play a significant role in treatment.[11] However, actual nutrient uptake rates in these systems have not been studied to determine rate or percentage of nutrients discharged into the system or taken up by the plant community. The microbial community may also play an equal role in the uptake of available nutrients in wastewater in these Arctic wetlands. Similar to plant communities, microbial activity is generally limited by temperature and available nutrients. Arctic microbial species are more efficient at lower temperatures than temperate microbial species; Arctic species continue to transform nutrients throughout the winter.[42,43] Hobbie and Chapin also suggested that microbial activity is able to utilize nutrients in soils at temperatures as low as −5°C.[36] Nutrient uptake at low temperatures was recently validated by Edwards and Jefferies.[16] These observations likely contribute to the rapid increase in wetland performance from late June to early July due to increases in microbial populations as a result of additional nutrient availability in still semi-frozen soils observed by Yates et al.[28] Whether winter microbial activity is sufficient to continue to mineralize organic matter and nutrients is unknown. It is likely that the microbial community would not be able to significantly consume the excess nutrient and organic loads at the top of the wetland, resulting in the gradual infilling of organics at the influence.

Natural ultraviolet radiation plays an important role in the disinfection of wastewater in surface wetlands and lagoon systems in more temperate systems. The long exposure of sunlight in the Arctic during the summer months in theory should promote increased disinfection. However, if water temperatures are not optimal, lysis of bacteria may not occur, as cold temperatures appear to stabilize populations, at least in lagoon environments.[2] In wetlands that do not maintain large areas of open water, solar radiation cannot penetrate the water column because of the plant canopy,[44] which is often the case in tundra wetlands that maintain dense stands of *Carex*.

Finally, sedimentation of solids occurs on the wetland surface, in various preferential flow channels throughout the wetlands, and also through entrapment in vegetation. Personal observations in field notes show accumulations of organic matter in many of the wetlands surveyed throughout the Arctic. As discussed earlier, decomposition rates by the microbial community are not as high as deposition rates. Although it was observed that water quality was low in organic load throughout much of the wetland, it would be expected that deposition would occur further down the wetland in the future.

Potential for CWs

The authors have also studied numerous other tundra wetland wastewater treatment systems throughout the Canadian Arctic observing similarly positive results. Examples of preliminary results can be found on Chesterfield Inlet's tundra treatment wetland,[28] as well as a subsurface flow CW in Baker Lake,[45] the latter being examined in some detail in the following discussion. Data from other communities that the authors have studied are included below and exemplify in/out performance of tundra treatment wetlands (Table 1).

Current findings in Arctic wetlands correspond with the results presented by Andersson et al. and Kadlec, demonstrating that natural wetlands can effectively polish pretreated wastewater, often in a much small area than was originally calculated by mass balance equations.[13,46] The performance results observed further prove the ability of wetlands, specifically natural systems, to treat wastewater in a cold climate, but more significantly, these early results demonstrate the resilience of wetlands to produce low-concentration effluents following approximately 9 months of frozen conditions. Although early studies by the authors did not aim to determine which mechanisms are largely responsible for tundra wetlands' high efficacy, specialized bacteria and macrophytes that have evolved in the low-temperature conditions of the Canadian Arctic are likely candidates. More importantly, these results indicate that ecotechnologies such as CWs could potentially be an appropriate technology for extreme cold climate wastewater treatment.

CWs or engineered wetlands have been applied around the world in numerous climates.[26,47–49] Most definitions of CWs simply acknowledge a CW as a man-made structure that emphasizes the natural characteristics of wetlands to transform and absorb contaminants.[30] Vymazal provides a similar definition: "CWs are engineered systems that have been designed and constructed to utilize natural processes involving wetland vegetation, soils, and the associated microbial assemblages to assist in treating wastewaters."[47] Throughout this entry, CWs are defined in the following manner: CWs are engineered systems that are lined to prevent significant exfiltration of wastewater into the underlying ground prior to passing through the system and maintain mechanisms to control influent and effluent flow. The preceding definition is used because various measures have been used to manipulate flow regimes in tundra wetlands in the Canadian Arctic. For example, some tundra systems have made use of some engineered structures, such as berms and inflow/outflow pipes, or make use of natural liners, such as bedrock, to contain or control flow. These systems are described as augmented natural wetlands.

Early belief was that cold climate conditions would not allow wetlands to optimally treat wastewater, and therefore, treatment wetlands would not find a place in cold climate wastewater treatment.[48] Studies from both North America and Scandinavia have largely shown that this has not been the case, and in most instances, only minor impediments to treatment have been observed.[50–52] Despite early convictions, CWs have shown great promise as alternative low-cost technologies to treat wastewater in remote, economically challenged regions and small communities even in cold climatic conditions.[53–55] However, despite their extensive successful use in cold temperate climates around the world,[48,51,52] they have yet to be tested in extreme cold climate conditions, like the Canadian Arctic. Communities in the Canadian Arctic in theory make excellent candidates for alternative wastewater treatment technologies, because of limited economic resources, physiographic characteristics, and trained personnel to operate and maintain more conventional mechanical treatment facilities.[18] For a number of decades, communities in the Canadian Arctic have been using tundra wetlands to treat their wastewater.[1,56] Although our knowledge is growing and understanding of treatment performance and mechanisms of the tundra wetlands is limited, some evidence has shown excellent (sometimes orders of magnitude below regulatory standards) removal for regulated wastewater effluent parameters during the summer months.[1,28] Because of the socioeconomic conditions and the extensive use of tundra wetlands in the Canadian Arctic, CWs warrant experimentation in this region. However, testing of these systems in the Canadian Arctic will require research trials on different design specifications to account for low soil/water temperatures, short frost-free period, slow rate of decomposition of organic matter, and therefore slow mineralization rates of various nutrients. Engineered designs to optimize existing tundra wetlands, augmented natural wetlands to increase hydraulic residency time (HRT), and increase active treatment zones (decrease areal loading rates) have been adopted in a few instances in the Arctic; Cambridge Bay, Nunavut, is an example of one such system.[1] However, the Arctic does provide an environment that in theory provides optimal treatment conditions, for example, 24 hours of sunlight in summer, and plants and bacteria that have evolved in a cold and nutrient-limited environment, giving them characteristics that allow them to utilize excess nutrients efficiently.

As tundra wetlands are extensively used in the Canadian Arctic, CWs have excellent potential to act as low-cost technologies for Arctic communities. The authors studied the performance of the first known experimental engineered HSSF system in the Canadian Arctic. The system demonstrated very promising results in its first year (2009) of operation despite high loading rates; observed reductions of wastewater concentrations were 25%, 31%, 52%, 99.3%, 99.3%, and 5% for cBOD_5, COD, TSS, *E. coli*, total coliforms, and TP, respectively.[45] In 2010, the system was operated with lower loading rates. It was expected that the system would achieve greater reductions, but this was not the case. Concentrations in the wetland effluent were observed to be greater than the effluent. Based on these observations, it was concluded that high organic loading prior to biofilm and plant establishment and high organic loading during the first year of study saturated the system with organics, resulting in the release of solids and unmineralized nutrients into a less concentrated influent. Overall, the HSSF system did not perform as expected but did demonstrate the potential for use in remote Arctic communities. Further investigations of other CW designs should be undertaken in the future.

The issues discussed to this point have largely pertained to wastewater management in the Canadian Arctic. However, they do reflect similar conditions in remote communities elsewhere in the world, cold and warm climates alike. Similar scenarios have been recently described by Jenssen in Greenland, which have similar demographics to the Canadian Arctic.[56] In the mid-1990s, rural communities in Estonia were also facing similar challenges with insufficient treatment facilities because of shortcomings in economic resources.[57] Denny and Kivaisi both describe how CWs could have potential for developing countries, specifically those in Africa.[55,58] As suggested by the previous examples, the discussion of wastewater management for developing countries is prevalent in the literature, yet little attention until this point has been directed towards remote underdeveloped communities in the Canadian Arctic. It is important to note that many common themes run throughout all of these regions that are not dissimilar to those described in the Canadian Arctic; these include but are not limited to low-economic capacity, absence of skilled labor, and complex sociocultural environments. The recommendations made for wastewater management in the Canadian Arctic contribute to knowledge development in all remote regions globally. Also, a similar set of approaches that include the use of an adaptable management framework, and accounting for differences in understanding from the experts in the field (e.g., engineers and planners) designing systems to those adopting the technology (e.g., wastewater operators) in the communities, could be easily adopted or tested outside the Canadian Arctic. The continued optimized use of wetlands, particularly CWs, is one approach that could be more extensively explored in all cases.

Modeling Treatment Wetlands

To support the United Nations Millennium Development Goals of reversing the loss of environmental resources as well as halving by 2015 the proportion of people without access to safe drinking water and sanitation, the United Nations Environment Programme promotes and facilitates environmentally sound technologies (ESTs). Natural wetlands and CWs are considered to be ESTs for wastewater treatment. Design and use of treatment wetlands are facilitated with the use of models to replicate processes and provide practical tools for sanitation.

SubWet, software for the design of subsurface horizontal flow artificial wetlands for water quality improvement and treatment, was originally developed by United Nations Environment Programme–Division of Technology, Industry and Economics–International Environmental Technology Centre (UNEP–DTIE–IETC). After being successfully used as a design tool in 15 cases in Tanzania, it was felt that the model should be upgraded for cold climate application. The Centre for Alternative Wastewater Treatment of Fleming College further developed a new version in collaboration with UNEP–DTIE–IETC, creating SubWet 2.0 to accommodate temperate and cold climatic conditions including summer Arctic and temperate winter conditions.[58] The model simulates removal of nitrogen (including nitrogen in ammonia, nitrate, and organic matter), phosphorus, and BOD_5 in milligrams per liter and the corresponding removal efficiencies in percentage. Design inputs in the model for the wetland are as follows: width, length, depth, slope, % particulate matter, precipitation factor (total flow rate included precipitation/flow rate of treated water), hydraulic conductivity, and selected flow rate (in cubic meters per day).

The forcing functions applied for the model are the following: volume of wetland; flow of water; porosity; input of BOD_5, ammonium, nitrate, total phosphorus, and organic nitrogen; fraction of BOD_5, phosphorus, and organic N as suspended matter; average oxygen concentration; and average temperature. The length of model simulations must be indicated as number of days. The model uses

16 parameters, for example, the temperature coefficient of nitrification, and has a version for warm climate and a version for cold climate. The difference between the two versions is only the set of parameter values. The model uses 25 differential process equations. The model calculates the values of BOD_5-out, nitrate-out (NIT-out), ammonium-out (AMM-out), total phosphorus-out (TPO-out), and organic nitrogen-out (ORN-out) and can be shown in the form of both tables and graphs.

SubWet 2.0 has been developed to support decision-making processes by assisting experts and water managers in the design and evaluation of CWs to improve water quality and treat domestic wastewater. Furthermore, SubWet 2.0 can also be used as a tool to improve the efficiency of low- or non-performing systems. Due to its characteristics, this software is very useful for training technicians and students who are interested in modeling natural and artificial wetlands used for wastewater treatment and can also be used as a tool by engineers and regulators.

Finally, some other technologies have emerged to try solving the challenge effectively and economically that are worth noting including chemical coagulation, UV, and peracetic acid disinfection in Greenland[59] and Bioelectrochemical Anaerobic Sewage Treatment, or BEAST. However, little data have been published on the success of these technologies to date in small Arctic communities.

Conclusion

Wastewater treatment in extreme cold climates will continue to be a challenge into the future until more knowledge is gained in the field and new technological advancements are tested in these regions. Socioeconomic barriers will likely persist even longer and will only become exacerbated in the short term as regions such as Canada's northern territories cope with rapid growth. However, as the authors have described, tundra wetlands can provide preferred levels of treatment of domestic wastewater in remote Canadian Arctic communities. The successful use of natural systems indicates that further experimentation of the use of CWs and engineered wetlands in extreme cold climates is warranted. Finally, much study is still required in tundra wetlands to identify the primary mechanistic functions responsible for the removal of nutrients and organic matter from wastewater in these systems.

Wastewater Treatment: Biological

Shaikh Ziauddin Ahammad, David W. Graham, and Jan Dolfing

Introduction

Human activities and population growth have placed the environment under increasing stress. Furthermore, indiscriminate use of natural resources is accompanied by increased local and global pollution levels, which are reflected in imbalances in our ecosystems. The generation of large quantities of wastewater with a high organic content and toxicants is one obvious product of excessive consumption. It has been known for many years that environmental discharges of high loads of organic matter can result in oxygen depletion in receiving waters due to stimulated microbial activity. This oxygen depletion and the presence of trace toxicants found in wastes also negatively influence ecosystems, including reduced biodiversity and environmental health. Therefore, negative environmental impacts have driven our need to understand the effect of pollution on water bodies and develop proper measures to reduce discharges, including treatment processes.

Different technologies are available to treat wastes. However, biological wastewater treatment methods are most valuable because their economic benefits are high, especially when coupled with waste stabilization and resource recovery. The optimal treatment processes depend on the waste type and treatment goals. Wastewater generally originates from two sources: 1) domestic wastewater from gray water, toilets, and other domestic activities; and 2) industrial wastewater, generated by industries during the normal course of activity, which often rely on the local sewerage systems for waste processing. Therefore, the composition of wastewater, including quantity and constituents, varies considerably from place to place, depending on suite of sources, social behavior, the type and number of industries within a catchment, climatic conditions, water consumption, and the nature of the wastewater collection system. Given this variety, wastewater treatment processes must be innately versatile, but also sometimes must be tailored to the specific waste and conditions. The purpose of this entry is to describe different biological treatment methods and then discuss their relative capacities to treat different wastes on the basis of waste characteristics and the desire for resource recovery.

Wastewater Treatment Options

Special handling and treatment of wastes have been performed for thousands of years in response to their perceived importance, although approaches have changed as perceptions have changed over history. In 4th century B.C. in Greece, the *Athenian Constitution* written by Aristotle[1] proscribed provisions for the appropriate handling of sewage. Concern was based on aesthetics, probably odors, because relationships between domestic wastes and health were not yet known. It was not until the mid-1800s that links between wastes and human health became more apparent, which led to a progression of waste management approaches and technologies to address health concerns.

Treatment technologies evolved slowly over time, including physical, chemical, and biological approaches, many of which are still used in different sectors. Physical methods are based on the application of physical forces, such as screening, mixing, flocculation, sedimentation, flotation, filtration, and gas transfer. Alternately, chemical processes treat contaminants by adding chemicals or by stimulating specific chemical reactions. Precipitation, adsorption, and disinfection are common examples of chemical treatment methods. Physical and chemical methods are often combined, especially in industrial treatment scenarios. In contrast to physiochemical processes, biological processes remove organic contaminants (e.g., biodegradable organic material) largely through microbiological activity. Commonly used biological treatment methods include aerobic treatment in ponds, lagoons, trickling filters, and activated sludge plants,[2] and anaerobic treatment[3,4] in similar reactor systems. Processes that combine anaerobic and aerobic unit operations are also common.[5]

The best overall treatment approach depends on the source and nature of waste, such as production rates, constituents, and relative concentrations. As such, optimal process trains and designs should be as simple as possible in design and operation, while being efficient in removing key pollutants and minimizing energy consumption and negative by-products. More complex operations are only used when absolutely necessary.

Within a typical treatment plant, each type of treatment has a different purpose. For example, the main objective of biological treatment is to treat soluble organic matter in the wastes, which often requires physical pretreatment to remove solids before biological treatment.[2] For domestic wastewater, the main objective is to reduce the organic content and, in growing numbers of cases, secondary nutrients (nitrogen, N; phosphorus, P). For industrial wastewaters, the objective is usually to remove or reduce the concentration of organic compounds, especially specific toxicants that can be present in some wastes, which is why chemical processes are also included in industrial treatment systems. However, biological processes are almost always used when possible.

Biological degradation of organics is accomplished through the combined activity of microorganisms, including bacteria, fungi, algae, protozoa, and rotifers. To maintain the ecological balance in the receiving water, regulatory authorities have set standards for the maximum amount of the undesirable compounds present in the discharge water. In a typical wastewater treatment plant, the following steps are carried out to achieve the desired quality of the effluent before it can be safely discharged into the receiving water.

Pretreatment/Preliminary Treatment

Pretreatment is primarily used to protect pumping equipment and promote the success of subsequent treatment steps. Pretreatment devices such as screen and/or grit removal systems are designed and implemented to remove the larger suspended or floating solids, or heavy matter that can damage pumps. Sometimes, froth flotation is also used to remove excessive oils or grease in the wastes.

Primary Treatment

Most of the settleable solids are removed from the wastewater by simple sedimentation, a purely physical process. In this process, the horizontal velocity of the water through the settle is maintained at a level that provides solids adequate time to settle and floatable material be removed from the surface. Therefore, primary treatment steps consist of settling tanks, clarifiers, or flotation tanks, which send separated solids to digestion units and supernatant to subsequent, typically microbiological, treatment units.

Secondary Treatment

Secondary treatment uses microbial communities, under varying growth conditions, to biochemically decompose organic compounds in the waste that have passed from primary treatment units. An array of reactors are employed for biological treatment, which include suspended biomass, biofilm, fixed-film reactors, and pond or lagoon systems.

Secondary Clarification

Most biological treatment processes produce excess biomass through the conversion of waste carbon to new cells. As such, before the final treatment steps, such as disinfection or nutrient removal, solids must be separated from the secondary treatment effluents. This is usually by settling, but membranes are also employed. The separated solids are either recycled back to the head of the process train or sent to digesters for solids reduction and processing, depending on the type of the digester system.

Tertiary/Advanced Treatment

Advanced or tertiary treatment consists of processes that are designed to achieve higher effluent quality than attainable by conventional secondary treatment methods. These include polishing steps such as activated carbon adsorption, ion exchange, reverse osmosis, electrodialysis, chemical oxidation, and nutrient removal. Although not technically a tertiary process, final effluent disinfection is often performed after secondary or tertiary treatment using chlorination, ultraviolet methods, ozonation, and other methods designed specifically to kill residual organisms in the wastewater after all previous treatment steps.

Biological Treatment Options

Biological processes are classified according to the primary metabolic pathways present in the dominant different microorganisms active in the treatment system. As per the availability and utilization of oxygen, the biological processes are classified as aerobic, anoxic, and anaerobic.

Aerobic Processes

Treatment processes that occur in the presence of molecular oxygen (O_2) and use aerobic respiration to generate cellular energy are called aerobic processes. They are most metabolically active, but also generate more residual solids as cell mass.

Anoxic Processes

These are processes that occur in the absence of free molecular oxygen (O_2) and generate energy through anaerobic respiration. Microorganisms use combined oxygen from inorganic material in the waste (e.g., nitrate) as their terminal electron acceptor. Anoxic processes are common biological nitrogen removal systems through denitrification.[2]

Anaerobic Processes

These are the processes that occur in the absence of free or combined oxygen, and result in sulfate reduction and methanogenesis. They usually produce biogas (i.e., methane) as a useful by-product and tend to generate lower amounts of biosolids through treatment.

Apart from a classification based on microbial metabolism and/or oxygen utilization, biological wastewater treatment processes also can be classified based on the growth conditions in the reactor (see Figure 1). In this case, the two main categories are suspended growth and attached growth processes.

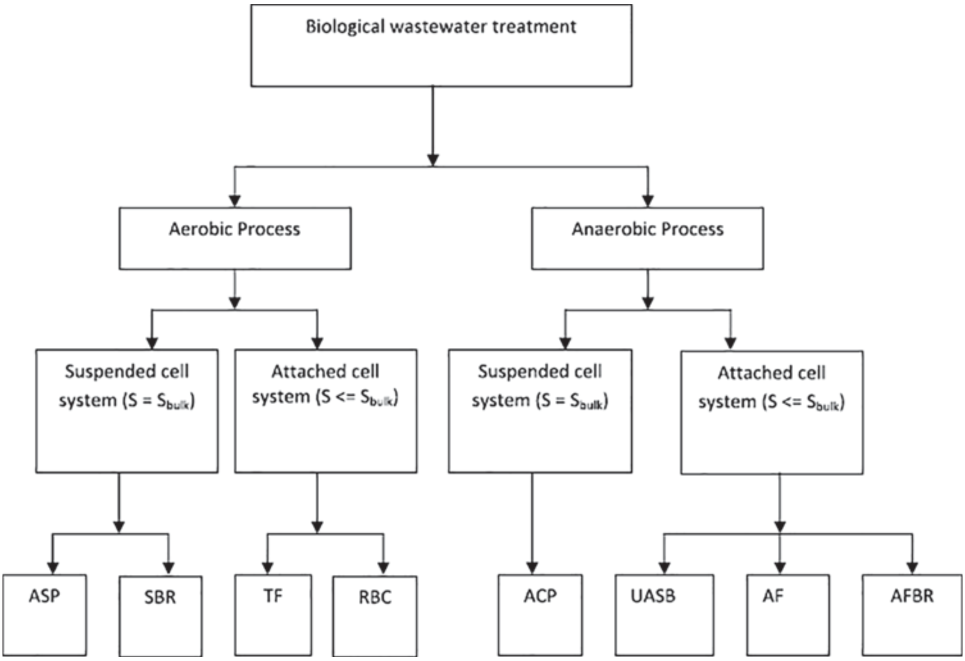

FIGURE 1 Different biological treatment processes. S, substrate concentration available to microorganisms; S_{bulk}, substrate concentration in the bulk of the liquid; ASP, activated sludge process; SBR, sequencing batch reactor; TF, trickling filter; RBC, rotating biological contactor; ACP, anaerobic contact process; AF, anaerobic filter; UASB, upflow anaerobic sludge blanket; AFBR, anaerobic fluidized bed reactor.

Suspended Growth Processes

In these processes, the microorganisms, which are responsible for the conversion of waste organic matter to simpler compounds and biomass, are maintained in suspension within the liquid phase. However, there are different types of aerobic and anaerobic suspended growth processes. Aerobic processes include activated sludge, aerated lagoons, and sequencing batch reactors, whereas anaerobic processes include bag digesters, plug-flow digesters, stirred-tank reactors, and baffled reactors with organisms primarily in the liquid phase.

Attached Growth Process

In these processes, the microorganisms responsible for degrading the waste are attached to surfaces (e.g., stones, inert packing materials), or are self-immobilized on flocs or granules in the system. Attached growth processes can be aerobic or anaerobic. Aerobic attached growth processes include trickling tilters, roughing filters, rotating biological contactors, and packed-bed reactors. Anaerobic systems include upflow packed-bed reactors, down-flow packedbed reactors, anaerobic rotating biological contactors, anaerobic fluidized bed reactors, upflow anaerobic sludge blanket (UASB) reactors, and various hybrid anaerobic reactors (HAR). UASBs are widely used reactors for the anaerobic treatment of industrial and domestic wastewater.

Aerobic Biological Waste Treatment Processes

Typical aerobic waste treatment systems provide a location where microbes are exposed to molecular oxygen (O_2) to oxidize complex organics present in the waste, producing carbon dioxide, simple organics, and new cell biomass. The activated sludge process (ASP) is very well known and the most widely used biological treatment process in developed countries.

Activated Sludge Process

Classic ASPs are aerobic suspended cell systems. Mineralization of waste organic compounds is accompanied by the formation of new microbial biomass and sometimes the removal of inorganic compounds, such as ammonia and phosphorus, depending on the particular process design. Activated sludge processes were first conceived in the early 1900s with the word "activated" referring to solids that catalyze the degradation of the waste. It was subsequently discovered that the "activation" part of the sludge was a complex mixture of microorganisms. The liquid in activated sludge systems is called the "mixed liquor," which includes both wastewater and the resident organisms.

There have been several incarnations of the ASP. The most common designs use conventional, step aeration, and continuous-flow stirred-tank reactors.[2] A conventional ASP consists of standard pretreatment steps, an aeration tank, and a secondary clarifier, an example of which is shown in Figure 2. The aeration tank can be aerated by subsurface or surface aerators designed to supply adequate dissolved oxygen to the water for the microorganisms to thrive. The wastewater flows through the tank and resident microorganisms consume organic matter in the wastewater. The aeration tank effluent flows to the clarifier where the microorganisms are removed. The clarifier supernatant is then transferred to disinfection or treatment units, and then ultimately discharged to the receiving water. Biosolids from the settler are recycled back to the head of the treatment system or sent to digesters for further processing.

Aeration Tanks

Aeration tanks are usually designed uncovered, open to the atmosphere. Air is supplied to the microorganisms by two primary methods: mechanical aerators or diffusers. Mechanical aerators, such as

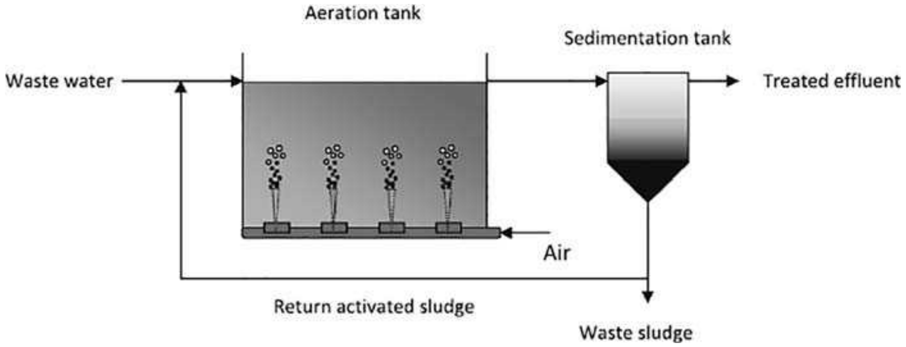

FIGURE 2 Activated sludge process.

surface aerators and brush aerators, aerate the surface of the water mechanically and promote diffusion of oxygen to water from the atmosphere. The concentration of dissolved oxygen in the liquid can be controlled by adjusting the speed of the rotors. Both mechanical aerators and diffusers are the largest energy consumers in aerobic biological wastewater treatment processes. Diffusers bubble air directly into the tank at depth and are usually preferred because of higher oxygen transfer efficiencies.

As previously indicated, aeration provides O_2 to the microorganisms and also serves to mix the liquor in the tank. Although complete mixing is desired, there are usually “dead zones” in the tank where anaerobic/anoxic conditions develop in poorly mixed areas. It is desirable to keep these zones to a minimum to minimize undesired odors and also problems with sludge bulking, which can reduce settling efficiency in secondary clarifiers.

Secondary Clarifiers

Clarifiers are used to separate the biomass and other solids coming out of the aeration tank by means of gravity settling. The flow rate of the liquid is maintained in such a way that the upflow velocity of the liquid is less than the settling velocity of the biosolids present in the liquid. As noted, some of the settled biosolids are returned back to the aeration tank to increase the solids’ contact time with the wastes and also maintain the desired biomass levels in the aeration tank.

Important Operating Parameters in Activated Sludge Systems

Key operating parameters and typical values for activated sludge systems are provided in Table 1. All parameters ultimately are used to guide and pseudo-control biosolids levels, and they profoundly affect process performance. The total suspended solids in the aeration tank are known as mixed-liquor suspended solids (MLSS). This term refers to the amount of solids in a certain volume of the water (usually milligram of solids per liter). The actual biomass fraction of the solids is estimated as the solids that can be volatilized at 550°C. The volatile fraction is known as mixed-liquor volatile suspended solids (MLVSS). Therefore, MLVSS is frequently used as a proxy for the active biomass treating the waste. MLVSS ranges from about 70% to 90% of the MLSS concentration in most activated sludge systems.[6]

Solid Retention Time

The most important design parameter in activated sludge systems is the mean cell residence time of cells in the reactor, also known as the sludge age or solid retention time (SRT). The SRT can be controlled by manipulating the rate at which excess sludge is wasted and is influenced by hydraulic flow conditions through the reactor. It is the ratio of the total solids in the system and the total solids leaving the system.

TABLE 1 Typical Design Parameters for ASP

Process Components or Variables	Typical Values	Reference
Aeration tank		[2]
Depth (m)	5–8	
Width (m)	7–12	
SRT (day)	5–15	[2]
MLSS (kg/m3)	1500–4000	[9]
SVI (kg/m3)	40–150	[7]
F/M	0.2–0.4	[6]
Organic loading rate (kg COD/m3day)	20–60	[6]
Oxygen requirement (kg/kg COD removed)	1.4–1.6	[9]

$$\mathrm{SRT} = VX/\left(QX_{\mathrm{e}} + Q_{\mathrm{w}}X_{\mathrm{w}}\right)$$

where SRT is the mean cell residence time (day); V is the volume of aeration basin (e.g., L); X is the mixed liquor suspended solids concentration (mg/L); Q is the volumetric flow rate (e.g., L/day); X_e is the effluent suspended solids concentration (mg/L); Q_w is the waste sludge flow rate (e.g., L/day); and X_w is the waste sludge suspended solids concentration (mg/L).

Sludge Volume Index

The sludge volume index (SVI) is another key parameter and used to describe the settling characteristics of the sludge. The SVI is expressed as the volume occupied by 1 g of sludge (mL/g) after 30 min of settling time. Well- settled sludge normally yields a clear separation between the water and the sludge. However, if the sludge has any problems, such as bulking, pinpoint floc formation of tiny, poorly settling floc, or ashing, the interface between the sludge and the water may not be seen clearly. Such conditions usually result from problems in the aeration tank and cause reduced effluent quality because of poor settling in the clarifier.

Dissolved Oxygen Concentration

Microorganisms in an activated sludge system require adequate oxygen to oxidize organics in the waste. The basic oxidation reaction for organics degradation can be approximated as (stoichiometry not provided)

$$\mathrm{CHON} + \mathrm{O_2} + \text{microorganisms} \rightarrow \mathrm{CO_2} + \mathrm{H_2O} + \mathrm{NH_3} + \text{more microorganisms}$$

Organics are consumed by microorganisms, and new microbial cells are synthesized with ratio of organisms produced relative to the organics consumed being the sludge yield. As noted, oxygen is supplied by mechanical aerators or diffusers in the aeration tank. Required oxygen levels in the system depend on the process, but the design goal is to minimize oxygen addition due to energy costs. The dissolved oxygen concentration can be controlled by either adjusting the speed of the air pump or throttling the air pipes. Air pumps are more widely used to aerate the wastewater because of their lower operational and maintenance costs.

Food-to-Microorganism Ratio

The food-to-microorganism ratio (F/M) is a good indicator for designing and regulating the operation of the aeration tank.[7] The F/M ratio is expressed as the amount of organic biodegradable material [milligrams of 5-day biological oxygen demand (BOD_5)] available for the amount of microorganisms present (mg MLVSS) per day.

$$F/M = \left(QS_o\right)/X$$

where F/M is the food-to-microorganism ratio (day^{-1}); S_o is the influent BOD_5 concentration (mg/L); X is the MLVSS concentration (mg/L); and Q is the volumetric flow rate (L/day).

The targeted F/M ratio for any treatment system varies depending on the design of the system, and values can range widely. However, since influent BOD cannot be controlled, MLVSS is typically modulated by varying the return activated sludge rate from the secondary clarifier, the goal being to maintain an optimum F/M ratio for specific activated sludge design.

Organic Loading Rate

The amount of organic matter in wastewater is commonly measured by BOD5, chemical oxygen demand (COD), or the total organic carbon content.[8,9] If there are excess organics in the influent or inadequate organisms in the aeration tank, incomplete treatment will result.

Common Microorganisms in Activated Sludge Systems

Activated sludge is a complex mixture of broadly differing microorganisms.[10] Major categories are as follows: bacteria, fungi, algae, protozoa (e.g., flagellates, ciliates, and rotifers), and viruses. Viruses and pathogenic bacteria are often present in wastewater, which is the primary reason for having post-biological disinfection steps in treatment plants.

Attached Growth Processes

Attached growth processes, such as trickling filters (Figure 3), can achieve similar treatment objectives as activated sludge systems. Conversion processes in these systems are typically mass transport limited: microorganisms in the outer layers of the biofilm contribute most to the overall substrate removal. The support material in trickling filters is chosen to provide sufficiently large pore spaces to allow air through the trickling filter regardless of biofilm growth and water trickling down the filter. Wastewater is distributed using rotary arms at the top and then trickles down the filter. Trickling filters are mainly used for the oxidation of carbon and ammonia, but can also achieve denitrification when convection of air through the system is optimized.[11]

Anaerobic Wastewater Treatment Processes

Anaerobic treatment technologies are widely practiced in different industries on the basis of their requirement and suitability. The processes have some advantages and disadvantages in treating different wastes, and few of them are summarized in Table 2. Under anaerobic conditions, organic matter is degraded through the sequential and syntrophic metabolic interactions of various trophic groups of prokaryotes, including fermenters, acetogens, methanogens, and sulfate-reducing bacteria (SRB).[12,13] Metabolic interactions between these microbial groups lead to the transformation of complex organic compounds to simple compounds such as methane, carbon dioxide, hydrogen sulfide, and ammonia.[14] The digestion process is essentially accomplished in four major reaction stages involving different microorganisms in each stage.[15,16]

Stage 1: Hydrolysis—The organic waste material mainly consists of carbohydrates, proteins, and lipids. Complex and large substances are broken down into simpler compounds by the activity of the microbes

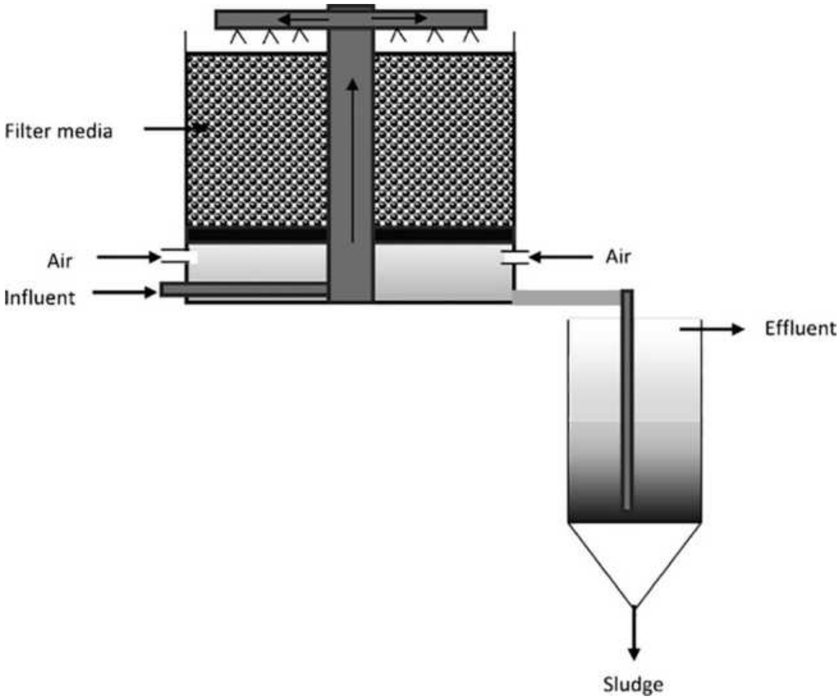

FIGURE 3 Aerobic trickling filter.

TABLE 2 Advantages and Disadvantages of Anaerobic Wastewater Treatment

Advantages

High efficiency: Good removal efficiency can be achieved in the system, even at high loading rates and low temperature.

Simplicity: The construction and operation of these reactors are relatively simple.

Flexibility: Anaerobic treatment can easily be applied on either a very large or a very small scale.

Low energy consumption: As far as no heating of the influent is needed to reach the working temperature and all plant operations can be done by gravity, the energy consumption of the reactor is almost negligible.

Energy recovery: Energy is produced during the process in the form of methane.

Low sludge production: Sludge production is low, well stabilized, and has good dewatering property.

Low nutrient and chemical requirement: Especially in the case of sewage, an adequate and stable pH can be maintained without addition of chemicals.

Disadvantages

Low pathogen and nutrient removal: Pathogens and nutrients are partially removed and hence post-treatment is needed.

Long start-up: Due to low growth rate of methanogenic organisms, the start-up takes longer time.

Possible bad odor: Hydrogen sulfide is produced. Proper handling of biogas is required to avoid bad smell.

Necessity of post-treatment: Post-treatment of the anaerobic effluent is generally required to reach the discharge standards for organic matter and pathogen.

Source: Data from Seghezzo et al.[22]

and the extracellular enzymes released by these microbes. The hydrolysis or solubilization is mainly done by hydrolytic microbes such as *Bacteroides, Bifidobacterium, Clostridium,* and *Lactobacillus.* These organisms hydrolyze complex organic molecules (cellulose, lignin, proteins, lipids) into soluble monomers such as amino acids, glucose, fatty acids, and glycerol. These hydrolysis products are used by the fermentative acidogenic bacteria in the next stage.[14,17]

Stage 2: Acidogenesis—Fermentative acidogenic bacteria convert simple organic materials such as sugars, amino acids, and long-chain fatty acids into short-chain organic acids such as formic, acetic, propionic, butyric, valeric, isobutyric, isovaleric, lactic, and succinic acids; alcohols and ketones (ethanol, methanol, glycerol, and acetone); carbon dioxide; and hydrogen. Generally, acidogenic bacteria have high growth rates and are the most abundant bacteria in any anaerobic digester.[18] The high activity of these organisms implies that acidogenesis is never the rate-limiting step in the anaerobic digestion process.[19] The volatile acids produced in this stage are further processed by microorganisms characteristic for the acetogenesis stage.

Stage 3: Acetogenesis—In this stage, acetogenic bacteria, also known as obligate hydrogen-producing acetogens, convert organic acids and alcohols into acetate, hydrogen, and carbon dioxide, which are subsequently used by methanogens and SRB. There is a strong symbiotic relationship between acetogenic bacteria and methanogens. Methanogens and SRB use hydrogen, which helps achieve the low hydrogen pressure conditions required for acetogenic conversions.[20]

Stage 4: Methanogenesis—It is the final stage of anaerobic digestion where methanogenic archaea convert the acetate, methanol, methylamines, formate, and hydrogen produced in the earlier stages into methane. The growth rate of methanogens is very low, and therefore, in most cases, this step is considered as the rate-limiting step of the anaerobic process, although there are also examples where hydrolysis is rate limiting.[21]

UASB Reactors

The most common and widely used anaerobic reactor is the UASB reactor.[22] It is an attached, self-immobilized cell system, which consists of a bottom layer of packed sludge bed (sludge blanket) and an upper liquid layer, as shown in Figure 4.[23]

Wastewater flows upward through a sludge bed consisting of bacterial aggregates floating blanket, and the microbes present in the sludge bed convert the complex organic materials to methane, carbon dioxide, and hydrogen.[24] The granular sludge (1–5 mm in diameter) has high biomass content (MLVSS) and specific activity, and good settling properties. The upward flow of the liquid inside the reactor is obtained by means of effluent recirculation. Because of the high density of biomass present in the self-immobilized granular sludge, the reactor is able to support a high SRT, which is diverse from the hydraulic retention time (HRT) and require no support material. The major drawback of the UASB is the requirement of high HRT to achieve desired biodegradation. Maintenance of high HRT demands huge reactor volume. These problems are overcome by using HAR where the advantages of AFBR are coupled with UASB operation by maintaining a high upflow velocity (4–8 m/hr) inside the reactor.[25] With higher upflow velocity, better mass transfer is obtained in the reactor, which reflects on the higher degradation with less HRT operation. The main purpose of these reactors is to achieve better degradation of waste and increase the production of biogas (methane) in a substantially reduced-size anaerobic reactor.

Important Operating Parameters in Anaerobic Reactors

Different operating parameters such as pH, temperature, HRT, and nutrients, among others, and their disturbances can manifest in case of industrial wastewaters treatment in anaerobic reactors, even under normal operational conditions.[26,27] Some of these factors are discussed below.

pH

The optimum degradation is achieved when the pH value of wastewater in the digester is maintained between 6.5 and 7.5. In the initial period of fermentation, as large quantities of organic acids are produced by acidogens and acetogens, a drop in pH occurs inside the digester. This low pH condition inhibits methanogens and subsequently reduces methane production. As the digestion proceed, the pH

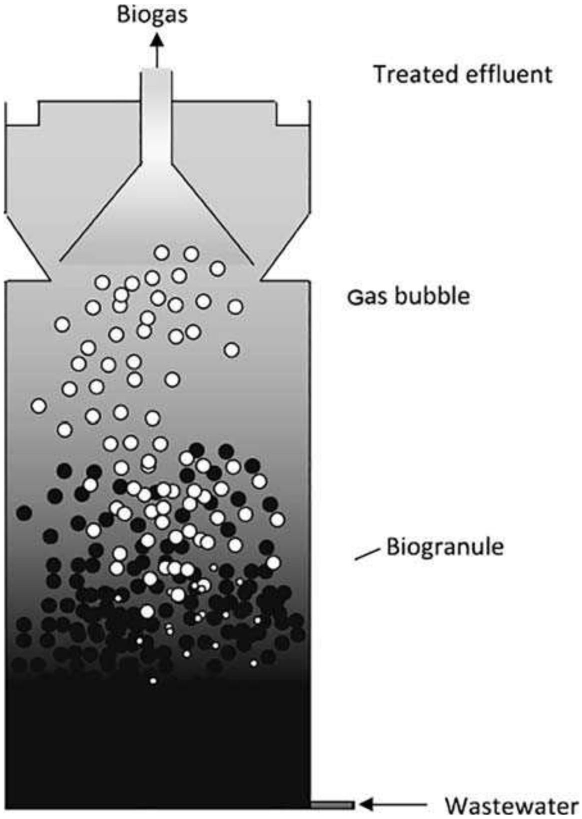

FIGURE 4 Upflow anaerobic sludge blanket reactor.

increases owing to the conversion of organic nitrogen to NH_4. When the methane production level is stabilized, the pH range remains buffered between 7.2 and 7.8.[28,29]

Waste Composition

To attain optimum degradation, wastewaters have to be nutritionally balanced in terms of carbon (C), nitrogen (N), phosphorous (P), and sulfur (S). The C/N/P ratio of 700:5:1 is recommended for efficient anaerobic digestion.[30] A fairly high concentration of acetate is required to prevent SRB outcompeting methanogens for acetate and hydrogen.[31]

Temperature

Methanogens are inactive at extremely high and low temperatures.[32] Few psychrophilic methanogens have been discovered, which can grow at a temperature range of 4–6°C.[33] Most of the methanogens can grow well from 25°C to 65°C temperatures.[34] The optimum temperature for the growth of the mesophilic methanogens is 35–37°C.[34] When the ambient temperature goes down to 10°C, gas production virtually stops. Satisfactory gas production takes place in the mesophilic range, from 30°C to 40°C.

Loading Rate

High organic loading rate may lead to acid accumulation and reduction of methane production. Similarly, if the plant is underfed, the gas production will also be low.[15]

Retention Time

The retention time depends on the growth rate of the microbial population and reactor configuration (attached cell or suspended cell system), waste strength, and waste composition.

Toxicity

The presence of toxicants in the wastewater, such as oxygen (lethal to obligate anaerobes), ammonia, chlorinated hydrocarbons, aromatic hydrocarbons, heavy metals, and long-chain fatty acids, among several others, may also result in occasional failures of anaerobic digesters.[15] The presence of trace amount of metals (e.g., nickel, cobalt, molybdenum) also stimulates the growth of microbes. Excess volatile fatty acid (VFA) concentrations are reported to inhibit the growth of several microbial species.[35] The undissociated forms of VFA can diffuse across the cell membrane and dissociate intracellularly, which results in reduction in growth rate.[35,36] The 50% inhibition of acetoclastic-methanogenesis in granular sludge was observed at a concentration of 13,000, 3,500, and 15,000 mg/L of acetate, propionate, and butyrate, respectively.[37] Small amounts of sulfide, a vital sulfur source, are beneficial for methanogens.[38] Acetoclastic methanogens are the most sensitive in terms of sulfide inhibition. Fifty percent inhibition was observed at total sulfide concentrations of 220–980 mg/L over the pH range 6.5–8.0.[39]

Granule Deterioration

Lipids present in the wastewater creates problem by forming long-chain fatty acids during hydrolysis in the anaerobic reactor. Long-chain fatty acid imparts toxic effect to acetogenic and methanogenic microbes. It also becomes adsorbed onto the sludge, inducing sludge flotation and resulting in washout.[40] Some long-chain fatty acids also act as surfactant at neutral pH and obstruct the floc formation by lowering the surface tension between water and the hydrophobic bacteria and promote their washout.[41] Addition of polyelectrolytes (calcium salts) may prevent inhibition to some extent, but it does not prevent flotation.[42]

Biological Removal of Nitrogen

The conventional biological nitrogen removal is a two- step process, nitrification followed by denitrification. The process is slow due to low microbial activity and yield. Nitrification involves a chemolithoautotrophic oxidation of ammonia to nitrate under strict aerobic conditions. This oxidation is a result of two sequential oxidative stages: ammonia to nitrite (ammonia oxidation) and nitrite to nitrate (nitrite oxidation). Different microorganisms involved in these stages use molecular oxygen as an electron acceptor and carbon dioxide as carbon source. The oxidation of ammonia to nitrite is performed by nitrifier microorganisms such as *Nitrosomonas, Nitrosococcus, Nitrosospira, Nitrosovibrio,* and *Nitrosolobus.* In the nitrite oxidation stage, *Nitrobacter, Nitrospira, Nitrospina, Nitrococcus,* and *Nitrocystis* are known to be involved in the production of nitrate.[10,43] Ammonia uptake rate varies according to reactor configuration, substrate type, and influent ammonium concentration. Denitrification is the second stage of the nitrogen removal process. It is a heterotrophic bioconversion process carried out by the heterotrophic denitrifiers under anoxic conditions. The oxidized nitrogen compounds (NO_2^- and NO_3^-) are reduced to nitrogen gas by the denitrifiers that use nitrite and/or nitrate as terminal electron acceptors and organic matter as carbon and energy source. *Pseudomonas, Alcaligenes, Paracoccus, Thiobacillus,* and *Halobacterium* are commonly found in dentrification systems.[44]

Few advanced processes, including partial nitrification, anaerobic ammonium oxidation (Anammox) and autotrophic nitrogen removal (Canon) are also being practiced in different treatment plants according to the characteristics of the wastewater. A combined system of partial nitrification and Anammox is advantageous as no extra carbon addition is needed, a negligible amount of sludge is produced, and less energy and oxygen are required compared with the conventional two-stage process.[45]

Sharon Process

The Sharon (single-reactor high-activity ammonium removal over nitrite) process is used for removal of ammonia through nitrite formation.[45,46] In this process, both autotrophic nitrification and heterotrophic denitrification take place in a single reactor with intermittent aeration. The denitrification in the Sharon process is achieved by adding methanol as a carbon source. Although the process is not suitable for all wastewaters due to a high temperature dependency, the Sharon process is suitable for removing nitrogen from waste streams having high ammonia concentrations (>0.5 g/L).

Anaerobic Ammonium Oxidation

Anaerobic ammonium oxidation (Anammox) is a highly exergonic, lithoautotrophic biological conversion process where ammonia becomes converted to nitrogen by the activity of a group of planctomycete bacteria.[47] These microorganisms use CO_2 as the sole carbon source and have a capability to oxidize ammonia to gaseous nitrogen by using nitrite as the electron acceptor in an anoxic condition.

Combined Nitrogen Removal

Ammonia-rich wastewater can be treated by Anammox, which requires nitrite as precursor. Thus, before feeding into the Anammox process, ammonia has to be preoxidized to nitrite. Thus, a partial Sharon process can be used before the Anammox process to improve the nitrogen removal efficiency. Partial nitritation (conversion of 55%–60% of ammonium to nitrite) is achieved in the Sharon process without heterotrophic denitrification. Nitrite-rich waste is then treated in an Anammox reactor. In the partial Sharon-Anammox digester, overall 83% ammoniacal nitrogen removal can be obtained from the waste stream has a total nitrogen load of 0.8 kg N/m^3/day.[48]

Canon Process

The Canon (completely autotrophic nitrogen removal over nitrite) process is also the combination of partial nitritation and Anammox processes. In this process, two groups of aerobic and anaerobic microorganisms (e.g., *Nitrosomonas* and planctomycetes) perform two sequential reactions in a single and aerated reactor. The nitrifiers consume oxygen and oxidize ammonia to nitrite. Consumption of oxygen creates an anoxic condition the Anammox process needed. The performance of the Canon process is very much dependent on operational parameters such as dissolved oxygen, biofilm thickness, nitrogen-surface load, and temperature.[49]

Biological Phosphorus Removal

The removal of phosphorus from the wastewater by the biological means is known as biological removal of phosphorus. The groups of microorganisms that are largely responsible for phosphorus removal are known as the polyphosphate-accumulating organisms (PAOs). These organisms are able to store phosphate as intracellular polyphosphate, leading to phosphorus removal from the bulk liquid phase through PAO cell removal in the waste activated sludge. Enhanced biological phosphorus removal can be achieved through the ASP by recirculating sludge through anaerobic and aerobic conditions.[50] Unlike most other microorganisms, PAOs can take up carbon sources such as VFAs under anaerobic conditions, and store them intracellularly as carbon polymers, namely poly-β-hydroxy-alkanoates (PHAs). The energy for this biotransformation is mainly generated by the cleavage of polyphosphate and release of phosphate from the cell. Reducing power is also required for PHA formation, which is produced largely through the glycolysis of internally stored glycogen.[51] The principal advantages of biological phosphorous removal are reduced chemical costs and less sludge production as compared with chemical precipitation.

The different types of bacteria used in biological phosphorus removal are *Acinetobacter, Pseudomonas, Microlunatus phosphovorus, Aeromonas,* and *Lampropedia. Acinetobacter calcoaceticus* has a very high capacity to intracellularly accumulate polyphosphate from various activated sludges. It can accumulate phosphate of an amount of 0.9%–1.9% of dry cell weight.

Conclusion

Biological treatment processes have a proven track record of dealing adequately with various kinds of wastes generated by human activities. They mimic natural processes occurring in streams and rivers. Waste treatment processes are increasingly engineered in such a way that they perform this task efficiently with a minimal input of energy. Traditionally, treatment has relied on technological approaches designed to mimic aerobic processes occurring in the water column of streams and rivers. To become truly sustainable, however, we must move away from energy-consuming aerobic processes and switch to anaerobic treatment processes, again mimicking natural processes, but now those occurring in the anaerobic sediments of the aforementioned streams and rivers. For example, there is a new focus in the water industry to integrate these two processes into systems where the waste is initially digested in an anaerobic step followed by an aerobic polishing step. Only by integrating these two processes, and variants thereof such as partial nitrification and Anammox wastewater treatment, will waste treatment become truly energy efficient and sustainable. Finally, it should be noted that anaerobic digestion to methane is not the only sustainable option. Great strides are now being made in microbial fuel cell technology within waste treatment with chemical energy from wastes being captured as electricity. All told, we are finally beginning to see again that wastes are not problems to be solved but are valuable resources, and new technologies continue to be developed to capture this capacity.

Wastewater Treatment: Conventional Methods

Sven Erik Jørgensen

Pollution Problems Associated with Wastewater

The water pollution problems associated with municipal and industrial wastewaters include their content of

- Nutrients (nitrogen and phosphorus) causing eutrophication
- Biodegradable organic matter causing oxygen depletion
- Bacteria and viruses affecting the sanitary quality of water, which is of particular importance, when the water is used for bathing, swimming, and drinking purposes
- Heavy metals, mainly lead, zinc, and cadmium from gutters, heavy metals from fungicides and other agricultural chemicals, and a wide range of other heavy metals in minor concentrations
- Refractory organic matter, originating from industries, hospitals, the use of pesticides, and the use of a wide spectrum of household entries

Wastewater Treatment

Tables 1 and 2 provide an overview of the wide range of conventional wastewater treatment methods, their efficiencies, and costs. Clearly, there is, with good approximations, a method available to virtually any of the aforementioned problems. This overview presents the conventional methods. To give a complete overview of all available methods, it is necessary to supplement this overview with a summary of low-cost methods and recently developed methods of wastewater treatment. Moreover, ecological engineering methods are not included. Particularly, the application of constructed wetland offers an attractive alternative to some of the methods presented here.

Industrial wastewaters can cause the same water pollution problems as municipal wastewater. In addition, they may contain higher concentrations of toxic organic and/ or inorganic compounds (particularly heavy metals and persistent organic pollutants). However, it is necessary in most cases to solve the problems associated with industrial wastewater at the source. They can hardly be solved by municipal wastewater treatment methods. It is also the general legislation all over the world today that industries are obliged to treat wastewater before it is discharged to the public sewage system. In many countries, the practice of the polluter-has-to-pay system has forced industries to solve their pollution problems to keep their production costs low. The major portion of toxic substances is therefore today removed by the industries themselves, at least in most industrialized countries. They are only partially removed, if at all, at municipal wastewater treatment plants, as this could contaminate the sludge produced at municipal wastewater treatment plants, thereby eliminating the possibility of the use of the sludge as a soil conditioner.

Application of the methods identified in Tables 1 and 2 gives only approximate results, and the indications should therefore be used with caution. However, first estimates such as those shown in the tables are useful for evaluations of various alternative solutions to wastewater pollution problems. The mentioned biological treatment may either be an activated sludge plant or a trickling filter of different design.

The cost of treating 100 m^3 of wastewater is based on approximate estimations, as the included cost (labor, electricity, and so on) varies from place to place, and is furthermore highly dependent on the size of the waste-water treatment plant. The costs are calculated as the running costs (electricity, labor, chemicals, and maintenance) plus 10% of the investment to cover interest and annual appreciation. The annual water consumption of one person in an industrialized country corresponds to approximately 100 m^3. For comparison, the treatment of municipal wastewater on waste stabilization ponds (WSPs) amounts to \$3–\$12/100 m^3, and that on constructed wetlands amounts to \$6–\$18/100 m^3. In most cases, WSPs cannot achieve a BOD_5 reduction above 85%–88%. In some cases, more than 90% efficiency is required. Constructed wetlands can, in most cases, with the right design, offer a fully acceptable water quality, particularly when they are used after WSPs.

The removal of high concentrations of biodegradable organic matter at the source is most often strongly recommended, since it is usually much more cost-effective to remove these pollutants, at least partially, when they are present in high concentrations. High concentrations of biodegradable organic matter are found in wastewater from slaughterhouses, starch factories, fish industries, dairies, and canned food industries.

The listed methods are often used in combinations of two or more steps to obtain the overall removal efficiency required by the most cost-moderate solution. The methods can of course also be applied in combination with cleaner technology or ecotechnology. Because wastewater treatment is often costly, it is recommended in the planning phase to examine *all* possible combinations of treatment options in order to identify the most feasible and appropriate one. For a more comprehensive presentation of all the features of the methods listed in Tables 1 and 2.[1]

A combination of treatment methods is needed in most cases, and the most applied combinations for treatment of municipal wastewater are presented in the entry "Municipal Waste Water."

Upgrading of Existing Wastewater Treatment Plants

Many existing municipal wastewater treatment plants were constructed years or decades ago, and may not meet today's higher standards. Nevertheless, upgrading existing wastewater treatment plants is possible and may be more cost-moderate than building new ones.[2,3] Because the funding allocated to pollution abatement is often limited, the overall effect of upgrading wastewater treatment plants that can be upgraded with sufficient efficiency will be to the benefit of the environment. An attractive solution is often to introduce *tertiary treatment* by chemical precipitation and flocculation in an existing mechanical–biological treatment plant, with the addition of chemicals and flocculants before the primary sedimentation phase. The installation costs for this solution are minor, and the additional running costs are limited to the costs of chemicals. The result is an 85%–95% removal of phosphorus at low cost. Similarly, nitrification and denitrification, ensuring an 80%–85% removal of nitrogen, can be realized with the installation of additional capacity for biological treatment (the overall water retention time in the plant is increased by 4–18 hr, depending on the standards and composition of the wastewater), which is considerably less costly than the installation of a completely new treatment plant.[4,5]

TABLE 1 Survey of Generally Applied Wastewater Treatment Methods

Method	Pollution Problem	Efficiency	Costs ($/100 m3)
Mechanical treatment	Suspended matter removal	0.75–0.90	3–5
	BOD5 reduction	0.20–0.35	
Biological treatment	BOD5 reduction	0.70–0.95	25–40
Flocculation	Phosphorus removal	0.3–0.6	6–9
	BOD5 reduction	0.4–0.6	
Chemical precipitation	Phosphorus removal	0.65–0.95	10–15
Al2(SO4)3 or FeCl3	Reduction of heavy metal concentrations	0.40–0.80	
	BOD5 reduction	0.50–0.65	
Chemical precipitation	Phosphorus removal	0.85–0.95	12–18
Ca(OH)2	Reduction of heavy metal concentrations	0.80–0.95	
	BOD5 reduction	0.50–0.70	
Chemical precipitation and flocculation	Phosphorus removal	0.9–0.98	12–18
	BOD5 reduction	0.6–0.75	
Ammonia stripping	Ammonia removal	0.70–0.95	25–40
Nitrification	Ammonium is oxidized to nitrate	0.80–0.95	20–30
Active carbon adsorption	COD removal (toxic substances)	0.40–0.95	60–90
	BOD5 reduction	0.40–0.70	
Denitrification after nitrification	Nitrogen removal	0.70–0.90	15–25
Ion exchange	BOD5 reduction (e.g., proteins)	0.20–0.40	40–60
	Phosphorus removal	0.80–0.95	70–100
	Nitrogen removal	0.80–0.95	45–60
	Reduction of concentrations	10–25	
Chemical oxidation (e.g., with Cl2)	Oxidation of toxic compounds	0.90–0.98	60–100
Extraction	Heavy metals and other toxic compounds	0.50–0.95	80–120
Reverse osmosis	Removes pollutants with high efficiency, but is expensive		100–200
Disinfection methods	Reduction of microorganisms	High, can hardly be indicated	6–10
Ozonation + active carbon adsorption	Removal of refractory compounds	0.5–0.95	100–120

Selection of Treatment Method

Any removal efficiency of pertinent parameters (BOD$_5$, nutrients, bacteria, viruses, toxic organic compounds, color, taste, heavy metals) can be obtained with a suitable combination of the available treatment methods, as is evident from Tables 1 and 2. However, which removal efficiencies are needed in a considered case? Because wastewater treatment is costly, the maximum allowable concentrations should not be set significantly lower than the lake or reservoir receiving the effluents can tolerate. The ban of phosphate detergents to decrease phosphorus concentrations in municipal wastewater treatment plant effluents is a point to consider in this context, as the treatment costs can be reduced considerably by the introduction of phosphorus- free detergents. On the other hand, it might be even more expensive to install an insufficient treatment plant. Thus, the potential effects of a wide range of possible pollutant inputs on water quality and on the receiving aquatic ecosystem should be assessed as the basis for selecting an acceptable option. This requires a quantification of the impacts of various possible pollutant inputs and the consideration of a wide range of solutions. All processes and components affected significantly by the impacts should be included in the quantification. It is usually very helpful to develop a water quality/ecosystem model to assist in the selection of specific

TABLE 2 Efficiency Matrix Relating Pollution Parameters and Wastewater Treatment

environmental treatment methods. It is important to emphasize that a model has an uncertainty in all its predictions that must be considered in making a final decision. Thus, it is essential to use safety factors to the benefit of the environment, in order to ensure that the selected treatment methods will have the anticipated effects. If the uncertainty is not taken into account for the sake of economy, as is unfortunately often done, the investment may be wasted because the foreseen recovery of the ecosystem will not be realized.

A problem in many developing countries is the relatively high cost of wastewater treatment. This cost justifies the application of "soft technology" or "ecotechnology," but proper planning at an early phase and the consideration of all predictable problems will always offer a wider range of cost-effective possibilities and may allow the prevention of pollution problems before they occur.

Corrections at a later stage, when pollution has already degraded the water quality and associated ecosystems, are possible, but will always be more expensive than the costs of proper wastewater treatment at an early stage. This is due in part to the fact that the accumulation of pollutants in an ecosystem over time will always cause additional problems and therefore result in additional costs. Thus, preventing pollution at an early stage is better than curing pollution at a later stage. Removal of phosphorus from wastewater at an early stage, for example, is always beneficial since the surplus phosphorus will accumulate in the sediments to a large extent, allowing its remobilization back into the water column under certain chemical conditions in the water body.

Completely new approaches have emerged in regard to sustainable development. For instance, serious consideration is being given to separation toilets in some locations, which collect urine separately from feces, thereby allowing utilization of the septic urine as fertilizer.

The selection of proper wastewater treatment methods for point sources of pollution is summarized in the following points:

- Develop models for the impacts of the wastewater on freshwater ecosystems, considering the impacts on the water quality and the entire lake ecosystem.
- Apply the model to identify the maximum allowable pollutant concentration in the treated wastewater. Any uncertainty associated with the model predictions should be reflected in identifying the lower maximum allowable concentrations.
- Select the combination of available treatment methods able to meet the standards at the lowest costs without impacting the proper operation of the plant.
- If the investment needed for a proper solution to a problem cannot be provided, the application of cost-moderate technology that will reduce the accumulation of pollutants in the aquatic ecosystem should be considered. Any measures taken at an early stage will inevitably reduce the costs at a later stage.

Water and Wastewater: Filters

Sandeep Joshi

Introduction

Windhoek, Namibia, a city in an arid region, suffered chronic freshwater scarcity. In the late 1960s, due to prolonged droughts, the only alternative for survival was to use treated wastewater for drinking purposes. In 1968, it became the first city in the world to directly supplement its drinking-water supplies with treated wastewater.[1] Windhoek has approximately 2,00,000 residents, with yearly increase of the population of about 5%. Since 1973, an epidemiological study of Windhoek residents has shown no adverse health impacts associated with drinking reclaimed wastewater. It provides 30% of the demand.

In 2002, this treatment plant was rebuilt, and the wastewater effluent is now the primary source for drinking water. This plant treats 24,000 m^3/day and has preozonation, flocculation, and filtration units comprising a rapid sand filter, a biological activated carbon filter, and two granular activated carbon (GACs) filters in a series, followed by ultrafiltration (UF).[2] This is a classic example of significance of filtration systems in water and wastewater treatment.

Water treatment commonly refers to the actions taken to purify water for domestic and industrial purposes. Generally, processes used for water treatment are physicochemical. Wastewater or sewage treatment processes are mainly biological. Most of the treatment plants purifying surface waters might have two stage processes—filtration and disinfection. For the wastewaters, normally, two more processes are added—pre- and postclarification. Water quality as far as suspended solids are concerned is achieved by filtration. Most of the filters are composed of granular media such as sand, anthracite, soil, etc. These filters have the ability to produce high-quality water when perfectly operated. Clarification and filtration processes are complimentary to each other.

Traditionally, settling of solids was the main process of clarifying water. Filtration was also practiced in ancient times. The earliest filters seem to be very simple—infiltration wells excavated near the banks or lakeshores. Wells on the seashore usually were dug tapping sweet water aquifers flowing from the land to the sea. The technology is modernized with addition of sophisticated UF or reverse osmosis for better-quality water. Filters can be classified based on the following: 1) filtration rate—slow, rapid, and pressured; 2) direction of flow—downflow, upflow, and biflow; 3) filtration medium—sand, soil, and synthetic media; 4) layers of media—single, dual, and multimedia; 5) input water quality—water, sewage, industrial effluents, etc.

Water or wastewater treatment is the process of removing undesirable chemical or biological contaminants. These can be gaseous or solid constituents. Concentration of gaseous contaminants is dependent on factors like solubility, temperature, partial pressure, etc. They can be removed physically by diffusion or temperature increment Size of solid contaminants may range from millimeters to angstroms—less than a nanometer. These contaminants are different types of solids that can be categorized based on their sizes or physicochemical properties. Origin of these solids can be nonbiological or biological. They can be divided into two—depending on their chemical composition—organic and inorganic, as shown in Figure 1. Suspended or dissolved solids having different sizes are shown in Figure 2. Solids larger than suspended solids are termed as floating solids like plastic, paper, cloth, etc. They can be easily removed by putting a screen across the path of water flow, but smaller particles need finer sieves.

Treatment of Water and Wastewater

Treatment includes physical, chemical, and biological processes to remove physical, chemical, and biological contaminants. Its objective is to produce an environmentally safe fluid waste stream (or treated effluent) and solid waste (or treated sludge, http://en.wikipedia.org/wiki/Sludge) suitable for disposal or

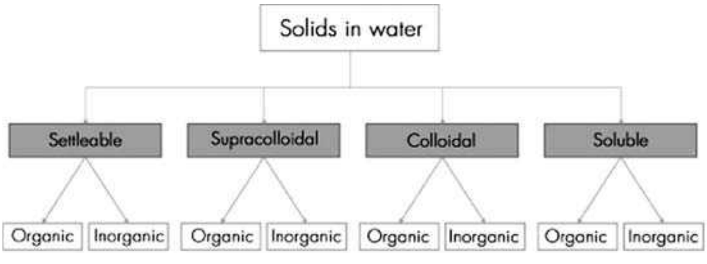

FIGURE 1 Classification of solids in water.

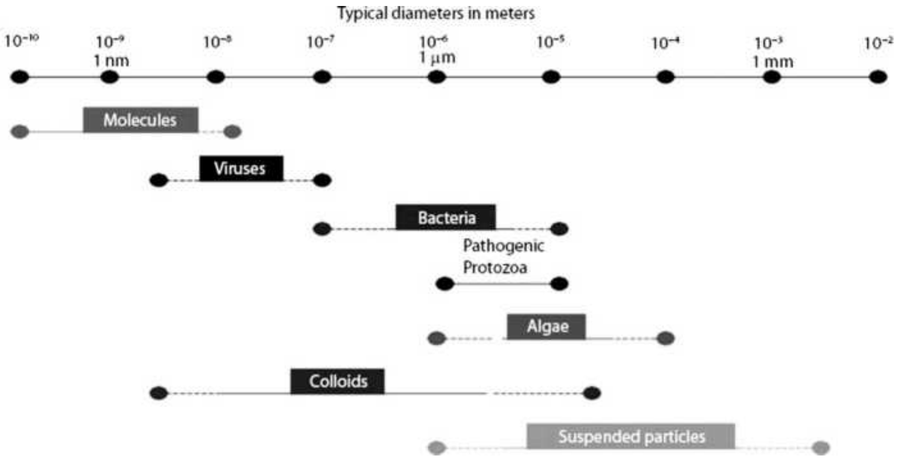

FIGURE 2 Different sizes of solid contaminants in water.

reuse (usually as farm fertilizer). Using advanced technology, it is now possible to reuse sewage effluent for drinking water. Singapore has advanced to convert sewage into drinking water on mass scale.

In general, a conventional water treatment plant usually consists of physical treatment (screening, sedimentation, flotation, and/or filtration) and chemical treatment (pH adjustment, coagulation-flocculation process, oxidation- reduction process, adsorption process).[3] The degree of the complexity of the treatment plant also depends on the quality of raw water and treated water requirement. In industrial processing, water is used in numerous applications requiring likewise different qualities of water. Examples of different uses are cooling water, water for rinsing and chemical production, boiler feed water, purified water, and water for injection. The growth in population, the increasing costs of treatment and distribution, contamination of fresh water sources, and the sophistication of end users somehow force the development of better water treatment technology.[4,5]

Filtration Process

Filtration means a process of solid-liquid separation using some form of physical barrier. In sedimentation or floatation, no barrier is used. Depending on other supportive mechanisms, the filters can be divided into mechanical or biological filters keeping the built-in solid–liquid stage. In 1685, Porzio, an Italian physician, used a filter to protect the health of soldiers in the Austro–Turkish war of that year. In 1790, James Peacock was granted the first patent for an upflow filter with graded support gravel and reverse- flow wash. James Simpson built a 1-acre slow sand filter, and it was commissioned satisfactorily in 1829. In 1858, the use of a rake was proposed to break the schmutzdecke (surface clogging layer). Holly, in the United States in 1871, patented the reverse-flow wash downflow filter, and in 1877, Cook developed the concept of a battery filter for keeping standby options during the washing of used filters.[6] In India, similarly, an underground filtration flow system was developed in Pune in 18th century to cater the people's needs for fresh and clean water.[7]

It has been noticed that very small particles and large particles are predominantly removed by diffusion and straining mechanisms, respectively. Five different mechanisms other than simple straining[8]

Generally, in conventional water or wastewater treatment plants, filtration is considered as the core of the process in which the solids are substantially removed. Incoming flow to the filters is clearly non-potable or turbid, but after filtration, it becomes clean and transparent. If the water is disinfected, then it can be used for human consumption.

The process of filtration is composed of passing water through a granular bed of sand or any other suitable medium at a designed flow rate. To achieve the desired quality of filtered water, the filtration system has to remove particles, and the sizes of the openings are crucial. It has been noticed that very small particles and large particles are predominantly removed by diffusion and straining mechanisms, respectively. Five different mechanisms other than simple straining[9] are identified in the filtration process when particles in a flow of water pass through a filter, viz., interception, sedimentation, diffusion, hydrodynamic action, and inertia (Figure 3).

Particles moving uniformly may collide with a grain of filter media; their transport is intercepted. Efficient interception is possible by decreasing the size of the media or increasing the size of the particle to be removed. Larger particles are removed more efficiently. Sedimentation is a result of gravitational forces acting on the particles depending on the ratio of settling velocity and velocity of the flow approaching the media. Diffusion as a result of Brownian motion is effective only for small particles. It becomes more pronounced with increasing temperature. Hydrodynamic action arising from the velocity gradient separates small particles from the flow. This is comparatively nonsignificant. Inertia (impaction) is useful only when hydrodynamic diversion is less. At less velocity, inertia is not significant. In addition to these mechanisms, coagulation, flocculation, adsorption, and absorption play major roles in the effectiveness of a filtration system.

Filtration with a granular bed is composed of indivisible grains that rest on each other, leaving voids in between. Dirt is removed when water flows through these voids. The real filter media are composed of irregular grains-often unpolished rounded edges. Sands are the most readily available material from natural sources such as the sea coast and riverbeds. Granular media can be obtained by crushing materials such as basalt, slag, and anthracite. The voidage increases with angularity of the material, e.g., crushed anthracite has more voidage (45%) than sand (38%) after gentle tapping. Filtration media retain solids while permitting water having turbidity less than 0.2 NTU (nephelometric turbidity unit) to pass.

Solids are collected on the surface of the filter bed, forming a surface mat or “mud cake.” This needs to be regularly cleaned to avoid resistance to flow. A granular bed filter having a mass of leading edges and space for accumulation of deposits helps in retaining the grains that are no longerin the line of flow. They are like silt on the sand bed of a river. These materials are comparatively cheaper than fibrous materials that are used for large-scale water or wastewater applications. If the grain does not dissolve in

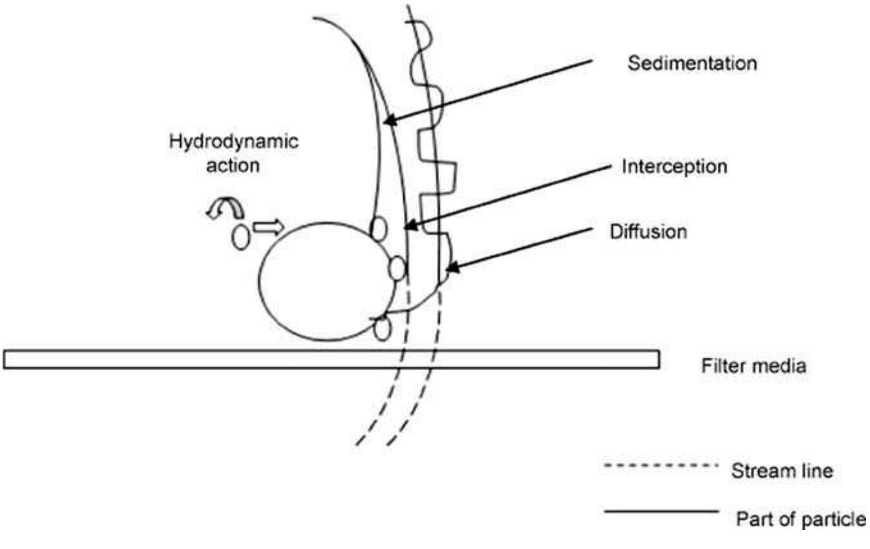

FIGURE 3 Filtration mechanisms.

water, then its chemical nature is not important. Therefore, structurally weak materials such as activated carbon (granular or powdered) can be used for filtration purposes.

Filters operate best normally at a low concentration of solids as a result of limited volume of pores (about 40% of the bed volume). A granular bed filter having a mass of leading edges and space for accumulation of deposits helps in retaining the grains that are no longer in the line of flow. Therefore, such filters operate at 0.2 bar (2 m head), but media such as a cloth, paper, porous sinter, or membrane tend to accumulate deposits, and then it requires high pressure (up to 7 bars) to maintain its permeability. The depth in simple granular filters may be 600–1000 mm for its desired effectiveness. Failure of the filters is associated with cleaning the mechanism either manually or mechanically with water or air backwash.

Types of Granular Filters

There are three basic types of granular filters, viz., sand filters, rapid gravity (RG) filters, and pressure filters. Slow sand filters—operating at low loading rates—are the oldest variety of filters. These filters made up of fine sand have two processes—physical straining and biological action. Rapid filters function at higher loading rates using coarse media with a higher permeability. In addition to sand, GAC is used to adsorb chemicals dissolved in water. Coagulation helps in effective removal of solids by RG filters. Simple RG filters use single-medium sand, but a multimedia version uses two or more types of media. These are cleaned by reversing the flow of water to wash out the dirt. Pressure filters are the variety operating under pressure in large closed vessels. These are normally used for treating groundwater sources, which are pumped from boreholes. Various types of filters are shown in Figure 4.

Slow Sand Filter

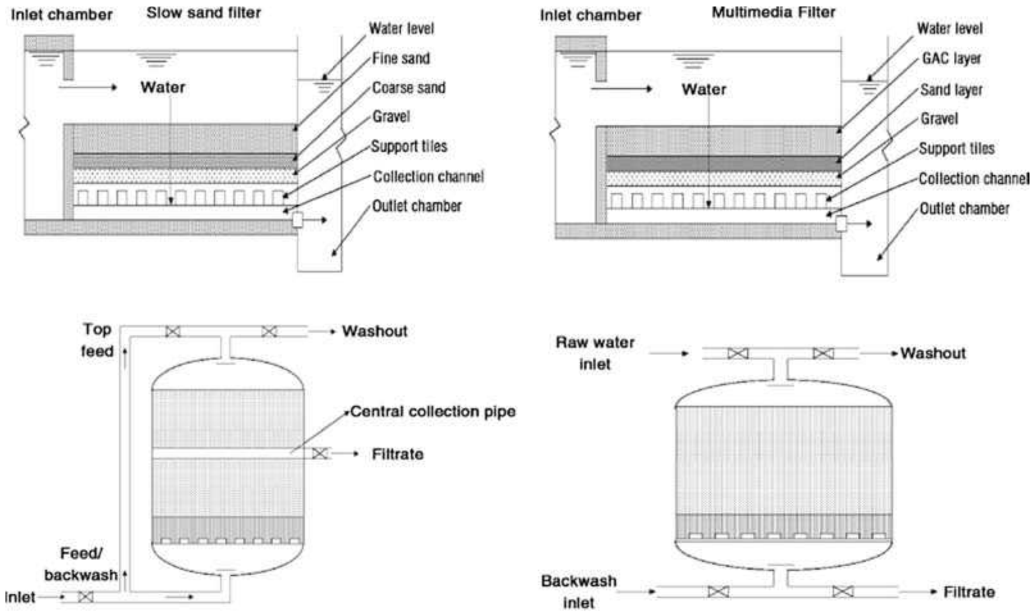
Slow sand bed filters are very-low-flow-rate filters. They are used in rural areas or where the water flow rate required is low. A slow sand filter can even remove turbidity and suspended solids. Pathogens are also removed, additionally producing water with very reasonable taste and no color. An operational advantage of slow sand filters is that no backwashing is done. They require few operator skills. Sometimes, slow sand filters are used in the treatment of sewage as a final polishing stage for the treated effluent and as a bed to dewater the sludge produced during treatment.

Rapid Gravity Filter with Coagulant Aid

Purification of water for drinking purposes is done using chemicals to flocculate as much particulate matter to be removed as quickly as possible in the filter. Coagulation of the particulate matter is achieved by adding highly charged cations, such as aluminum sulfate (alum) and small amounts of charged polymer chains. Coagulation and flocculation processes require contact time and agitation in tanks before the water is filtered so that a reasonably sized floc can be formed. This process is pH dependent. Thus, it is necessary to adjust the pH of the water to ensure efficient removal of water. A rapid gravity sand filter strains out the floc and the particles, including bacteria trapped within them. The medium of the filter has grain sizes to allow the water to pass through the filter rapidly. This filter is backwashed with clean water on a regular basis as the pores are clogged by particulate matter (flocs), indicated by a rapid drop-off in the flow rate of water through the filter. This backwash water is run into settling tanks so that the floc can settle out, and it is then disposed of as residue. Supernatant water is then run back into the treatment process or disposed of as a wastewater stream.

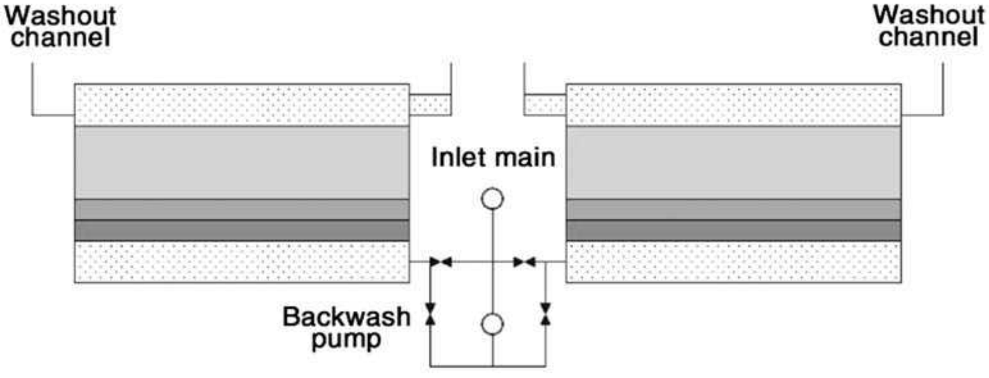
Pressure Sand Filter

Applying pressure to the water passing through a sand filter will give a greater flow rate, while using smaller grains of sand in a filter allows a greater surface area of filtration medium to remove



Central feed/collection sand filter

Gravity sand filter with backwash system



Sand filter in a series/parallel with backwash system

FIGURE 4 Different types of filters.

particulate matter. Smaller grain size requires more pressure to drive the water through the sand bed. Sand grain size in pressure filters is typically 0.6–1.2 mm, and large particulates (>100 pm) are removed. This causes rapid blinding of the filter with floc and the need for too-frequent backwashing. Pressure sand filters are typically 0.6–1.8 m in depth and operate under a maximum flow rate of about $9m^3/m^2/hr$ under a feed pressure of between 2 and 5 bars. Buildup of particulate solids causing an increase in pressure across the bed for a given flow rate will need to be backwashed when the pressure drop is around 0.5 bar. Particulate solids are then washed away with the backwash water. It is diverted to a settling tank to separate the solids from water. A small amount of sand can be lost in the backwashing process. Then, the sand bed may need to be topped up from time to time. Most pressure filters in industry or large water works employ an automated multiport valve together with sophisticated pressure and flow sensors.

Cartridge Filter

This type of filter has a removable housing, into which different types of filtration elements can be placed. A domestic cartridge filter element will often be rated at 30–50 μm or larger, whereas specialist industrial filter elements may be rated at 5 μm or less. Some cartridge filters are made effective by using some resins that are designed to remove specific contaminants from the water, such as nitrates, fluoride, or lead. Granulated activated carbon is used in filters to remove color, odor, volatile organics, and chlorine from water.

Biofilters

Biological treatment or biofiltration has become the mainstay of wastewater treatment systems over a period of time because of simplicity. Odor control using biofiltration has been patented from the 1950s for huge trickling filter plants and soil filters. Biofilters have primary applications for odor control at wastewater treatment plants and composting operations. They are being used also in the treatment of volatile organic compounds (VOCs), as an innovative method to treat toxic air emissions from industrial processes. The chronological development of biofilters is as shown below:

- 1923: To treat odorous compounds, Bach thought of using a biologically active biofilter to control emissions of H_2S from a wastewater treatment plant.
- 1955: A biofilter was applied to treat odorous emissions in low concentrations in Germany.
- 1959: A soil bed was installed at a sewage treatment plant in Nuremberg for the control of odors from an incoming sewer main.
- 1960s: Biofiltration was first used for the treatment of gaseous pollutants both in Germany and the United States.
- 1970s: Biofiltration became widespread in Germany.
- 1980s: Biofiltration is used for the treatment of toxic emissions and VOCs from industry.

Biological Aerated Filters

Biological aerated filters or biofilters combine filtration with biological carbon removal and nitrification or denitrification processes. A biologically aerated filter usually includes a reactor filled with a filter medium, which is either in suspension or supported by a gravel layer at the foot of the filter. The dual purpose of this medium is to support highly active biomass that is attached to it and to filter suspended solids. Carbon reduction and ammonia conversion occur in aerobic mode and are sometimes achieved in a single reactor, while nitrate conversion occurs in anoxic mode. Biological aerated filters are operated either in up- flow or downflow configuration.

Trickling Filters

The first trickling filter became operational in 1893. The concept of trickling filters was developed from contact filters—which were watertight basins filled with stones. Clogging, long resting period, and relatively low loading rate were some of the limitations of contact filters. The modern trickling filter is composed of a permeable medium (rock or plastic media) for the attachment of bacteria. Through this biofilter, wastewater percolates—trickles down. The filter medium is either rock (size varies from 25 to 100 mm) or slag or plastic packing materials. The depth of the rock medium is about 1–2.5 m. Wastewater is distributed on the top of the rock bed by rotary distributor. Plastic media are either round or square or irregularly shaped. Depth of plastic media varies from 4 to 12 m. Depending on packing, the trickling filter can be categorized into three groups, viz., vertical flow, cross-flow, and random.

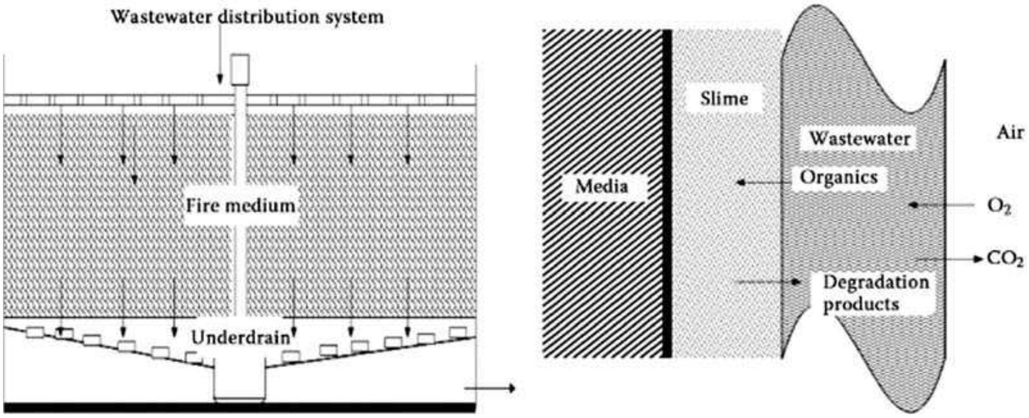


FIGURE 5 Trickling filter and slime layer.

The components of a trickling filter are the following:

- A bed of filter medium on which a layer of microbial slime is developed
- A container that houses the bed of filter medium
- Distribution of wastewater over the filter medium
- Removal and disposal of any sludge from the treated effluent

Filters are provided with underdrains for collection of treated wastewater and biosolids detached from the media. Underdrain systems are important as far as air circulation is concerned. Organic matter is degraded by the microorganisms present in the biological film or slime layer attached to the filter media (Figure 5). The outer layer of biofilm, about 0.1–0.2 mm, is aerobic, and the layer near the surface of filter media becomes anaerobic due to diffused oxygen and thus cannot penetrate the full depth of the slime layer. The inner layer is starved of nutrition of pollutants as the slime layer thickens. Endogenous degradation of bacteria in the inner layer leads to sloughing due to shear velocity of trickling water. Facultative microorganisms dominate the biological communities in the slime layer of the trickling filter. With these organisms, fungi, algae, protozoans, worms, insect larvae, and sometimes snails also dwell in the trickling filter.[9,10] Their presence in the filter is useful to maintain the bacterial population in a state of high growth or high rate of food consumption.

An excellent material for trickling filter is that having more surface area per unit volume, low cost, durability, and no tendency for clogging. Until the 1960s, a commonly used material was high-quality granite or blast furnace slag. River gravel or crushed stones were also used. All underdrains are developed to maintain and facilitate air ventilation. Sufficient airflow in the system is a key to successful operation of the trickling filter. In case of natural ventilation, the temperature difference between the ambient air and air in the pores of media is the key reason for air circulation. Good design may provide airflow at least 0.3 $m^3/minm^3$ of the filter area in either direction. Trickling filters can be classified on the following bases: 1) frequency of hydraulic and organic loading—slow rate, high rate, batch, intermittent, continuous; 2) nature of filtering media—natural, synthetic; 3) direction of inflow—downflow, up- flow, sectionalized; 4) internal environment of the filter— aerobic, anaerobic, anoxic; 5) depth of media—shallow, deep; 6) method of ventilation—natural, forced; and 7) extent of treatment expected—complete, roughing, polishing.

Membrane Filtration

The major breakthrough in the development of membrane technology was recorded in the late 1950s. The membrane bioreactor (MBR) has developed quite rapidly to become this important. The idea of combining sludge digestion with a very fine filter was first developed in the mid-1960s by Dorr Oliver, as a system with flat-plate membranes in a sidestream loop. This development was made possible by the appearance on the market of commercial-scale microfiltration (MF) and UF membranes. Membrane bioreactors have served industries that can afford an expensive system. The submerged membrane was innovated in Japan in 1989, which led to a Japanese government initiative to find better ways of wastewater treatment. Submerged or immersed MBRs used less energy than the sidestream version. This version entered the European market in the mid-1990s. Since 1990, the numbers of MBR installations have grown exponentially.

Technologies of secondary biological treatment systems for municipal wastewater generally involve microorganisms suspended in the wastewater to treat it. They have some deficiencies, including the difficulty of growing the exact types and numbers of microorganisms and the physical requirement of a large site. Application of MFMBRs surmounts many limitations of conventional systems. These membrane filtration systems combine the suspended biological growth with solids removal via filtration (Figure 6).

The basic MBR consists of two processing steps—a bioreactor, in which aerobic bacteria digest organic material in the presence of dissolved oxygen, and a membrane module, through which relatively pure water separates from the suspension of organic matter and bacteria. These two units may be set up to run in succession (i.e., the liquid flows first through the bioreactor, where it is held for as long as necessary for the reaction to be completed, and then through a loop containing the membrane separation stage), with a recycle of some of the separated sludge to the bioreactor. This is often called sidestream (or external) operation. Membranes are suspended in the slurry in the bioreactor, which is appropriately partitioned to achieve the correct airflows, with the surplus sludge withdrawn from the base of the bioreactor at a rate to give the required sludge retention time. This is termed as a submerged (or immersed) MBR.

Membranes can be designed for and operated in small spaces and with high removal efficiency of contaminants such as total suspended solids, nitrogen, phosphorus, biochemical oxygen demand (BOD), and bacteria. The membrane filtration system in effect can replace the secondary clarifier and sand filters in a typical activated sludge treatment system for large sewage treatment plants. Membrane filtration allows a higher biomass concentration to be maintained, thereby allowing smaller bioreactors to be used.

Membrane filtration involves the cross-flow of water containing pollutants across a membrane. Waste matters left behind do not accumulate at the membrane surface. They are removed from the system by gravity for disposal. Water passing through the membrane is called the permeate or filtrate, while water with more concentrated pollutants is called the concentrate, retentate, or reject. Membranes are composed of cellulose or other polymers having a number of pores. The requirement is that the membranes

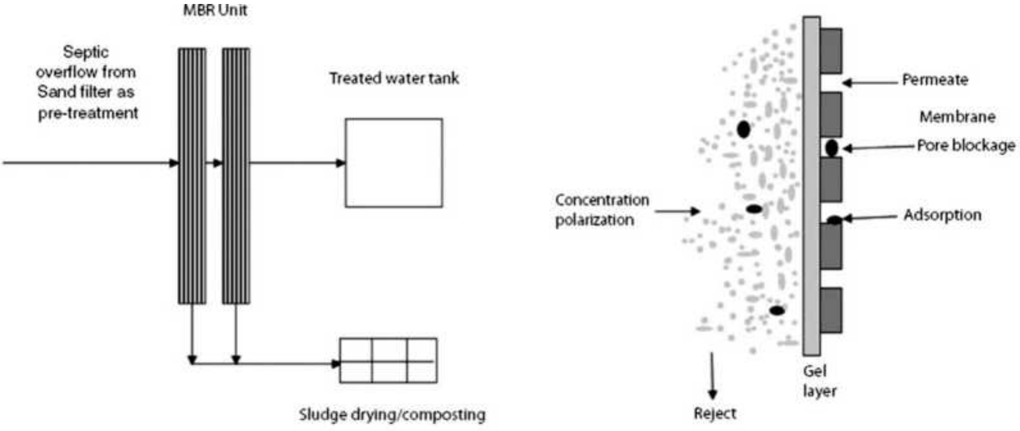

FIGURE 6 Typical flow chart of membrane filtration for sewage treatment and filtration through membrane.

filter out particles and microorganisms more than 1 μm (0.001 mm) in size. Two configurations most often used are hollow fibers grouped in bundles or flat plates for MBR designs.

Membrane filtration is an alternative to remove waterborne pathogens in water treatment, replacing the disinfection step in conventional water treatment plants to avoid risks and side effects of chemicals. Membrane processes can be classified in many ways, i.e., based on their nature, structure, or driving force. Hydrostatic pressure differences are used in MF and nanofiltration (NF), as well as in reverse osmosis (RO) and gas separation as a driving force for mass transport through the membrane. The MBR takes the place of the whole secondary stage of conventional activated sludge processing—and does it better and in a much smaller space. The excess biodegradation products can be removed for subsequent treatment.

The sludge settlement stage of the conventional secondary process is a slow one, so the removal of the clear liquid from the slurry by membrane filtration is a better option. A major advantage of the MBR system is that it can operate at a much higher concentration of solids in the bioreactor than that of a conventional activated sludge plant. An MBR plant can work effectively at concentrations of mixed liquor suspended solids typically in the range of 8000–12,000 mg/L (or 0.8%–1.2%) and can be extended up to 3%, whereas conventional activated sludge plants work at about 2000–3000 mg/L, because of the limitations on settling. This high sludge concentration capability enables an MBR system to deal effectively with strong industrial wastes, especially in places where water is short and factories are seeking to close their water cycles. It also results in a much smaller digestion tank, and thus a much smaller footprint for the whole plant. The smaller space footprint of an MBR plant will make it much more attractive for construction in developed urban areas.

The longer sludge retention times in the MBR permit the destruction of molecules difficult to biodegrade, such as detergents. With proper system design, nitrogen and phosphorus content can also be significantly reduced. The quality of water produced as effluent by an MBR is excellent and usually well under the local consent limits. Figures of less than 2 mg/L for BOD and less than 0.5 mg/L for total suspended solids are readily achievable, along with ammoniacal nitrogen of less than 0.5 mg/L and turbidity of less than 0.2 NTU. Particularly relevant are the capabilities of UF membranes (the most common form used) for removing pathogens such as protozoa, bacteria, and most viruses.

Most membrane filtration processes require quite a high transmembrane pressure in order to produce an acceptable permeate flow rate. However, an MBR operates with a low differential, about 0.5 bar. This can be provided by a vacuum pump, sucking on the permeate discharge line, through a receiver, or by the hydrostatic head of a deep bioreactor tank, or by a low level of pressurization of the tank.

Future Developments of MBR

The MBR (including its most common form, submerged MBR—not to be confused with the moving bed bioreactor) is a fascinating combination of two steps of waste treatment: the bacterial digestion of waste organic matter and the separation of the treated effluent from residual suspended solids. Its prime advantage is that it can constitute the whole of the secondary phase of the traditional three- phase municipal sewage treatment process and can eliminate some parts of the tertiary phase.

In the long history of wastewater treatment (over 110 years), the MBR is quite a recent invention, and so, not surprisingly, it is still in a period of intense development. Key areas of system investigation include the following:

- Aeration system design, to ensure minimal energy consumption and maximum mixing and scouring
- Use of enriched air or pure oxygen for aeration
- The possible use of non-membrane MF media
- The design and manufacture of MBR membranes truly defying fouling, enabling a realistic “fit-and-forget” situation

- Development of an MBR capable of continuous use
- Use of MBR "in reverse" to add nutrients in a controlled fashion to remove gases from bioreactor
- Extraction of specific pollutants from bioreactor zone
- Development of an MBR for use in gray water recycling
- Conversion of MBR from an aerobic process to anaerobic operation, thus producing more energy (in the form of methane) than the plant consumes, the anaerobic digestion UF system

A major disadvantage of MBR systems is the higher capital and operating costs than conventional systems for the same quantum of wastewater. Operation and maintenance costs include membrane cleaning, fouling control, and eventual replacement of membrane Energy costs are also higher because of the need for air scouring to control bacterial growth on the membranes. Additionally, the waste sludge from such a system may have a low settling property.

Applicability

Membrane bioreactor systems are also well suited for some industrial and commercial applications. The high- quality treated water produced by MBRs makes them particularly applicable to reuse applications and for surface water discharge applications requiring extensive nutrient (nitrogen and phosphorus) removal. Designers of MBR systems require only basic information about the wastewater characteristics (e.g., influent characteristics, effluent requirements, flow data) to design an MBR system. Depending on effluent requirements, certain supplementary treatment steps can be clubbed with the MBR system, e.g., chemical coagulation before the primary settling tank or before the secondary settling tank, before the MBR or final filters for phosphorus removal.

Ultrafiltration

Ultrafiltration is a fractionation technique that can simultaneously concentrate macromolecules or colloidal substances in a process stream.[11] It can be described as simultaneous purification, concentration, and fractionation of macromolecules or fine colloidal suspensions.

Ultrafiltration membranes are developed from both organic (polymer) and inorganic materials. The preference of a given polymer as a membrane material is dependent on very specific properties such as molecular weight, chain flexibility, and chain interaction. Some of these materials are polysulfone, polyethersulfone, polyvinylidene fluoride, polyacrylonitrile, cellulosics, polyimide, polyetherimide, and aliphatic polyamides. Inorganic materials have also been used such as alumina and zirconia.[9] The structure of a UF membrane can be symmetric or asymmetric. Thickness of symmetric membrane ranges from 10 to 200 μm. Resistance to mass transfer is determined by the thin top layer. Membrane material should have chemical, thermal, and mechanical stability. Specification of UF is determined based on molecular weight cut-off—a measure of membrane pore dimensions—to describe the retention capabilities of UF membrane. It is the molecular mass of a macrosolute (typically, polyethylene glycol, dextran, or protein) for which the membrane has a retention capability greater than 90%.

Performance of UF

One of the critical factors determining the overall performance of aUF system is the rate of solute or particle transport in the feed side. Steady state conditions are achieved when the convective transport of solute to the membrane is equal to the sum of the permeate flow plus the diffusive back-transport of the solute.[12] The accumulation of solutes/particles at the membrane surface can affect the permeate flux in two ways.[13] First, the accumulated solute can generate an osmotically driven fluid flow back across the membrane from the permeate side toward the feed side, thereby reducing the net rate of solvent transport. Second, the solutes/particles can irreversibly foul the membrane due to specific physical and/or chemical interactions, thereby generating an additional hydraulic resistance. These interactions can be attributed to one or more of the following mechanisms: 1) adsorption; 2) gel layer formation; and 3) plugging of the membrane pores. The severity depends on the membrane material, the nature of solutes, and other variables such as pH, ionic strength, solution temperature, and operating pressure.[14]

Ultrafiltration System Design

Ultrafiltration is a low-pressure system operating at transmembrane pressures of 0.5–5 bars. A UF system comprises series/parallel modules operating according to various modes, ranging from an intermittent single-stage system to a continuous multistage system.[15] Ultrafiltration membranes can be fabricated essentially in tubular or flat sheet forms. Two major types of UF modules can be used, i.e., hollow fibers (capillary) and spiral wound. Other modules are plate and frame, tubular, rotary modules, vibrating modules, and Dean vortices. Operation of a UF membrane can be performed in two different service modes, viz., dead-end flow and cross-flow. The dead-end flow approach allows optimal recovery of feed water in about a 95%–98% range, but is generally limited to feed streams of low suspended solids (<1 NTU). The cross-flow mode differs from the dead-end mode in that there is an additional flow—the concentrate. The cross-flow mode of operation typically results in lower recovery of feed water, about 90%–95%.[16]

Ultrafiltration in Water Treatment

Ultrafiltration can be used to replace clarification steps, i.e., coagulation, sedimentation, and filtration, in a conventional water treatment plant. Thus, it can be defined as a clarification and disinfection membrane operation. All particulate biological contaminants, viz., viruses and bacteria, are rejected. The main advantages of low- pressure UF membrane processes compared with conventional clarification processes are no need for chemicals and size-exclusion filtration for constant quality of treated water in terms of particle and microbial removal.

Source water quality directly impacts UF membrane performance. Depending on the quality of raw water, UF can be operated as single operation or in combination with another process (coagulation, adsorption, etc.), or hybrid membrane system (UF/MF). In water application, UF can be the main process or used as pretreatment, for example, in an RO system.[17] It is a preferred alternative to conventional technology to remove water-borne pathogens in the preparation of drinking water.[16]

Ultrafiltration alone is not very effective for removing dissolved substances in general. It has limited capability in removing organic matter. Thus, the use of powdered activated carbon (PAC) in combination with a UF membrane is attracting increasing interest for the removal of organic compounds in drinking-water treatment.[17] It is found that the combination of UF with PAC/GAC could improve the removal of organics and other micropollutants such as agrochemicals. Another potential application of UF is to produce ultrapure water, acting as a pretreatment of RO unit. Microfiltration/UF can be considered as an alternative water treatment in aquaculture.[18] A sufficient supply of good-quality water is essential to any aquaculture operation. Ultrafiltration generates highly pathogen-free water.

Reverse Osmosis System

Reverse osmosis is a hi-tech filtration method that removes many types of large molecules and ions from solutions by applying pressure to the solution. Dissolved solids are not removed by any other filtration technique. The result is that solute is retained on the pressurized side of the membrane, and the pure solvent is allowed to pass to the other side. Selectively, this membrane does not allow large molecules or ions through the pores (holes) but allows smaller components of the solution (such as the solvent) to pass freely. The process of osmosis through semipermeable membranes was first observed in 1748 by Jean Antoine Nollet. For the following 200 years, osmosis was only a phenomenon observed in the laboratory. In 1949, the University of California at Los Angeles first investigated desalination of seawater using semipermeable membranes.

In the normal osmosis process, the solvent naturally moves from an area of low solute concentration, through a membrane, to an area of high solute concentration. The movement of a pure solvent to equalize solute concentrations on each side of a membrane generates pressure, i.e., osmotic pressure. Applying an external pressure to reverse the natural flow of pure solvent is the RO. The process is very similar to membrane filtration, but the only difference is between flow of solvents and filtration. Reverse osmosis involves a diffusive mechanism so that separation efficiency is dependent on solute concentration, pressure, and water flux rate.[19] The membranes used for RO have a dense barrier layer in the polymer matrix where most separation occurs. In most cases, the membrane is designed to allow only water to pass through the dense layer, while preventing the passage of solutes such as salt ions. This process requires high pressure, usually 2–17 bars (30–250 psi) for fresh and brackish water and 40–70 bars (600–1000 psi) for seawater (http://en.wikipedia.org/wiki/Reverse_osmosis-cite_note-2http://en.wikipedia.org/wiki/Reverse_osmosis-cite_note-water-0).

One of the first membrane applications for the utilization of membrane technology was the conversion of seawater into drinking water by RO. AnRO system separates dissolved solutes (includes single charged ions, such as Na^+, Cl^-) from water. Reverse osmosis can be described as a diffusion-controlled process. Physical holes may not exist in an RO membrane, which differentiates it from other filtration systems. An RO membrane is very hydrophilic; therefore, water will be able to readily diffuse into and out of the polymer structure of the membrane. An RO membrane is capable of rejecting contaminants as small as 0.001 μm.[20]

Four types of modules are used for RO membrane, i.e., plate and frame, tubular, hollow fiber, and spiral wound. However, the spiral-wound element is the most common by far for the production of drinking water. Reverse osmosis configurations include single-stage, two-stage, and two-pass systems. A two-stage system is common for brackish water use, where it is necessary to increase the overall recovery ratio.[21] Nowadays, the RO system has become a popular water treatment technology in industry requiring desalination and in residential units to improve the taste of water and to remove unhealthy contaminants. Reverse osmosis has increased the water supply by making possible the use of brackish waters. Recent advances in membrane materials and pretreatment have made RO desalination economically attractive even for seawater. The scale of membrane applications is now very large; plants with capacity in excess of 19 million liters per day (MLD) are common.[22] An RO desalination plant with a capacity of 100 MLD is being developed in Chennai, India.[23]

Reverse osmosis membranes are comparatively more sensitive than thermal desalination processes to scaling, fouling, and chemobiological attacks. The susceptibility to fouling is one of the major shortcomings of the RO membrane. Hence, though RO is an energy-efficient alternative to thermal processes, it still continues to face competition due to the requirements of pretreatment. Pretreatment is important when working with RO and NF membranes due to the nature of their spiral-wound design (Figure 7). Material is engineered in such a fashion as to allow only one-way flow through the system. Since accumulated material can-not be removed from the membrane surface systems, they are highly susceptible to fouling. Therefore, pretreatment is a necessity for any RO or NF system.

Pretreatment has four major components:

- *Screening of solids.* Suspended solids to be removed to prevent fouling of the membranes by fine particles or biological growth to reduce the risk of damage to high- pressure pump components.
- *Cartridge filtration.* String-wound polypropylene filters used to filter particles between 1 and 5 mm.
- *Dosing.* Oxidizing biocides, such as chlorine added to kill bacteria, followed by bisulfite dosing to deactivate the chlorine, which otherwise can destroy a thin-film composite membrane.
- *Prefiltration pH adjustment.* If the pH, hardness, and alkalinity in the feedwater result in a scaling tendency (estimated using the Langelier saturation index), acid is dosed to maintain carbonates in their soluble carbonic acid form. Use of antiscalant is recommended[24] (http://en.wikipedia.org/wiki/Reverse_osmosis - cite_note-8).

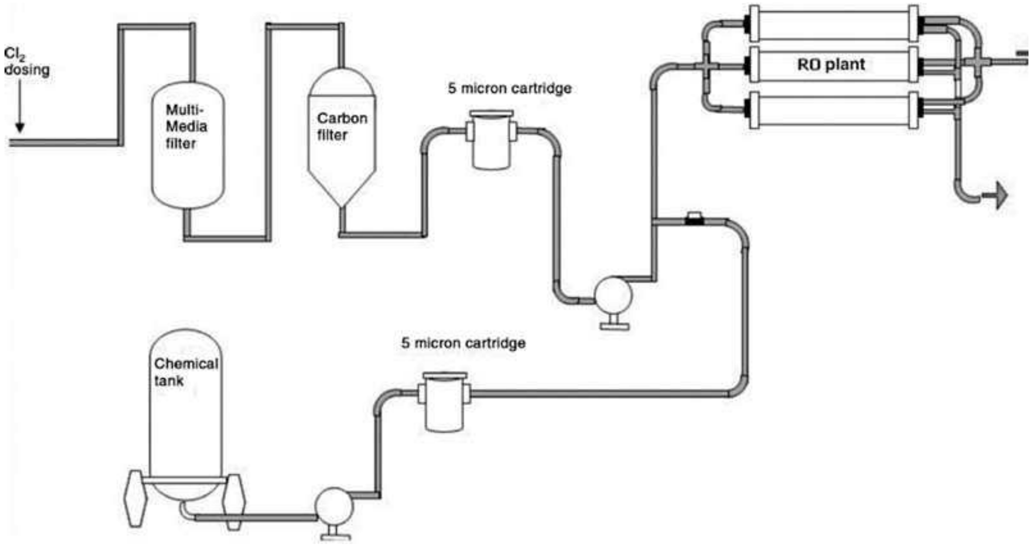

FIGURE 7 Pretreatment for RO system.

Integrated Membrane System

The integrated membrane system (IMS) design approach to water treatment systems has some significant advantages over RO systems designed with conventional pretreatment. The pretreatment of feed water prior to RO is intended to lower the silt density index, remove excessive turbidity or suspended solids, and adjust and control the pH.[25] The choice of IMS system depends on the fouling properties of the feed water, which may necessitate additional (pre)treatment based on the local circumstances. The combination of UF with a precoagulation at low dose helps in controlling the UF membrane fouling and providing filtered water in a steady-state condition.[26] Operation of an RO seawater unit at a higher flux and recovery rate enables optimization of the RO process and reduction of water cost.[27]

Water and Wastewater Purification

Rainwater collected from storm drains can be purified using reverse osmosis. Treated water can be used for landscape irrigation and industrial cooling. It works out to be an acceptable solution to the problem of water shortages. It is also used to purify the effluent and brackish groundwater. The effluent in larger volumes should be treated in an effluent treatment plant first, and then the clear effluent is subjected to reverse osmosis system. The process of reverse osmosis can be used for the production of deionized water. The RO process for water purification does not require thermal energy. Flow through an RO system can be regulated by a high-pressure pump. In 2002, the Singapore government developed NEWater using reverse osmosis to treat domestic wastewater before discharging the NEWater back into the treated water storages.

Eco-Filtration Systems

Zero-electricity systems with comparatively negligible maintenance can be developed using the ecosystem approach. Constructed wetlands, soil scape filters (vertical eco-filtration), green bridge (horizontal eco-filtration), etc., are useful in absorbing the pollutants and rendering them nontoxic through various degradative pathways to such an extent that they become nutrients for various groups of organisms.

Various applications like in situ treatment are evolving to cope with the pollution from nonpoint sources for which there is no economically viable solution in conventional systems.

Constructed Wetlands

Constructed wetlands can either be surface-flow or subsurface-flow and horizontal- or vertical- flow systems.[28] They may include engineered reedbeds and plant beds and belong to the family of phytorestoration and eco-technologies. A high degree of biological improvement takes place due to bioassimilation of pollution. These systems can act as a primary, secondary, and sometimes tertiary treatment. They are known to be highly productive systems as they copy natural wetlands, called the "kidneys of the earth" for their fundamental recycling capacity of the hydrological cycle in the biosphere. Robust and reliable, their treatment capacities improve as time goes by, the opposite of conventional treatment plants whose machinery ages with time. They are being increasingly used, although adequate and experienced designs are more fundamental than for other systems, and space limitation may impede their use (Figure 8).

Soil Biotechnology

Some advancement is being developed by researchers in erstwhile soil-based technologies for odor control in the 20th century. A process called soil biotechnology (SBT), developed in the Indian Institute of Technology in Mumbai, has encouraging results in process efficiency enabling total water reuse, due to extremely low operating power requirements of less than 50 J per kg of treated water.[32] Typically, SBT systems can achieve chemical oxygen demand (COD) levels less than 10 mg/L from sewage input of 400 mg/L COD. Soil biotechnology plants exhibit high reductions in COD values and bacterial counts as a result of the very high microbial densities available in the media. Unlike conventional treatment plants, SBT plants produce insignificant amounts of sludge, precluding the need for sludge disposal areas that are required by other technologies.[29]

Potential and Scope of Eco-Technology

Engineering applications of ecological principles and succession of biological communities are very useful inconsuming organic and inorganic pollutants from the water and bioconverting them into nontoxic form.[30,31] The consortia of organisms at different trophic levels utilize pollutants as nutrients.

FIGURE 8 Flourishing artificial wetland wastewater treatment system (courtesy of SERI, Pune, India).

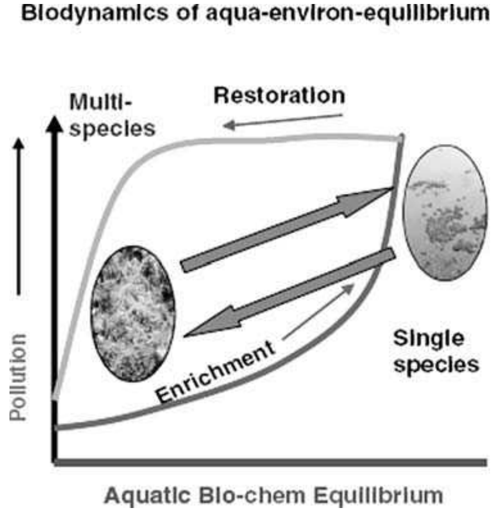

FIGURE 9 Aquatic biochemical equilibrium.

These eco-transformations, eco-conversions, and degradation or bioutilization of pollutants to nutrients are part of ecological and biogeochemical cycles. An attempt has been made to apply natural flora and fauna in a well-designed manner to develop technologies like Green Bridge, Green Lake Eco-Systems, Green Channel, BIOX (Biological Oxidation) and Stream Eco-Systems.

Many growing cities need cost-effective and less energy-intensive treatment methodology to control their pollution emanating from point and nonpoint sources. The eco-technological treatment systems, vertical filtration systems for point sources, and horizontal filtration systems promise results with minimal electricity as compared with conventional aerobic or anaerobic treatment systems.

Eco-filtration (vertical and horizontal) systems are based on the principle of living systems in action for pollution treatment. Efficiency of treatment is dependent on expression of multispecies intelligence—adaptability of organisms to changing environmental conditions while continuing the degradation or conversion of pollutants into utilizable form. When changes occur in the natural systems due to external inputs, biogeochemical cycles and food chains are reorganized and balanced. A new dynamic order emerges in the eco-filtration systems suitable to the environmental changes superimposing on it (Figure 9).

Detritus-feeding organisms in the eco-filtration systems consume the pollutants and wastes (biodegradation products) generated from this process and are useful for green plants. Secondly, the green plants absorb carbon dioxide from the atmosphere and produce oxygen, which is transferred to the eco-reactor in the rootzone area. Thus, the pollutants are transferred to natural cycles, i.e., biogeochemical cycles, and carbon gets stored in vegetation and subsequently in the soil. Plants store carbon in the form of live biomass. Once plants die, the biomass becomes a part of the food chain again and eventually enters the soil as soil carbon. This is a natural process that does not need electricity at all or any chemical for coagulation or activated carbon for adsorption. This makes the eco-filtration system very economical and routine operations very simple.

Soil Scape Filter

This is the simulation of natural filtration of wastewater through the ecofert—mixed cultures and fragmented rock materials. A soil scape filter contains layers of bioactive (i.e., biologically activated) organic material—bacterial mixtures derived from nontoxic and nonhazardous materials. This vertical

FIGURE 10 Sewage treatment using soil scape filter (courtesy of SERI, Pune, India).

eco-filtration process harnesses the ecological principles of interactions and interrelationships of biota with their environment and eco-transformations of substrates into assimilable form by treating, transforming, and detoxifying the pollutants using solar energy[33] (Figure 10).

Green Bridge Technology

Green Bridge technology uses filtration power of biologically originated cellulosic/fibrous material in combination with sand, gravels, root systems of green plants, and microorganisms.[34] It is an innovative approach to minimize the cost of pollution treatment when the cellulosic/ fibrous materials like coconut coir, dried water hyacinth, or aquatic grasses are compacted and woven to form a bridge/porous wall-like structure strengthened by stones and sand (Figure 11). All the floatable and suspended solids are trapped in this biological bridge, and the turbidity of flowing water is reduced substantially. The green plants growing there help in absorption of soluble substances, including heavy metals.

Other Emerging Filtration Techniques

Disc Filters

With disc filters, the divergence in woven filtration media and flow pattern makes each application unique. Both inside-out and outside-in configurations perform to expectations, considering that these devices have been marketed for the relatively clean waters of municipal tertiary applications. Inside-out technique provides better sustainability and life cycle cost. One major drawback of these systems is the biological growth that occurs on the inside face (the filtrate side) of the filter cloth. It is common with unchlorinated filter feed/secondary effluents. Another problem of these systems is the need to shut down the process in order to accomplish the washing of cloth/filtering medium. These negative aspects result in lengthy rinsing schedule, sizeable washwater volumes, and redundancy requirements to ensure continuous wastewater treatment.

FIGURE 11 Green Bridge installation for ecological restoration of Ahar River of Udaipur, India (courtesy of SERI, Pune, India).

Pleated Filtration Panel innovation

Inside-out and outside-in techniques rely on filtration media configured in a flat panel design. The effective filtration area is therefore the available area that is perpendicular to the direction of flow and should not account for any impervious surfaces of supporting structures such as frames, panel boxes, and metal works.

The disc filter with inside-out configuration brings a pleated design to the filtration panels, increasing the effective filtration area by 40% over flat panel designs. This also augments the overall strength of the filtration panel, allowing higher operating headloss. The pleated configuration makes the filtration panel less prone to deformities of the cloth media. Combination of higher filtration surface area and depth of the disc filter leads to high throughput capacity. The internal assembly of the disc/drum has a sliding cover of stainless steel for ease of inspection and maintenance. This is beneficial during installations in any weather conditions.

Conclusion

Technology can be related on the basis of—type of solids—colloidal or dissolved—chemical or biological species—capital and operational costs. Various types of sand filters are useful in treating surface or subsurface waters for drinking purposes. They can be supplemented with GAC or membrane filtrations to yield high-quality water required for industrial processes and production. Trickling filters, biofilters, and eco-technological filters have applications in treating domestic wastewaters before being discharged into the receiving water bodies or for land irrigation. These wastewater filters can be used as polishing systems also to improve the quality of secondarily treated water by reducing the expenditures on tertiary treatment. Eco-technological filters are found to be useful in treating industrial wastewaters by reducing the ecological toxicity of polluted waters. Disc filters or pleated filters are in the development stage. All these filters can be selected to treat waters or wastewaters depending on their source, the desired quality of treated water, land availability, electricity, skilled manpower requirements, etc.

Wetlands: Constructed Subsurface

Jan Vymazal

Introduction

Constructed wetlands (CWs) with subsurface flow have been used to treat various types of wastewater for more than four decades.[1] In general, there are two types of CWs with subsurface flow: horizontal flow (HF) and vertical flow (VF).[2–4]

In HF CWs, the wastewater is continuously fed in at the inlet and flows slowly through the porous medium under the surface of the porous filtration material planted with emergent vegetation to the outlet where it is collected before leaving via a water level control structure.[4,5] As a consequence of the continuous saturation, the majority of the processes responsible for pollutant removal are either anoxic or anaerobic.[3] VF CWs are fed intermittently on the wetland surface. Wastewater then percolates down through the bed and is collected by a drainage network at the bottom. The bed drains completely and that allows air to refill the bed. Thus, VF CWs provide greater oxygen transfer into the bed, thus allowing for aerobic processes, such as nitrification, to occur.[4]

Horizontal and vertical CWs could be combined in several stages in so-called hybrid systems. These systems use the advantages of both types of systems to enhance removal of pollution, especially nitrogen. Hybrid systems may comprise various types of CWs but the combination of VF and HF CWs is the most common.[6]

During the 1980s and the early 1990s, the CWs with subsurface flow were used primarily in Europe for treatment of municipal or domestic wastewater.[7] During the late 1990s and 2000s, subsurface flow CWs spread throughout the world and were used to treat also various industrial and agricultural effluents, landfill leachate, and various stormwater runoff waters.[2,3]

Technology Background

HF Systems

Horizontal subsurface flow CWs are lined trenches or beds about 0.8 m deep, filled with porous materials such as pea gravel (Figure 1) and planted with wetland emergent macrophytes. The filtration material should be coarse enough to sustain subsurface flow. In the early systems designed by Seidel, coarse sand was proposed as filtration material.[8] The later concept proposed by Kickuth[9] used heavy cohesive soils that provided high level of treatment but failed to sustain subsurface flow due to clogging problems.[10] Based on the experience in the United Kingdom in the late 1980s,[4] the HF CWs have used gravel since then, usually with size fraction between 5 and 20 mm. During passage through the filtration material, the wastewater comes into contact with a network of aerobic, anoxic, and anaerobic zones. Most of the bed is anoxic/anaerobic due to permanent saturation of the beds. The aerobic zones occur around roots and rhizomes that leak oxygen into the substrate.[4,5]

The macrophytes growing in CWs have several properties in relation to the treatment process that make them an essential component of the design.[11] The macrophytes, among other functions, provide oxygen to the rhizosphere through the radial oxygen loss,[12] insulate filtration bed during winter periods,[13] provide substrate for the growth of attached bacteria,[14] can contribute to nutrient removal when harvested,[3,15] and exudate various antimicrobial compounds.[16] Therefore, they should 1) be tolerant of high organic and nutrient loadings; 2) have rich belowground organs (i.e., roots and rhizomes) in order to provide substrate for attached bacteria and oxygenation (even very limited) of areas adjacent

FIGURE 1 Constructed wetlands with horizontal subsurface flow. Left: filtration bed sealed with plastic liner, right: filtration bed filled with crushed rock with inflow and outflow zones filled with stones.
Source: Photos courtesy of Jan Vymazal.

to roots and rhizomes; and 3) have high aboveground biomass for winter insulation in cold and temperate regions and nutrient removal via harvesting.[17,18] The most frequently used plant for HF CWs is Common reed (***Phragmites australis***) (Figure 2).[3]

A large number of wetland systems have shown an exponential decrease of pollutant concentration level with the distance through the wetland from inlet to outlet. The observation is consistent with a first-order removal model, with the removal rate being proportional to the pollutant concentration. The removal can thus empirically be described with first-order plug-flow kinetics:[2,4,19]

$$\left(\ln C_{\mathrm{i}} - \ln C_{\mathrm{o}}\right) = A\ k_A / Q \tag{1}$$

$$C_{\mathrm{o}} = C_{\mathrm{i}}\ \exp^{(-A\ k\mathrm{A}/Q)} \tag{2}$$

or for the *k*-*C** model:[20]

$$\ln\left[\left(C_{\mathrm{i}} - C^{*}\right) / C_{\mathrm{o}} - C^{*}\right)\right] = A\ k_{\mathrm{A}} / Q \tag{3}$$

where

A = area of the bed (m^2)
Q = average flow rate (m^3 day^{-1})
C_{i} = inflow concentration of the pollutant (mg L^{-1})
C_{o} = outflow concentration of the pollutant (mg L^{-1})
k_{A} = first-order areal rate constant (m day^{-1})
C* = background concentration of a pollutant (mg L–1),

which is a concentration caused by an internal release of particulate and dissolved biomass to the water.[20]

As BOD (biochemical oxygen demand) was the primary target, the value of first-order areal rate constant k_{A} used for the design was k_{BOD}. The formerly proposed value of 0.19 m day^{-1} by Kickuth[9,19] resulted in too small area of the bed and consequently lower treatment effect. The extensive field measurements in Denmark in the mid-1980s found the average $\mathrm{k}_{\mathrm{BOD}}$ value of 0.083 ± 0.017 m day^{-1}.[21] Cooper et al.[4] reported values between 0.067 and 0.1 m day^{-1} in the United Kingdom and Vymazal and Kröpfelová[3] reported an average k_{BOD} value of 0.087 m day^{-1} for 31 systems in the Czech Republic. This generally

TABLE 1 First-Order Areal Rate Constant kA (m day–1) for Total Suspended Solids (TSS), Total Phosphorus (TP), Total Nitrogen (TN) and Ammonia-Nitrogen (NH4-N) Reported by Various Authors in the Literature

Reference	TSS	TP	TN	NH4-N
[3]	0.085	0.026	0.025	0.024
[10]		0.025	0.033	
[22]	2.74	0.033	0.074	0.093

means that the value of A is about 5 m^2 per one population equivalent (PE) for mechanically pretreated municipal or domestic wastewater. However, HF CWs may be designed with other target parameters than BOD$_5$ and therefore appropriate constants were developed for other pollutants as well (Table 1). When a CW is designed with more target parameters at the same time, e.g., BOD5, TSS, nitrogen, and phosphorus, then it is necessary to select the largest area according to all four calculations.

At present, the state-of-the-art *k-C** model seems to be best available design tool if the designer makes sure that all the assumptions are fulfilled and if he or she is aware of many pitfalls in the model.[22] One of the most important uncertainties comes from the fact that background concentrations inevitably change over the operation period as the system matures. In addition, Stein et al.[23] suggested that C^* is temperature dependent. Kadlec and Knight[20] suggested C^* values (in mg L^{-1}) for BOD$_5$ ($3.5+0.053C_i$), TSS ($7.8+0.063C_i$), TP (0.02), and TN (1.5).

Recently, the so-called *P-k-C** model has been developed:[2]

$$\left(C_o - C^*\right)/\left(C_i - C^*\right) = 1/\left(1 + k_A/Pq\right)^P \tag{4}$$

where

k_A = modified first-order areal constant (m day^{-1})
P = apparent number of TIS (tanks in series)
q = hydraulic loading rate (HLR) (cm day–1)

In HF CWS, pollution is removed through a complex of aerobic, anoxic, and anaerobic processes that occur simultaneously in the filtration bed with aerobic processes being restricted only to the thin area adjacent to macrophyte roots.[3,24,25] The treatment efficiency of HF CWs has recently been thoroughly evaluated by Vymazal and Kröpfelová.[3] Organic compounds are removed primarily by microbial processes; particulate and colloid organics may be filtered out through the wastewater passage through the bed. Suspended solids are removed in HF CWs via filtration and sedimentation. Systems that have been designed with a specific area of about 5 m^2 PE^{-1} have usually very high treatment efficiency for organics and suspended solids. The removal efficiency in most cases equals the efficiency of conventional treatment systems. However, contrary to conventional treatment systems, e.g., activated sludge systems, HF CWs can handle wastewaters with very low concentrations of organics such as wastewaters from combined sewer systems.[26,27]

Removal of nitrogen is usually low due to lack of oxygen in filtration bed, which limits nitrification of ammonia-nitrogen.[28] On the other hand, HF CWs provide suitable conditions for denitrification due to anoxic/anaerobic conditions in the filtration beds. Plant uptake is responsible for removal of only small part of the inflow nitrogen loading and usually does not exceed 10% of the inflow.[29,30] For municipal sewage, the removal of ammonia-N usually varies between 20% and 40%.[3]

HF CWs are seldom built with phosphorus being the primary target of the treatment, and therefore, materials with relatively low sorption capacity but high hydraulic conductivity such as river gravel or crushed rock are commonly used.[3] In this case, removal efficiency for municipal sewage is usually between 20% and 50%. In order to achieve high phosphorus removal, it is necessary to select materials with high P adsorption capacity. Such materials may include minerals with reactive Fe or Al hydroxide or oxide groups on their surfaces, or calcareous materials that can promote precipitation of Ca-phosphate,[31–33] lightweight aggregates,[34] industrial by-products and waste products such as electric arc furnace steel slags[35,36] or fly ash.[31] By using materials with high sorption capacity, the phosphorus removal efficiency may exceed 90%, but it is necessary to keep in mind that the sorption capacity is always limited and the material will have to be replaced in the future in order to keep a high rate of P removal.

Microbial pollution is removed through a complex of physical, chemical, and biological factors, which all participate in the reduction of the number of bacteria of anthropogenic origin. Physical factors include mechanical filtration, straining, adsorption, and sedimentation. Chemical factors include oxidation, exposure to biocides excreted by some plants, and adsorption to organic matter; biological removal factors include antibiosis, predation by nematodes, protozoa and zooplankton, attack by lytic bacteria and viruses, and natural die-off.[3,37–40]

One of the major threats for the long-run treatment performance of HF CWs is clogging and subsequent surface flow[41,42] and therefore efficient mechanical pretreatment should always be installed before the wastewater enters the filtration beds. For small systems, septic tank is usually used; for larger systems, Imhoff tank is suitable. In case of combined sewer systems, i.e., systems where wastewater is mixed with stormwater runoff, grit chamber should be included (Figure 3).

VF Systems

The earliest form of VF CW is that of Seidel in Germany in the 1960s where vertical filters were used to oxygenate anaerobic septic tank effluents.[43] Interest in the particular process seemed to wane, but it has been revived in the 1990s because of the need to produce beds that nitrify.[4]

FIGURE 3 Mechanical pretreatment: screens and horizontal grit chamber. (**Source:** Photo courtesy of Jan Vymazal).

VF CWs comprise a flat bed of sand or graded gravel planted with macrophytes (Figure 4). Contrary to HF CWs, vertical systems are fed intermittently with large batches on the bed surface. The distribution system should allow for even wastewater distribution across the bed (Figure 5). The intermittent feeding creates conditions where the filter completely drains, thus enabling oxygen to diffuse into the bed. On the other hand, VF CWs do not provide suitable conditions for denitrification to complete conversion to gaseous nitrogen forms that escape to the atmosphere. The major purpose of macrophyte presence in VF CWs is to help maintain the hydraulic conductivity of the bed.[4]

The early VF systems have usually been composed of several stages with two to four beds in the first stage that were fed with wastewater in rotation. Such VF systems are now called first-generation VF systems.[44] The early VF systems were frequently the first stage of the hybrid systems.[45,46] Recently, VF systems with only one bed have been used. These systems are called second-generation VF CWs or compact VF beds.[47,48]

FIGURE 5 Vertical flow CWs at Saint Thomé, France. (**Source:** Photo courtesy of Jan Vymazal).

VF CWs require pretreatment in order to prevent clogging, but in France, hundreds of systems are fed directly with raw sewage onto the first stage, allowing for easier sludge management in comparison to dealing with primary sludge from an Imhoff tank.[49,50] While compact VF systems are usually small, VF systems treating raw sewage in France are often much larger. The calculation of VF bed area has evolved in years, but at present, the area varies between 2 m^2 PE^{-1} (split into 1.2 m^2 and 0.8 m^2 for the first and second stage, respectively) in France[49] and 4 m^2 PE^{-1} in Austria and Germany.[51–53] Danish design recommendations are set for 4 m^2 PE^{-1}.[54] One of the major threats of good performance of VF systems is clogging of the filtration substrate,[55,56] and therefore, it is important to properly select the filtration material and the HLR and distribute the water evenly across the bed surface. HLRs reported in the literature vary greatly between about 3 cm day^{-1} up to 150 cm day^{-1},[47,57] but to avoid flooding due to clogging, HLRs should probably be kept below 80 cm day^{-1}.[58]

VF CWs provide high removal of organics and suspended solids and are also effective in removing ammonia- N. However, they have very limited capacity to denitrify; therefore, the removal of total nitrogen is about the same as for HF CWs. Removal of phosphorus is also within the same range as for HF CWs unless special media with high sorption capacity are used.[3]

Hybrid Systems

Various types of CWs may be combined in order to achieve higher removal efficiency, especially for nitrogen. Many of these systems are derived from original hybrid systems developed by Seidel at the Max Planck Institute in Krefeld, Germany.[43] The design consists of two stages, several parallel VF beds followed by two or three HF beds in series. The VF wetland is intended to remove organics and suspended solids and to provide nitrification, while in the HF wetland, denitrification and further removal of organics and suspended solids occur.

In the early 1980s, several hybrid systems of Seidel's type were built in France with the systems at Saint Bohaire and Frolois being the best described.[59] A similar system was built in 1987 in the United Kingdom at Oaklands Park,[60] and in the 1990s and the early 2000s, VF–HF systems were built in many countries such as Norway,[61] Ireland,[62] Estonia,[63] or Thailand.[64]

In the mid-1990s, Brix and Johansen[65] introduced a HF–VF hybrid system with a large HF bed placed first and a small VF bed as the second stage. In the first bed, removal of organics and suspended solids takes place while nitrification takes place in the second VF wetland. In order to remove nitrate produced during nitrification, the water have to be recirculated to the front end of the system where denitrification can take place in the less aerobic HF bed using the raw feed as a source of carbon needed for denitrification.[65] The hybrid systems of this type have been reported from other European countries,[66,67] North America,[68] or Asia.[69]

Use for Various Types of Wastewater

Subsurface flow CWs have predominantly been used to treat municipal (secondary as well as tertiary treatment) or domestic wastewater.[1–4] However, recently, they have been used to treat a variety of wastewaters including industrial and agricultural effluents, landfill leachate, or stormwater runoff (Table 2).

When organics and suspended solids are the primary target of the treatment, the HF CWs are usually used. These systems perform effectively and the operation and maintenance costs are very low as compared to conventional treatment systems. When removal of ammonia is required, VF CWs are more effective. These systems usually require electricity, but despite that, the operation and maintenance costs are still relatively low. However, to remove both ammonia- and nitrateN, hybrid CWs provide a suitable and effective option. Hybrid CWs are also often used to treat more complex wastewaters (Table 2).

TABLE 2 Examples of the Use of Subsurface CWs for Various Types of Wastewater

Type of Wastewater	Location	Type of CWs	Reference

Conclusions

Constructed treatment wetlands have evolved during the last five decades into a reliable treatment technology applicable to all types of wastewater including sewage, industrial and agricultural wastewaters, landfill leachate, and stormwater runoff. The subsurface CW technology started in Germany but spread quickly to all continents. At present, subsurface constructed treatment wetlands provide a viable alternative to conventional treatment systems.

The subsurface technology has substantially improved over the years, but there are still gaps that need to be solved. Among others, the low-cost filtration medium that provides high removal of phosphorus is still to be determined, and the problem of system longevity and filtration material replacement or cleaning are under investigation. Recently, also more attention has been paid to dual-purpose or multipurpose services of constructed treatment wetlands such as flood control, carbon sequestration, or wildlife habitat. Another gap where a lot of work has been done recently is the modeling of HF CWs.[106]

Wetlands: Sedimentation and Ecological Engineering

Timothy C. Granata
and J.F. Martin

Problems of Sedimentation in Wetlands

Sediment Accretion

The accretion of particulate material in wetlands limits the lifetime of these systems, advancing their succession to a terrestrial ecosystem as a function of sedimentation rates. Three sources of particulate material can be identified: suspended particles derived from the inflow, production of microbial particles in the wetland, and the production of detritus from macrovegetation. The latter two increase with increased primary production in wetlands. The former is a function of hydraulic loading, defined as the flow, Q, per unit area of wetland, A, i.e., QA^{-1}. Natural wetlands are prominent components of riparian ecosystems that exist either as floodplains, receiving periodic submersion, or as part of the riparian corridor, receiving continuous, though varying, inflow. In both cases, flow transports suspended sediments to wetlands. Suspended material is often deposited as current velocities decrease in broad, shallow expanses of wetlands. Sediment transport is a function of total flow (and thus rainfall intensity) in a watershed but also depends on the slope of the landscape and the susceptibility of soils to erosion. Steep slopes with highly unconsolidated soils will contribute to large suspended sediment loads during high runoff events. For low-flow events suspended sediment concentrations do not exceed 20 mg/L while for high flows they can exceed 80 mg/L.[1] In extreme cases of accretion, sedimentation rates of 26.67 cm/yr can bury emergent grasses because sediment accumulation outpaces plant growth.[2] In contrast, constructed wetlands are designed to treat wastewater having steady and high suspended solid concentrations, ranging from 20 to 75 mg/L, and volumetric ratios of settable solids from 5 to 20 mL/L.[3]

Reduced Conductivity of the Bed

Wetlands can experience reduced infiltration rates as particulate matter clogs bottom substrates. Generally, a reduction of hydraulic conductivity occurs with increasing hydraulic loading to the wetland. As a consequence of lower current velocities and higher sedimentation rates with increasing distance from the inlet, the hydraulic conductivity is lowest near the inlet and highest near the outlet. A general design criterion for wetlands is a hydraulic conductivity 1500 m/ day based on bed of 1.25–2.5 cm diameter gravel.[4]

Phosphorus Accumulation

The accretion of organic material on the bed results in wetlands with a high ion exchange capacity. The beds are partially responsible for removal of phosphates by sorption until they become saturated. The movement of phosphorus through the bed is slower than the hydraulic conductivity as a result of the storage (exchange) capacity of the bed.[5] Plant uptake of phosphates is limited because a reduced hydraulic conductivity decreases infiltration and thus transport of phosphates to plant roots.[6] A more consistent process for phosphate removal is by adsorption onto suspended sediments and their subsequent deposition.[7] Phosphorus (P) loading is directly proportional to suspended sediment concentrations and hydraulic loading. It is estimated that 40 mg P accompanies each gram of suspended solids entering wetlands.[1] Higher loading rates occur for flows over landscapes rich in P, such as agricultural lands. During periods of inundation, wetlands are characterized by aerobic and anaerobic soil zones. In anaerobic zones the decreased redox potential leads to an increase in the solubility of particulate phosphorus, which may be discharged from the wetlands. This dynamic feedback between removal of P by sedimentation and release of P after particulate accretion often leads to variable retention of P by wetlands. Despite mineralization of particulate P, wetlands are generally sinks for P, with removal as high as 97%.[8] The retention of P, however, decreases as P loading increases[9] and often decreases through the life of the wetland.[10]

Particle Types and Sedimentation Processes in Wetlands

The size distribution of particles in a wetland varies from nanometer-sized colloidal material through micrometer phytoplankton and heterotrophic organisms to millimeter- and centimeter-sized leaf detritus and sediments. For discrete particles, settling results from the force balance between particle weight (F_w) and drag on the particle such that

$$F_w = F_D = \rho C_D A_{pr} \frac{w^2}{2} = \left(\rho_p - \rho\right) V_g \tag{1}$$

where C_D is the drag coefficient on a 2D surface, A_{pr} is the projected area of the particle, w is the settling speed, ρ_p and ρ are the particle and water densities, respectively, V is the volume of the particle, and g is the gravitational acceleration (9.8 m/sec^2). Solving for settling rate, w, gives

$$w = \sqrt{2 \frac{\left(\rho_p - \rho\right) V_g}{\rho A_{pr} C_D}} \tag{2}$$

Thus, the settling rate of a particle is proportional to the excess density of the particles over that of water and the length scale of the particle defined by VA_{pr}^{-1}. Providing flow is not turbulent, specified as a Reynolds number Re <0.1, and particle shape is unimportant to the drag; C_D can be approximated as

$$C_D = \frac{24}{\mathrm{Re}} = \frac{24\nu}{2Rw} \tag{3}$$

where R is the radius of the particle. Assuming a spherical particle, the above equation reduces to

$$w = \frac{2\rho' g R^2}{9\nu} \tag{4}$$

the celebrated Stokes' Law for sinking particles. Here the excess density is written as

$$\rho' = \frac{\rho_p - \rho}{\rho} \tag{5}$$

For biological material, excess density is less than 0.1%, and size is the determining factor. For this reason small microbial organisms will sink slower than larger detrital material. The excess density of suspended sediments can reach 260%, indicating that the density is responsible for the high settling rates of suspended sediments.

Sedimentation in a wetland will occur if the settling speed is greater than the surface loading rate per area of wetland, or $w > QA^{-1}$. Given the large spectrum of particle types in natural flows, w is usually calculated based on the size and density of the particle type to be removed. Dividing the depth by the sinking rate gives the retention time in the wetland. Particles that are vertically well mixed as they enter a wetland will have a uniform concentration distribution comprised of the spectrum of particle sizes. If the settling rate of the particle, w_p, is greater than w, the particle will be deposited in the wetland cell. For particles with $w_p < w$, the fraction of particles that will be removed is X_p. Thus, the total particle removal by a wetland can be calculated as

$$\text{FR} = (1 - X_c) + QA^{-1} \sum X_r \Delta x \tag{6}$$

where $1–X_c$ is the fraction of particles removed with sinking speeds $w_p > w$ and $QA^{-1}\Sigma X_r \Delta x$ is the fraction with a settling speed $w_p < w$ that are removed over a distance Δx, along the path of the flow.[3] The crucial step in determining the sedimentation rate in wetlands is first determining the settling rate of each concentration fraction, either by settling columns or size-concentration measurements.

Often aggregations of particles form in wetlands,[11] a process called flocculation. Sedimentation rates of aggregates are dominated by organic particles of fractal dimension.[12] Aggregates tend to settle faster than their discrete component particles, and the only way to determine removal rate is by carefully transferring flocs to a settling column and determining the percent removal as a function of the height of the column and time.[3]

In wetlands with a high concentration of suspended solids, settling is affected by the contact between particles. This would occur in the bottom sediments of most wetlands where two settling processes can be identified: hindered and compression settling.[3] The hindered zone is marked by a large gradation in particle concentrations, which is less than the total concentrated in the compression zone. By plotting the concentration of particles over the height of a settling column as a function of time, a break point can be found in the time from hindered settling to compression settling.[3]

Because large, heavy particles settle out first, the highest sedimentation rates in wetlands are near the inlets. As mentioned above, the hydraulic conductivity through the bottom sediment decreases as clogging occurs. Because clogging is also a function of distance from the inlet, the most accurate estimate of the hydraulic conductivity is to measure the change in water surface elevation with increasing distance from the inlet. However, as Kadlec and Watson[11] show, this is not a simple function of Darcy's Law but must include evapotranspiration in the wetland. For newly constructed wetlands, the hydraulic conductivity of the bottom substrate (gravel, sand, and mud) cannot be used because clogging will result from sediment accretion.[4]

Ecological Engineering Solutions to Sedimentation

To keep suspended particles entrained by flows from accruing in wetlands and clogging bottom sediments, one or more settling basins can be included between the inlet channel and the wetland cell. This would have two effects: first, to collect all but the finest and least dense suspended particles and, second, to remove phosphorus from the inflow.

To overcome the problem of detrital accumulation in wetlands, woody plants could be substituted for grasses and periodically harvested. This would not only reduce the amount of biomass accrued in the wetland but would also increase the efficiency of nutrient uptake in the unclogged root zone and provide a potentially marketable resource. Because phytoplankton are the most abundant nutrient filters in a wetland and have intrinsically low sinking rates, a wetland could be designed with low retention of suspended plankton to further reduce sedimentation while improving nutrient removal. A settling basin could then be sized to accumulate these nutrient-rich particles for harvesting before nutrients are remineralized. To keep flocs of particles from forming in wetlands, cells could be mixed with aerators or inlet pumps. This would break up flocs, which would be exported as discrete particles.

Conclusions

Because wetlands are always shallow to promote macrophtye growth, they essentially act as flat plate collectors of sinking particles. The dominant particles in wetlands are suspended particles in the inflow and biomass of vegetation resulting from growth in the wetlands. The processes of sedimentation can reduce a wetland's storage capacity, its efficiency to retain nutrients, and its lifetime. Future efforts should be aimed at enhancing nutrient removal while reducing sedimentation. This can be done with engineered structures, such as settling basins and grit chambers, or by less costly technologies such as stilling wells. More innovative green solutions are on the horizon.

Wetlands: Treatment System Use

Constructed vs. Natural Wetlands

Kyle R. Mankin

How Do Wetlands Work?

Wetlands can be used to treat wastewater because they process contaminants. However, they treat wastewater more slowly than traditional treatment plants. Oxygen, and the manipulation of oxygen levels, is a primary concern for wastewater treatment because many of the necessary biological and chemical treatment processes require oxygen. Traditional treatment plants can easily manipulate oxygen levels by pumping air into the wastewater. Oxygen enters wetlands by slower, natural processes. Increasing oxygen concentration, by increasing wastewater contact with air, plant roots, or photosynthetic algae, often can enhance the processing ability of wetlands.

When considering wastewater treatment by constructed wetlands, five contaminant groups are of primary importance: sediments, organic matter, nutrients, pathogenic microbes, and metals. Wetlands slow down water movement, allowing sediments to settle out of the water. Organic matter can be processed, or decomposed, by highly competitive microbes. Less competitive microbes called nitrifiers process nitrogen. Both microbe types require oxygen. Because the nitrifiers are less competitive, oxygen levels become very important to insure that both organic matter and nitrogen are fully processed. The other two, pathogenic microbes and metals, are more situational, related to the specific waste being treated. Wetlands treat pathogenic microbes by detaining them until they naturally die off, are eaten by other predatory organisms in the wetland, or are exposed to UV radiation near the water surface. Metals are processed by being adsorbed to other particles and settling out of the water.

The remainder of this entry further explains wetland processes and design considerations. References are provided for more in-depth information.

Treatment Wetland Types

Constructed vs. Natural Wetlands

Wetlands constructed as treatment systems differ from natural wetlands in several important ways. Constructed wetlands usually are built with uniform depths and shapes designed to provide consistent detention times and maximize contaminant removal. In contrast, natural wetlands are irregular in depth and shape, which causes irregular flow, allows water to by-pass the shallow treatment zones by moving through the deeper channels, and leads to less effective treatment. In addition, water-quality regulations in the United States dictate that if a natural wetland is associated with an existing water body of the United States, as most are, wastewater discharges into the wetland must meet specific quality standards, similar to other water bodies. Wetlands constructed as wastewater treatment systems typically are located in uplands where wetlands did not exist before and are not subject to inflow water-quality regulations. Natural wetlands are *not* recommended for use as treatment wetlands.

Constructed wetlands increasingly are being used for wastewater treatment in a variety of applications (Table 1). Examples can be found of wetlands being used to treat municipal sewage, urban runoff, onsite residential wastewater, animal feedlot and barnyard runoff, cropland runoff, industrial wastewater, mine drainage, and landfill leachate. Each application takes advantage of a combination of physical, chemical, and biological processes characteristic of natural wetlands to reduce the concentration of contaminants in water. Such contaminants include sediments, organic materials, nutrients (particularly nitrogen and phosphorus), metals, microbial pathogens, and pesticides.

Free-Water vs. Submerged-Bed Wetlands

Constructed wetlands have two common types. Free-water surface (FWS) wetlands (also called surface-flow wetlands) have plants that grow in a shallow layer of water over a soil substrate (Figures 1 and 2). The location of the plants in the system can vary: the plants can float on the water surface with their roots suspended in the water (free-floating macrophyte systems); they can be rooted in the soil with the

entire leaves and stems below the water surface (submerged-macrophyte systems); they can be rooted in the soil having leaves and stems that rise above the water surface (emergent macrophyte systems); or the wetland may use a combination of planted and open-water zones. About two-thirds of existing wetlands as of 1994 were FWS.[1] In vegetated submergedbed (VSB) wetlands (also called subsurface flow wetlands or rock-plant filters), plants are rooted in a porous media, such as sand or gravel, and water flows through the media in either horizontal or vertical direction (Figures. 3 and 4). About one-quarter of treatment wetlands were VSB systems.[1] However, these systems are currently used in thousands of smaller-scale, onsite residential applications in the United States that do not appear in this database.

Treatment Processes

Many wastewaters entering constructed wetlands must be pretreated to avoid excessive contaminant loading, particularly of mineral and organic solids. Pretreatment technologies include septic tanks for onsite systems or anaerobic lagoons for animal waste, municipal, or mine-drainage treatment systems. In each case, the anaerobic condition in the pretreatment process reduces production of additional algae solids. Typical contaminant levels entering treatment wetlands are summarized in Table 2.

The wetland type impacts the processes used to retain or remove contaminants. In a VSB system, wastewater flows through pore spaces of the media and comes into direct contact with the roots of plants. In a FWS system, water flows across the media surface and contacts plant stems and leaves. In either system, solid particles, including sediments (clay and silt particles and colloids) and organic matter (manure particles, organic residues, and algae or other phytoplankton), settle out of the water column or are trapped or filtered as water passes through a wetland. Contaminants that are adsorbed

Landfill leachate[4]	312–729	241–7840	287–670	254–2074	0–3	0.9	

Note: BOD5 = 5-day biochemical oxygen demand, TSS = total suspended solids, TN = total nitrogen, NH4-N = ammonium nitrogen, NO3-N = nitrate nitrogen, TP = total phosphorus, FC = fecal coliform bacteria. FWS wetlands

to sediments (e.g., P, NH4, fecal bacteria) or absorbed within organic solids (e.g., nutrients) are also removed. However, these constituents can be re-suspended or desorbed back into the wetland water. This natural cycling of materials is an important function of wetlands, although it makes system design and interpretation of treatment complex.

Once entrapped, organic materials and associated contaminants are decomposed in wetlands by microbial and chemical transformations. In the degradation process, microbes use oxygen. The amount of oxygen used is related to the amount of organic material in the water. The controlled measurement of biochemical oxygen demand (BOD) is a common way to illustrate the amount of organic matter in water. When wastewater lacks oxygen, or is anaerobic, it requires the addition of oxygen to degrade organic matter. Oxygen is also required for transformation of ammonium to nitrite and nitrate (nitrification), whereas anaerobic conditions are required for transformation of nitrate to nitrogen gas (denitrification). Aerobic wetland conditions often remove metals by aerobic oxidation of iron; subsequently iron hydroxides and other metals precipitate in the wetland.[5] Although some oxygen diffuses into a wetland from the air, a common assumption is that oxygen also is transported through wetland plants and made available to microbes in close proximity to leaky roots.[6] This mechanism may be less important than once thought, though.[2] Treatment wetlands are thought to function effectively because they combine anaerobic zones in the water column with aerobic zones near the water interfaces with air and roots. However, because the microbes that break down organic carbon can out compete nitrifiers for oxygen, nitrogen removal in higher strength wastewaters is often low.

Design Considerations

Design and resulting effectiveness of constructed wetlands (Table 3) depend upon many factors: climate (precipitation, temperature, growing season, evapotranspiration), wastewater characteristics (constituents, loading, flow rate, and volume), topography, and wildlife activity. Wetland designs must specify total area; the number, depth, and size of wetland cells; hydraulic retention times; vegetation types and coverage; inlet and outlet configuration and location; and internal flow patterns.[2] Details for design can be found in numerous references[2,7–11] and some elements are discussed here.

VSB Wetlands

Properly designed VSB systems can achieve high removal rates. Treatment in a VSB wetland is governed by system residence time and wastewater contact with media and plant-root surfaces. Because of this, depth is a critical dimension and is often chosen according to the rooting depth of the selected plant (e.g., cattails: 30 cm; reeds: 40 cm; bulrush: 60 cm). Once depth is chosen, crosssectional area (and thus wetland width) is selected to assure adequate flow rates. Then, volume (and thus wetland length) is determined from the retention time needed to treat the wastewater to the desired quality. Proper design of inlet and outlet control structures helps maintain uniform flow patterns and depth, avoids problems with clogging and freezing, and minimizes system operation and maintenance (O and M) problems. High loading from influent solids and clogging can lead to surface flows and poor treatment. VSB systems must receive influents that are pretreated to remove solids (e.g., septic tank and effluent filter or anaerobic lagoon).

Properly designed FWS systems also can achieve high removal rates. Design typically follows one of two methods. The areal loading approach allows a designer to select the wetland surface area according to the influent load and the desired effluent quality.[13] Another approach allows a designer to select the wetland area by knowing the biological reaction rate, wastewater concentration, and flow rate along with selected water depth and target outflow water quality.[7,8] Again, depth is a critical dimension and is governed by plant tolerance to standing water and treatment objectives.

TABLE 3 Wetland Treatment (%)

Wastewater Type	BOD5	TSS	TN	nh_4-n	TP	FC	Metals
Municipal[11] [avg.]	74	70	53	54	57	—	—
Livestock[13] [avg.]	65	53	42	48	42	92	—
Landfill leachate[12] [range]	11–90	45–97	7–45	13–88	—	—	8–95+

Note: BOD5 = 5-day biochemical oxygen demand, TSS = total suspended solids, TN = total nitrogen, NH_4–N = ammonium nitrogen, TP = total phosphorus, FC = fecal coliform bacteria, metals = Fe, Cu, Pb, Ni, or Zn.

FWS vs. VSB Systems

Selection of the most appropriate wetland system depends on wastewater characteristics, treatment requirements, and site constraints. VSB systems generally require less land area, are less susceptible to freezing and mosquito problems, and have no exposed wastewater at the surface (avoiding contact-related health problems). FWS systems are less expensive to construct (without the cost of media), have greater potential for wildlife habitat, and are easier to maintain if solids accumulate.

Operation and Maintenance

O and M of treatment wetlands are relatively simple. The goal of an O and M plan is to assure that the wetland system continues to operate as planned, designed, and constructed. Several sources provide specific O and M guidance,[14] and most design manuals also contain such guidelines. Operation should be consistent with treatment objectives while maintaining structural integrity of the system, uniform flow conditions, and healthy vegetation as well as minimizing odors, nuisance pests and insects. Most maintenance plans require such items as checking water levels, checking for evidence of leaks or wildlife damage, and maintaining plant health on a weekly or monthly basis.

Conclusion

Constructed wetlands are complex natural-treatment systems that are well suited for many applications. They are low in cost and maintenance, provide significant reductions of many contaminants, and offer an aesthetic appearance. More work is needed to characterize treatment processes in constructed wetlands and improve design procedures to account for variability in wastewater and climate.

Acknowledgments

The author extends his gratitude to Kristina M. Boone, Associate Professor of Agricultural and Environmental Communications, Kansas State University for her significant review contribution to this entry, and to those at Kansas State University who have supported wetlands research and education.

Cyanobacteria: Eutrophic Freshwater Systems

Anja Gassner and
Martin V. Frey

Factors Leading to Cyanobacterial Dominance

The taxonomic composition of phytoplankton communities, the abundance and the relative dominance of the different species and groups present, undergo seasonal changes. This process of continuous community change is termed succession. Under undisturbed conditions, most phytoplankton populations are of relatively short duration. Typically, the growth and decline cycle of one specific population lasts, on average, 4 to 8 weeks. The "seasonal paradigm" of phytoplankton succession[1] describes the typical pattern of phytoplankton succession corresponding to the prevailing nutrient cycle in temperate, undisturbed lakes: a spring maximum of diatoms, sometimes followed by a second maximum in the autumn, an early summer maximum of Chlorophyceae (green algae) and a late summer maximum of Cyanophyta (blue-green algae).

It is generally accepted that with excess nutrients in the water column, in particular phosphorus, the phytoplankton flora deviates from the traditional seasonal community pattern with a shift toward cyanobacterial dominance. However, it must be stressed that nutrient limitation does not, in itself, provide cyanobacteria with the ability to become dominant; it is the combination of a multitude of abiotic and biotic factors. Enrichment experiments demonstrated that the maximum biomass of temperate lakes is ultimately limited by the phosphorus supply.[2] Increasing supplies of phosphorus lead to an increase of phytoplankton growth until other essential nutrients become limited. The first nutrient to become limited after phosphorus is usually nitrogen. Cyanobacteria are the only species that are able to fix atmospheric nitrogen. Whereas other algae become nitrogen limited, the ascendancy of nitrogen-fixing cyanobacteria is favored.

Apart from their ability of fixing atmospheric nitrogen, cyanobacteria feature some adaptations that enable them to outcompete other species. Eutrophic conditions result in large suspended stocks of phytoplankton, which reduce light penetration. Cyanobacteria possess gas vacuoles to control buoyancy. When subjected to suboptimal light conditions, they respond by increasing their buoyancy (regulated by the rate of photosynthesis) and move nearer to the surface and hence to the light.[2] Additionally, the possession of chlorophyll *a* together with phycobiliproteins allows them to harvest light efficiently and to grow in the shade of other species. Cyanobacteria are supposed to be more tolerant of high pH conditions and have an additional selective advantage at times of high photosynthesis because of their ability to use CO_2 as carbon source.[3] Some genera are able to offset the effects of photoinhibiting UV radiation encountered by near-surface populations. The resistance to photoinhibition is achieved by producing increased amounts of carotenoid pigments, which act as "sunscreens."[4] Once established, cyanobacteria are able to inhibit the growth of other algae by producing secondary metabolites that are toxic to species of other genera.[5]

Consequences of Cyanobacterial Blooms

Like any phytoplankton, bloom proliferation of blue-green algae reduces water quality in terms of human water use but also results in a reduction in diversity of the aquatic species assemblage at all trophic levels. The presence of "pea soup green" water, the accumulation of malodorous decaying algal cells, and the buildup of sediments rich in organic matter lead to user avoidance with the associated problems and implications for water quality management. The most obvious sign of an advanced blue-green algae bloom is the formation of green "scum," which leads to deoxygenation of underlying waters, subsequent fish kills, foul odors, and lowered aesthetic values of affected waters.[6] In addition, certain genera and species produce taste and odor compounds, typically geosmin and 2-methyl iso-borneol, which cause non-hazardous but unpleasant problems for suppliers and users of potable water.[4]

The most serious public health concerns associated with cyanobacteria arise from their ability to produce toxins. Since the first published reported incidence of mammal deaths related to a toxic cyanobacterial bloom in 1978, more than 12 species belonging to nine genera of blue-green algae have been implicated in animal poisoning.[7] For human exposure, routes are the oral route via drinking water, the dermal route during recreational use of lakes and rivers, or consumption of algal health food tablets. Toxins produced in a random and unpredictable fashion by cyanobacteria are called cyanotoxins and classified functionally into hepatotoxins, neurotoxins, and cytotoxins. Additionally, some cyanobacteria produce the lesser toxic lipopolysaccharides (LPS) and other secondary metabolites that may be of potential pharamacological use.[8] One of the most tragic encounters of humans with cyanobacterial toxins led to the deaths of 60 dialysis patients due to contaminated water supply used in a hemodialysis unit.[9] Presently, a drinking water guideline of $1\,\text{ng L}^{-1}$ of toxin has been developed and implemented only for microcystin-LR.[4] Haider et al.[8] stress that the biggest challenge for water treatment procedures for the removal of cyanobacterial toxins is that one is faced with soluble and suspended substances. Thus, the most common treatment, chlorination, in general has been found not to be an effective process in destroying cyanotoxins.

Monitoring and Management of Algal Blooms

Drinking water treatment strategies are not always successful in removing algal toxins. Thus, detection of early-stage (emergent) blooms of cyanobacteria, especially if the bloom has not started to produce toxins, is important to allow municipalities and recreation facilities to implement a response plan. It has been shown that remote sensing technology can be used to estimate the concentration and distribution of cyanobacteria through measurement of the concentration of the pigment phycocyanin.[10]

Once detected, the growth of nuisance algae is prevented by the use of chemicals; the commonest is copper sulfate. Other algicides include phenolic compounds, amide derivatives, quaternary ammonium compounds, and quinone derivatives. Dichloronaphthoquinone is selectively toxic to blue-greens. The inherent problem of algicides is that on cell lysis, toxins contained in the algae cell are released into the surrounding water. In 1979, almost 150 people had to be hospitalized for treatment of liver damage after a reservoir contaminated with *Cylindrospermopsis* was treated with copper sulfate.[4] Biological control by zooplankton is, in principle, possible, although not always practical or effective because of the low nutrient adequacy, toxicity, and inconvenient size and shape of most blue-green algae.

The only zooplankton reported to successfully graze on blue greens is *Daphnia* sp., but it tends to decrease with increasing nutrient content of the water[11] More effective is the use of microorganisms, as certain chytrids (fungal pathogens) and cyanophages (viral pathogens) specifically infest akinetes and other heterocysts, whereas Myxobacteriales (bacterial pathogens) can affect rapid lysis of a wide range of unicellular and filamentous blue-greens, although heterocysts and akinetes remain generally unaffected.[12]

The consensus regarding the management of blue-green algal blooms is the management of excess nutrient loads into receiving water bodies.[13,14] Management options can be divided into two broad categories: catchment management (decrease of nutrient export) or lake management (decrease of internal nutrient supply). Catchment options are, e.g., management of urban and agricultural runoff, biological and chemical treatment of wastewater, nutrient diversion, and implementation of legislation. Lake management options are dredging, chemical sediment treatment, and biomanipulation.[13]

Conclusions

Cyanobacteria pose a serious threat to ecosystem health and human livelihood. From a human perspective, the most serious threat associated with blue-greens are their toxins. Routes for human exposure are the oral route via drinking water, the dermal route during recreational use of lakes and rivers, or consumption of algal health food tablets. Removal of these algae and their toxins from water bodies poses a great logistical problem. However, it is important to understand that the proliferation of blue-greens and thus the presence of their toxins is a response to human-induced "cultural" eutrophication. Increasing awareness of the need of proper watershed management is urgently needed among municipalities and stakeholders, especially because chlorination has been shown not to be very effective in removing toxins from the water.

Estuaries

Claude
Amiard-Triquet

Introduction

In the whole world, estuaries are the seat of the same paradox: they are among the most productive ecosystems while being strongly impacted by anthropogenic activities. Considering the value of the world's ecosystem service and natural capital, estuaries are among the most productive systems.[1] More than 76% of all commercially and recreationally important fish and shellfish species are estuarine dependent.[2] By using the specific search term "estuary" in the Marine Pollution Bulletin database, 553 titles emerged to date (July 2011), highlighting the importance of pollution threats to these ecosystems. This estuarine paradox is well exemplified in Figure 1, showing the mouth of the Loire estuary, one of the big estuaries along the northwestern Atlantic coast. On the north bank, the town of Saint Nazaire (65,000 inhabitants) is highly industrialized, being particularly famous for its shipyards. Between Saint Nazaire and the urban community of Nantes (580,000 inhabitants) 60 km upstream, industrial areas receive large plants, such as a company producing fertilizers, an oil refinery, and an electrothermal plant. Agricultural areas destined to meadows and livestock farming, open fields, and specialized cultures (market gardening, horticulture, wine yards, etc.) are inserted between industrial areas. The south bank is less urbanized, less industrialized, and consequently less artificialized. As shown in the picture, at low tide, large mudflats emerge. They are home to rich invertebrate fauna, including small crustaceans, bivalves, and worms, which are at the bases of food chains leading to different fish species (flounder, eel, sole, sea bass, etc.) of economic interest and to vast populations of wading birds.

Worldwide, there are some 1200 major estuaries (discharges of 10 m^3/s), with a total area of approximately 50 million ha.[1] Tidal flats and estuaries have been widely degraded and lost. Sea traffic has required the fitting of dikes, the dredging of channels, and land reclamation to support harbors and industry with drastic ecological consequences such as the reduction of mudflats and also wetlands, which are important for the protection of water quality and are ecosystems of floristic and faunistic interest.

FIGURE 1 The Loire estuary near its mouth showing the contrast between the north bank, urbanized and industrialized, and the south bank, with intertidal mudflats that are crucial for feeding of fish and wading birds.

Origins of the Problems of Estuaries

Drivers of loss and change to wetland ecosystems have been listed in the Millennium Ecosystem Assessment.[1] Influx of nutrients due to river transport is at the basis of the biological wealth of estuarine areas, but on the other hand, the fluxes of reactive (biologically available) nitrogen and high phosphorus loading from anthropogenic sources result in eutrophication.[3] The degradation of primary producers responsible for eutrophication is oxygen consuming as is also the degradation of anthropogenic influx of NH_4 (present in wastewater treatment effluents) into nitrates. Thus, episodes of hypoxia may be observed, and in many estuaries they are also favored by the presence of a natural entrapment zone [estuarine turbidity maximum (ETM)] where the accumulation of suspended organic and mineral matter enhances bacterial activity.[4] In estuarine environments, bacteria are generally attached to particles, and their behavior is related to the dynamics of suspended matter.[5] Bianchi[3] reports that the abundance and production of virus-like particles (viriobenthos) in sediments are considerably higher than those found for water column virus particles (virioplankton).

The processes controlling movement of sediments in estuaries have been described by Bianchi.[3] The location of the ETM is generally considered to be controlled by tidal amplitude, volume of river flow, and channel bathymetry. Due to rapid and high sedimentation rates in the ETM, the accumulation of particles in the benthic boundary layer can result in the formation of mobile and fluid muds, [3] but resuspension episodes frequently occur, for instance, during spring tide and storm events.

Urban and industrial activities are responsible for the input of contaminated effluents and microbes in the aquatic environment, whereas agriculture results in diffuse inputs of pesticides and fertilizers. Contaminants are a source of concern for the growth and reproduction of cultivated species as well as a risk for the health quality of seafood products, particularly for pollutants able to biomagnify in food chains (e.g., methylmercury, polychlorinated biphenyls [PCBs]). In industrial areas, the role of estuaries as waterways leads to dredging activities in order to keep a convenient bathymetry. Because dredged sediments are loaded with a cocktail of many classes of contaminants, dredging activities are a serious source of concern.

The *Eisler's Encyclopedia of Environmentally Hazardous Priority Chemicals*[6] provides 142 instances when using the search terms "estuary" or "estuarine." Bianchi[3] also provides a review of the literature dealing with nutrients and contaminants entering estuaries: trace metals, either essential at low doses (e.g., Cu, Zn) or nonessential and toxic even at low doses (e.g., Hg, Pb); PCBs, very stable so they are still present despite their ban; and polycyclic aromatic hydrocarbons (PAHs). Bianchi[3] also reports that inputs of these multiple stressors can interact to reduce, enhance, and/or mask the individual effects of each. Emerging contaminants of concern in coastal and estuarine environments have been reviewed by Hale and La Guardia.[7] They include brominated flame retardants, natural and synthetic estrogens, alkylphenol ethoxylates, and associated degradation products, pharmaceuticals, and personal care products. The recent advances in nanotechnology and the increasing use of nanomaterials in every sector of society have resulted in uncertainties regarding environmental impacts. Deposit-feeding benthic estuarine organisms may be particularly at risk given the likelihood of nanoparticles to agglomerate, aggregate, and settle.[8]

The public and scientists realized environmental problems of estuaries first because of the disastrous depletion of populations of migratory fish, especially salmon and eels. This blindness is partly explained by the erroneous confidence in the following: 1) the power of dilution of pollutant fluxes in huge volumes of seawater at river mouths; and 2) the ability of estuarine species to cope with chemical stress as they are able to cope with dramatic changes in ecological conditions (salinity, temperature, turbidity, oxygen). On the contrary, organisms living at the limits of their tolerance to natural variations are generally more sensitive to any additional stress.[9,10]

Environmental Assessment of Estuarine Ecosystems

Environmental assessment is classically based on a triad of analysis including the following: 1) chemical analyses in environmental matrices; 2) bioassay methods for the evaluation of toxic effects of contaminants; and 3) biological responses at the level of community structure. This approach was particularly well developed as the Sediment Quality Triad[12] since in the aquatic environment, sediment is the main store for most contaminants entering ecosystems. In estuaries, all assessment techniques need to consider the unique and complex dynamic processes at work, in particular, salinity effects, but also key estuarine parameters such as temperature, pH, dissolved O_2, redox potential, hydrodynamics and sedimentary processes, and their spatiotemporal changes.[13,14] These parameters, indeed, strongly influence estuarine biogeochemical processes, controlling contaminant exchanges between sediment and the water column as well as contaminant bioavailability and toxicity.[13] They also govern the biological features of estuarine communities according to the concept of the estuarine quality paradox.[15,16]

Legislation has been adopted on a worldwide scale to determine the ecological integrity of surface waters including estuaries (United States' Clean Water Act [CWA], 1972; European Community Water Framework Directive, [WFD]).[17] The so-called ecological quality status (EcoQS)[17] must be assessed by comparison with undisturbed conditions, but at the beginning of the third millennium, the formulation of reference values is highly questionable. Anyway, effects at the community level become significant only after severe environmental degradation has already occurred, thus leading to expensive remediation processes. In this context, the methodology of biomarkers provides predictive tools applicable much earlier in any environmental degradation process.[18,19]

Chemical Analyses in Environmental Matrices

Knoery and Claisse[20] have described the experience of the French marine chemical monitoring network over the last 33 years. They highlight the rationale for using different environmental matrices, namely, water, sediment, and biota (suspension feeders such as *Mytilus* sp. and *Crassostrea gigas,* as recommended in NAS[21]), to describe spatiotemporal variations of chemical pollution (PAHs, PCBs, organochlorinated pesticides, metals). Despite being recognized in the WFD, water is not a suitable matrix to answer this aim due to analytical problems at environmentally very low levels of contaminants combined with the low spatial and temporal representativeness of water samples collected at insufficient frequencies (even if recent progress in the field of passive samplers allows the measurement of time-weighted average concentrations; see, for instance, Mills et al.[22]). Using analyses in organisms, which reflect past exposure in the environment, with higher contaminant levels due to bioaccumulation, tremendously increases the reliability of data. This strategy was complemented by monitoring chemical contaminants in sediments for integration over several years. The public can access the data as time series plots through Ifremer's Web site at http://wwz.ifremer.fr/envlit/resultats/surval__1 and as maps at http://wwz.ifremer.fr/var/envlit/storage/documents/parammaps/contaminants-chimiques/index.html. The main estuaries are clearly among the most contaminated sites.

However, the gross concentrations of contaminants in any of the compartments of the environment have poor ecotoxicological significance. A greater knowledge of the biogeochemical cycling in estuaries, which involves the transformation, fate, and transport of chemical substances, is critical in understanding the effects of contaminants.[3] The role of bacteria in biogeochemical cycles is well established, and in the field of pollution studies, a focus has been made on the role of bacteria in the methylation of mercury, a process that is responsible for a higher bioavailability and a higher toxicity of this element for aquatic organisms.[6] More generally, there is clearly a need to put more "bio" into biogeochemical cycles (Ouddane et al. in Ref. [14]).

Bioassay Methods for the Evaluation of Toxic Effects of Contaminants

In their book devoted to *Coastal and Estuarine Risk Assessment,* Newman, Morris, and Hale[7] underlined the predominant freshwater focus for risk assessment and discussed the use of more abundant data for freshwater species to predict consequences to saltwater species. They concluded that improving the current practice effectively will require substantially more data for marine species. In an inventory of marine biotest methods, estuarine species, belonging to different taxa, are listed among relevant biological models.[23] On the copepod *Acartia tonsa*—known as highly tolerant toward salinity and temperature fluctuations—combined stresses from suboptimal temperature and salinity and toxic stress were tested.[24] However, toxicological stress altered the established response pattern of *A. tonsa* toward temperature and salinity, confirming that organisms living in stressful or extreme environments may experience profound interaction effects of anthropogenic and natural stress factors. On the other hand, a review performed by the European Centre for Ecotoxicology and Toxicology of Chemicals[25] suggests a reasonable correlation between the ecotoxicological responses of freshwater and saltwater biota.

Bioassays are used for the determination of predicted no-effects concentrations (PNECs) as described in detail in the Technical Guidance Document on Risk Assessment (TGD) in support of European Commission regulations.[26] The determination of the PNECs takes into account the number of bioassay results available for different species representative of different trophic levels and the availability of long-term toxicity data. However, the notion of long term in the framework of the methodology of bioassays[23] differs from the notion of long term when considering ecological consequences at higher levels of biological organization.

The relevance of the TGD[26] for in situ assessment in estuarine environments was tested by determining local PNECs for atrazine in a highly polluted estuary, the Seine estuary, France. For downstream, middle, and upstream sections of this estuary, key species important for local food chains were selected. Because the number of ecotoxicological data was restricted at the local scale compared with the global scale, a higher security factor needed to be used. In fact, differences between European Union PNECs[27] and local PNECs were limited.[28]

Estuarine Community Structure

Estuarine Quality Paradox

In agreement with Dauvin[15] and Elliott and Quintino[16] describe this paradox as follows: "the dominant estuarine faunal and floral community is adapted to and reflects the high spatial and temporal variability of highly naturally-stressed areas. However, this community has features very similar to those found in anthropogenically-stressed areas, thus making it difficult to detect anthropogenically-induced stress in estuaries. Furthermore, as estuaries are naturally organically rich, the biota thus is similar to anthropogenically-organic rich areas. Because of this, there is a danger that any indices based on these features and used to plan environmental improvements will be flawed." Although numerous bioindicators and indices are used to define the EcoQS of coastal waters, very few of them were developed specifically for environments with a mosaic of conditions and salinity levels. Natural and anthropogenic stressors make estuaries highly heterogeneous environments, which may generate thousands of potential combinations (Figure 2). According to the WFD, the elements of biological quality must be determined by comparison with reference conditions. Because of habitat heterogeneity in estuaries, it has been proposed that reference conditions should be habitat specific in order to reflect natural gradients.[29]

Tolerance and the Monitoring of Communities

This topic has been recently reviewed by Berthet et al.[11] A biological community is composed of different species, the inherent sensitivity of which toward a given toxicant is highly variable. Thus, in a contaminated environment, the most sensitive organisms are lost, whereas tolerant organisms are maintained. The variability of interspecific responses is used in the concept of the pollution-induced community tolerance developed by Blanck, Wängberg, and Molander[31] and revisited by Tlili and Montuelle.[11] Depending on the functional role of different species in the community, different indirect effects of tolerance may be expected. If a sensitive species is a prey or a host species, its extinction will lead to a depletion of its predator or symbiont populations. On the other hand, the extinction of a sensitive species that is a competitor or a predator of a tolerant species will favor the latter.

Determining ecological integrity to answer the needs of legislations (CWA, WFD) typically emphasizes analyses of phytoplankton, macroalgae, angiosperms, benthic macrofauna, and ichthyofauna. In this aim, existing data were revisited, whereas new data were obtained, for instance, in the framework of the WISER Project (Water bodies in Europe: Integrative Systems to assess Ecological status and

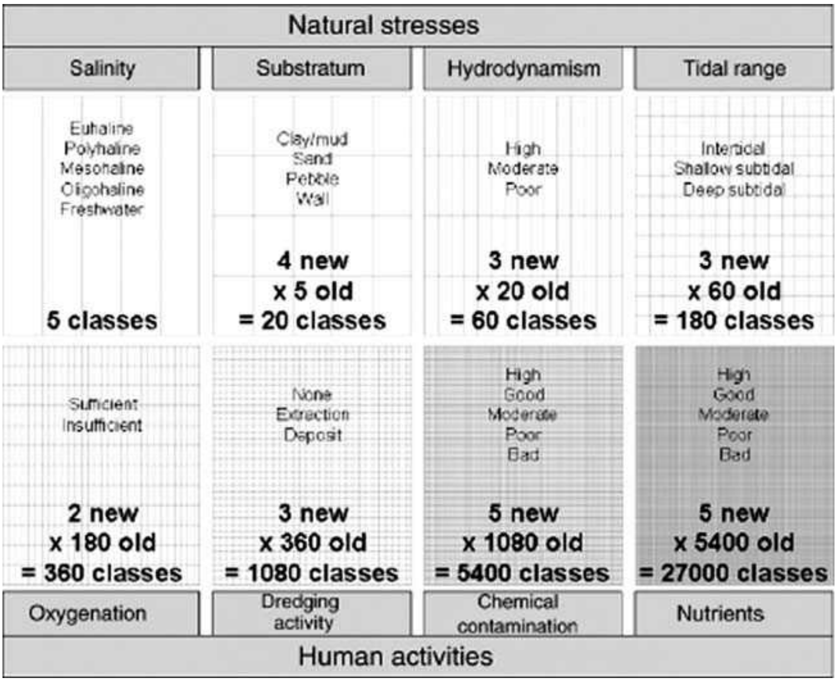

FIGURE 2 Heterogeneity of estuarine conditions that can potentially result from interactions between natural stressors and anthropogenic activities.
Source: Adapted from Dauvin et al.,[30] with permission.

Recovery, http://www.wiser.eu/programme/). Only a few results had already been published in international journals, but many reports have been prepared, and an inventory was made by Courrat, Foussard, and Lepage[32] for the different categories of biotic communities in the framework of BEEST (for good ecological status of large estuaries), a research project funded by the French ministry of environment, http://seine-aval.crihan.fr/web/pages.jsp?currentNodeId=7).

Concerning phytoplankton, the WISER project aims at developing assemblage phytoplankton metrics, including the potential use of pigment data, taking into account sources of uncertainty on the determination of biomass and community composition due to spatiotemporal heterogeneity. In the ETM region of macrotidal estuaries, high light attenuation results in low primary production, at least as phytoplankton in the water column.[33,34] Thus, it has been proposed to explore the feasibility of using microphytobenthos, an important component in primary estuarine production.[35] The spatiotemporal variability of microphytobenthos on intertidal mudflats is largely unknown because traditional techniques based upon spot sampling techniques do not allow a sound assessment of large-scale distribution. It is only recently that remote sensing techniques have been applied to obtain synoptic information on microphytobenthos distribution in estuarine intertidal zones.[36,37]

Due to phytoplankton paucity in the ETM region, it is interesting to propose another indicator for the water column. In estuaries, the omnivorous copepod *Eurytemora affinis* is especially prevalent in ETM regions worldwide(Forget-Leray et al. in Ref. [14]).[33] Many references quoted in Souissi and Devreker[38] show that the life cycle of certain species is well described and responds to the presence of pollutants or toxins. These authors also highlight that estuarine copepods, restricted to water masses with a well-defined salinity, are not affected by spatiotemporal natural fluctuations as much as benthic species. This limitation of confounding factors favors clear responses to stress. An international inquiry about the potential use of zooplankton as an indicator of estuarine water quality (22 participants from 13 countries in Europe, North America, and Asia) was made in the framework of BEEST.[38] Because of its abundance and key role in the estuarine trophic web, zooplankton was recognized as a good candidate.

Indicators and index approaches based on benthic macroinvertebrate communities are the most consistently emphasized methods for the environmental assessment of aquatic ecosystems. According to Dauvin, Bellan, and Bellan-Santini,[39] this is because macrobenthic organisms are "relatively non-mobile and therefore useful for studying the local effects of physical and chemical perturbations; some of these species are long-lived; their taxonomy and their quantitative sampling is relatively easy; and there is extensive literature on their distribution in specific environments and on the effect of the various stresses that these organisms could encounter." In the framework of the WISER project, 13 single metrics (abundance, number of taxa, and several diversity and sensitivity indices) and 8 of the most common indices used within the WFD for benthic assessment were tested. The different indices are largely consistent in their response to pressure gradient (preliminary classification based on professional judgment), but in transitional waters, inconsistencies between indicator responses were most pronounced.[40]

Fish-based indices have been recently reviewed.[32,41] In most European countries, sound scientific bases exist for regional assessment (Basque country, [42] the United Kingdom, [43] Belgium, [44] France[45,46]).

Amiard-Triquet and Rainbow[14] have underlined that on estuarine intertidal mudflats, bacteria, microalgae, and meiofauna (including foraminiferans, nematodes, and harpacticoid copepods) are relatively abundant compared with macrofaunal taxa. They also tend to exhibit higher diversity than macrofauna, increasing the range of potential responses to pollutants and potential sensitivity for the detection of an impact. Thus, data can be obtained with small samples and minimized impact on the study site while having high information content that facilitates statistical analysis. In addition, because of short generation times and low dispersal characteristics of most of these taxa, rapid population responses to environmental perturbations may be expected. On the other hand, such microscopic taxa often require specialist taxonomic skills, expertise that is of decreasing availability throughout the world.

Question of the Reference Site

All index developers invest a large amount of effort on the formulation of reference values, that is, the quality or conservation value given to pristine, undisturbed, condition, or reference status.[41] At the best, sites as clean as possible may be used as references, but of course, they will not be found among large estuaries, strongly occupied by human populations, but only in small estuaries, less affected by human impacts, but which also differ from large ones by many natural factors.[14] These confounding factors, which cannot be controlled (salinity, granulometry, organic content, hydrodynamics, food availability, etc.), must at least be measured in parallel with ecological and ecotoxicological determinations to mitigate the interpretation of indicators and indices. In this context, the WFD provides a list of hydromorphological, chemical, and physicochemical parameters that must be monitored as sustaining biological parameters.

The notions of biological or ecological integrity and the good chemical and ecological status, which are, respectively, at the basis of the U.S. CWA and the WFD, are still topics of discussion. They are based on an ecocentric point of view including the conservation of biodiversity with reference to a nearly undisturbed situation, in agreement with the concepts of climax and resilience, which have been developed in the 1960s but today are reexamined by scientific ecologists.[47,48] For nonscientists involved in ecology, reaching the good status may be more or less perceived as the recovery of a kind of Garden of Eden, the so-called pristine areas that in fact no longer exist at the present time. Sociological inquiries carried out in France in the framework of the BEEST project showed that for users and inhabitants living in estuarine areas, points of view differ depending on their relation to estuaries: fishing, social and recreational activities, aesthetic relationship, etc.

Concurrently to the ecocentric approach, an anthropocentric approach (Figure 3), based on the conservation of goods and services, may be proposed. It leads to the concept of good ecological potential

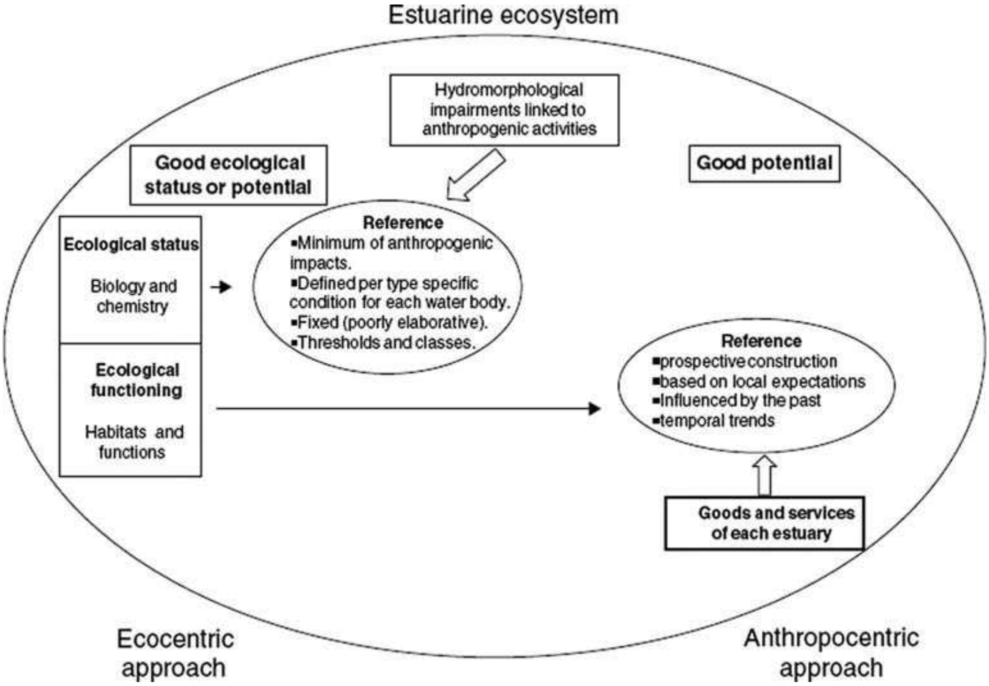

FIGURE 3 From the ecological integrity (CWA) or good ecological status (WFD) to the good potential of estuaries. **Source:** Adapted from Synthèse du projet BEEST Vers une approche multicritère du Bon Etat des grands ESTuaires atlantiques.[49]

rather than good ecological status, allowing a prospective construction including, for instance, expectations and demands of the public or uncertainties like global change. It is also in agreement with the WFD, which mentions limitations that must be taken into account (environmental and social needs, excessive costs, maintaining people's security, higher general interest) and explicitly imposes the information, consultation, and involvement of the public, including users.

Assessing the good potential of an estuary needs tools other than those useful to describe only the situation at a given time (Figure 3). It is indispensable to characterize the key elements of ecological functioning through the following: 1) by considering the concept of functional habitat; 2) by using indicators allowing a better integration of functional aspects of estuarine ecosystems; and 3) by searching out evolutionary trends rather than quality thresholds, which are not really relevant in this highly variable context.[49]

New Tools

Ecosystem Functioning or Ecosystem Structure?

According to Elliott and Quintino,[16] "functional characteristics either as well as or rather than structural ones should be used in detecting environmental perturbations in estuaries." Indicators described above may be used for a better characterization of ecosystem functioning. Phytoplankton and microphytobenthos may serve as proxies for primary production, and in addition, Underwood and Kromkamp[35] underscore that microphytobenthic biofilms may play an important role in biogeochemical cycles (exchanges between sediment deposits and water phase, effects on bacterial processes). Because of its central place in the trophic web, zooplankton is a useful indicator of good ecological functioning rather than an indicator of structure.[38] Fish-based indices are generally constructed by using ecological and trophic guilds, thus allowing the description and explanation of transitional waters' community structure and estuarine functionalities.[46] For instance, taking into account juvenile marine fish can allow the characterization of the role of a given estuary as nursery.

Biomarkers

Despite biomarkers having been defined by Depledge in 1994[50]: "A biochemical, cellular, physiological or behavioral variation that can be measured in tissue or body fluid samples or at the level of whole organisms that provides evidence of exposure to and/or effects of, one or more chemical pollutants (and/or radiations)," they are still "new" since their use is limited or ignored in environmental regulations (CWA, WFD) even if they are well incorporated in some monitoring procedures, for instance, under the OSPAR Convention. They suffer mainly from three kinds of criticisms: 1) their responsiveness to confounding factors; 2) their insufficient specificity of response toward a given class of chemical; and 3) their lack of ecological relevance.

As for other parameters reviewed above, biomarkers may be responsive to spatiotemporal changes of natural conditions. In addition, they also respond to biological parameters such as the size, sex, and reproductive status of organisms. Thus, before using a sentinel species, it is needed to determine the sources of fluctuations[51,52] to limit them and, for those that cannot be controlled, to determine correction factors.[53]

"Specific" and "nonspecific" biomarkers may complement each other to assess the health status of estuarine ecosystems.[14] Among nonspecific biomarkers, those that are linked directly or indirectly to the success of reproduction and the sustainability of populations have been termed "biomarkers of ecological relevance."[54] They include changes in lysosomal stability, immunotoxicity, energy metabolism, behavior, endocrine disruption, and genotoxicity. When such impairments are demonstrated, it is necessary to identify the main classes of contaminants which may be responsible for such impairments by using a multibiomarker approach based on "more specific biomarkers" (e.g., metallothioneins induced by different metals, delta aminolevulinic acid dehydratase, specific to lead toxicity; imposex of gastropods in the presence of tributyltin). Then, the quantification and characterization (specific fractions, metabolites) of chemicals in water, sediments, and biota may allow the validation of hypotheses based on biomarker studies.

How Can We Solve the Problem?

Preventing and controlling pollution must be based on a combined approach aiming at reducing pollution at source by determining emission limit values and environmental quality standards (EQSs, e.g., WFD). Environmental management aiming at the improvement of chemical and ecological quality in estuaries must be based on robust risk assessments. Retrospective risk assessments are performed when sites have potentially been impacted in the past. When they show a degradation of environmental quality, the restoration of degraded habitats and ecosystems must be addressed. Prospective or predictive risk assessments aim at assessing the future risks of anthropogenic pressure such as climate change or chemical releases into the environment.

Environmental Quality Standards and Guidelines

Establishing EQSs (concentration in water, sediment, or biota that must not be exceeded) is a major tool to protect the aquatic environment and human health. The procedures recommended for their determination[17] are similar to those described for PNECs in the TGD,[26] and very often, EQSs are identical to PNECs. In Europe, EQSs for priority substances and certain other pollutants in surface waters have been recently published.[27] However, for persistent, bioaccumulative, and toxic pollutants, it is not possible to ensure protection against indirect effects and secondary poisoning by EQS for surface water alone. It is therefore appropriate to establish EQS for sediment and biota. The PNECoral is the quality standard for biota tissue with respect to secondary poisoning of top predators as an objective of protection. According to the OSPAR/International Council for the Exploration of the Sea (ICES) experts,[55] the risk to marine predators is calculated as the ratio between the concentration in their food (marine fish) and the no-effect concentration for oral intake (PNECoral-predator) with the help of bioaccumulation models (Abar-nou in Ref. [14]). However, in estuaries, the presence of top predators is limited, and the major risk is for human consumers, which is a reason why oyster culture or fishing is forbidden in certain sites as a consequence of the overrun of quality standards for human health.

At this stage, no EQSs were set in sediments under the WFD partly because the significance of gross concentrations of potentially toxic chemicals in sediments is not easily established, and this is particularly difficult in estuaries where the mobility and bioavailability of contaminants is deeply affected by salinity changes.[13] In the United States, the Washington State Department of Ecology has published sediment management standards.[56] Bioavailability may be examined by using the methods described by Hansen et al.[57] for PAH mixtures and U.S. Environmental Protection Agency (EPA)[58] for metals. When EQSs are not available, sediment quality guidelines (SQGs) are commonly used by official organisms. such as the effects-range low (ERL) and the effects-range median (ERM) values that were derived for the National Oceanic and Atmospheric Administration (NOAA) with numerous modeling, laboratory, and field studies performed in marine and estuarine sediments.[59] Australian sediment quality guidelines were adapted from ERL/ERM.[60] The threshold effect level (TEL) and the probable effect level (PEL) initially described by MacDonald et al.[61] are also used by the NOAA.[62]

Mean SQG quotients can be calculated by dividing chemical concentrations in sediments by their respective SQGs and calculating the mean of quotients for individual chemicals. The resulting index provides a method of accounting for the presence and concentrations of multiple chemicals in sediments, relative to their effects-based guidelines.[56]

Sediment quality guidelines are also of great use in the regulation of dredging activities. This activity is particularly well regulated at the international level, and all these regulations share the same philosophy. For details, the reader can refer to the revised OSPAR guidelines for the management of dredged material.[63]

Environmental monitoring is indispensable to verify if EQSs are honored or if it is necessary to adopt decisions in order that the environment and human health may be adequately protected. Once again, the procedures are comparable in different areas in the world, at least in economically developed countries, and for instance, the Coordinated Environment Monitoring Programme (CEMP) provides a monitoring manual Web page that is regularly updated to take into account scientific and technical advances provided by the OSPAR commission in collaboration with the ICES (http://www.ospar.org/content/content.asp?menu=00900301400135_000000_000000).

How the Biota Will Respond to Restoration

From a large number of examples examined by Borja et al.,[64] including the recovery from a list of different stressors, it appears that only in a few cases, recovery can take less than 5 years, but more frequently, a minimum of 15–25 years is needed to attain the original biotic composition, and diversity may lag far beyond that period. Similarly, Hering et al.[65] conclude that it cannot be expected that European aquatic ecosystems will fully recover within 15 or even 30 years from over a century of degradation. Considering such situations, the common saying "an ounce of prevention is worth a pound of cure" makes sense.

Predictive Risk Assessment of New and Existing Chemicals

Predictive risk assessment aims at assessing the future risks from chemical releases into the environment. In the United States, the Federal Toxic Substances Control Act gives the EPA authority to regulate, and even ban, the manufacture, use, and distribution of both new and existing chemicals. In Europe, a significant improvement has occurred recently with a new chemical policy, REACH (Registration, Evaluation, and Authorization of Chemicals).[66] The pros and cons of REACH have been analyzed, with some details in Hansen[24] and Verdonck et al.[67]

Risk assessment under REACH will be carried out mainly by applying existing methodologies.[26] The risk quotient approach needs the determination of predicted environmental concentrations (PECs) and PNECs. Very simplistically, if the PEC/PNEC ratio is greater than 1, the substance is considered to be of concern, and risk reduction measures must be envisaged. According to Verdonck et al., [67] uncertainty is hidden and concealed in risk quotient numbers that appear to be certain and, therefore, create a false sense of certainty and protectiveness. These authors propose strategies to improve uncertainty analysis in risk assessment of chemicals. Management obstacles have been summarized by Hansen, [24] who considers that "there are few areas of applied science where the connection between science and policy is as difficult and complicated as in the area of risk management of chemicals." She underlines the lack of communication of uncertainties between assessors and decision makers. Even in the cases where there is an important set of data on a given chemical, there may be little consensus regarding what the actual risk is. Quoting Chapman,[68] Hansen[24] bewails that the effect of all this uncertainty is generally the continued production and use of possible harmful chemicals. Even with "old" contaminants very well studied, the complexity of field situations often leads to a lack of decision. This is well illustrated by Hameedi et al.:[62] despite substantive scientific evidence that points to copper as a contaminant of concern in the St. Lucie Estuary, it is debatable as to how much the observed levels of copper in the estuary are adversely affecting the flow of products (such as fish) or services (such as recreation) of the estuary. This approach poses the problem of what is environmental risk for different actors, as previously mentioned in the section "The Question of the Reference Site."

Conclusions

In aquatic environments, an important set of methods and techniques is available to provide decision makers with tools allowing the prevention, control, and remediation of pollution inflows and impacts. However, because estuaries are highly dynamic and complex systems, the application of these methods is particularly complicated, generating a high degree of uncertainty, whatever the category of assessment tools considered among the classical triad of analysis (chemistry, bioassays, community structure) as well as other assessment strategies such as biomarkers. Many authors have underlined that only a few toxicity data are available for estuarine species compared with marine and, moreover, freshwater species. Thus, toxic impacts on estuarine biota are often derived from toxicological parameters determined in non-estuarine species.

Among tolerant organisms, some are keystone species, with important roles in ecosystem functioning, on which numerous species will depend. Depending on the harshness of natural conditions in different ecosystems, the number of species able to fulfill the same functional role is strikingly variable. As estuarine species are much less numerous than freshwater or marine species, it is evident that the extinction of even a small number of species is sufficient to affect ecosystem functioning.

The state of knowledge would allow considerable improvement of risk assessment and monitoring. The integration of scientific advances in regulations and management needs decade(s). Some of the reasons for that are the higher technicity and the higher cost of certain new tools. Is the society ready to pay for better conservation of the environment? Furthermore, for what kind of conservation: recovery of the Garden of Eden or sustainability of estuaries for the benefits of nature to human beings?

Everglades

Kenneth L. Campbell, Rafael Munoz-Carpena, and Gregory Kiker

Introduction

The Everglades of south Florida was originally a broad, shallow "River of Grass"[1] that extended from the south shore of Lake Okeechobee to Florida Bay at the southern tip of the state, east to the Coastal Ridge, and west to the Immokalee Ridge. Historically, the area was a vast sawgrass marsh, dotted with tree islands and interspersed with wet prairies and sloughs covering an area about 40 mi wide by 100 mi long. One of the unique regions of the world, it has steadily decreased in size and declined in health during the past century. Half its wetland area has been lost to agriculture and urban development and the remaining segments are impacted by lack of a clean, dependable water supply. Natural water flows have been diverted for irrigation, drinking water, and flood protection. The conveyance system of canals, levees, structures, and pumps developed for flood control has altered natural patterns of water flow and storage, adversely affecting food webs that supported a diverse ecosystem. Nutrient runoff from urban and agricultural sources is transported by the conveyance system to the remaining natural wetland areas, causing undesirable changes in flora and fauna. Hydroperiod changes have altered natural fire patterns and stimulated invasion of exotic species. A multi-agency state and federal task force has developed a Comprehensive Everglades Restoration Plan (CERP)[2] to address and reverse these major changes to this unique wetland ecosystem. The major hydrologic modifications to be addressed in the Everglades restoration include: 1) regain lost storage capacity; 2) restore more natural hydropatterns; 3) improve timing and quantities of fresh water deliveries to estuaries; and 4) restore water quality conditions. The Comprehensive Plan, considered the world's largest such project, includes more than 60 components proposed for implementation over a period of four decades with an estimated investment approaching $8 billion. State and federal legislation provides for a 50/50 cost share between the federal and state governments to implement the plan.

Everglades Water Management—Past, Present, and Future

History

Primitive canals were dug in portions of the Everglades as early as the late 1800s in attempts to reclaim fertile swampland for agriculture.[3] Early promoters and developers led people to believe that a productive subtropical agriculture was possible in the entire Everglades region. These early attempts at land reclamation were largely unsuccessful until the 1920s when a period of less than normal rainfall helped dry the region around Lake Okeechobee for farming. Following severe hurricane damage in the region in the late 1920s and again in 1947, the focus was shifted from land reclamation to flood protection and the Central and Southern Florida Flood Control Project was authorized and implemented beginning in 1948. Over the next 15 years, this project resulted in a perimeter dike around Lake Okeechobee and the extensive conveyance system of canals, levees, structures, and pumps currently in place. It also allowed development of the Everglades Agricultural Area (EAA), a highly productive, 700,000-acre region of organic soils in the northern Everglades used primarily for sugar cane and winter vegetable production.[4]

Environmental Issues

By the mid-1960s, concerns were already growing about conservation issues and adverse environmental impacts. Additional areas along the eastern border of the Everglades have since experienced urban encroachment. A total of about 1 million acres, roughly 50% of the Everglades wetlands, have been transformed for human uses during the past half-century. The 1700 mi of canals and levees in the region have interrupted connections between the central Everglades and the adjacent wetlands, resulting in over-drainage in some areas and excessive flooding in others. This system provides water supply, flood protection, water management, and other benefits to south Florida, but it must be modified to reduce the negative impacts on the environment. The current canal system works very effectively, discharging an average of 1.7 billion gal of water per day to the ocean and gulf. This discharge must be reduced if future urban, agricultural, and environmental demands for water are to be met.

Today's remaining Everglades have been significantly affected by the current water management system. Wading birds and other wildlife populations are greatly decreased. Tree islands, with their unique combination of wetland and terrestrial vegetation and wildlife, are considered to be an excellent indicator of the overall health of the Everglades. Many of these tree islands have disappeared from the northern Everglades over the past 50 years, and many others have been taken over by exotic vegetation. These effects are mainly due to changes in the quantity, quality, timing, and distribution of water that have occurred over the years as a result of changed water management. Water depth, duration, and timing are important to both wildlife and vegetation. The sawgrass wetlands of the Everglades developed under very low nutrient conditions with rainfall as the main source of phosphorus. Nutrient inflows, especially phosphorus, as a result of development and modified water management have influenced changes in vegetation type.[5] Where phosphorus concentrations have increased, sawgrass and spike rush have been replaced by cattail causing undesirable changes in the ecosystem. Native vegetation remains healthy where phosphorus concentrations are low.

Restoration

Restoration of the remaining Everglades depends upon a knowledge and understanding of the original conditions. Efforts are focusing on improving upstream water quality and the distribution, timing, depth, and flow of surface water into and through the Everglades. Early historical information sources, combined with further interpretation and analysis, are being used to estimate original drainage patterns and soil, topographic and vegetation conditions before canal drainage began in the late 1800s. Results of these studies indicate that the predrainage landscape of the Everglades probably was configured in subtle ridges and sloughs with two major flow pathways: a flow path southeastward to the Atlantic Ocean, and a southwestward flow path along Shark Slough to the Gulf of Mexico.[6] These flow patterns may have influenced the ridge and slough landscape configuration that is important to the health of the ecosystem. Redevelopment of these flow patterns and landscape configuration will be important to the restoration process. About 70% less water flows through the Everglades today compared to the historic Everglades system.

The main goal of Everglades restoration is to deliver the correct amount of water, with the correct quality, to the correct locations, and at the correct time.[7] Most of the water currently lost to the ocean or gulf will be stored in surface and subsurface storage areas until needed, when 80% of it will be allocated to the environment and 20% to increase urban and agricultural water supplies. Water to be stored for future use will be routed through surface storage reservoirs and wetland-based stormwater treatment areas to improve its quality. Additional water quality improvements can be expected from comprehensive integrated water quality planning efforts currently in progress. To restore water flow paths, more than 240 mi of canals and levees will be removed in the Everglades. This will allow more natural overland water flow in the remaining natural areas of the Everglades. Water held and released will be managed to match natural discharge patterns more closely. Operational plans will be developed in some areas to simulate natural rainfall patterns with water releases to improve the timing of water flowing through the Everglades ecosystem. These strategies are all being designed to enhance not only ecosystem restoration, but also urban and agricultural water supply and flood protection as part of the process of moving toward a more sustainable south Florida.

Conclusion

The Everglades landscape is a unique combination of subtropical wetlands and uplands, including sawgrass marshes, sloughs, wet prairies, tree islands, tropical hardwood hammocks, pinelands, and mangroves. It provides important habitat for many threatened and endangered species. Water management for flood control and water supply purposes has caused some areas to become drier and others to become wetter than normal. More than half of the original wetland area has been lost to agricultural and urban development. The introduction of increased nutrients resulting from this development has caused undesirable shifts in vegetation communities. Hydrologic changes have altered the extent of naturally occurring fires and promoted the growth of exotic species. While the current water management system performs well for flood protection it must be modified to reduce adverse environmental impacts and conserve more fresh water to meet a variety of needs. A Comprehensive Everglades Restoration Plan received initial authorization in 2000 to begin the restoration of the south Florida ecosystem and provide for water-related needs of the region. This plan addresses the quantity, quality, distribution, and timing of water to the Everglades. A large amount of additional information regarding the Everglades is available on the web at http://www.sfwmd.gov/koe_section/2_everglades.html and http://www.evergladesplan.org/.

The following quote from the Comprehensive Everglades Restoration Plan web site[7] conveys the importance of the Everglades and the current restoration program. The significance of the remaining Everglades to the nation and the world has been affirmed time and again. Congress established Everglades National Park. The Everglades have also been designated an International Biosphere Reserve, a World Heritage Site, and a Wetland of International Significance. Identified as one of the world's major ecosystem types, the Everglades are home to 68 threatened or endangered plant and animal species. The benefits and functions of these plants and animals may never be known if we do not restore and protect their habitat. Saving the Everglades requires us to save the entire south Florida ecosystem. The ecological and cultural significance of the Everglades is equal to the Grand Canyon, the Rocky Mountains, or the Mississippi River. As responsible stewards of our natural and cultural resources, we cannot sit idly by and watch any of these disappear. The Everglades deserves the same recognition and support.

Water Quality: Range and Pasture Land

Thomas L. Thurow

Introduction

Livestock and clean water are two products that can be simultaneously obtained from range and pasture lands. This requires that ecological and hydrological principles be applied when crafting a grazing management strategy that is compatible with *predetermined* water quality goals. Making protection of water quality the starting point of land use planning is a philosophical foundation of 1972 U.S. Clean Water Act and subsequent amendments. This goal is operationalized by management agencies establishing total maximum daily load (TMDL) standards for waterways. A TMDL is a calculation of the maximum amount of a pollutant from all contributing point sources (a specific location such as a confined animal feedlot operation [CAFO]) and non-point sources (pollution that occurs over a wide area such as may originate from grazing).

Physical Characteristics

Suspended Sediment

Suspended sediment is the most pervasive non-point source pollutant from grazing lands. All waterways naturally contain some suspended sediment attributable to the geologic (natural) erosion influenced by stream type (primarily determined by the geology, topography, and location within the watershed) and ecological factors (e.g., climate, vegetation, soil). Therefore, formulation of TMDL suspended sediment standards must be catchment specific so that geologic erosion can be differentiated from accelerated erosion associated with human activities such as grazing management.

Grazing management can effect the erosion rate of a site primarily by influencing the degree to which livestock impact the soil and vegetation.

Livestock Impacts on Soil

Soil structure is the arrangement of soil particles and intervening pore spaces. The size of soil particles (aggregation) and their stability when wetted determines the porosity of the soil, which governs the rate at which water will enter the soil (infiltration). If the rainfall rate is greater than the infiltration rate, water will run off the site, carrying sediment with it.

Livestock trampling compacts the soil, increasing the bulk density (i.e., the pore volume is reduced resulting in decreased infiltration rate). The degree of damage associated with trampling at a particular site depends on soil type, soil water content, seasonal climatic conditions, and the intensity of livestock use.[1] Compacted trails form on sites where livestock traffic is concentrated. The density of trails tends to increase as the number of pastures is increased within an intensive rotation grazing system. Another common reason for trail formation is repeated movement to and from limited sources of water, mineral supplements, or shelter. The low infiltration rate of trails results in concentrated runoff, which may eventually create gullies. Roads across hilly range and pasture lands are also a serious erosion source, especially since they are often poorly designed and maintained.[2]

Another way livestock trampling causes surficial problems is by churning dry soil to dust. This is very detrimental to infiltration because the disaggregated soil particles are carried by water and lodge in the remaining soil pores making them smaller or sealing them completely. This “washed in” layer where clay particles clog soil pores is a common way that soil crusts are formed. Soil crusts can reduce infiltration by 90%, thereby dramatically increasing runoff and sediment transport.[3] Trampling a crusted soil does break the crust and incorporates mulch and seeds into the soil. However, this benefit is short lived because the subsequent impact of falling raindrops re-seals the soil surface after several minutes. To effectively address a soil- crusting problem, livestock grazing systems must concentrate on addressing poor aggregate stability, which is the cause of crusting. This requires protecting the soil surface from direct raindrop impact through maintaining vegetation cover and facilitating organic matter buildup in the soil via litter deposition.

Livestock Impacts on Vegetation

Direct raindrop impact on soil represents the greatest potential erosive force on grazing land; therefore it is very important that raindrop energy be dissipated by striking some form of cover before reaching the soil.[4] The amount of cover is positively associated with vegetation litter deposition. Litter slows overland flow, resulting in reduced ability to transport sediment. Litter also aids formation of stable aggregates (associated with high infiltration and low erosion rates) by binding soil particles together with adhesive byproducts produced by decaying litter and microbial synthesis.[5]

Grazing impacts on the vegetation community may be manifest by physical removal of standing vegetation through herbivory or through a gradual change in the composition of vegetation. As grazing pressure increases, the amount of cover and the amount of organic matter returned to the soil is reduced, resulting in an increased likelihood of runoff and erosion. Cover and infiltration rate tends to be greatest under trees and shrubs, followed in decreasing order by bunchgrass, shortgrass, and bare ground.[6] There is little impact on species composition with moderate or light grazing but composition change is great in response to heavy grazing, regardless of grazing strategy.[7] Often the change in species composition associated with heavy grazing is toward dominance by annuals or shortgrass species that have more runoff and erosion associated with them.[8] By the time erosion becomes obvious it may be too late to implement economically viable conservation options. Early recognition of a developing degradation pattern requires knowledge of range ecology, for the first signs of an impending erosion problem almost invariably are manifest by changes in plant density, composition, and vigor.[9]

Chemical Characteristics

Dissolved Chemicals

Nutrient loss from grazing lands via leaching or runoff is normally negligible, i.e., less than the input of nutrients from rainfall.[10] Most of the dissolved chemical constituents in runoff are contributed from the soil. Nutrients and organic matter adsorbed to the soil particles are also lost via erosion. Therefore, the most important role of a grazing system in nutrient loss is manifest through land use activities that alter the volumes or timing of runoff and erosion.[11]

Most of the nitrogen in urine is lost via volatilization, and most of the nitrogen in feces is sequestered by microorganisms or eventually transferred to soil organic matter. Nitrate is very mobile during heavy rain periods but loss by leaching is probably insignificant on most grasslands.[12] Feces contain almost all of the phosphorus excreted by livestock. Phosphorus is very resistant to leaching as it is rapidly precipitated or absorbed by other soil minerals. Nitrogen or phosphorus contamination of waterways is only of imminent concern when livestock are allowed to congregate near waterways.[13] Because of this concern, the U.S. Environmental Protection Agency interpretation of the Clean Water Act has deemed location of feedlots near waterways an unacceptable practice.

Dissolved Oxygen

Dissolved oxygen decreases when organic matter, such as animal manure, is added to water. This decrease occurs because biological decomposition processes consume available oxygen, as does oxidation of other reduced compounds such as ammonium. Excessive additions to surface water of nutrients such as nitrogen or phosphorus lead to eutrophication, often expressed by enhanced growth of aquatic plants and reduced water transparency (especially due to increases in algae). As the aquatic plants decay the microbes consume oxygen, lowering the concentration of oxygen available needed to support higher forms of aquatic life such as macroinvertrebrates and fish.

Biological Characteristics

The primary types of pathogens associated with livestock and wildlife feces are bacteria (e.g., *Campylobacter jejuni, Escherichia coli, Leptospira interrogans, Salmonella* spp.) and water-borne protozoa (e.g., *Cryptosporidia parvum, Giardia duodenalis*). These infectious pathogens can pose potential health risks to human drinking water supplies. Environmental fluctuation in temperature and soil moisture of grazing land creates a harsh environment for bacteria and the oocycsts of protozoa. Fecal coliforms can survive for several months in soil but can survive for up to a year within feces.[14] There is a rapid mortality of most oocysts when feces are deposited on land,[15] however, viable oocysts can be transported overland, especially when fresh feces are washed by an intense storm.[16] Once pathogens reach a water body, the threat of contamination may last from days to months,[17] with freshwater sediments being the site of greatest concentration and survival.[18]

Few detailed studies have explicitly studied the link between livestock grazing and water-borne pathogens. Much of the research has relied upon indicator coliforms that are more easily cultured but have been shown to be poorly correlated with some types of pathogenic bacteria.[14] Furthermore, many wildlife species harbor the same pathogens that livestock do, thus the natural occurrence of pathogens must be considered when analyzing water quality and making the relationship to livestock use of an area. The greatest threat of pathogen contamination of waterbodies occurs when livestock are allowed to concentrate along streams.[19] In situations where risk of bacteriological contamination is unacceptable, it is necessary to restrict livestock access to streams or riparian areas. Livestock use of these sensitive sites can be significantly reduced through development of water supply away from streams.[20]

Conclusions

Two broad objectives must be achieved to protect water quality associated with range and pasture grazing.

Limit Runoff and Erosion

Suspended sediment is the most common pollutant associated with grazing. Best management practices (BMPs) to limit runoff and erosion rely on maintenance of soil structure. Vegetation provides the organic matter necessary to enhance formation of stable aggregates and provides the cover to dissipate the erosive force of direct raindrop impact. Appropriate range and pasture grazing systems are designed to maintain vegetation cover and composition by adjusting intensity, frequency, and season of use. Flexibility needs to be built into grazing systems to adjust for unexpected fluctuation in the climate or market prices. The underdevelopment of climate and market risk management planning and policy regarding grazing plans is perhaps the most formidable threat to progress in improving water quality since these variables continue to be used as an excuse for water quality deterioration and/or the lack of progress in improving it.[21]

Limit Direct Livestock Use of Waterways and Sensitive Riparian Areas

Contamination of waterways by nutrients and pathogens is a predominant concern only on sites that allow livestock to congregate near water. On sites with limited water distribution, livestock tend to stay in the vicinity of water so long as forage is available. This increases the likelihood of excrement being deposited directly into the waterway. It also causes deterioration of the soil structure and plant community near the waterway, resulting in accelerated runoff and erosion. Streambanks and moist soil around springs and streamside meadows are particularly susceptible to erosion damage and compaction. Livestock impacts to streams and riparian sites can be limited by providing water, mineral supplements, and shelter at locations away from natural water sources. Special fencing or livestock herding may also be needed to protect sensitive areas from excessive use at critical times. Another reason for protecting wetland or riparian sites is that they serve as vegetation buffer strips that slow runoff and trap sediment before it reaches a waterway.

Water: Drinking

Marek Biziuk
and Matgorzata
Michalska

Introduction

Water is a source and a basis of life on earth, and is a substance vital and necessary for humans and their well-being. It is a main part of our daily diet, transporting many necessary macro- and microelements in the human body. Excluding fat, water composes approximately 70% of the human body by mass. We drink 2 to 3 L of water every day; thus, the quality of drinking water is important. Humans can survive for several weeks without food, but for only a few days without water. Additionally, clean water is becoming a much desirable and expensive product. Desertification of large areas of the world, increasing industrialization, and intensification of agriculture result in a large input of toxic organic and inorganic compounds, significantly reducing the quality of surface waters, which are a source of drinking water for a large part of the world population. Other dangers include biological pollution by bacteria and viruses, human fecal pathogens, and parasites, causing waterborne diseases. Over large parts of the world, humans have inadequate access to potable water and use sources contaminated with unacceptable levels of dissolved chemicals or bacteria and viruses. Thus, water, especially drinking water, can create a serious hazard to human health and life, as well as to the life and health of flora and fauna. Sources of drinking water include spring water and groundwater; surface water from rivers, streams, lakes, and glaciers; water from precipitation (rain, snow); and seawater after desalination. All industrialized countries have 100% access to safe drinking water (data from the United Nations Children's Fund from 2000); however, some countries, especially those from Africa (Kenya, Uganda), have limited access.[1] The population percentages from chosen countries with limited access to safe drinking water are listed in Table 1. It was estimated that in 2006, about 1.1 billion people lacked proper drinking water. Waterborne diseases were estimated to cause 1.8 million deaths each year.[2]

Unfortunately, quality water from groundwater supply, which is practically non-renewable, is diminishing. In addition, anthropogenic groundwater pollution has become a fact of life. The majority of anthropogenic water pollutants are toxic not only to humans but also to animals and plants. These pollutants should be removed or destroyed during water treatment, and determined and monitored in surface and tap water. Water pollutants can be divided into physical, biological, radioactive, inorganic, and organic.

TABLE 1 Percentage of Population with Access to Safe Drinking Water (2000)

Source: United Nations Children's Fund (UNICEF).[1]

For many millennia, the basic criteria of water suitability for drinkable purposes was organoleptic analysis—checking the taste, smell, and appearance of water. These criteria are included, even now, in guidelines for drinking water quality; however, they had to be dramatically verified when in 1854 it was established in London that water from the well at Brad Street, very popular because of its taste, smell, and appearance, was the source of a cholera epidemic.[3] Threshold limit values for bacteriological contamination of water (the so-called coliform count) were the first standard introduced for controlling drinking water quality (in 1914 in the United States). The presence of coliform bacteria is the most convenient for a class of harmful fecal pathogens. This standard is still valid today. Microbial pathogenic parameters are very important because of their immediate health risk. The following were included in guidelines for drinking water quality: metals and anions since 1925, organic compounds since 1942, and radioactive substances since 1962. The Public Health Service and later the Environmental Protection Agency (EPA) have prepared such guidelines for the United States.[4,5] The World Health Organization (WHO)[6] worldwide and the European Community (EC)[7,8] in Europe also elaborate and publish such guidelines. On these guidelines, each country defines its maximum admissible concentrations (MACs) of contaminants in drinking water. Each member state is responsible for establishing the required policing measures to ensure that the legislation is implemented.[9]

Drinking water should fulfill the following requirements:

- It should be clear, without smell, colorless, and refreshing in taste
- It should not contain pathogenic bacteria; animal parasites and their larvae or eggs; toxic compounds; and excessive quantities of calcium, magnesium, iron, or manganese compounds
- It should be easily accessible, be always of good quality, and occur in appropriate amounts
- It should be permanently protected from contamination.
- It should contain substances that are necessary for human life in the proper amounts

Inorganic Components and Pollutants of Drinking Water

The problem of the presence of mineral components and anions in drinking water is very complicated because some elements are necessary for human life.[10–12] They play a significant role in physiological processes and metabolic functions. We can divide these into two groups:

- Macroelements, such as carbon, hydrogen, oxygen, nitrogen (the main components of organic matter), as well as sulfur, potassium, magnesium, calcium, sodium, phosphorus, and chlorine
- Microelements, such as boron, cobalt, chromium, copper, fluorine, iron, lithium, molybdenum, manganese, nickel, rubidium, selenium, silicon, vanadium, and zinc (which also participate in the metabolic function and are components of enzymes), as well as hormones, vitamins, etc

Table 2 shows some macro- and microelements, their recommended daily intake, and the effects of deficiency in these elements. Some of these elements are toxic at higher concentrations, and very often

TABLE 2 Macro- and Microelements, Their Recommended Daily Intake, and the Effects of Deficiency

Element	Recommended Concentration in Drinking Water in Poland (mg/L)	Recommended Daily Intake (mg)	Effects of Deficiency
Ca	—	900–1200	Osteoporosis, rickets, neurological disorders
Fe	0.2	14–18	Anemia
P	—	700–900	Muscular weakness, bone aches, lack of appetite
Mg	30–125	300–370	Gastrointestinal problems, muscular cramps
Na	200	1000	Gastrointestinal problems, diarrhea, weakness, headache
K	—	2–3.5	Muscular weakness, neurological disorders
Zn	—	13–16	Hair loss, skin lesions, reduced resistance to infection
Cu	2	2–2.5	Anemia, heart arrhythmia, blood vessel rupture
F	1.5	1.5–4	Tooth decay
I	—	0.15–0.16	Underactive thyroid, goiter
Se	0.01	0.06–0.075	Cancer, heart diseases, reduced resistance to microbiological and viral infection, reduced antibody production

the difference between an indispensable and a toxic dose is very small. Insufficient or excessive daily intake of these elements can cause harmful effects (see Tables 2 and 3).[9,11,12] In drinking water, we can find all elements and inorganic substances present in nature and introduced by industry, some not needed by organisms and toxic to humans. The most dangerous are lead, mercury, cadmium, and arsenic (the so-called Big Four), but the following are hazardous as well: aluminum, antimony, asbestos, barium, boron, chromium, cobalt, copper, cyanides, manganese, nickel, silver, tin, vanadium, and zinc.[12–49] The harmfulness of metals is mainly due to their persistence in the environment and biomagnification in the food chain, as well as their tendency to accumulate in selected tissues. Metals can be transported with water and air, and thus can endanger humans also through the water they drink. In Table 3, the toxicity of the most dangerous elements, their daily intake, and their typical and recommended concentrations in drinking water are listed.[4–9,23–34]

Underground and even mineral water, used as a source of drinking water, are not as clean as we would expect. Very often, overly high natural concentrations of manganium, iron, fluorides, ammonia, and hydrogen sulfide occur, and these waters should be treated before consumption. Volatile compounds such as ammonium and hydrogen sulfide can be removed by aeration, whereas manganium and iron can be removed by precipitation in the form of hydroxides and filtration or biotechnological methods. Fluorides present the biggest problem.[50] The best solution is to mix high-fluoride water with water containing no or very small concentrations of fluorides. An additional problem concerns pipes made from asbestos-cement materials or lead, used in the past in water distribution systems. Lead can be diluted in water, particularly when water is treated by chlorination or ozonization. Asbestos can contaminate drinking water as a result of corrosion, and thereby accumulate in lung tissues, resulting in symptoms that can develop many years after exposure. Asbestos fibers in water are usually shorter than 10 pm, and can cause cancer of the gastrointestinal and urinary systems. When they are transferred from water to air, after water spillage and drying, asbestos fibers can cause lung and throat cancer upon inhalation. Such an episode was described by Webber,[51] when in Woodstock, New York, in water transported by eroded asbestos-cement pipes in the distribution system; 10,000 asbestos fibers per liter was detected in some samples and up to 0.12 fiber per milliliter was detected in household air.

All these elements and substances and their recommended MACs are listed in the WHO and EC Guidelines for Drinking Water Quality, or in the EPA and national MACs,[4–9] and have to be determined

TABLE 3 Toxicity of the Most Dangerous Elements, Their Daily Intake, and Typical and Recommended Concentrations in Drinking Water

	Concentration in Drinking Water (mg/L)

in drinking water. In Tables 2 and 3, recommended MACs for some metals from the WHO Guidelines for Drinking Water Quality and Polish standards are listed as examples. Excessive concentrations of pollutants, above maximum contaminant levels, not only warn consumers but also signal the existence of uncontrolled discharge of wastes, improperly operating treatment plant, lack of enforcement of legislation dealing with water management, or other violations of environmental laws. To be able to monitor environmental pollutants properly and effectively, analysts need a variety of methods for the isolation and determination of these contaminants, taking into account both physical-chemical properties of individual compounds and groups of compounds, as well as the characteristics of the matrices in which these compounds occur.

Consequently, there is a need for continuous monitoring of the degree of pollution of potable and surface waters by all these elements and substances. The following have been used mainly for final analysis: flame atomic emission spectrometry; flame atomic absorption spectrometry; electrothermal atomic absorption spectrometry; inductively coupled plasma (ICP) coupled with atomic emission, atomic absorption, or mass spectrometry (MS); and electrochemical methods (anodic stripping voltammetry).[12,24,52–63]

Organic Pollutants of Drinking Water

The majority of organic compounds in water are of natural origin. They represent a large and diversified group of mostly unidentified compounds such as humic and fulvic acids, tannins, peptides, amino acids, etc. Their total concentration varies from 0 to 1 mg/L in groundwater, from 1 to 5 mg/L in most surface waters, and from 20 to 25 mg/L in some waters with the highest concentration of organic matter.[20,52,53,63–67] These compounds are predominantly non-toxic, but they can be precursors of toxic compounds in the process of water treatment. The main hazard to life and health of humans and flora and fauna comes from anthropogenic organic compounds. The number of known organic compounds is now estimated to be about 16 million,[3] 2 million of which are produced by synthesis alone. Every year, approximately 250,000 new compounds are synthesized, about 1000 of which are manufactured on an industrial scale.[68] Presently, ca. 70,000 organic compounds are commercially available with an annual global production of 100–200 million tons. Approximately one- third of all organic compounds produced end up in the environment, including water. More than 700 chemical compounds, including more than 600 organic compounds,[64,69] many of which are biologically active, have been detected in some water supply samples. Using gas chromatography (GC)-MS, Coleman et al.[69] identified approximately 460 organic compounds in Cincinnati drinking water.

Particularly important pollutants among organic compounds are volatile organohalogen compounds and pesticides as a result of their common use, persistence in the environment, and toxicity. They are primarily anthropogenic. Volatile organohalogen compounds are used mainly as solvents, cleaning and degreasing agents, blowing agents, polymerization modifiers, and heat-exchange fluids. It is estimated that the annual global production of organohalogen solvents alone amounts to several million tons.[64] The most important source of organohalogen compounds in drinking water, particularly volatile ones, is water disinfection by chlorination[14,63–65,70–75] for killing pathogenic bacteria. It is a paradox that during this process, harmless and naturally occurring humic and fulvic compounds in water (the so-called precursors) are converted into organohalogen compounds, which are dangerous to human life and health (see Figure 1). The largest group of compounds formed during chlorination comprises trihalomethanes (THMs), i.e., trichloromethane (chloroform, the most abundant compound), bromodichloromethane, dibromochloromethane, and tribromomethane. Organobromine compounds are formed when the water being chlorinated contains a large amount of bromides or when the chlorine used for disinfection is contaminated with bromine. Hypobromous acid formed in the reaction of bromide ions with hypochlorous acid reacts with an organic matrix about 200 times faster than hypochlorous acid does.[76] The amount and kind of organohalogen compounds formed depend on the water pH, the amount of chlorine used, and the content of organic matrix (total organic carbon, TOC) in chlorinated water.

Apart from THMs, other organohalogen compounds are formed in the course of chlorination, in smaller quantities. Volatile organohalogen compounds such as tetrachloromethane, chloroethylene, 1,1-dichloroethylene, 1,1,2-tri-chloroethylene, tetrachloroethylene, 1,1,1-trichloroethane, and 1,2-dichloroethane are also commonly found in chlorinated water. In addition, more than 100 other derivatives after chlorination of humic substances have already been identified, including chlorinated

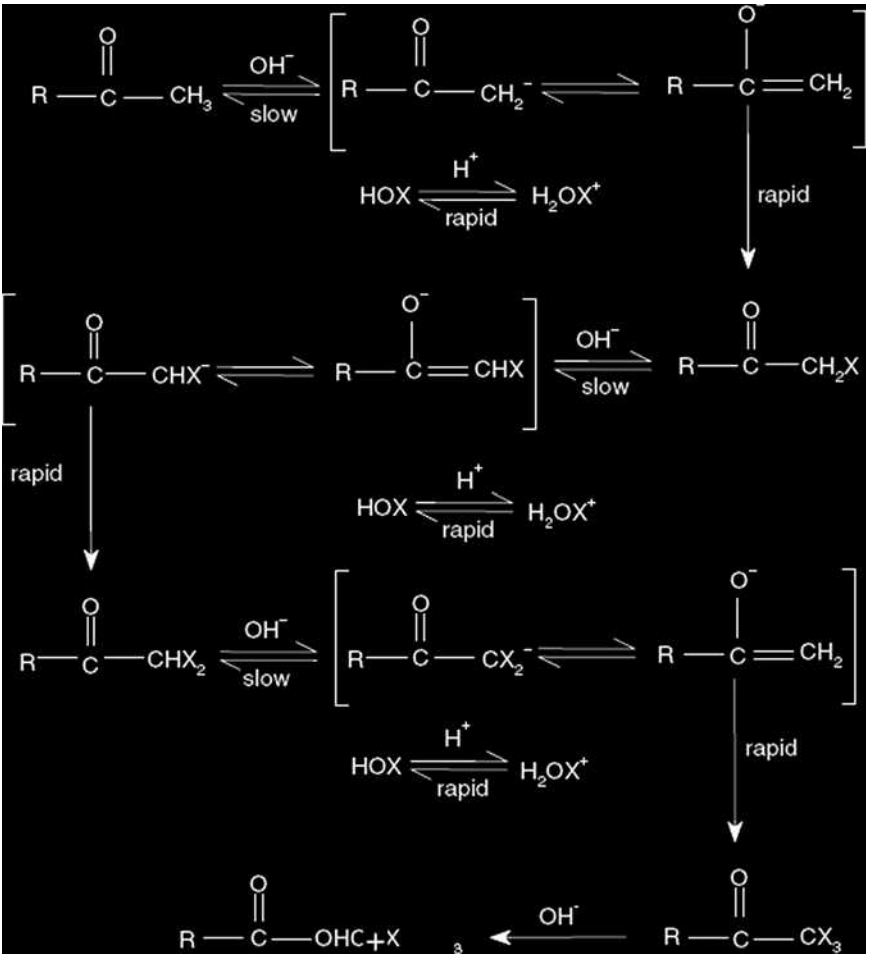

FIGURE 1 The haloform reaction—THMs formation.

acetone, chlorinated acetonitrile, chloropicrin, chloral, chloroacetic acids, chlorinated ethers, chlorophenols, chlorinated ketones, etc.[71] Koch and Krasner[74] estimated that among organohalogen compounds formed during chlorination of water, 77% are THMs, 15% are haloacetic acids, 3% are halonitriles, 4% is trichloroacetaldehyde hydrate, and 1% are the remaining compounds. Typical concentrations of trichlorometh-ane (chloroform), the most frequently present compound in chlorinated water, varied from 1 to 30 μg/L. Volatile organohalogen compounds have been determined primarily in tap water;[3,63–65,68–76] however, they also occur in surface water, groundwater, rainwater,[65,70,77,78] or even in the water and ice of polar regions.[65] Several volatile organohalogen compounds fall into the category of known or suspected carcinogens. In Table 4, the carcinogenic potential of organohalogen compounds occurring in drinking water and recognized by the EPA[2,4,5] as toxic or carcinogenic is presented. The MAC for drinking water varied from 0.3 μg/L for 1,1-dichloroethene (WHO, Norway) to 100 μg/L (EU, WHO, EPA, United Kingdom) and 350 μg/ L (Canada) for the total THMs. The MAC in the directives of WHO, Poland, and Great Britain for chloroform in tap water is 30 μg/L. Besides the groups of compounds discussed above, large amounts of other toxic pollutants, including pesticides, polychlorinated biphenyls (PCBs), polycyclic aromatic hydrocarbons (PAHs), crude oil derivatives, phenols, endocrine disruptors, etc., can be present in drinking water. Pesticides enter water either directly

TABLE 4 Carcinogenic Potential of Organohalogen Compounds Occurring in Drinking Water and Recognized by the U.S. EPA as Toxic or Carcinogenic

Compound	Carcinogenic Potential (μg/kg body/day)	Certainty of Hazard
Chloromethane	2.5	S
Dichloromethane	2.2	3
Trichloromethane (causes hepatocellular carcinomas and liver and kidney tumor in mice, and renal tumor in rats after chronic exposure)	11	CA
Tetrachloromethane (induces preneoplastic changes in the liver of rats, and liver tumors in male rats and mice)	0.4	CA
Bromodichloromethane	55	S
Dibromochloromethane	250	S
Tribromomethane	1100	S
Dichloroiodomethane	2.2	S
1,2-Dichloroethane	9.4	CA
1,1,1-Trichloroethane	20	S
Vinyl chloride	0.017	CU
Trichloroethylene (causes increases in the incidence of hepatocellular carcinomas, pulmonary carcinoma, and malignant lymphomas in mice)	1.6	CA
Tetrachloroethene (induces high incidence of nephropathy in mice and rats, and hepatocellular carcinomas in mice)	0.73	CA
1,4-Dichlorobenzene	1.4	S
1,3-Dichlorobenzene	88	S
1,2-Dichlorobenzene	6.9	S
1,2,4-Trichlorobenzene	4.4	S
2,4-Dichlorophenol	1.7	S
Pentachlorophenol	40	S
Polychlorinated biphenyls	53	S

Note: CA, animal carcinogen; CU, human carcinogen; S, suspected carcinogen.

by their application for mosquito control, or indirectly from drainage of agricultural lands, permeation through soil, erosion, wastewater from pesticide production, municipal wastes (fungicides and bactericides), etc. Consequently, a number of papers have been published confirming the presence of pesticides and PCBs not only in surface waters but also in potable water, particularly in water from wells existing in agricultural areas, in rainwater, as well as in water and ice from polar regions.[66,79–81] For humans, the major route of exposure to these pollutants is the gastrointestinal system, mainly by way of food (because of bioaccumulation and biomagnification in the food chain), but also through drinking water. Pesticides, PCBs, phenols, and some PAHs are carcinogenic, mutagenic, and teratogenic, and cause cardiovascular, neurological, and other diseases;[14,20,64,66,69,82] thus, there is a need for continuous monitoring of the degree of pollution by these compounds of potable and surface waters. Owing to the possibility of bioaccumulation of organic compounds, even low concentrations can result in poisoning of an organism. WHO, the EC, and most countries, including Poland, introduced a MAC for some toxic organic compounds present in tap water.[4–9,83] In Table 5, the MACs for toxic organic compounds recommended by WHO and those established by Poland are listed.[6,9]

Consequently, there is a need for continuous monitoring of the degree of pollution of potable and surface waters by toxic anthropogenic organic compounds. To be able to monitor environmental pollutants properly and effectively, analysts need a variety of methods for the isolation and determination of these contaminants, taking into account both physical-chemical properties of individual compounds

and groups of compounds and the characteristics of the matrices in which these compounds occur. Volatile organohalogen compounds, pesticides, and other organic pollutants occur in water at relatively low concentration levels; thus, there is a need for the isolation of organic compounds from a complex aqueous matrix and their preconcentration.

Methods of isolation and preconcentration of organic compounds from water are closely associated with the kind of analytes, their volatility, polarity, stability, water solubility, solubility in organic solvents, etc. Numerous techniques for the isolation and enrichment of organic analytes have been developed, the most common ones being solvent extraction, solid sorbent extraction, techniques utilizing the distribution of solute among the liquid and the gaseous phase (headspace, purging), as well as less commonly used techniques such as freezing out, lyophilization, vacuum distillation, steam distillation, and membrane processes (reverse osmosis, ultrafiltration, dialysis).[53–58,61–70,84–91] A schematic diagram of utilization of various isolation techniques for the determination of organic compounds in water is shown in Figure 2. The only method of determination of organohalogen compounds in water that avoids the isolation and preconcentration step uses direct injection of an aqueous sample onto a GC column and an electron capture detector (direct aqueous injection-electron capture detection, DAI-ECD).[63,65,70,92–97] This method requires a special injector allowing cold on-column injection and special capillary columns (see Figure 3). Cooling of the injector prevents sample evaporation from the needle of a syringe before its withdrawal. The DAI-ECD technique has been successfully used for the determination of volatile organohalogen compounds containing one or two carbon atoms (the products

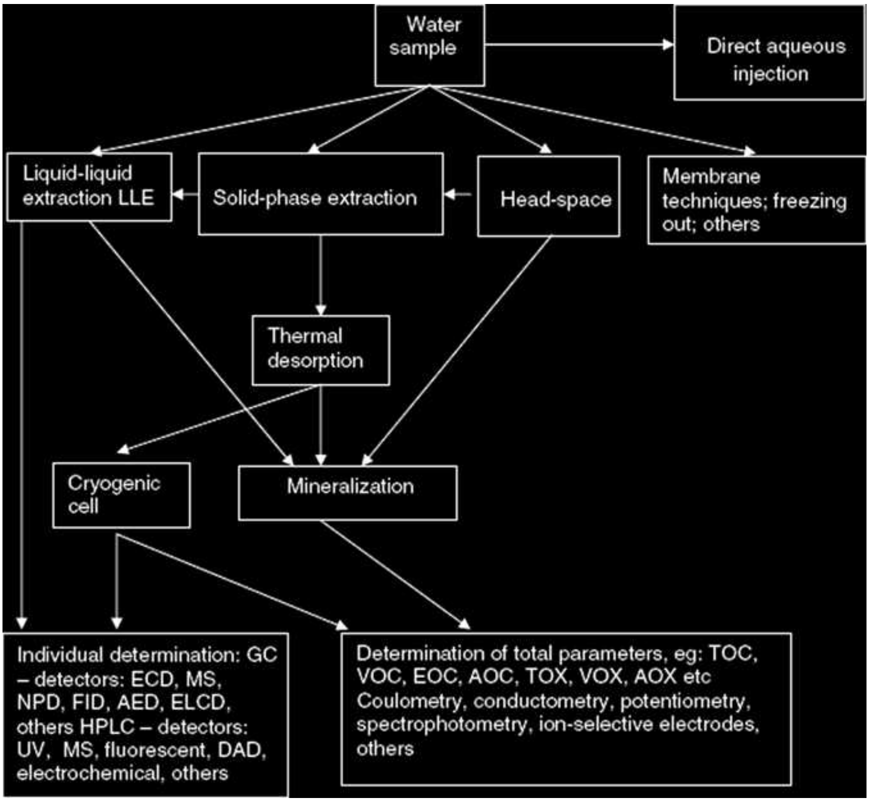

FIGURE 2 A general procedure for the analysis of trace organic pollutants in water.

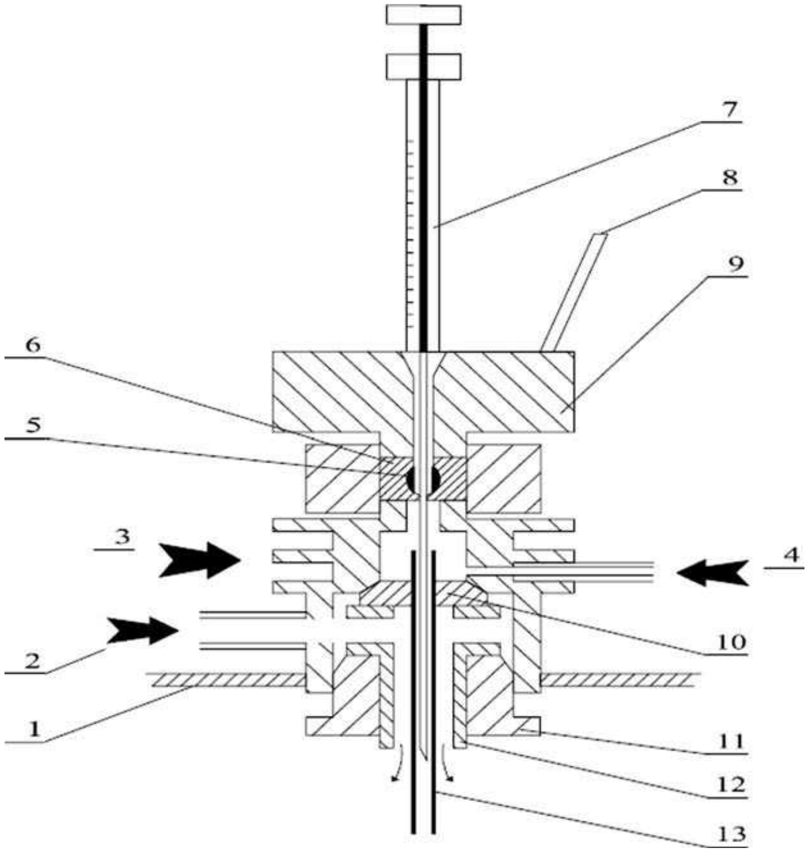

FIGURE 3 Schematic diagram of non-vaporizing septum-less, cold on-column injector: 1—the oven wall; 2—the secondary air cooling; 3—the principal air cooling system; 4—the carrier gas inlet; 5—the stainless steel rotating valve; 6—the valve seal; 7—the syringe; 8—the valve lever; 9—the upper part of injector; 10—the column seal; 11—the bottom part of injector; 12—the cooling jacket; 13—the capillary column.

of chlorination of humic substances; THMs) in tap water and surface water.[63,65,90,92–96] The method avoids the problems associated with incomplete recovery of the analytes during their isolation from the aqueous phase, the effect of potential contaminants when using solvent or solid-phase extraction, and losses of the analytes during the enrichment step. The main advantages of DAI-ECD include its simplicity (no isolation and preconcentration methods are necessary), repeatability, reduction of the possibility of sample contamination, and low detection limits (0.015–0.6 μg/L depending on the percentage of halogen in the compound). The detection limit of the method is related to the amount of the analyte in the sample injected onto the column and the volatility of the analytes.

For final determination, GC with specific detectors such as ECD, nitrogen-phosphorus detector (NPD), flame photometric detector, atomic emission detector (AED), and electrolytic conductivity detector (ELCD), or GC with universal detectors such as flame ionization detector (FID) or mass spectrometry (MS) is used. Liquid chromatography methods with ultraviolet (UV), MS, diode-array (DAD), electrochemical, or fluorescent detectors are also often used.[53–58,62,63,65–68,92–96] In Figure 2, two main ways of determining organic compounds in water are shown: determination of individual compounds or of total parameters. Total parameters such as total organic carbon or halogen (TOC, TOX), dissolved organic carbon or halogen (DOC, DOX), and suspended organic carbon or halogen (SOC, SOX) are used to characterize the content of organic compounds in water. Other parameters are defined in terms of the method of isolation of an organic fraction from water: volatile (VOC, VOX) or purgeable (POC, POX), extractable (EOC, EOX), and adsorbable (AOC, AOX) organic carbon or halogen. However, total parameters measuring the carbon content in an organic fraction are not particularly suitable as an estimate of anthropogenic water pollutants and their hazard to human health since a decisive majority of organic compounds in water are biogenic.

Characteristics of Some Water Bacteria and Pathogens in Drinking Water

Natural non-contaminated groundwater and surface water contain relatively low numbers of microorganisms. In general, groundwater has fewer bacteria than surface water. Microbial abundance and species composition depend on the depth of water-bearing stratum, soil type, and the geological structure and sanitary conditions in the given area. Aquatic bacteria are both autochthonic and allochtonic organisms. Autochthonic organisms, the so-called local microbes, reside permanently in the waters of a given water body, while allochtonic (alien) organisms are transferred into the water basin from the atmosphere and soil and through municipal and industrial wastewaters. Autochthonic microflora consists of autotrophic bacteria that are capable of photo- and chemosynthesis. It also includes heterotrophic organisms that cannot synthesize their own food. Purple as well as green bacteria are among the photosynthesizing autotrophs. Chemosynthetic bacteria are represented by nitrifying bacteria, iron- and sulfur-oxidizing bacteria, and hydrogen bacteria. Many species of autochthonic bacteria are heterotrophic organisms that feed exclusively on non-organic matter of allochthonous origin. Typical heterotrophic bacteria belong to the genera *Pseudomonas, Spirocheta, Vibrio,* and *Aeromonas.* Allochthonic organisms are mostly heterotrophic. They consist of saprophytes (feeding on organic compounds that are the products of decomposing remnants of plants and animals) as well as parasites (feeding at the expense of other live organisms). The most abundant saprophytic group is represented by a rod-shaped species such as *Escherichia coli*, *Aerobacter aerogenes*, and *Serratia marcescens*. Moreover, the rods from the genera *Bacillus* and *Clostridium* that become transferred from soil into the natural waters during rainfall can be classified as allochtonic aquatic bacteria. Water, which is not the natural environment of disease-causing microorganisms, plays a very important role in the process of their transfer. In cases when infectious diseases occur among the general public or when people become disease carriers, it is possible that potable water can become contaminated with the excrements of infected humans. The use of such water for drinking or food preparation and the exposure to it during washing may result in infection. The survival times of disease-causing organisms in the aquatic environment depend on many factors, inter alia, the pH of water, UV radiation, the presence of chemical compounds, and the level of water contamination. The main source of disease-causing microorganisms in natural waters is wastewater of human and animal origin. Pathogenic bacteria that become transferred into the water bodies through excrements, wastewater, and runoff from the fields are mainly related to digestive tract disorders in humans and animals.[98–100] The most typical bacteria of this kind come from the rod-shaped genus *Salmonella* and cause a variety of digestive system infections. The main genera of disease-causing bacteria that are transferred by water and the diseases caused by these bacteria are presented in Table 6. In water delivered by the water supply system, there can be microorganisms that have no influence on human health but form a film or membrane on the inside of the pipeline walls. The growth of such bacteria has a detrimental effect on water quality. A typical manifestation of biological fouling inside the water supply system is the altered color, turbidity, and undesirable taste and smell of water. In addition, the parameters of water exploitation may worsen owing to microbiological corrosion, plugging of the water-bearing stratum, and the lowered efficiency of the well.

TABLE 6 Main Kinds of Pathogenic Bacteria Found in Water and the Diseases They Cause

No.	Pathogenic Bacteria	Diseases
1	Rod-shaped Salmonella	Abdominal typhoid fever, Paratyphoid fever, salmonellosis
2	Rod-shaped Shigella	Bacterial dysentery
3	Curved rods Vibrio cholerae	Cholera
4	Francisella tularensis	Tularemia
5	Spirochaeta from Leptospira genus	Spirochetal jaundice, leptospirosis
6	Rod-shaped Escherichia coli	Acute dysentery, infection sticks of colon
7	Legionella pneumophila	Acute pneumonia, Legionnaires' disease
8	Aerobic, spore-forming bacilli Bacillus	Corneal abrasion, ankylosing spondylitis, feed poisoning, anthrax
9	Rod-shaped Mycobacterium	Tuberculosis
10	Yersinia enterocolitica	Yersiniosis

Microbiological Research Methods for Analysis of Drinking Water

The danger of humans contracting infections from water necessitates the permanent sanitary control of drinking water by bacteriologists and hygienists. Simple methods that can indicate the presence of pathogenic organisms are used because indirect methods are laborious and time consuming. Currently, in routine studies, intermediate methods based on indicative bacteria are used. The organism indicative of contamination has to comply with the following conditions:

- It has to be a permanent inhabitant of the intestine that occurs in large numbers
- It cannot be a pathogenic bacterium
- It cannot form spores
- It cannot multiply in water
- should be easy to detect
- It has to exist longer than pathogens in the natural environment (water, soil)
- It should be removed during the water conditioning in a similar way as the pathogen organisms

Water samples for microbiological analysis must always be collected in a sterile container. The samples should be refrigerated and transported to the testing laboratory as soon as possible. Fecal contamination of water can be determined by the presence of fecal coliforms or enterococci in a water sample by the multiple-tube technique. The bacteria can also be detected by the membrane filtration technique. The membrane filtration technique is based on the entrapment of the bacterial cells by a membrane filter (pore size, 0.22 or 0.45 μm). After filtration, the membrane with the microorganisms is placed on a petri dish containing the appropriate medium and incubated. After incubation at the correct temperature and time, characteristic colonies on the membrane surface are counted. Confirmatory tests are carried out where necessary. The membrane filtration method is especially useful for testing drinking water because large volumes of sample can be analyzed in a short time. The main indicating organisms of water fecal contaminations are *E. coli,* lacto-positive bacteria, coliform bacteria, thermotolerant *E. coli* types, fecal enterococcus, and *Clostridium* species. Several of the above-mentioned indicator conditions are fulfilled by *E. coli* and, to a lesser extent, by coliform bacteria and thermotolerant *E. coli* types. *E. coli* belongs to the family Enterobacteriaceae. It is a small, non-spore-forming, gram-negative, rod-shaped bacterium. It lives in the large intestine of humans and animals, where its density reaches a maximum of 10^9 cells per gram of fecal matter. These bacteria are grown at temperatures of 44–45°C on complex culture media. Usually, they are able to ferment lactose and mannitol with formation of acid and aldehyde, and they are able to produce indole from tryptophan. *E. coli* possesses two enzymes: β-galactosidase and β-glucoronidase; however, it does not form oxidase and does not hydrolyze urea. Lacto-positive bacteria are able to form colonies in aerobic conditions at 36±3°C on culture medium with lactose, with acid formation. Coliform bacteria are non-spore-forming, oxidase-negative, gram-negative, rod-shaped bacteria that are able to ferment, at 35–37°C, lactose to acids and aldehydes within 24–48 hr. Thermotolerant *E. coli* types are able to ferment lactose at 44–45°C. *Enterobacter, Citrobacter,* and *Klebsiella* also belong to this group. Coliform bacteria do not have to be directly connected with fecal contamination or with the occurrence of pathogens in drinking water. They could be present in drippings, in nutrient-rich water, in soil, and in decayed vegetable residues. These bacteria cannot occur in conditioned drinking water. Their presence in water suggests improper conditioning of water, secondary contamination, and excessive content of nutrient substances in conditioned water. These bacteria could be exploited as an indicator of the effectiveness of water conditioning. The frequency of indicative bacteria is determined to set the coliform titer—the lowest volume of water (milliliters) in which these bacteria are detected. According to ISO standards, the final Result is given as an index of coliform bacteria of *E. coli* in 100 mL of water tested. Fecal enterococci are spherical or oval, catalase-negative, gram-positive bacteria, occurring as a short chain. They can reduce 2,3,5-triphenyltetrazolic chloride to formazine and hydrolyze esculin at 44°C. They express D Lancefield antigen. The term *fecal Enterococcus* refers to those bacteria that occur in droppings of humans. Fecal enterococci that are not found in droppings of humans but occur in droppings of animals do not belong to the fecal enterococcus group. They die quickly in the external environment, faster than many pathogenic bacteria. The presence of fecal enterococcus in water can indicate fresh contamination of water; thus, it also proves the potential menace of pathogenic bacteria. Because these bacteria are resistant to drying, they could be helpful in routine control of water quality carried out after new water supply systems are built or after their repair. After *E. coli*, they could be the second fecal enterococcus that can be used as an indicative organism of contamination. Clostridial bacteria are sulfite-reducing, gram-positive, spore-forming bacilli that can survive in soil and water for a long time (even for many years). They are usually found in droppings, but they can originate from other sources. These bacteria are grown at 37°C. Breeding of these species can indicate a very "old" water contamination, after the death of all pathogenic bacteria. The spores of *Clostridium* are resistant to disinfection; thus, their presence in disinfected water may indicate a shortcoming in water conditioning. These bacteria are not recommended for the routine monitoring of water quality or detecting fresh contamination because of their length of survival. *Clostridium* might be present for a long time after the appearance of the contamination and far away from the place of this contamination. In sanitary analysis of drinking water, besides the presence of indicative bacteria, the general number of psychrophilic and mesophilic bacteria in 1 mL of water is determined. Culturing of psychrophilic bacteria is carried out on a solid agar culture medium for 72 hr at 22°C—the optimum conditions for these bacteria. A large quantity of these bacteria can indicate the inflow of organic substances to water, which creates favorable conditions for the growth of saprophytic bacteria. Culturing of mesophilic bacteria is performed on a solid agar culture medium for 24 h or 48 h at 37°C. The thermal optimum for these bacteria is the temperature of the human body, 37°C. The overall quantity of mesophilic bacteria consists of effluent bacteria and some soil bacteria. Their presence in water is a proof that contamination with domestic sewage and industrial waters has occurred.

Water: Surface

Victor de Vlaming

Introduction

In numerous aquatic ecosystems across the United States losses of biodiversity and significant population declines of multiple species have been documented over the past 40 years. These aquatic ecosystems are imperiled due to human activities such as habitat destruction, damming and diversion of waters, introduction of exotic species, and release of toxic concentrations of chemicals, including pesticides, into surface waters.

Pesticide Use

Quantities of pesticides used in the United States have increased approximately 50-fold since the 1960s such that more than a billion pounds of pesticide active ingredients are used each year.[1] Hundreds of different pesticides have been developed for application in agricultural and other settings to control weeds, insects, fungus, and other pests. The characteristics of pesticides have evolved over the past 30 years from chemicals such as the organochlorines (OC) that are very persistent in the environment but tend to have relatively low toxicity, to chemicals such as organophosphorus (OP) and carbamate insecticides that are toxic at very low concentrations (e.g., parts per trillion) but generally are not very persistent. The majority of pesticide use is agricultural (70%–80% of total), but there is also use in urban areas for gardens, lawns, homes, and buildings, as well as in forestry, along roads and railways, and in various industrial and commercial situations.

Pesticide Transport and Patterns of Occurrence

Unfortunately pesticides do not always remain where they are applied. Off-site movement occurs irrespective of applications made according to label instructions. Off-site movement can occur by aerial drift of sprays, by evaporation, in storm and irrigation water runoff, and by seepage. Surface waters are vulnerable to pesticide contamination because most agricultural and urban areas drain into streams and rivers. Since pesticides are designed to be lethal to organisms, they pose a significant risk to biota when they enter aquatic ecosystems. Many of the currently used pesticides are so lethal that runoff of less than 1% of the quantities applied in a watershed into surface waters can have profound effects on aquatic biota.

The most extensive program for monitoring surface waters for chemical contaminants in the United States is the National Water-Quality Assessment (NAWQA) Program of the U.S. Geological Survey. Initiated in 1991, the focus in NAWQA has been on major watersheds distributed throughout the United States, encompassing 60%–70% of national water use. Pesticides have been one of NAWQA's top priorities. Much of the information summarized below was collected in the NAWQA program.[1–3]

Pesticides have been detected in every region of the United States where surface waters were analyzed for these chemicals. Although no individual study analyzed for every pesticide, a wide variety of pesticides including insecticides, herbicides, and fungicides have been identified in surface waters throughout the United States. The distribution of pesticides in surface waters generally follows geographic and seasonal agricultural patterns and also the influence of urban areas. That is, frequency of detections and highest concentrations are recorded in streams and rivers where agriculture is a major land use and pesticide use is intense. In most agricultural areas, the highest concentrations of pesticides occur as seasonal pulses, with duration of a few weeks to several months. Frequency of occurrence and highest concentrations also are associated with seasonal application patterns, being greatest coincident with or after applications. In urban-dominated streams, seasonal patterns are less obvious, pesticide concentrations being elevated for longer periods. In these urban streams, insecticides are detected at higher frequencies and concentrations than in streams draining agricultural areas. The largest areas where high quantities of pesticides are applied to crops occur in California, Florida, the Midwest, the lower Mississippi River Valley, and the coastal areas of the Southeast.

Herbicides are detected more frequently, and at the highest concentrations, than other pesticides in surface waters. Considering data collected from across the United States, herbicides occurring most frequently and at the highest concentrations are atrazine, simazine, metolachlor, prometon, DEA, alachlor, and cyanozine. The insecticides measured most frequently and at the highest concentrations are diazinon, chlorpyrifos, carbaryl, carbofuran, and malathion.

Pesticides are encountered most often and at elevated concentrations in streams and rivers draining agricultural areas just prior to and during the growing season. Also, a greater number of pesticides occur in surface waters coincident with these periods. These mixtures of pesticides have a potential for additive and synergistic adverse impacts on aquatic ecosystem health. An exposure pattern that is developing is one of long-term exposure to relatively low concentrations of pesticide mixtures punctuated with seasonal pulses of high concentrations, the effects of which are not currently known.

Off-site movement is a critical issue with regard to pesticide contamination of aquatic ecosystems. The relationship between quantities of pesticides applied (amount per unit area and total area of application) and detection frequency, as well as concentrations in surface waters was stated above. While this is a general principle, it does not apply to all pesticides and situations. Some pesticides, which are used rather extensively in agriculture, are seldom detected in surface waters. This low detection rate in surface waters relates to physical/chemical and/or degradation properties. Some such properties can result in pesticides adsorbing to particles (organic or soil) that may reduce off-site movement while different properties of other pesticides favor rapid degradation.

One might conclude that use of pesticides with a lower potential for off-site movement would reduce risk of impacting aquatic ecosystem health. While there is some truth in this idea, such physical/chemical properties often render pesticides more persistent. Furthermore, organic and soil particles to which pesticides are adsorbed can be transported by erosion (associated with rainfall, irrigation, or wind) into streams and rivers. Pesticides adsorbed to particles can settle into surface water sediments and have deleterious effects on bottom-dwelling organisms. Such physical/chemical properties also tend to result in bioaccumulation by aquatic organisms. These pesticides can bioaccumulate in aquatic species to levels that are detrimental and/or biomagnified to adverse levels in the food chain as contaminated organisms are eaten.

Examination of fish and bivalve tissues reveal that they are being exposed to a variety of bioaccumulable pesticides in both agricultural- and urban-dominated waterways. Residues of some pesticides in fish tissues can be such that they are harmful to human health. Organochlorine (e.g., DDT, chlordane), pyrethroid, and other hydrophobic insecticides are examples of pesticides that adsorb to organic materials, are persistent, bioaccumulate, and biomagnify. Unfortunately, there is a paucity of information on what pesticide tissue residue levels are deleterious to organisms or to other species that eat them.

Effects of Pesticides

The occurrence of pesticides in surface waters of the United States is widespread. What is the significance of this phenomenon? Adverse effects of chemicals, including pesticides, are determined by concentration, as well as by duration and frequency of exposure. The federal Clean Water Act (CWA) was enacted to protect human and aquatic organism health, requiring that no chemical can occur in surface waters at toxic concentrations. CWA requirements are implemented through enforceable water quality standards for specific chemicals and toxicity. Water quality standards and criteria have been established by various agencies for only a few pesticides. These standards and criteria are an estimate of a chemical concentration in water below which detrimental effects are not expected to occur. Comparing concentrations of a chemical in surface water to such standards and criteria provides an indication of potential antagonistic impacts on aquatic biota.

Standards for human health apply to treated drinking water supplied by community agencies. Therefore, the standards do not apply directly to most surface waters. While these standards do not pertain to concentrations of pesticides in surface waters, they do afford a benchmark to which measured pesticide concentrations can be compared. Chemical analyses of surface water samples do not include all pesticides; however, few pesticides included in analyses were detected at concentrations exceeding any drinking water standards. The pesticides most often exceeding standards are the triazine and acetanilide herbicides, atrazine, alachlor, cyanazine, and simizine.[1] Some, but not all, treatments of water to be used for drinking destroy or remove these herbicides.

For the more than 120 pesticides detected in surface waters there exist only 13 U.S. Environmental Protection Agency criteria developed for the protection of aquatic ecosystem health. For most currently used insecticides and for all herbicides there are no criteria for the protection of aquatic life. Canada has a larger number of aquatic life criteria, which are more stringent than U.S. criteria. U.S. pesticide aquatic life criteria are commonly exceeded in streams and rivers collecting from agricultural lands and/ or urban areas. Aquatic life criteria of four OP insecticides, azinphos-methyl, chlorpyrifos, diazinon, and malathion are the most frequently exceeded by concentrations in surface waters. Data collected from across the United States indicate that azinphos-methyl and chlorpyrifos exceed aquatic life criteria for more days per year than other insecticides monitored.[1,3] Major concerns regarding OP insecticides are that they are toxic to aquatic species at very low concentrations, different OPs repeatedly co-occur in surface waters, and their toxicity is additive.

In some regions of the country, where their use is high, carbamate insecticides are threats to aquatic biota. More than 20 years after being banned, OC insecticides continue to be detected in surface waters and sediments at concentrations that exceed aquatic life criteria. Especially in streams and rivers draining agricultural areas, but also in urbandominated streams, two or more pesticides often cooccur at concentrations that exceed their respective aquatic life criteria. Several studies from across the country reported high occurrences of diseased, deformed, and highly parasitized fish, as well as fish with a high incidence of tumors in surface waters where pesticide concentrations exceed aquatic life criteria and/or are elevated.

Measuring pesticide concentrations in surface waters does not furnish direct information of bioavailability (the percentage of the analytically measured amount of a chemical that produces toxic effects) or toxicity to aquatic biota. Toxicity testing of surface waters provides a direct measure of capacity of these waters to support healthy aquatic organisms. Standardized toxicity tests with aquatic species are available that measure lethal and sublethal (e.g., inhibition of reproduction, growth, etc.), effects. As a diagnostic tool for assessing water quality, toxicity testing has several merits. Toxicity tests afford an integrative measure of adverse effects of chemicals on organism health and viability, as well as the bioavailabity of chemicals.[4] Also, results of these toxicity tests have been reliable predictors of impacts on aquatic ecosystem biota. Chemical analyses of water cannot provide such information.

Statewide monitoring programs in California have disclosed that, on a seasonal basis, agricultural- and urban-influenced streams and rivers are lethal to test species.[4,5] Complex toxicological, chemical, and physical procedures (toxicity identification evaluation-TIE) that specifically identify the chemical(s) causing toxicity demonstrated that the pesticides most commonly responsible for the surface water toxicity are diazinon and chlorpyrifos. Carbofuran, malathion, carbaryl, methyl-parathion, thiobencarb, diuron, and molinate also have been shown to be causes of toxicity in California's surface waters. These surface water toxicity testing programs are not common in other regions of the United States. Such surface water toxicity is likely to occur in most urban streams and in surface waters collecting runoff from areas where agriculture is the predominant land use and where pesticides are used intensively.

Gaps in Knowledge

Pesticide adverse impacts on aquatic ecosystem health throughout the United States are most likely underestimated for several reasons. 1) The number of U.S. streams and rivers thoroughly monitored is very limited so that the distribution and extent of pesticide contamination is unknown. 2) Most investigations have been incomplete for one or more reasons, including too few sampling sites, sample collection was in frequent, and study duration was abbreviated. 3) None of these monitoring investigations included the complete range of pesticides that could impact aquatic biota. 4) Analytical detection limits for pesticides have been a problem in assessing detrimental effects on aquatic ecosystem health. In most monitoring projects analytical detection limits for many pesticides were higher than known toxic effects on aquatic species, as well as above aquatic life criteria. 5) Sublethal and delayed effects of pesticides, including bioaccumulation and biomagnification responses, generally are not evaluated. For example, several pesticides, including alachlor, atrazine, 2,4-D, metribuzin, trifluralin, aldicarb, carbaryl, parathion, some pyrethroids, benomyl, mancozeb, maneb, zineb, and ziram, commonly used in U.S. agriculture, have been shown to disrupt endocrine systems in some aquatic species.[6,7] Existing aquatic species toxicity screening procedures are inadequate for assessing endocrine disruption. 6) Seldom are indirect effects considered. For example, direct adverse effects on zooplankton during a period when they are critical food for larval fish could indirectly impact fish populations. 7) As stated above, aquatic organisms are exposed to pesticide mixtures in many watersheds across the United States. Assessments of impacts infrequently involve analysis of exposures to multiple chemicals.

Pesticides, especially insecticides, are having widespread impacts on surface water quality and aquatic ecosystem health throughout the United States. To reduce risks of pesticide impacts on aquatic ecosystem health, measures should be identified, developed, and implemented to eliminate or reduce off-site movement of these chemicals. More extensive and thorough monitoring of pesticides and of toxicity caused by these chemicals is advisable to assess the extent of pesticide-caused water quality degradation, as well as the effectiveness of remediation projects.

Wetlands

Ralph W. Tiner

Introduction

Wetland is a universal term used to describe the collection of flooded or saturated environments that have been referred to as marshes, swamps, bogs, fens, salinas, pocosins, mangroves, wet meadows, sumplands, salt flats, varzea forests, igapo forests, bottomlands, sedgelands, moors, mires, potholes, sloughs, mangals, palm oases, playas, muskegs, and other regional and local names. It has been defined as a basis for inventorying these natural resources, for conducting scientific studies, and, in some countries, for regulating uses of these areas. Given that wetlands include a diverse assemblage of ecosystems, classification schemes have been developed to separate and describe these different systems and to group similar habitats. Wetlands provide a number of functions that are considered valuable to society (e.g., surface water storage to minimize flood damages, sediment retention and nutrient transformation to improve water quality, shoreline stabilization, streamflow maintenance, and provision of vital habitat for fish, shellfish, wildlife, and plants that yield food and fiber for people). Because of these values and the widespread recognition of wetlands as important natural resources, numerous wetland definitions and classification systems have been developed to inventory these resources around the globe. The purpose of this entry is to provide readers with an understanding of what wetlands are (wetland definition), how they vary globally (wetland types), and their extent as determined by various inventories. This entry should serve as a starting point for learning about wetlands, with the listed references being sources of more detailed information.

Wetland Definitions

Wetlands are aquatic to semiaquatic ecosystems where permanent or periodic inundation or prolonged waterlogging creates conditions favoring the establishment of aquatic life. Wetlands are often located between land and water and have, therefore, been referred to as ecotones (i.e., transitional communities). However, many wetlands are not ecotones between land and water, since they are not associated with a river, lake, estuary, or stream.[1] Wetlands may derive water from many sources, including groundwater, river overflow, surface water runoff, precipitation, snowmelt, tides, melting permafrost, and seepage from impoundments or irrigation projects.

While the term "wetland" has many definitions, all definitions have common elements (see Table 1; some definitions even include deepwater habitats.). The presence of water in wetlands may be permanent or temporary. Their water may be salty or fresh. Wetlands may be natural habitats or artificially created.

TABLE 1 Examples of Wetland Definitions Used for Inventories

Country/Organization	Wetland Definition [Source]
International/Ramsar	"areas of marsh, fen, peatland, or water, whether natural or artificial, permanent or temporary, with water that is static or flowing, fresh, brackish, or salt, including areas of marine water the depth of which at low tide does not exceed 6 m ……. may incorporate riparian and coastal zone adjacent to wetlands, and islands or bodies of marine water deeper than 6 m at low tide lying within the wetlands."[2]
Australia	"areas of seasonally, intermittently, or permanently waterlogged soils or inundated land, whether natural or artificial, fresh or saline, e.g., waterlogged soils, ponds, billabongs, lakes, swamps, tidal flats, estuaries, rivers, and their tributaries.[12]
Canada	"land that is saturated with water long enough to promote wetland or aquatic processes as indicated by poorly drained soils, hydrophytic vegetation, and various kinds of biological activity which are adapted to a wet environment."[3]
U.S.	"lands transitional between terrestrial and aquatic systems where the water table is usually at or near the surface or the land is covered by shallow water." Wetland attributes include hydrophytic vegetation, undrained hydric soil, or saturated or flooded substrates.[4]

Source: Photos courtesy of U.S. Fish and Wildlife Service.

They range from shallow water environments to temporarily wet (i.e., flooded or saturated) areas. All are wet long enough and often enough to, at least, periodically support hydrophytic vegetation and other aquatic life (including anaerobic microbes), to create hydric soils or substrates, and to activate biogeochemical processes associated with wet environments.

Wetland Types

Differences in climate, soils, vegetation, hydrology, water chemistry, nutrient availability, and other factors have led to the formation of a multitude of wetland types around the globe. In general, wetlands are characterized by their hydrology (e.g., tidal vs. nontidal, inundation vs. soil saturation, frequency and duration of wetness), the presence or absence of vegetation (vegetated vs. nonvegetated), the type of vegetation (forested or treed, shrub, emergent, or aquatic bed), and soil type (e.g., organic vs. inorganic, peatland vs. nonpeatland). Table 2 presents brief descriptions of some North American types and Figure 1 shows examples of vegetated wetlands.

Various countries have devised classification systems for describing differences among their wetlands and for categorizing wetlands for natural resources inventories. Scientists have created systems to organize certain wetlands into meaningful groups for analysis and management (e.g., peatland classifications; see Tiner[1] for details). In 1998, the Ramsar Convention Bureau published a multinational classification system to provide consistency for inventorying wetlands and designating wetlands of international importance.[2] This system includes 11 types of marine or coastal wetlands (i.e., shallow water and intertidal habitats: permanent shallow marine waters; marine subtidal aquatic beds; coral reefs; rocky marine shores; sand; shingle or pebble shores; estuarine waters; intertidal mud, sand, or salt flats; intertidal marshes; intertidal forests; coastal brackish/saline lagoons; coastal freshwater lagoons). This system also includes 19 inland wetland types (i.e., permanently flooded aquatic habitats to intermittently flooded sites are represented: permanent inland deltas; permanent rivers/streams/creeks; seasonal, intermittent, or irregular rivers/streams/creeks; permanent freshwater lakes; seasonal or intermittent freshwater lakes; seasonal or intermittent saline/brackish/alkaline lakes and flats; permanent saline/brackish/alkaline marshes and pools; seasonal or intermittent saline/brackish/alkaline marshes and pools; permanent freshwater marshes and pools; seasonal or intermittent freshwater marshes and pools; nonforested peat-lands; alpine wetlands including meadows and temporary snowmelt waters; tundra wetlands; shrubby-dominated wetlands; freshwater tree-dominated wetlands on inorganic soils; forested peatlands; freshwater springs and oases; geothermal wetlands; and subterranean karst and cave hydrological systems). Lastly, nine man-made wetland types (aquaculture ponds; ponds; irrigated land

TABLE 2 Brief Nontechnical Descriptions of Some Wetland Types in North America

Wetland Type	General Description
Marsh	Herb-dominated wetland with standing water through all or most of the year, often with organic (muck) soils
Tidal marsh	Herb-dominated wetland subject to periodic tidal flooding
Salt marsh	Herb-dominated wetland occurring on saline soils, typically in estuaries and interior arid regions
Swamp	Wetland dominated by woody vegetation and usually wet for extended periods during the growing season
Mangrove swamp (Mangal)	Tidal swamp dominated by mangrove species
Peatland, mire, moor, or muskeg	Peat-dominated wetland
Bog	Nutrient-poor peatland, typically characterized by ericaceous shrubs, other woody species, and peat mosses
Fen	More or less nutrient-rich peatland, often represented by sedges and/or calciphilous herbs and woody species
Wet meadow	Herb-dominated wetland that may be seasonally flooded or saturated for extended periods, often with mineral hydric soils
Bottomland	Riverside or streamside wetland, usually on floodplain
Flatwood	Forested wetland with poorly drained mineral hydric soils located on broad flat terrain of interstream divides, common on coastal plains and glaciolacustrine plains
Farmed wetland	Wetland cultivated for rice, cranberries, sugar cane, mints, or other crops

Note: These types may be defined differently in other regions.

including rice paddies; seasonally flooded agricultural land; salt exploitation sites; water storage areas including impoundments generally more than 8ha; excavations; wastewater treatment areas; and canals and drainage channels) are also included in the system.

In North America, the Canadian and United States wetland classification systems were developed by government agencies interested in wetland conservation and management. The Canadian system emphasizes wetland origin (class), form, and vegetation in describing the wetland types.[3] Five wetland classes are recognized: bog, fen, marsh, swamp, and shallow water. Within each class, different forms and types are characterized. Eight general vegetation types are defined by the presence or absence of vegetation (treed, shrub, forb, graminoid, moss, lichen, aquatic bed, and nonvegetated). These types may be subdivided into other types (e.g., treed into coniferous or deciduous, shrub into tall, low, and mixed, graminoids into grass, reed, tall rush, low rush, and sedge, aquatic bed into floating and submerged). The U.S. Fish and Wildlife Service's wetland and deepwater habitat classification[4] is the official federal system used for mapping wetlands and for reporting the status and trends of wetlands in the U.S. The features separating wetlands include general ecological and physical factors and specific features such as vegetation, soil/substrate composition, hydrology, water chemistry, and human alterations. Classification follows a hierarchical approach with five main levels designated: ecological system (marine, estuarine, lacustrine, riverine, and palustrine), subsystem, class (vegetated: forested, scrub-shrub, emergent, and aquatic bed; nonvegetated: unconsolidated shore, rocky shore, streambed, and reef), subclass, and modifiers. The modifiers are used to describe a wetland's hydrology (water regime), pH and salinity (water chemistry), soils, and the influence of humans and beaver (special modifiers). Common types include estuarine intertidal emergent wetlands (e.g., salt and brackish marshes), estuarine intertidal unconsolidated shore (e.g., tidal flats and beaches), palustrine emergent wetlands (e.g., marshes, fens, and wet meadows), palustrine forested wetlands, and palustrine scrub-shrub wetlands (e.g., shrub bogs and shrub swamps).

A hydrogeomorphic approach (HGM) to wetland classification has also been developing in the U.S.[5] The HGM system emphasizes abiotic features important for assessing wetland functions. Seven

FIGURE 1 Some examples of North American wetlands: (a) tidal salt marsh, (b) inland marsh, (c) pothole marsh, (d) wet meadow/shrub swamp, (e) northern peatland, (f) bottomland swamp, (g) hardwood swamp, and (h) flatwood wetland.

hydromorphic classes are identified: riverine, depressional, slope, mineral soil flats, organic soil flats, lacustrine fringe, and estuarine fringe. The U.S. Fish and Wildlife Service has adapted the HGM approach to provide additional modifiers to its classification system on a pilot basis. These HGM-type descriptors include landscape position (i.e., lotic, lentic, terrene, estuarine, and marine), landform (i.e., slope, basin,

TABLE 3 Estimates of the Current Extent of Wetlands in Different Regions of the World

Region/Country	Wetland Extent (ha)	Source
Africa	121,321,683–124,686,189	[13]
Asia	211,501,790–224,117,790	[14]

Middle East	7,434,790	[18]
Neotropics	414,996,613	[19]
North America		
Canada	127,199,000–150,000,000	[20]
U.S.	114,544,800	[1]
Oceania	35,748,853	[21]
South America		
Tropical region	200,000,000	[22]

interfluve, floodplain, flat, island, and fringe), and water flow path (i.e., inflow, outflow, throughflow, bidirectional flow, isolated, and paludified).[6] These descriptors provide the required information to aid the evaluation of functions of wetlands across watersheds and large geographic areas.

Extent of Wetlands

Comprehensive wetland inventories do not exist in most countries. There are many inconsistencies among the inventories (e.g., different levels of effort, focus on particular types, and artificial wetlands such as rice paddies are often not included in wetland inventories).[7] Consequently, comparative analysis is fraught with problems. Nonetheless, Table 3 provides some perspective on the extent of wetlands in many regions. Most of the data came from a series of reports produced for the Bureau of the Ramsar Wetlands Convention.[8] Globally, estimates for wetlands range from about 750 million ha[7] to about 1.5 billion ha. Ten countries have over 2 million ha of peat-lands alone, with Canada leading at nearly 130 million ha (represents about 18% of the country) followed by the former U.S.S.R. at 83 million ha.[9,10] About a third of Finland is covered by peatlands (10 million ha). The Pantanal of South America, perhaps the largest wetland in the world, reportedly covers about 200,000 km^2 (or 2 million ha) during the wet season.[11]

PRO: Basic Environmental Processes

68

Eutrophication

Sven Erik Jørgensen

Eutrophication Problem

Many aquatic ecosystems suffer from eutrophication: lakes, reservoirs, estuaries, lagoons, fjords, and bays. It is a worldwide problem and, together with the oxygen depletion problem, is probably the most serious pollution problem of aquatic ecosystems.

The word eutrophy is generally taken to mean "nutrient rich." In 1919, Nauman introduced the concepts of oligotrophy and eutrophy, distinguishing between oligotrophic lakes containing little planktonic algae and eutrophic lakes containing much phytoplankton. The eutrophication of aquatic ecosystems all over the world has increased rapidly during the last decade due to increased urbanization and the consequently increased discharge of nutrients. The discharges in industrialized countries are about 1.8 kg N/yr and 0.5 kg P/yr. The production of fertilizers has grown exponentially in this century, and the concentration of phosphorus in many lakes reflects this.

The word eutrophication is used increasingly in the sense of the artificial addition of nutrients, mainly nitrogen and phosphorus, to waters. Eutrophication is generally considered to be undesirable, but this is not always true. The green color of eutrophied lakes makes swimming and boating less safe due to the increased turbidity, and from an aesthetic point of view, the chlorophyll concentration should not exceed 100 mg/m^3. However, the most critical effect from an ecological point of view is the reduced oxygen content of the hypolimnion, caused by the decomposition of dead algae, particularly in the fall. Eutrophic aquatic ecosystems sometimes show a high oxygen concentration (at the surface during the summer time) but a low concentration of oxygen in the hypolimnion, which may be lethal to fish. The oxygen depletion in the hypolimnion will often imply that the eutrophication is more difficult to abate, because anaerobic sediment will more easily release its content of phosphorus. Iron (III) is reduced to iron (II) by anaerobic conditions. As iron (III) has a very insoluble phosphorus salt, while iron (II) phosphate is readily soluble, the phosphorus release by anaerobic conditions is dependent on the composition of the sediment, particularly of course the iron content. One of the most applied lake restoration methods is the pumping of air or oxygen to the hypolimnion, which is used to significantly reduce the release of phosphorus from the sediment.

Water makes up 75%–90% of the total wet weight of plant tissue. It means that except for oxygen and hydrogen, the relative composition on dry weight basis would be 4–10 times higher. For phytoplankton, the carbon, nitrogen, and phosphorus content on dry weight basis are, respectively, approximately 40%–60%, 6%–8%, and 0.75%–1.0%. Phosphorus is considered the major cause of eutrophication in lakes, as it was formerly the growth-limiting factor for algae in the majority of lakes. Its use has increased tremendously during the last decade. Nitrogen is limiting in a number of East African lakes as a result of the nitrogen depletion of soils by intensive erosion in the past. Nitrogen is furthermore often limiting in the coastal ecosystems, at least for part of the year. However, today, nitrogen may become limiting in lakes as a result of the tremendous increase in the phosphorus concentration caused by the discharge of wastewater, which contains relatively more phosphorus than nitrogen. While algae use 5–10 times more nitrogen than phosphorus (see the content of these two elements in phytoplankton above), wastewater generally contains only 3 times as much nitrogen as phosphorus. In lakes, a considerable amount of nitrogen is furthermore lost by denitrification (nitrate → N_2). Lakes that have received wastewater for a longer period may therefore be limited by nitrogen. In environmental management, the key question is, however, not which element is the limiting factor but which element can be most easily controlled as a limiting factor. As phosphorus generally can be removed more easily and cheaply, it is often the most effective abatement of eutrophication to remove phosphorus effectively from wastewater discharge to the lake. Further details are given below.

It is a good management strategy for an abatement of eutrophication in aquatic ecosystems to find quantitatively all the sources of nitrogen and phosphorus. In most cases, based on this information, it is easy to find possible solutions and the corresponding costs. In this context, it is beneficial to apply an ecological model. Eutrophication models have been developed and applied for all these ecosystems. Many eutrophication models have been applied for environmental management, particularly for lakes and reservoirs. The *Handbook of Ecological Models Used in Ecosystem and Environmental Management*[1] gives a good overview of the available ecological models, including eutrophication models.

Growth of Phytoplankton

The growth of phytoplankton is the key process of eutrophication, and it is therefore important to understand the interacting processes that regulate growth. Primary production has been measured in great detail in a number of aquatic ecosystems and presents the synthesis of organic matter. The overall process can be summarized as follows:

$$\text{Light} + 6CO_2 + 6H_2O \rightarrow C_6H_{12}O_6 + 6O_2 \tag{1}$$

The composition of phytoplankton is not constant. The composition of phytoplankton and plants in general reflects to a certain extent the concentration of the water. If, e.g., the phosphorus concentration is high, the phytoplankton will take up relatively more phosphorus—this is called luxury uptake. Phytoplankton consists mainly of carbon, oxygen, hydrogen, nitrogen, and phosphorus: without these elements, no algal growth will take place. This leads to the concept of the limiting nutrient, which has been developed by Liebig as the law of the minimum. However, the concept has been considerably misused due to oversimplification. First of all, growth might be limited by more than one nutrient. The composition as mentioned above is not constant but varies with the composition of the environment. Furthermore, growth is not at its maximum rate until the nutrients are used, at which point growth stops, but the growth rate slows down as the nutrients become depleted.

The sequence of events leading to eutrophication has often been described as follows: Oligotrophic waters will have a ratio of N to P greater than or equal to 10, which means that phosphorus is less abundant than nitrogen for the needs of phytoplankton. If sewage is discharged into the aquatic ecosystem, the ratio will decrease, since the N-to-P ratio for municipal wastewater is 3:1, and consequently, nitrogen will be less abundant than phosphorus relative to the needs of phytoplankton, as indicated above. In this situation, however, the best remedy for the excessive growth of algae is not necessarily the removal of nitrogen from the sewage, because the mass balance might then show that nitrogen-fixing algae will give an uncontrollable input of nitrogen into the system. It is particularly the case if the aquatic ecosystem is a lake or reservoir. It is necessary to set up mass balances for each of the nutrients as already pointed out, and these will often reveal that the input of nitrogen from nitrogen-fixing blue-green algae, precipitation, and tributaries is contributing too much to the mass balance for the removal of nitrogen from the sewage to have any effect. On the other hand, the mass balance may reveal that the phosphorus input (often more than 95%) comes mainly from sewage, which means that it is better management to remove phosphorus from the sewage than nitrogen. Thus, what is important in environmental management is not which nutrient is most limiting, but rather, which nutrient can most easily be made to limit the algal growth.

The conceptual diagram in Figure 1 shows the nitrogen cycle, and Figure 2 shows the phosphorus cycle of aquatic ecosystems and illustrates the processes behind the cycling of these nutrients. As clearly pointed out above, it is always beneficial to use a mass balance to choose the most important components, forcing functions, and state variables to be considered in the management context. Let us illustrate the needed mass balance considerations by use of an example. Let us anticipate that it is an open question whether birds should be included in the selected management strategy (and in the eutrophication model). Birds may contribute considerably to the inputs of nutrients by their droppings. If the nutrients—nitrogen and phosphorus—coming from the birds' droppings are insignificant compared with the amounts of nutrients coming from drainage water, precipitation, and wastewater, inclusion of birds in the management strategy is only an unnecessary complication that only would contribute to the uncertainty. There are, however, a few cases where birds may contribute as much as 25% or at least more than 5% of the total inputs of nutrients. In such cases, it is of course important to include birds in the management and as a model component or at least as an important forcing function. A mass balance is always needed to uncover the main sources of a pollution problem—in the example of the inputs of nutrients. It is, however, rare (a good guess based on the author's experience is about 1% of aquatic ecosystems) that it is necessary to consider the droppings of birds as a significant source of eutrophication.

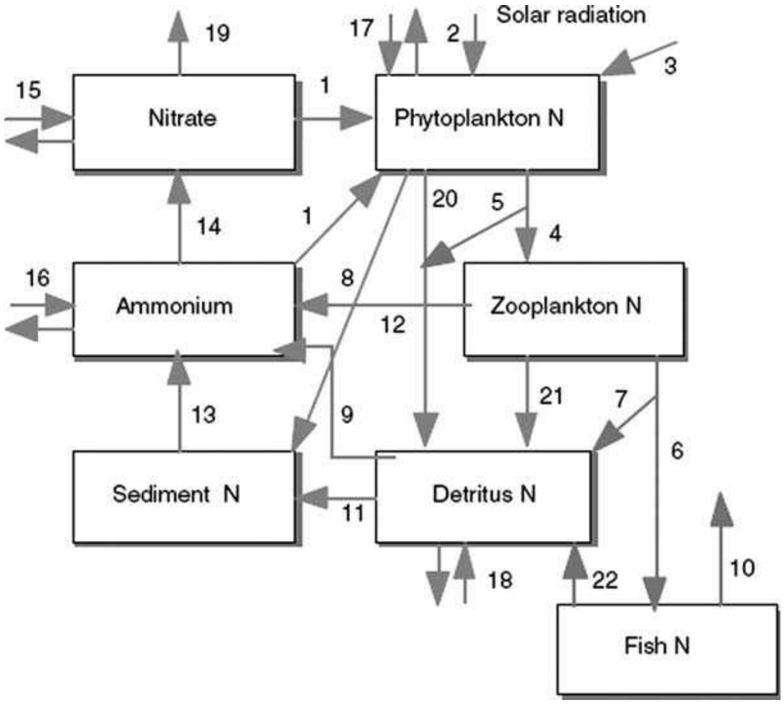

FIGURE 1 The conceptual diagram of a nitrogen cycle in an aquatic ecosystem. The processes that connect the state variables and forcing functions are the following: 1) uptake of nitrate and ammonium by algae; 2) photosynthesis; 3) nitrogen fixation; 4) grazing with loss of undigested matter; 5–7), predation and loss of undigested matter; 8) settling of algae; 9) mineralization; 10) fishery; 11) settling of detritus; 12) excretion of ammonium from zooplankton; 13) release of nitrogen from the sediment; 14) nitrification; 15–18) inputs/outputs; 19) denitrification; and 20–22) mortality of phytoplankton, zooplankton, and fish.

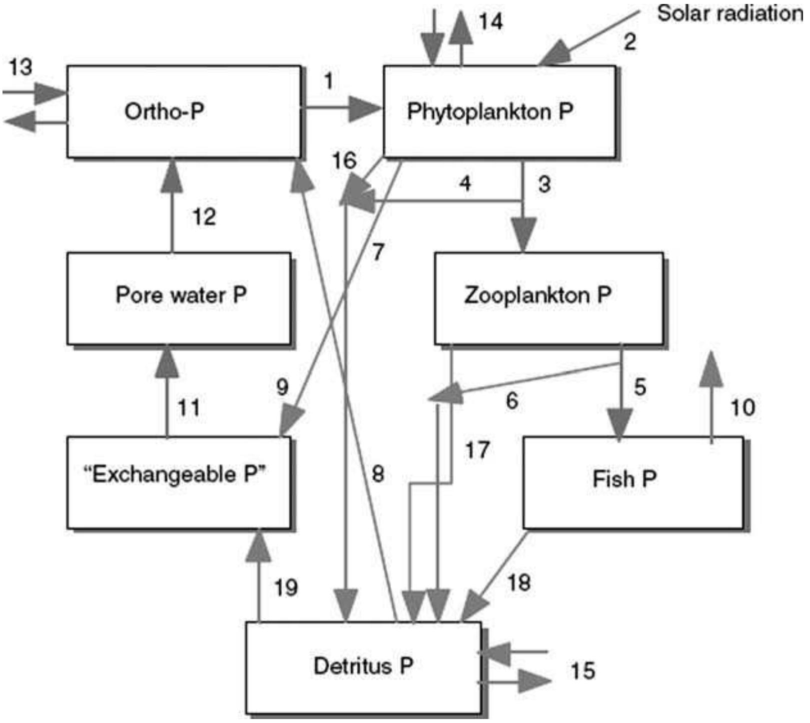

FIGURE 2 The phosphorus cycle. The processes are the following: 1) uptake of phosphorus by algae; 2) photosynthesis; 3) grazing with loss of undigested matter; 4–5) predation with loss of undigested material; 6, 7, 9) settling of phytoplankton; 8) mineralization; 10) fishery; 11) mineralization of phosphorous organic compounds in the sediment; 12) diffusion of pore water P; 13–15) inputs/outputs; 16–18) mortalities; and 19) settling of detritus.

The so-called Michaelis–Menten equation can be applied to describe the growth of phytoplankton:

$$\mathrm{gr} = \mathrm{grmax\ NS}/(\mathrm{kn}+\mathrm{NS}) \tag{2}$$

Or

$$\mathrm{gr} = \mathrm{grmax\ PS}/(\mathrm{kp}+\mathrm{PS}) \tag{3}$$

dependent on which nutrient is limiting, N or P. grmax, kn, and kp are parameters. If both nutrients are limiting in different periods of the year, the formulation is

$$\mathrm{gr} = \mathrm{grmax\ min}\big(\mathrm{NS}/(\mathrm{kn}+\mathrm{NS}),\ \mathrm{PS}/(\mathrm{kp}+\mathrm{PS})\big) \tag{4}$$

The product or average of several limiting factors has also been proposed and applied.

For the influence of the temperature, there are two possible formulations:

$$K_{\mathrm{t}}^{(\mathrm{TEMP}-20)}(\text{the so} - \text{called Arrhenius equation}) \tag{5}$$

Or

$$\exp\big(A^{*}(\mathrm{TEMP}-\mathrm{OPT})/(\mathrm{TEMP}-\mathrm{MAXTEMP})\big) \tag{6}$$

K_t is a parameter, which in most cases is between 1.04 and 1.06 and is on average 1.05. OPT is the optimum temperature for phytoplankton growth, and MAXTEMP is the maximum temperature. OPT, MAXTEMP, and A are all parameters that are different for different phytoplankton species.

The description of phytoplankton growth by equations using the constant stoichiometry approach is a simplification, because the phytoplankton growth is in reality a two-step process, as illustrated in Figure 3 and applied in the non-constant approach. The first step is uptake of nutrients, and the second step is growth of phytoplankton (increase of the biomass). The more correct description can be formulated mathematically by the following equations:

$$\text{Uptake rate } P = \mathrm{d}\text{PA}/\mathrm{d}t = \text{PA}^{*}\text{maxupp}^{*}\big(\text{PS}/\big(\text{kp}+\text{PS}\big)\big)$$

$$^{*}\ \big((\text{PAMAX}-\text{PA})/(\text{PAMAX}-\text{PAMIN})\big)$$

$$\text{Parallel for uptake rate } N \tag{7}$$

$$\text{Uptake rate } C = \mathrm{d}\text{CA}/\mathrm{d}t = \text{CA}^{*}\text{maxupc}^{*}\big(\text{CS}/\text{kc}+\text{CS}\big)^{*}$$

$$\big((\text{CAMAX}-\text{CA})/(\text{CAMAX}-\text{CAMIN})\big)^{*}\ \big((L/\text{KL}+L)-\text{RESP}$$

$$\text{IF } L\big\langle \text{L1}, L \text{ is used; if } \text{L2}\big\rangle L > \text{L1}, \text{L1 is used;}$$

$$\text{if } L > \text{L2}, \text{L1}+\text{L2}-L \text{ is used for } L \tag{8}$$

PA, NA, and CA are state variables that cover the amount of phosphorus, nitrogen, and carbon, in the form of phytoplankton, expressed as mg P, N, or C per liter of water. Notice that the unit is mg in 1 L of water. maxupp, maxupn, macups, kp, kn, kc, PAMAX, PAMIN, NAMAX, NAMIN, CAMAX, CAMIN, KL, L1, and L2 are all parameters. PAMAX, PAMIN, NAMAX, NAMIN, CAMAX, and CAMIN are,

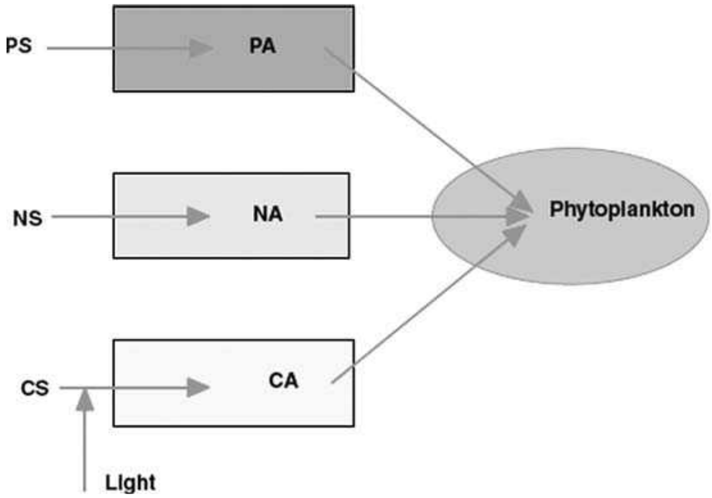

FIGURE 3 The two-step model of phytoplankton growth. The first step is uptake of nutrients PS, NS, and CS, followed by a growth of phytoplankton dependent on the nutrient concentrations in the phytoplankton cells, PA, NA, and CA. The uptake of carbon is dependent on light, while the uptake of phosphorus and nitrogen can take place even in darkness. It is a more physiologically correct description of phytoplankton growth than the (constant stoichiometry) approach.

however, known fairly well. They are the phytoplankton concentration times, respectively, 0.025, 0.005, 0.12, 0.05, 0.6, and 0.4 with good approximations. It is of course more difficult to calibrate the two-step growth equations than the constant stoichiometry approach due to the higher number of parameters in the NC equations, although the approximate knowledge that is available to the six parameters, PAMAX, PAMIN, NAMAX, NAMIN, CAMAX, and CAMIN, facilitates the calibration slightly. Notice that the uptakes of phosphorus, nitrogen, and carbon are, according to the equations, dependent both on the concentrations of the nutrients in the water and on the concentrations of nutrients in the cells.

The closer the nutrient concentrations in phytoplankton are to the minimum, the faster is the uptake. When a nutrient concentration, on the other hand, has reached the maximum value, the uptake stops. The carbon uptake opposite the uptake of phosphorus and nitrogen is dependent also on light, according to a Michaelis–Menten expression that includes the light prohibition. Finally, RESP covers the respiration. Of course, only carbon is involved in the respiration.

The growth process is quantified by the following equation:

$$\begin{aligned}\text{Growth} = \text{grmax}^{*}\ \text{phytoplankton}^{*}\ (min((PA - PAMIN)/\\(PAMAX - PAMIN)), ((NA - NAMIN)/\\(NAMAX - NAMIN)), ((CA - CAMIN)/\\(CAMAX - CAMIN)))\end{aligned} \tag{9}$$

grmax is a parameter in line with the corresponding parameter in Eq. 1. Eq. 9 indicates that the higher the nutrient concentrations are compared with the minimum levels, the faster the growth is.

The phytoplankton growth model based on this approach has four state variables: PA, NA, CA, and phytoplankton. They are all assumed to be expressed in mg/L. As the minimum and maximum values are presumed to be a parameter times the phytoplankton concentration, they are also expressed in mg/L.

The two-step description is of course more difficult to calibrate, validate, and use generally, which of course raises the following question: when should the two-step description be applied instead of the more easily applicable constant stoichiometric approach? Di Toro and Conolly[2] have revealed that the need for the two-step description increases with the shallowness and eutrophication of the aquatic ecosystem; see Figure 4. It is definitely recommended for shallow, very eutrophied aquatic ecosystems to apply the two-step description, while it is hardly needed for deep mesotrophic or oligotrophic aquatic ecosystems.

Solutions to the Eutrophication Problem

It is usually necessary to apply a wide spectrum of methods to solve eutrophication problems, because the nutrients have many sources. The amount of nutrients discharged with the wastewater can be reduced by several wastewater treatment methods; see for instance the overview of conventional wastewater treatment methods and municipal wastewater and its treatment. Nutrients can be discharged by drainage water, including drainage water from agriculture, which may have high nutrient concentration; this can be removed or reduced by a number of ecological engineering methods, for instance, wetlands; see these entries.

It is possible to reduce the nutrient concentrations in the aquatic ecosystems by use of environmental technological methods, ecotechnological methods, cleaner technology, and environmental legislation. There are a number of cases where a consequent environmental strategy has solved the problems, but there are also many examples of insufficient environmental management, which has led to only a partial solution or no solution at all of the eutrophication problem. From experience, it can be concluded that quantitative nutrient balances, including all sources of nutrients, are the best starting point for a good

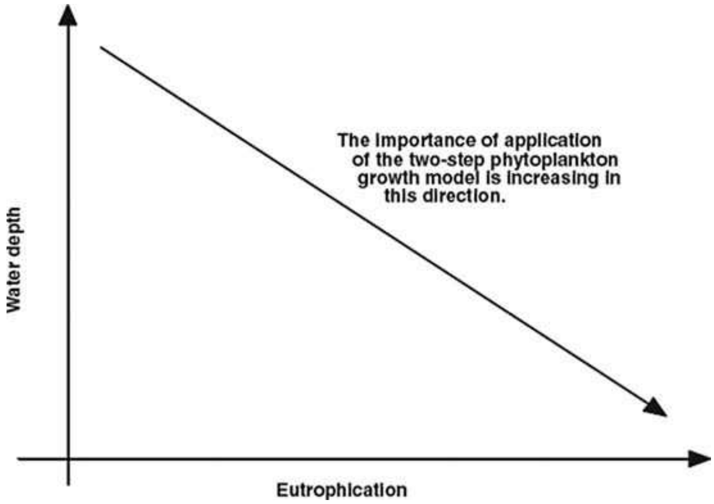

FIGURE 4 The need for the two-step description of phytoplankton growth increases with nutrient concentration and decreases with depth.

environmental management strategy, because the nutrient balances show clearly which sources are important to eliminate or reduce, and they facilitate a comparison of the costs for various management strategies. For further details about selection of an environmental management strategy, see Jørgensen[3] and Jørgensen et al. [4]

Wastewater Use in Agriculture

Manzoor Qadir,
Pay Drechsel, and
Liqa Raschid-Sally

Introduction

The volume of wastewater generated by domestic, industrial, and commercial water use has increased with population, urbanization, improved living conditions, and economic development. With the increase in wastewater generation, its productive use in agriculture has increased, particularly downstream of cities where often farmers have no or limited alternative sources of reliable irrigation water.[1–3] In developing countries, treated, partly treated, diluted, or untreated wastewater is used in urban and peri-urban areas to produce vegetables as a market-ready product. In addition, rice, wheat, fodder, and industrial crops are produced. In developed countries, wastewater is treated and mostly used for landscape irrigation, particularly in cities though extensive and well-regulated use in agriculture occurs as well.[4]

Despite official restrictions and potential health implications, farmers in many freshwater-scarce developing countries tend to opt for wastewater irrigation where available because (1) wastewater is a reliable or often the only water source available for irrigation throughout the year; (2) wastewater irrigation often reduces the need for fertilizer application as it is a source of nutrients; (3) wastewater use involves less energy cost even when pumping, if the alternative clean water source is from deep groundwater; and (4) wastewater generates additional benefits such as greater income generation from cultivation and marketing of high-value crops such as vegetables, which create year-round employment opportunities.[5,6]

As wastewater irrigation is in most instances part of the informal irrigation sector, authorities face challenges controlling or regulating the practice. The protection of consumer and farmer health and environment is especially the main concern.[7] Thus, sustainable use of wastewater must address three major aspects: pertinent policies, regulations, and institutional arrangements; wastewater treatment per intended reuse option; and risk management practices that eliminate or minimize the health and environmental impacts, particularly when wastewater treatment is limited. This entry addresses on-farm management practices with a focus on crop, water, and soil management interventions.

Crop Selection and Diversification

Where wastewater is used for irrigation, crop selection is determined by more factors than usual freshwater irrigation conditions. While the market potential of the crop is always an important criterion, the suitability of the crop to its biophysical environment requires more attention than is usually given. Even more important is the potential risk to consumers, which becomes a decisive factor influencing enforcement of regulations and crop restrictions. Especially if irrigated crops are eaten raw, as with salad greens, microbial contamination can be high; hence, different crops should be chosen. In guidelines addressing safe use of wastewater, it is advised to avoid cultivating crops eaten uncooked and prefer cereal and fodder crops, and trees.[8]

A particular challenge for farmers is the salinity of the wastewater as considerable variation exists among crops in their ability to tolerate saline conditions.[9] An appropriate selection of plant species capable of producing adequate biomass is vital while using saline water for irrigation.[10] Such selection is generally based on the ability of the species to withstand elevated levels of salinity in irrigation water and soil[9] while also providing a salable product or one that can be used on-farm.[11,12] The salt tolerance of a crop is not an exact value because it depends on several soil, crop, and climatic factors. This diversity can be exploited to identify local crops that are better adapted to saline and/or sodic soil conditions.[13,14]

Based on the linear response equation proposed by Maas and Hoffman,[9] crops can be characterized for their salt tolerances. The following are two parameters obtained from the Maas–Hoffman equation: (1) the maximum allowable soil salinity for a crop without yield reduction (the threshold soil salinity) and (2) the percent decrease in crop yield per unit increase in salinity beyond the threshold salinity level for the crop (the slope). Both values can be used to calculate relative yield for any given soil salinity exceeding the threshold level (Table 1).

Research efforts have led to the identification of several field crops, forage grasses and shrubs, biofuel crops, and fruit-tree and agroforestry systems, which can suit a variety of salt-affected environments.[15] Such systems linked to secure markets should support farmers in finding the most suitable

TABLE 1 Yield Potentials of Some Grain, Forage, Vegetable, and Fiber Crops as a Function of Average Root Zone Salinity

		Yield Potential (%) at Specified Salinity (dS/m)		
Common Name	Tolerance Based On	50%	80%	100%
Durum wheat	Grain yield	19	11	6
Barley	Grain yield	18	12	8
Cotton	Seed cotton yield	17	12	8
Rye	Grain yield	16	13	11
Sugar beet	Storage root	16	10	7
Wheat	Grain yield	13	9	6
Sorghum	Grain yield	10	8	7
Alfalfa	Shoot dry weight	9	5	2
Spinach	Top fresh weight	9	5	2
Broccoli	Shoot fresh weight	8	5	3
Eggplant	Fruit yield	8	4	1
Rice paddy	Grain yield	7	5	3
Potato	Tuber yield	7	4	2
Maize	Ear fresh weight	6	3	2

Source: Based on the salt tolerance data of different crops and percentage decrease in yield per unit increase in root zone salinity in terms of dS/m as reported by Maas and Grattan.[14]

Note: These data serve only as a guideline to relative tolerances among crops. Absolute tolerances can vary between varieties also depending on climate, soil conditions, and cultural practices.

and sustainable crop diversifying systems to mitigate any perceived production risks, while ideally also enhancing the productivity per unit of saline wastewater and protecting the environment.

Aside from excess salts in the water, there is an increasing possibility of heavy metal contamination where industrial effluent contributes to the water that farmers use. In terms of potential toxicity of the metals and metalloids, Hamilton et al.[16] classified them into four groups based on their retention in soil, translocation in plants, phytotoxicity, and potential risk to the food chain. They categorized cadmium, cobalt, selenium, and molybdenum as posing the greatest risk to human and animal health because they may appear in wastewater-irrigated crops at concentrations that are not generally phytotoxic; that is, farmers cannot rely on their plants dying before concentrations reach levels not recommended for humans.

Guidelines for maximum allowable levels of metals and metalloids in irrigation water are summarized in Table 2. Where these limits are exceeded, Simmons et al.[17] describe available methods for damage control.

TABLE 2 Recommended Maximum Concentrations (RMCs) of Selected Metals and Metalloids (mg/L) in Irrigation Water

Element	RMC[a]	Remarks
Aluminum	5.00	Can cause non-productivity in acid soils ($pH < 5.5$), but more alkaline soils at $pH > 7.0$ will precipitate the ion and eliminate any toxicity
Arsenic	0.10	Toxicity to plants varies widely, ranging from 12 mg/L for Sudan grass to less than 0.05 mg/L for rice
Beryllium	0.10	Toxicity to plants varies widely, ranging from 5 mg/L for kale to 0.5 mg/L for bush beans
Cadmium	0.01	Toxic at concentrations as low as 0.1 mg/L in nutrient solution for beans, beets, and turnips. Conservative limits recommended
Chromium	0.10	Not generally recognized as an essential plant growth element. Conservative limits recommended
Cobalt	0.05	Toxic to tomato plants at 0.1 mg/L in nutrient solution. It tends to be inactivated by neutral and alkaline soils
Copper[b]	0.20	Toxic to a number of plants at 0.1–1.0 mg/L in nutrient solution
Iron[b]	5.00	Non-toxic to plants in aerated soils, but can contribute to soil acidification and loss of availability of phosphorus and molybdenum
Lithium	2.50	Tolerated by most crops up to 5 mg/L. Mobile in soil. Toxic to citrus at low concentrations with recommended limit of <0.075 mg/L
Manganese[b]	0.20	Toxic to a number of crops at a few tenths to a few milligrams per liter in acidic soils
Molybdenum	0.01	Non-toxic to plants at normal concentrations in soil and water. Can be toxic to livestock if forage is grown in soils with high concentrations of available molybdenum
Nickel	0.20	Toxic to a number of plants at 0.5–1.0 mg/L; reduced toxicity at neutral or alkaline pH
Lead	5.00	Can inhibit plant cell growth at very high concentrations
Selenium	0.02	Toxic to plants at low concentrations and toxic to livestock if forage is grown in soils with relatively high levels of selenium
Zinc[b]	2.00	Toxic to many plants at widely varying concentrations; reduced toxicity at $pH \geq 6.0$ and in fine textured or organic soils

Source: Modified from Ayers and Westcot.[22]

[a] The maximum concentration is based on a water application rate that is consistent with good irrigation practices (10,000 m^3/ha/yr). If the water application rate greatly exceeds this, the maximum concentrations should be adjusted downward accordingly. No adjustment should be made for application rates less than 10,000 m^3/ha/yr. The values given are for water used on a long-term basis at one site.

[b] Synergetic action of copper and zinc, and antagonistic action of iron and manganese have been reported in certain plant species' absorption and tolerance of metals after wastewater irrigation. If irrigation water contains high concentrations of copper and zinc, copper concentrations in the tissue may increase greatly. In plants irrigated with water containing a high concentration of manganese, manganese uptake in plants may increase, and consequently, the concentration of iron in the plant tissue may be reduced considerably. Generally, metal ion concentrations in plant tissue increase with concentrations in irrigation water. Metal ion concentrations in roots are higher than those in leaves[26] and metal ion concentrations such as cadmium concentrations in leafy vegetables are higher than those in non-leafy species.[27]

The examples show that the selection of crops for irrigation with wastewater has to consider a range of factors uncommon in freshwater irrigation. Finding the best compromise between the various criteria while targeting profits (i.e., high market demand) limits the choice of crop significantly in most cases.

Irrigation Management

In addition to the choice of the most appropriate crop(s), irrigation water management (ranging from water access to the type of irrigation, application rates, and scheduling) offers a variety of important management practices to address the particularities of wastewater irrigation.[15,17,18]

There are different ways in which crops are irrigated with wastewater, such as surface or flood irrigation, manual irrigation with watering cans, furrow irrigation, sprinkler irrigation, and micro-irrigation such as drip or trickle irrigation. There are also different ways of water access, from manual water fetching to pumping and gravity flow. Each method has a different level of risk for farmers (through farmers' contact with the irrigation water) and consumers [through the contact of the harvested (and eventually consumed) crop part and the water]. Several parameters for the evaluation of commonly used irrigation methods in relation to risk reduction are given in Table 3.[7,19] Key criteria are health risks, costs, and water use efficiency.

Flood irrigation is usually a low-cost method with, however, also low water use efficiency. Health protection is limited for the farmers and—if the crops are low growing—for the consumers as well. With medium level of health protection, furrow irrigation needs more soil preparation and is suitable when

TABLE 3 Parameters for Evaluation of Selected Irrigation Methods in Relation to Risk Reduction for Crops and Humans

Evaluation Parameter	Irrigation Method			
	Furrow Irrigation	Flood Irrigation	Sprinkler Irrigation	Drip Irrigation
Farmer exposure to pathogens	Low to medium	Medium to high	Low when sprinkler is off	Very low
Crop exposure to pathogens	Low if planted on ridge	High only for low-growing crops	High	Very low
Possibility of leaf damage from salts resulting in poor yield	No foliar injury as the crop is planted on the ridge	Some bottom leaves may be affected, but the damage is not so serious as to reduce yield	Severe leaf damage can occur resulting in significant yield loss	No foliar injury likely
Root zone salt accumulation with repeated applications	Salts tend to accumulate in the ridge, which could harm the crop	Depending on soil texture, salts might move vertically downwards or can accumulate in the root zone	Salt drainage is limited as water amounts are low. Surface crusting possible	Salt movement is radial along the direction of water movement. A salt wedge is formed between drip points; clogging of pipes can occur
Ability to maintain high soil water potential (risk of soil moisture stress)	Plants may be subject to stress between irrigations	Plants may be subject to water stress between irrigations	Not possible to maintain high soil water potential throughout the growing season	Possible to maintain a high and well-targeted soil moisture content throughout the growing season
Suitability to handle brackish wastewater without significant yield loss	Fair to medium. With good management and drainage, acceptable yields are possible	Fair to medium. Good irrigation and drainage practices and conditions can produce acceptable levels of yield	Poor to fair. Crops might suffer from leaf damage resulting in low yields	Excellent to good. Almost all crops can be grown with very little reduction in yield, unless the pipes clog

Source: Modified from Pescod.[19]

TABLE 4 On-Farm Options for Pathogen Reductions

Control Measure	Pathogen Reduction (Log Units)	Notes
Alternative safe water source	>6	Depends on availability of safe groundwater and/or alternative farm land
Crop restrictions	>6	Acceptance depending on controls and profit margin of the alternative crop
Drip irrigation	2–4	2-log unit reduction for low-growing crops, and 4-log unit reduction for high-growing crops
Pathogen die-off	0.5–2 per day	Die-off after last irrigation before harvest (rate depends on climate, crop type, etc.)
Slow sand filter	1–3	Depends on appropriate particle size
Furrow irrigation	1–2	Might reduce cropping density and yield
Reduced splashing	1–2	Splashing adds contaminated soil particles onto the crop, which can be avoided
Allow sedimentation in ponds and dugouts	1–2	During dry season via natural die-off. Reduction of helminths to less than 1 egg over 2–3 days possible

Source: Modified from WHO.[8]

there is a greater leaching need to remove high levels of salts. Irrigation with sprinklers is medium to high cost, does not require soil preparation, but has medium-level water use efficiency. Sprinkler irrigation systems have the advantage of reducing the amounts of water and salts applied to soil and crop.[20,21] The disadvantage compared to flood and furrow irrigation is that sprinklers distribute any water contaminants straight on the top of the plants. The same applies to the use of watering cans unless they are directed towards the roots. Overhead irrigation may also cause leaf burn under direct sunlight, from salts absorbed directly through wetted leaf surfaces,[22] which can be avoided by irrigating at night.[14,23,24]

Drip irrigation systems are costly, but highly efficient in water use along with the highest levels of health protection for farmers and consumers. The clogging of drippers on the other hand may limit the use of drip irrigation systems for many types of wastewater. Therefore, prior filtration is needed to prevent clogging of emitters.[25]

Irrigation frequency is an ambivalent issue in wastewater irrigation. Because soluble salts reduce the availability of water in almost direct proportion to their concentration, irrigation frequency should generally be high. This will help in maintaining the moisture content and salinity of irrigated soils at acceptable levels, which is important especially during seedling establishment.[23] On the other hand, a low frequency of irrigation—if possible even the cessation of irrigation for several days before harvest—supports the natural die-off of pathogens and is an important low-cost measure for health risk reduction.[7]

Other options for on-farm interventions addressing risks from pathogens are summarized in Table 4. Options to cope with salinity or heavy metals were recently summarized by Qadir and Drechsel[10] and Simmons et al.[17]

Soil- and Health-based Interventions

Good management practices play a crucial role in the preservation of key soil properties while irrigating with wastewater. Soil-based interventions are important, particularly in case of inorganic contaminants, which usually accumulate in the upper part of the soil because of strong adsorption and precipitation phenomena. For moderate levels of metals and metalloids in wastewater, there is no particular management needed if the soils are calcareous, i.e., contain appreciable levels of calcite that renders most metals immobile. However, metal ions may be a problem in acid soils, which need specific management measures such as liming, avoiding use of fertilizers with acidic reactions, and selection of crops that do

TABLE 5 Contribution of Irrigation with Recycled Wastewater in Terms of Nutrient Addition to the Soil

		Fertilizer Contribution (kg/ha)	
Nutrient	Concentration (mg/L)	Irrigation at 3,000 m^3/ha	Irrigation at 5,000 m^3/ha
Nitrogen	16–62	48–186	80–310
Phosphorus	4–24	12–72	20–120
Potassium	2–69	6–207	10–345
Calcium	18–208	54–624	90–1040
Magnesium	9–110	27–330	45–550

Source: Lazarova and Bahri.[20]

not accumulate the metals of concern.[22] In case of irrigation with wastewater containing elevated levels of sodium, care should be taken to avoid soil structure deterioration. Application of a source of calcium such as gypsum is desirable. Procedures to determine the rate of gypsum application to mitigate the effects of sodium resulting from sodic wastewater irrigation are available.

The quality and depth of groundwater prior to wastewater irrigation determine the detrimental effects of salts, nitrates, and metals reaching groundwater. The deeper the groundwater, the longer it will take to have such effects. In case of shallow groundwater or coarse-textured soils, i.e., sandy soils, which are highly permeable, care must be taken to prevent groundwater pollution.

Although the fertilizer value of undiluted wastewater, in particular, is of great importance as nutrients in wastewater contribute to crop requirements, periodic monitoring is required to estimate the nutrient loads in wastewater and adjust fertilizer applications accordingly.[20] Excessive nutrients not only can cause nutrient imbalances, undesirable vegetative growth, and delayed or uneven maturity, but can also reduce crop quality while polluting groundwater and surface water. The amount of nutrients applied via wastewater irrigation can vary considerably if it is raw, treated, or diluted with stream water. The contribution in terms of nutrient addition to the soil from irrigation with recycled wastewater is given in Table 5.

It becomes obvious that irrigation with wastewater has a variety of implications steering farmers' decision-making process in view of crop selection as well as soil and water management. Most of them are limiting the choice of options. However, while a wrong choice, for example, in view of salinity management or any other phytotoxic hazard usually results in a quick learning process for the farmer, hazards affecting farmers' and especially consumers' health might remain less obvious and hidden among various confounding factors, such as poor sanitation at home. With economic interests being of paramount importance in most cases, it is not surprising that farmers might opt for those options that yield highest returns while keeping investments as low as possible. The result is the common picture of high-value exotic vegetables irrigated with low-cost watering cans or via flood irrigation, both imposing high risks for human health. Increasing awareness about these risks and providing incentives and regulations to encourage alternative crop choices in spite of possible disadvantages will create the conditions that would favor the utilization of farm-based interventions for the safe and productive use of wastewater in irrigated agriculture.

Conclusions

In the arid and semi-arid areas of the world, wastewater is mainly used for agriculture because of the competition between agriculture and municipal sectors. While wastewater is managed safely and used in treated form mostly for landscape irrigation in developed countries, the situation is different in developing countries, where wastewater is rarely used in treated form but mostly in partly treated, diluted, or untreated forms to produce a range of crops, mostly vegetables as a market-ready product. Such wastewater use in developing countries continues to offset local water scarcity despite official restrictions and potential health implications. Thus, it is important to consider a range of risk management practices to eliminate or minimize the health and environmental impacts, particularly in situations where wastewater is used for irrigation in partly treated, diluted, or untreated forms. On-farm management practices can play a major role to eliminate or minimize the health and environmental impacts. The following aspects are the key features and have to be considered: 1) selection and diversification of wastewater-irrigated crops to reduce possible health risks, accounting for their market value and tolerance against ambient stress from salts, metals, and metalloids; 2) irrigation water management addressing water access, on-farm treatment, type of irrigation, application rates, and irrigation scheduling; and 3) soil- and health-based interventions considering soil characteristics, soil preparation practices, and application of fertilizers and amendments. Increasing awareness about health and environmental risks, and knowledge and implementation of best farm-based interventions by the wastewater-irrigating farmers will help create the conditions that would favor the safe and productive use of wastewater in agriculture.

Wetlands: Biodiversity

Jean-Claude
Lefeuvre and
Virginie Bouchard

Role of Hydrology

Wetlands differ significantly in their water source and seasonal hydrologic regime. Hydrological patterns (i.e., flooding frequency, duration and hydroperiod) influence physical and chemical characteristics (e.g., salinity, oxygen and other gas diffusion rates, reduction–oxidation potential, nutrient solubility) of a wetland. In return, these internal parameters and processes control flora and fauna distribution as well as ecosystem functions. Plants, animals and microbes are often oriented in predictable ways along the hydrological gradient (Figure 1). Conversely, the biotic component affects the hydrology by eventually modifying flow or water level in a wetland.[1,2] Species also influence nutrient cycles and other ecosystem functions.[3]

A Landscape Perspective

Although the hydrology is part of the ecological signature of an individual wetland, wetlands are neither considered as aquatic nor terrestrial systems. They have characteristics from both systems and are defined as ecotones placed under this dual influence.[4] Because wetlands are located at the interface of multiple systems, they assure vital functions (e.g., wildlife habitats) beneficial at the landscape level. Reduction of wetland area often reduces biodiversity in the land-scape.[2,5] Increases in biodiversity occur when wetlands are created or restored in a disturbed landscape.[6]

Wetland Flora

Wetland plants are adapted to a variety of stressful abiotic conditions (e.g., immersion, wave abrasion, water level fluctuation, low oxygen conditions). Identical adaptations to common environmental features have led taxonomically distinct species to sometimes look similar in terms of morphology, life cycle and life forms.[7] Traditionally, wetland plants have been classified into groups of different life forms, primarily in relation with hydrological conditions. Helophytes are defined as plant species with over-wintering buds in water or in the submerged bottom.[8] They are differentiated from hydrophytes in that their vegetative organs are partially raised above water level.[8] Hejny's classification is based on relatively stable vegetative features that determine the ability of wetland plants to survive two unfavorable conditions, cold and drought.[7] This classification uses the types of photosynthetic organs present in both the growth and flowering phases. Other classifications include both life form and growth form. When a species has a range of growth form, it is classified under the form showing the greatest achievement of its potential.[7]

Plant communities in wetlands can be more or less homogeneous, mosaic-like, or distributed along a gradient resulting in a clear zonation of species. A gradient exists if one or several habitat parameters change gradually in space. This phenomenon is common in fresh water marshes that present a gradient of water depth and water saturated soils (Figure 1). Such a gradient is often accompanied by differences in peat accumulation that is influenced by waves or currents. General principles of the zonation of aquatic plants have been largely described.[7,9,10] Littoral vegetation can belong to several types of communities, which derived from the general principle that, from deeper water to the shore, we may expect successively submergent, floating, and emergent macrophytes. The most important habitat factor is water depth, depending on slope and peat accumulation.[10] Other factors may be poor irradiance caused by high turbidity or exposure to waves or flow.[7,10]

Riparian ecosystems are found along streams and rivers that occasionally flood beyond confined channels or where riparian sites are created by channel meandering in the stream network. Riparian or bottomland hardwood forests contain unique tree species that are flood tolerant. Species distribution is associated with floodplain topography, flooding frequency, and flooding duration.[11,12] In southeastern U.S. bottomland, seasonally flooded forests are colonized by *Platanus occidentalis* (sycamore), *Ulmus americana* (American elm), *Populus deltoides* (cottonwood) and are flooded between 2% and 25% of the growing season (Figure 1). Other species such as *Fraxinus pennsylvanica* (green ash), *Celtis laevigata* (sugarberry) and *Carya aquatica* (water hickory) colonized bottomlands that are flooded by less than 2% of the growing season.[11] Freshwater marshes are dominated with emergent macrophytes rooted in

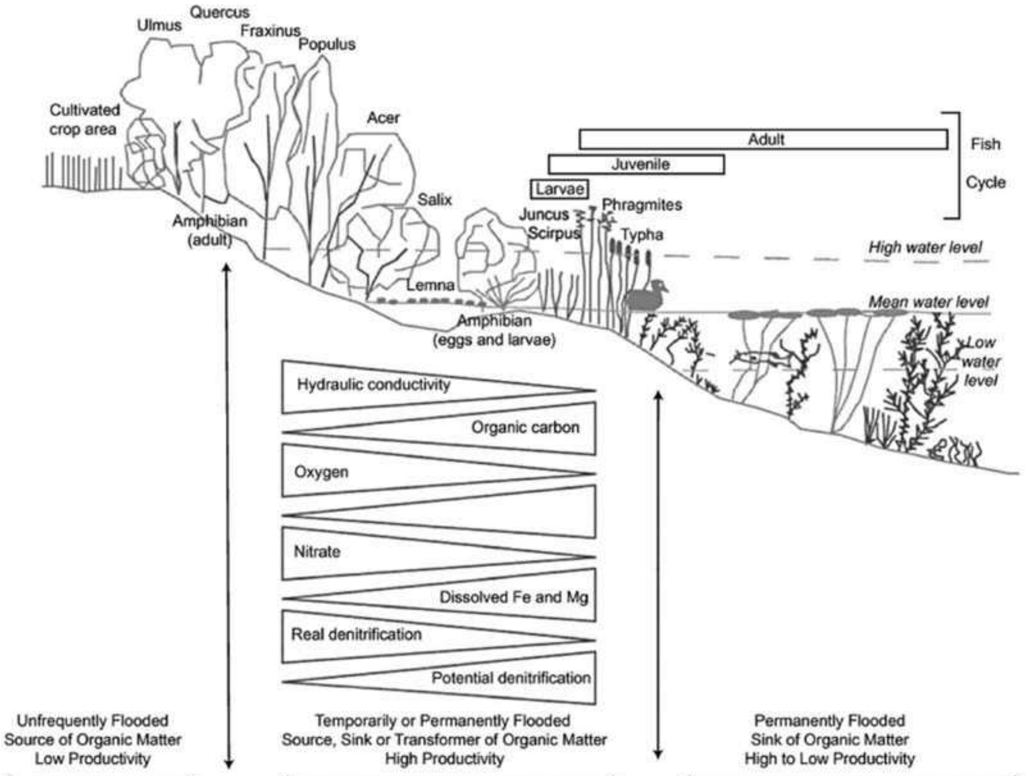

FIGURE 1 Species distribution along the hydrological gradient in a freshwater marsh.

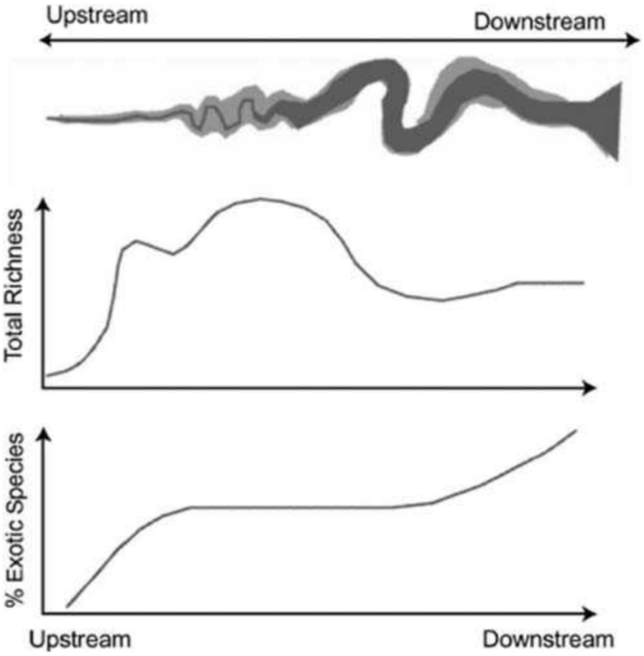

FIGURE 2 Total richness and invasive species distribution along a stream longitudinal gradient.
Source: Planty-Tabacchi.[14]

the bottom with aerial leaves (i.e., helophytes). Species such as *Typha* (cattail), *Phragmites* (reed grass) and *Scirpus* (bulrush) are often clonal. A plant community is usually organized in sequence of patches that are dominated by one species. The second plant groups are the rooted plants with floating leaves (*Nymphaeid*). Lotus (*Nelumbo*) and water lilies (*Nymphea*) have very identical morphology (i.e., similar leaves and flowers) but a genetic analysis showed that lotus is more closely related with plane-tree than with water lilies.[10] Submerged plants include elodeids (i.e., cauline species whose whole life cycle can be completed below the water surface or where only the flowers are emergent) and isoetids (i.e., species growing on the bottom whose whole life cycle can be completed without contact with the surface). Submerged species include species such as coontail (*Ceratophyllum demersum*) and water milfoil (*Myriophyllum* spp.). Plant species found in salt marshes are called halophytes (i.e., plants which complete their cycle in saline environments). A saltmarsh can be divided into low, middle, and upper marsh, according to flooding frequency and duration. Each zone is dominated by different plant species according to their tolerance to saline immersion.[10]

A dominant competitive species—often a clonal species—can modify the theoretical zonation. Change in water chemistry (i.e., eutrophication) or hydrology may favor a particular species over the natural plant community. Highly competitive species are often invasive and aggressive in displacing native species. The expansion of *Phragmites australis* into tidal wetlands of North America causes a reduction in biodiversity as many native species of plants are replaced by a more cosmopolitan species.[13] In riparian ecosystems, biodiversity is usually higher in the intermediate zones, whereas it is lower upstream and downstream (Figure 2). The percentage of exotic species is low in upstream areas, but can represent up to 40 in downstream zones (Figure 1).[14]

Wetland Fauna

Diversity of vertebrate and invertebrate species is the result of a diverse community composed of resident and transient species, which use the space differently and at various times of day and year. The density and variety of animal populations at a particular wetland site is also explained by climatic events that affect geographic areas on a large scale. For example, the population of waterfowl during winter is largely dependent on climate variations in the northern part of the continents.[15]

Resident species are often dependent on the type of vegetation. Animal communities are generally distributed along a zonation pattern, parallel to the plant communities, which is driven by the hydrological gradient. A few species depend entirely on a single plant species for their survival. One beetle (*Donacia* spp.) may depend on reeds, at least during its larval stage where another beetle (*Gale-rucella* spp.) uses only water lilies as their habitat and diet. For many other residents, their habitats extend to several plant communities during their life span. It is generally the case for many vertebrates such as amphibians, rodents, passerines, and waterfowl.

Many amphibian species depend on wetland or riparian zones for reproduction and larval stage. Likewise, wet meadows are necessary as a reproduction zone and nursery for a number of freshwater fishes. About 220 animals and 600 plant species are threatened by a serious reduction of wetlands in California, and the state's high rate of wetland loss (91% since the 1780s) is partly responsible.[15] Many waterfowl species are sensitive to areas of reduction, patch size and distribution, wetland density, and proximity to other wetlands.[16] When the Marais Poitevin (France), one of the principal wintering and passages sites for waterfowl in the Western Europe, underwent agricultural intensification in the 1980s, the population of ducks and waders declined tremendously. This decline was partly due to a 50% reduction of wet meadows between 1970 and 1995, primarily caused by the conversion to arable farmlands.[17] Thus, maintenance of biodiversity depends on the existence of inter connections between wetlands, and between aquatic and terrestrial ecosystems. In fact, some authors have pointed out that increase in biodiversity occurs when wetlands are created or restored in a disturbed landscape.[6,18]

Conclusions

Despite the importance of wetlands, conservation efforts have ignored them for a long time. It is urgent to conserve the existing wetlands, and also to restore and create wetland ecosystems. A wide range of local, state, federal, and private programs are available to support the national policies of wetland "No Net Loss" in the U.S., and around the world. From a biodiversity perspective, on-going wetland protection policies may not be working because restored or created wetlands are often very different from natural wetlands.[19] Created wetlands often result in the exchange of one type of wetland for another, and result in the loss of biodiversity and functions at the landscape level.[19] We know now that it takes more than water to restore a wet- land,[20] even if an important place should be given to the ability of self-design of wetland ecosystems.[21]

Wetlands: Carbon Sequestration

Virginie Bouchard
and Matthew
Cochran

Introduction

The increase in the concentration of "greenhouse gases" in the troposphere and its relation to human activities is now well-documented.[1] Carbon fixation via photosynthesis and carbon release during decomposition have always been two important processes regulating the concentrations of CO_2 and CH_4 in the atmosphere, even in prehistoric and pre-industrial times. In addition to these internal processes, wetland ecosystems receive and release organic carbon through hydrologically-driven mass fluxes. Thus, the carbon pool within any wetland ecosystem is in balance between primary production, microbial decomposition, and carbon fluxes within interconnected ecosystems (Figure 1). Wetlands play a particularly complex role in controlling greenhouses gases, as these ecosystems are intimately associated with all aspects of the production and consumption of both CO_2 and CH_4 (Figure 2).

Carbon Sequestration with Primary Production

The concept of primary productivity is directly related to the ideas of energy flow in ecosystems. A portion of the photosynthetically active radiation (PAR), which is radiation in the 400–700 nm wave band, received by an ecosystem is absorbed by autotrophic organisms (photosynthetic plants and microorganisms). The absorbed energy is reradiated, lost as latent heat, or stored by the activity of photosynthesis in organic substances. This last flow of energy corresponds to net primary production (NPP). Fundamental ecological questions relating to the global carbon budget, the location of the missing carbon sink, and predictions of global climate change rely on obtaining good estimates of NPP.

Wetland ecosystems can have very high standing biomass values and correspondingly high NPP.[2,3] The annual aboveground NPP of macrophytes is reported to be up to 5 kg dry matter in the most productive sites.[2] This production varies according to species, wetland type, and latitude[2,3] and is often well correlated with the maximum aboveground standing crop. Belowground production is much more difficult to estimate because roots and rhizomes grow and die at different rates and times and because materials are translocated to and from shoots. The ratio of belowground to aboveground production can vary from 0.2 to 2.5 according to various studies.[2] The connectivity of a wetland to hydrological fluxes

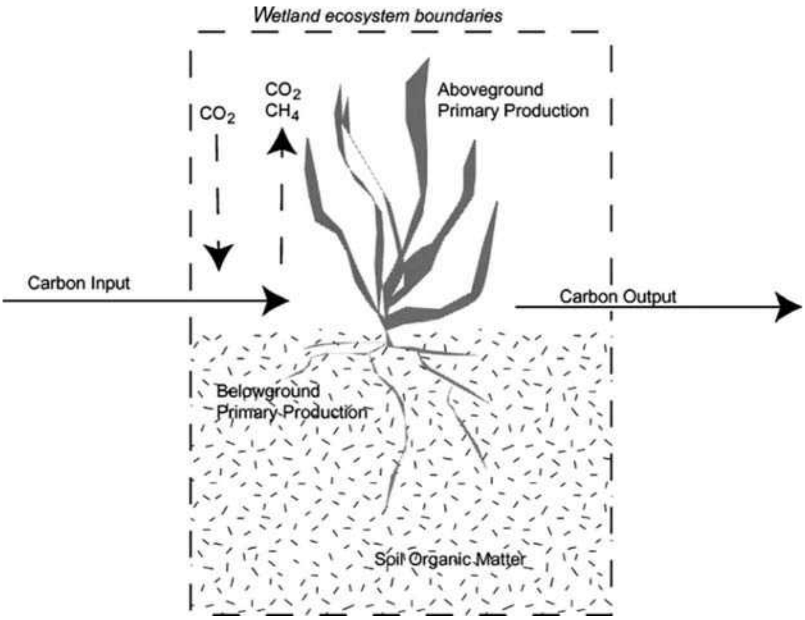

FIGURE 1 Conceptual model showing the fluxes of organic carbon in wetlands.

FIGURE 2 View of a freshwater wetland.

(i.e., saltmarshes flooded by tides, coastal freshwater marshes flooded by seiche, riparian bottomland forests flooded by floods) is one of the most important factors enhancing primary productivity.[4]

Net carbon capture from herbaceous vegetation is minimal compared to the long-term accumulation of carbon in bottomland hardwood forests. At the end of the growing season, most of the carbon trapped in the biomass of herbaceous macrophytes is found in dead plant litter and is released as CO_2 or CH_4 during decomposition or exported as dissolved or particulate organic matter to adjacent systems.

Bottomland hardwood forests store carbon in tree biomass for a much longer period of time. The productivity of bottomland forest ranges between 200 g and 2000 g dry organic matter per year.[5]

Carbon Sequestration in Soils

Carbon fixed in photosynthesis either remains in the sediment as carbon accretion or is decomposed to CO_2 and CH_4 by a suite of fermentative microbes involved in soil organic matter decomposition. A diversity of biological, chemical, and physical mechanisms is also known to selectively “protect” different pools of soil organic matter from decomposition by soil microorganism. Most of the recalcitrant carbon destined for sediment accretion is derived from heavily lignified biomass. Organic soil is a result of the anaerobic conditions created by standing water or poorly drained conditions.

Carbon is even better protected in acidic environments, in marine sediments and under low temperatures. Peat accumulation is a result of reduced oxidation of the biomass produced in wetlands. The northern peatlands have accumulated 25–38 Pmol C since the last glaciation, equivalent to 50%–70% of the total amount of carbon currently present in the atmosphere.[6] Peat accumulation is greater in bogs than in fens due to differences in nutrient availability. Decomposition rates are enhanced in minerotrophic fens receiving nutrients from adjacent mineral soils relative to ombrotrophic bogs, which are fed only by rainwater.

Canadian wetland soils store about 154 Gt C, representing an average of 60% more carbon than what is stored in Canadian forests (95 Gt C in biomass and soils), which in turn is two orders of magnitude larger than the agricultural soil carbon pool[7] (Table 1). Peatlands are a sink for between 20 and 30 g Cm^{-2} yr^{-1}, which means that Canadian peatlands sequester about 0.03 Gt Cyr^{-1} (Table 1). The sequestration rate of peatlands is currently smaller than the rate computed for boreal forests. However, the major difference between forests and peatlands is that a forest sink is transient and cannot be sustained continuously. If peatlands also have a theoretical limit to growth, it is reached only after many thousands of years.[8] However, the fluxes of CO_2 and CH_4 from peatlands vary highly according to seasons, years, species and sites. Inter-annual measurement schemes—such as those that have been developed for forest ecosystems with the Ameriflux and Euroflux programs—are needed are needed to establish more precise fluxes of CO_2.

Impact of Human Activities on Carbon Storage

Rates of plant production are limited by phosphorus supply in freshwater systems and by nitrogen supply in saltwater and terrestrial systems.[9,10] An excess of nutrients leads to an increase of both primary production and decomposition in terrestrial systems.[11] Decomposition rates increase, however, at a slower rate than primary production, leading to a potential increase of carbon storage in soil.[11] In wetlands, little is known about the effect of excess nutrients on the denitrification process, which is directly linked to the amount of soil organic matter.[12]

Wetlands have been drained on all continents due to human development. Rapid changes occur in organic soils after drainage as aerobic microbial decomposition is enhanced, releasing large amounts of CO_2 into the atmosphere. Carbon losses can lead to subsidence of the soil profile, changes in bulk density, and decreases in carbon content of the remaining soil.

TABLE 1 Summary of Carbon Stocks and Fluxes in Canadian Wetlands/Peatlands, Forests and Agricultural Fields

Land Use	Area (km^2)	C Stock (Gt C)	Fluxes (Gt C yr^{-1})	Potential Duration (Years)
Peatlands/wetlands soils	1.24 × 106	154	−0.03	1000 years (?)
Forests	5.15 × 106	95	−0.2	50
Agriculture fields	0.45 × 106	6	0.0034	50

Source: Adapted from Roulet.[7]

Creation of Wetlands to Sequester Carbon

Wetlands—particularly bottomland hardwood forests— are considered as potentially excellent "carbon sinks" because they take carbon dioxide out of the atmosphere and store it in living plant tissues and soil organic matter. Wetland creation might provide an opportunity to positively address wetland habitat losses while also addressing global warming [8,13] However, a question, still remains: are we capable of constructing wetlands that function in similar ways as natural wetlands? How well these created and constructed wetlands mimic natural wetlands is still being debated.[14,15]

Various studies have indicated that created wetlands might not function in the same capacity as adjacent reference wetlands.[16] In created *Spartina alterniflora* salt marshes, vegetation rapidly achieves 100% cover, although soil nitrogen and organic matter are slow to accumulate. Salt marshes constructed in North Carolina 25 years ago have lower soil organic carbon (SOC) and lower total N reservoirs than a 2000-year-old natural marsh.[16]

Their C accumulation rates are similar to those of reference sites, but N accumulation rates are higher, thus C/N ratios have declined over time. In Oregon, 95 restored freshwater marshes had lower soil organic matter than natural marshes and no evidence of accumulation.[17]

Because bottomland hardwood forests combine both a long-term carbon storage in tree biomass and a slow release of soil organic carbon under flooded conditions, they are considered as excellent ecosystems that could potentially be used to sequester carbon. Restoration of bottomland hardwood forests on marginal agricultural lands in the Mississippi River Valley offers significant net carbon sequestration in the south-central region of the U.S.[13] However hardwood plantings have problems with slow initial growth and excessive early mortality rates. The use of herbaceous weed control and bedding may offer the potential to overcome these difficulties.[13] Under the initiative of the U.S. Department of Energy, an 80 acre pilot study is currently underway in Louisiana. Abandoned marginally productive agricultural fields were planted in January 1997 with seven bottomland hardwood species. Following planting, the site will be monitored for planting success and survival. When the trees attain heights >4.5 ft, growth data and carbon sequestration per acre will be calculated.[13]

Conclusions

The primary production in wetland ecosystems is greatly enhanced by hydrological fluxes, which leads to high biomass, primary production and accretion rates. The carbon that is either fixed stored in standing biomass, released by soil decomposing microorganisms, or stored in soil sediments. With the continual destruction of wetlands worldwide, more of this sequestered carbon is released to the atmosphere. The protection of wetlands will preserve the amount of carbon already stored in these ecosystems.

The creation and restoration of new wetlands will certainly contribute to sequestration of carbon and should be considered as one way to mitigate greenhouse emissions.

SECTION I APC: Anthropogenic Chemicals and Activities

SECTION II COV: Comparative Overviews of Important Topics for Environmental Management

SECTION III CSS: Case Studies of Environmental Management

SECTION IV DIA: Diagnostic Tools: Monitoring, Ecological Modeling, Ecological Indicators, and Ecological Services

SECTION V ENT: Environmental Management Using Environmental Technologies

SECTION VI PRO: Basic Environmental Processes

Preface

Given the current state of the world as compiled in the massive Millennium Ecosystem Assessment Report, humans have changed ecosystems more rapidly and extensively during the past 50 years than in any other time in human history. These are unprecedented changes that need certain action. As a result, it is imperative that we have a good scientific understanding of how these systems function and good strategies on how to manage them.

In a very practical way, this multi-volume *Environmental Management Handbook* provides a comprehensive reference to demonstrate the key processes and provisions for enhancing environmental management. The experience, evidence, methods, and models relevant for studying environmental management are presented here in six stand-alone thematic volumes, as follows:

VOLUME 1 – Managing Global Resources and Universal Processes
VOLUME 2 – Managing Biological and Ecological Systems
VOLUME 3 – Managing Soils and Terrestrial Systems
VOLUME 4 – Managing Water Resources and Hydrological Systems
VOLUME 5 – Managing Air Quality and Energy Systems
VOLUME 6 – Managing Human and Social Systems

In this manner, the handbook introduces in the first volume the general concepts and processes used in environmental management. The next four volumes deal with each of the four spheres of nature (biosphere, geosphere, hydrosphere, and atmosphere). The last volume ties the material together in its application to human and social systems. These are very important chapters for a wide spectrum of students and professionals to understand and implement environmental management. In particular, the features include the following:

- The first handbook that demonstrates the key processes and provisions for enhancing environmental management.
- Addresses new and cutting-edge topics on ecosystem services, resilience, sustainability, food–energy–water nexus, socio-ecological systems, etc.
- Provides an excellent basic knowledge on environmental systems, explains how these systems function, and gives strategies on how to manage them.
- Written by an outstanding group of environmental experts.

Since the handbook covers such a wide range of materials from basic processes, to tools, technologies, case studies, and legislative actions, each handbook entry is further classified into the following categories:

APC: Anthropogenic chemicals—the chapters cover human-manufactured chemicals and activities
COV: Indicates that the chapters give comparative overviews of important topics for environmental management

CSS: The chapters give a case study of a particular environmental management example
DIA: Means that the chapters are about diagnostic tools—monitoring, ecological modeling, ecological indicators, and ecological services
ELE: Focuses on the use of legislation or policy to address environmental problems
ENT: Addresses environmental management using environmental technologies
NEC: Natural elements and chemicals—the chapters cover basic elements and chemicals found in nature
PRO: The chapters cover basic environmental processes.

Overall, these volumes will be a valuable resource for all libraries supporting programs in environmental science and studies, earth science, geography, and policy.

In this volume, #5, the focus is on managing air quality and the closely related topic of energy systems, as represented in over 50 entries. Energy basics and physics for conventional and alternative sources are considered. Specific impacts such as global climate change, acid rain, and ozone are covered. New entries include specific tools to measure road traffic emissions, the importance of managing micropower grids, and the role of individual and household behavior in emission scenarios. Case studies look at energy conversion and the impact of wind farm noise. This volume contains a number of entries on air pollution control strategies.

Editors

Brian D. Fath is Professor in the Department of Biological Sciences at Towson University (Maryland, USA) and Senior Research Scholar at the International Institute for Applied Systems Analysis (Laxenburg, Austria). He has published over 180 research papers, reports, and book chapters on environmental systems modeling, specifically in the areas of network analysis, urban metabolism, and sustainability. He co-authored the books *A New Ecology: Systems Perspective* (2020), *Foundations for Sustainability: A Coherent Framework of Life–Environment Relations* (2019), and *Flourishing Within Limits to Growth: Following Nature's Way* (2015). He is also Editor-in-Chief for the journal *Ecological Modelling* and Co-Editor-in-Chief for *Current Research in Environmental Sustainability*. Dr. Fath was the 2016 recipient of the Prigogine Medal for outstanding work in systems ecology and twice a Fulbright Distinguished Chair (Parthenope University, Naples, Italy, in 2012 and Masaryk University, Czech Republic, in 2019). In addition, he has served as Secretary General of the International Society for Ecological Modelling, Co-Chair of the Ecosystem Dynamics Focus Research Group in the Community Surface Modeling Dynamics System, and member and past Chair of Baltimore County Commission on Environmental Quality.

Sven E. Jørgensen (1934–2016) was Professor of environmental chemistry at Copenhagen University. He received a doctorate of engineering in environmental technology and a doctorate of science in ecological modeling. He was an honorable doctor of science at Coimbra University (Portugal) and at Dar es Salaam (Tanzania). He was Editor-in-Chief of *Ecological Modelling* from the journal inception in 1975 until 2009. He was Editor-in-Chief for the *Encyclopedia of Environmental Management* (2013) and *Encyclopedia of Ecology* (2008). In 2004, Dr. Jørgensen was awarded the Stockholm Water Prize and the Prigogine Medal. He was awarded the Einstein Professorship by the Chinese Academy of Sciences in 2005. In 2007, he received the Pascal Medal and was elected a member of the European Academy of Sciences. He had published over 350 papers, and has edited or written over 70 books. Dr. Jørgensen gave popular and well-received lectures and courses in ecological modeling, ecosystem theory, and ecological engineering worldwide.

Genotoxicity and Air Pollutions

Eliane Tigre Guimarães and Andrea Nunes Vaz Pedroso

Air Pollutants

Air pollution can be generated by natural and anthropogenic sources. The natural sources, such as electrical discharge, decomposition of organic matter, volcano eruption, and natural fires, do not depend on human actions and emit large amounts of pollution, usually in restricted and sparsely populated areas.

The anthropogenic sources can be stationary or mobile. Stationary sources are mainly industries that cause local problems of air contamination. Their pollution emissions are determined by the characteristics of the manufacturing processes, which include the sort of raw materials and fuels used and the products furnished, as well as by the efficiency of the industrial processes and the control measurements adopted.

Mobile sources consist of automotive vehicles, trains, airplanes, ships, and motorboats, which release pollutants into the atmosphere due to incomplete burning of fossil fuels. However, the automotive vehicles are the main mobile sources.

The atmosphere in large cities is usually contaminated by a range of pollutants from stationary and mobile sources. The pollutant emissions of mobile sources are difficult to be controlled, mainly because of the increasing number of automotive vehicles in the last 50 years. This number increased tenfold during this period.[1] The emissions of air pollutants in urban centers have been causing great concerns all over the world and have been causing harmful effects on living organisms.

The main pollutants in urban centers are gases such as carbon, nitrogen, and sulfur oxides, and organic compounds such as hydrocarbons, volatile organic compounds (VOCs), and particulate matter. They will be described below.

The gas carbon monoxide is an odorless, colorless, and tasteless gas formed during the incomplete combustion of carbon-containing fuels.[2]

The main source of sulfur dioxide (SO_2) is the combustion of fuels. Fossil fuels have 1%–5% sulfur in their composition. During combustion, the sulfur is converted to SO_2. Nowadays, in developed countries, a large quantity of the sulfur is removed from motor fuels during the refining process and gas emission from chimneys. However, in developing countries, unabated burning of coal and the use of fuel oils and automotive diesel with higher sulfur content are major sources of SO_2.[2]

The nitrogen derived from the combustion process of fossil fuels is converted to nitrogen oxides[2] such as nitrogen monoxide (NO) and nitrogen dioxide (NO_2). They are considered the precursors of tropospheric ozone (O_3) formation. Nitrogen dioxide diffuses into the atmosphere, where it is usually oxidized and can react with water to form acid rain, causing corrosion in materials and damage to human beings.[3]

The nitrogen oxides and VOCs are considered precursors and produce by photochemical reactions many secondary pollutants, among them O_3 and peroxyacetyl nitrate,[1,3] which compose so-called photochemical smog.

When O_3 is formed in an atmosphere without pollutants, it is consumed within minutes by the photostationary equilibrium between NO and NO_2. Nevertheless, in a polluted atmosphere, NO is converted to NO_2 and can be consumed by RO_2 (organic radical), and, as a consequence, O_3 is accumulated.[3,4] The O_3 is considered one of the most damaging gaseous pollutants to human health and plants, because it forms the reactive oxygen species (ROS) such as superoxide, hydrogen peroxide, and hydroxyl, among others. Reactive oxygen species are oxidative and affect lipids, proteins, and nucleic acids; the cell membranes, composed by polyunsaturated fatty acids, represent the initial target of ROS, changing their permeability and triggering lipid peroxidation,[5] amino acid oxidation, and inactivation of enzymes.[6]

The particulate matter (PM) is a mixture of solid or liquid particles suspended in the air, including smoke, fumes, soot, and other combustion by-products, besides natural particles such as wind-blown dust, sea salt, pollen, and spores.[7] These components can be characterized by their size and composition.[1] Based on the aerodynamic diameter, which ranges from 0.002 to 100 μm, the particulate matter is classified into three categories: 1) coarse particles, ranging from 2.5 to 100 μm; 2) fine particulate matter, below 2.5 μm; 3) ultrafine particles, below 0.1 μm.[8]

Air quality is now regulated by standard concentrations established by laws, based on experiments on humans and/or animals and epidemiological investigations. The standards for air pollutants in Europe are proposed by the European Commission and in the United States by the Environmental Protection Agency (EPA). In Brazil, the standard values for air quality control are defined by a resolution proposed by the National Council of Environment (CONAMA; Table 1).[9]

Although these standards are often revised in order to protect the human health, the World Health Organization states that around 2.4 million people still die each year due to causes related to air pollution.

TABLE 1 Standard Values for Pollutants Established by Environmental Agencies (European Commission, EPA, and CONAMA)

Pollutant	Sampling Time	European Commission	EPA	CONAMA
CO (carbon monoxide)	1 hr	26 ppm	35 ppm	35 ppm
	8 hr	10 mg/m^3	–	–
NO_2	8 hr	–	–	9 ppm
	1 hr	200 μg/m^3	100 ppb	320 μg/m^3
PM_{10} (particulate matter)	Annual	40 μg/m^3	53 ppb	100 μg/m^3
	24 hr	50 μg/m^3	150 μg/m^3	150 μg/m^3
$PM_{2,5}$ (particulate matter)	Annual	25 μg/m^3	150 μg/m^3	50 μg/m^3
	24 hr	–	35 μg/m^3	–
O_3	8 hr	120 μg/m^3	80 ppb	120 μg/m^3
	24 hr	–	120 ppb	125 μg/m^3
SO_2	24 hr	125 μg/m^3	140 ppb	125 μg/m^3
	Annual	–	75 ppb	80 μg/m^3

–, Limit not defined.

About 1.5 million deaths are attributable to indoor air pollution (estimated deaths).[2] Epidemiological studies suggest that Americans and Europeans have high rates of deaths from cardiopulmonary diseases arising from air pollution.[10] Worldwide, the number of deaths per year caused by pollution is greater than that caused by car accidents.[11] The individual response to air pollutants depends of the type of pollutant, the degree of exposure, the health conditions and the individual genetics[12] and still, socioeconomic profile.[13,14]

Air pollutants affect the vital molecules of human beings, such as nucleic acids, causing genotoxic effects, among numerous other health problems. Thus, this will be the main focus of this entry from here on. The genotoxic effects most commonly reported in the literature and bioassays proposed for prognosis of genotoxic risks will be reported. Finally, other effects to human health will be mentioned at the end of this entry.

Genotoxic Effects of Air Pollutants

Genotoxicity is defined as every alteration occurring in genetic material that causes loss of cellular integrity.[15]

The literature defines that mutations can modify the amino acid sequence of the gene encoding the protein or damage in the DNA molecule. They may occur over the life span of living beings. This process is of extreme importance for the evolution of species. Among gene mutations, we may find the following cases: 1) when a single nucleotide base is replaced by another; and 2) when extra base pairs are added or deleted from the DNA. These are also referred to as insertions and deletions, respectively. These mutations can be devastating, because the messenger RNA is translated into new groups of three nucleotides and the protein produced can cause serious damage.

The mutations that encompass larger portions of DNA are called macrolesions, which change the structure of chromosomes, resulting in damage of the genotype and phenotype of the organism, such as translocations, inversions, deletions, and duplications. They occur most frequently during meiosis.[19]

The mutation may result from exposure to different environmental or chemical agents. Throughout the numerous and successive divisions, the cell can accumulate a large number of mutations and trigger the loss of division control and contribute to the initial stage of tumor development.[20] Therefore, the genotoxic agents are considered mutagenic or carcinogenic,[15] and there is a slight difference between these classifications: 1) mutagenic effect is an alteration in the genetic material of the cell of a living organism that is more or less permanent and that can be transmitted to the cell's descendants; and 2) carcinogenic effects are caused by genotoxic substances that can produce tumors, abnormal tissue growths caused by a loss of control in cell replication. Nevertheless, repairing mechanisms of DNA are present in all organisms, and their complexity is directly proportional to the complexity of the organism.[21] The mechanisms can be classified into direct reversal, damage excision, or recombination.[22]

In human beings, most of the pollutants studied are particulate matter.[7,23,24] In the previous section, we said that smaller fractions of PM, i.e., $<2.5\,\mu m$, are more harmful, and this was confirmed by Rossner and colleagues,[25] who analyzed the organic fractions of PM of polluted sites and found DNA damage. A similar result was found by Coronas and colleagues;[26] they employed cells of lymphocytes and buccal mucosa cells to assess the genotoxic potential of PM in people living and working near refinery oil. The authors used two genotoxicity assays—comet assay and micronucleus assay—and pointed out that the comet assay was more sensitive. These tests will be detailed in the next section.

Other studies show organic extracts of particulate matter to cause genotoxicity. Roubicek and colleagues[27] found that in regions polluted in Mexico City, organic extracts of PM containing Cd and PAHs induce micronucleus formation in human epithelial cells. In several European cities were collected organic extracts mixtures of PAHs and particulate matter, confirmed this genotoxic, using HepG2 cells have the metabolic capacity for PAHs similar to human hepatocytes and represent the best in vitro model for investigating the genotoxic potential of complex mixtures containing PAHs.[28]

Another study found DNA damage in human lung cells when exposed to particulate matter.[29] Still, Gilli and colleagues[30] obtained positive correlations statistically between PM_{10} and mutagenicity, bioavailable iron, sulfates, and nitrates.

Genotoxicity Tests

Currently, there are numerous protocols with prokaryotic and eukaryotic organisms, which evaluate the mutagenic effects of different substances in order to identify risks that living organisms are exposed to. The genotoxic tests most used to detect genotoxicity of air pollutants will be mentioned below.

The Ames test is also known as the *Salmonella* mutagenicity test. This test was developed by Bruce Ames and colleagues and aimed to evaluate the carcinogenic potential of different substances using mutant strains of auxotrophic *Salmonella typhimurium* with respect to histidine. It detects mutagens that cause the displacement of the reading frame (frameshift) or substitution of base pairs of DNA.[31,32]

Other tests use eukaryotic organisms, aiming to evaluate the mutagenic potential of different substances by means of numerical and/or structural chromosomal abnormalities involving at least 10 million base pairs (10 Mb). Among them, we may include the in vitro cytogenetic test in mammalian cells (mouse lymphoma assay) that quantifies the genetic changes that affect the expression of the TK gene of the enzyme thymidine kinase (tk) cells in cultures of L5178Y tk+/tk– lymphoma mice. Although the mammalian cells present locus heterozygosity, only one gene copy is functional in this mouse strain. Loss of locus heterozygosity of the enzyme thymidine kinase, when the gene is affected by a mutagen, causes the resistance of cells mutated to supplementation of medium with trifluorothymidine (TFT). The TFT causes inhibition of metabolism, preventing cell division and leading to death of cells that have the entire way of nucleotides recovery. This test was developed by Clive and colleagues in 1979[33] and modified by Cole and colleagues in 1990.[34]

The comet assay is also a well-known test. It is used to detect not chromosomal mutations but genomic lesions. The test is based on the technique of gel electrophoresis, which detects DNA damage. Since DNA is negatively charged, the electric current causes migration of small broken pieces through the gel, faster and farther than larger pieces. As a result, the damaged cell looks like a comet, with the pieces of damaged DNA forming the tail. The smaller the pieces of DNA, the more they migrate from the cell body. Therefore, a longer tail with smaller pieces implies a greater genetic damage. The content and fragment length of the tail are directly proportional to the amount of DNA damage.

Among mutagenic tests, the micronucleus test is widely used because it is applicable with different eukaryotic organisms. By definition, the micronucleus is a small nucleus, regarded as a product of breakage of genomic DNA of eukaryotic cells. During cell division, genetic material is duplicated and distributed equally between two daughter cells. Radiation and chemicals can cause chromosomal breakage or damage, affecting the distribution of genetic material between daughter cells. Parts or fragments of chromosomes resulting from this damage can be distributed to any of the daughter cells. It is not incorporated into the new core; they may be presented in the form of micronuclei clearly observable on optical microscope.[35]

The micronucleus test in erythrocytes of bone marrow of rodents was developed by Matter and Schmid[36] and modified by Heddle and Salamone[37] in the following years and more recently by Mavournin and colleagues.[38] The test is based on the fact that the effect of genotoxic agent is observed in polychromatic erythrocytes. In addition, the micronuclei are easily observed, and the frequency of micronuclei is dependent on the sampling time.

The micronucleus test in human peripheral blood lymphocytes is also used to detect the mutagenic potential of substances. Nonetheless, some technical problems occur due to the fragility of the cell and the variability in the process of mitotic lymphocytes. These problems were solved by cell hypotonization[39] and radioactive labeling with cytochalasin B to identify the cells that suffered mitosis by inhibiting cytokinesis without blocking mitosis.[40]

Although studies on animals used to detect the effects of air pollution are successful,[41] simple and more efficient analyses to investigate the environmental risks and to determine the genotoxicity induced by pollution are needed. The bioassays with plants are generally more sensitive than other systems for this purpose.[42] Several studies with genus *Tradescantia* have been considered since 1960 as effective biomarkers for determining the genotoxic potential of air pollutants.[43–50]

The *Tradescantia* micronucleus bioassay is the quantification of micronuclei formed in meiotic prophase I, better seen in the young tetrad stage.[44] Among the genus *Tradescantia,* we may highlight the 4430 clone (hybrid between *Tradescantia hirsutiflora* and *T. subacaulis*).[44,48] A cultivar of *T. pallida* Purpurea from Mexico and Honduras has also been used for the micronucleus test since 1999.[47,49]

Nonetheless, in urban areas, gaseous and particulate pollutants interact with each other, thereby enhancing the genotoxic effects on the living organisms. Some studies with *Tradescantia* showed a significant increase in genotoxic potential in plants exposed in the urban environment compared with the rural environment,[49,51,52] also to detect the genotoxic potential of water-soluble fraction of PM_{10}[47] and a dose of 60 ppb ozone in fumigation chambers.[53]

Furthermore, other tests are also conducted with micronuclei in different plant species such as *Allium cepa* and *Vicia faba*; however, the micronuclei are formed from errors in mitotic division in those species.[50]

Another test used to evaluate the risks caused by mutagens also using the genus *Tradescantia* is the *Tradescantia* stamen hair bioassay.[54] It was developed by Arnold H. S. Sparrow based on the fact that the stamen hair cells of plants are heterozygous for color, making it possible to detect mutations based on the change in pigmentation from blue (dominant) to pink (recessive).[55] A pink mutant cell can continue to divide, giving rise to a series of contiguous pink cells, representing a single mutation event. Two mutant cells separated by blue cells are considered two mutation events.[54,56]

In addition to the genotoxic tests using plant species, there is another test known as pollen abortion, which has the ability to detect lethal mutations in haploid cells (microsporous) that end up affecting the development of pollen grains.[57,58] This was confirmed by Micieta and Murín,[59] who evaluated approximately 40 species of native vegetation in Slovakia subjected to industrial pollution, and they observed a positive relationship, i.e., high rate of pollen abortion in polluted area.

Other plant species used in genotoxic tests, like *Nicotiana tabacum*, in different degrees of polluted environments show the largest amount of DNA damage in high pollutant concentrations.[52]

The genotoxic effects caused by air pollutants are studied with more emphasis on the respiratory system in human beings. Effects as changes in pulmonary functions, modification of biochemical and cellular functions, or secretions could happen in the respiratory epithelium. Pacini and colleagues[60] observed a higher amount of DNA damage in people living in the polluted region in Florence, when compared with those living in less polluted areas in Sardinia, both in Italy. In Suwon, Korea, the genotoxic potential of organic extract of $PM_{2,5}$ in lung bronchial epithelial cells was also detected.[61] In addition, the same genotoxic effect can be observed when human beings were exposed to different concentrations of NO_2.[62] Additionally, Tova-lin and colleagues[63] noted the severity of DNA damage in workers in a large urban center, due to the combination of air pollutants VOC, PM_{25}, and O_3.

A considerable amount of tests to detect the mutagenicity of different substances is available, although only the most used were described. A review on urban air mutagenicity and experimental systems reported that 50% of the studies apply the *Salmonella* assay (Ames test); about 30% apply the plant systems (micronucleus tests, chromosomal aberrations, among others); and the other 20% of the studies used other bioassays (such as damage in DNA), animals, and other combinations of studies.[64]

Air Pollutants and Other Health Effects

Historically, the harmful effects of air pollution on human health have become evident. The association between high levels of pollution and diseases manifested by the population exposed has been long detected. Perhaps the most known episode occurred in London in December 1952, where a thermal inversion was responsible for 4000 deaths in 2 weeks.[65] Other similar episodic events confirm this evidence, for example, Meuse Valley in Belgium in 1930,[66] Donora in Pennsylvania in 1948.[67] and St. Louis in 1985.[68]

There is evidence to support the concept that particulate matter causes human mortality, morbidity,[69,70] and genotoxic effects.[71] There is an association between particulate matter and alteration in the respiratory system with restricted activity and severe breathing conditions (acute bronchitis and asthma), resulting in difficulty in breathing and insomnia in adults,[72] emergency room visits, hospital admissions,[73] and pulmonary vasoconstriction.[74,75] It affects lung growth in rats after chronic exposure[76] and significant association between lung cancer and long-term exposure to fine particles, reinforcing the role of fine particulates in the pathogenesis of lung cancer.[77]

Still, in the circulatory system, the fine particulate matter reaches the alveolar regions, transposes the alveolar capillary barrier, and, as a consequence, intensifies the risk of functional abnormalities,[78] such as acute vascular dysfunction, increases thrombus formation,[79,80] arrhythmia, and sudden death.[81]

The toxicity of carbon monoxide has been widely investigated and is well known. Studies show that a major change in humans is the formation of a stable complex between CO and hemoglobin, called carboxyhemoglobin. It decreases the release transport of oxygen to the tissues via blood.[82] In relation to nitrogen dioxide, epidemiological studies have shown that it affects the respiratory system of humans when inhaled[83] and, in high levels of concentration, can be correlated with increased symptoms of asthmatic bronchitis and reduced lung function in children.[2]

In humans, high concentrations of O3 are associated with reduced forced expiratory volume in 1 sec and forced expiratory flow at 50% and 75% of forced vital capacity.[83] Regions with higher ozone concentrations present a higher incidence of asthmatic patients.[83,84] Additionally, according to Pereira et al.,[85] this pollutant showed a positive correlation with the incidence of lung and larynx cancer. Animal studies suggest that O_3 may damage the ciliate cells of the epithelium with changes in the air–blood barrier permeability, causing an inflammatory response.[86]

The complex mixtures of pollutants may affect the human circulatory system, with changes in the levels of fibrinogen, increases erythrocyte count, and plasma viscosity.[87–89] Some studies evidenced deleterious effects on lung defense mechanism, causing inflammatory changes in the airway and distal lung parenchyma.[90–92] Others confirm the carcinogenic effect resulting from air pollution, which acts as a promoter and/or initiator of pulmonary tumor in mice.[93,94]

Over the past few years, some evidence focused particularly on male fertility and pregnancy, showing the negative effects of urban air pollutants on reproductive health in humans.[95–97] Moreover, few studies have been able to demonstrate an association between air pollution and changes in fertility in women, probably due to multiple factors involved in female reproductive function.[98] Male and female mice exposed to urban pollution in São Paulo, Brazil, show changes in the genus distribution in their offspring, suggesting that air pollution can change the proportion of XY sperm in exposed animals.[99]

Previous studies showed that air pollution has a significant impact on female reproductive function in mice. Exposure to fine particulate matter has been implicated in disruption of the pattern of segregation of inner cell mass and trophectoderm cell lineages at the blastocyst stage,[100,101] an important marker of embryo viability and development potential.[102] A retrospective epidemiological study confirmed the increased risk of early pregnancy loss, which was already observed in experimental studies in women exposed to air pollution. In addition, an association between brief exposure to high levels of environmental particles during pre-conception and early pregnancy loss was found, independently from conception method (natural or after in vitro fertilization treatment), and the risk of miscarriage increased 2.6-fold.[100] Furthermore, a positive association between air pollution and intrauterine mortality was found in a study conducted in São Paulo, southeastern Brazil, suggesting that pollution in São Paulo may promote adverse effects on fetuses.[103]

Conclusion and Remarks

Air pollution is a reality in megacities, and it is intensified mainly by a huge number of vehicles circulating. According to the literature, the major air pollutants that human populations are exposed to in urban areas have a number of substances with carcinogenic activity. These substances can cause mutations and trigger neoplasias.

Therefore, the high levels of vehicular emissions require complex demands and strict actions from the government. These solutions can be taken individually with proper maintenance of vehicles; indeed, need the improvement of public transport, which means efficient and rapid tubes, trains, trams, and buses. Alternative measurements such as rodizio have been implemented in large cities such as São Paulo, Mexico City, and Beijing, aiming to reduce the daily and enormous traffic and, consequently, the direct emissions from sources.

Although not emphasized in this entry, industrial air pollution also should not be underestimated. However, the emissions of industries are more easily controlled and must be applied, followed by periodic monitoring, employment of cleaner technologies, and cleaning up of filters on the chimneys, which should be constructed with enough height to guarantee adequate dispersion of pollutants. Furthermore, it is important to choose raw materials that produce waste with lower pollution potential at the end of the production process. It is mandatory to apply more resources to develop new technologies, which can be developed at universities, research institutes, and private companies. The use of cleaner energy sources, such as wind and biogas, is desirable.

Nevertheless, the pollutants produced locally may not stay in the same place and its surrounding area. It can also damage remote areas of the planet due to long-term transportation. Each country has its own formulation of public policies that impose limits on environment pollution levels. Finally, not only signed agreements among governments will bring significant changes to reduce emissions of pollutants. Individual and local actions organized by nongovernmental organizations, schools, and media are equally important to preserve life.

Methane Emissions: Rice

Kazuyuki Yagi

Introduction

The atmospheric concentration of methane (CH_4) has increased rapidly in recent years. Because it is a radiative trace gas and takes part in atmospheric chemistry, the rapid increase could be of significant environmental consequence. Of the wide variety of sources, rice fields are considered an important source of atmospheric CH_4, because the harvest area of rice has increased by about 70% during last 50 years and it is likely that CH_4 emission has increased proportionally. Recent estimates suggest that global emission rates of CH_4 from rice fields account for about 4%–19% of the emission from all sources.[1] Due to the large amount of the global emission from rice cultivation, reduction of CH_4 emission from this source is very important in order to stabilize atmospheric concentration. In addition, because of the possibility of controlling the emission by agronomic practices, rice cultivation must be one of the most hopeful sources for mitigating CH_4 emission.

Processes Controlling CH_4 Emissions from Rice Fields

Table 1 provides a summary of measured methane emissions at a number of specific research sites around the world.[2] It should be noted that methane fluxes from rice fields show pronounced diel and seasonal variations and vary substantially with different climate, soil properties, agronomic practices, and rice cultivars.

Processes involved in CH_4 emission from rice fields are illustrated in Figure. 1. Like other biogenic sources, CH_4 is produced by the activity of CH_4 producing bacteria, or methanogens, as one of the terminal products in the anaerobic food web in paddy soils. Methanogens are known as strict anaerobes that require highly reducing conditions. After soil is flooded, the redox potential of soil decreases rapidly by sequential biochemical reactions.

Flooded paddy soils have a high potential to produce CH_4, but part of CH_4 produced is consumed by CH_4 oxidizing bacteria, or methanotrophs. In rice fields, it is possible that a proportion of CH_4 produced in the anaerobic soil layer is oxidized in the aerobic layers, such as the surface soil–water interface and the rhizosphere of rice plants.

The emission pathways of CH_4 that is accumulated in flooded paddy soils is: diffusion into the flood water, loss through ebullition, and transport through the aerenchyma system of rice plants. In the

TABLE 1 Methane Emission from Rice Fields in Various World Locations[a]

			Season Total	
Country	Daily Average (g/m^2 day)	Flooding Period (days)	Average (g/m^2)	Range (g/m^2)
China	0.19–1.39	75–150	13	10–22
India	0.04–0.46	60	10	5–15
Italy	0.10–0.68	130	36	17–54
Japan	0.01–0.39	110–130	11	3–19
Spain	0.10	120	12	
Thailand	0.04–0.77	80–110	16	4–40
U.S.A.	0.05–0.48	80–100	25	15–35

[a] The data are for the fields without organic fertilizer.

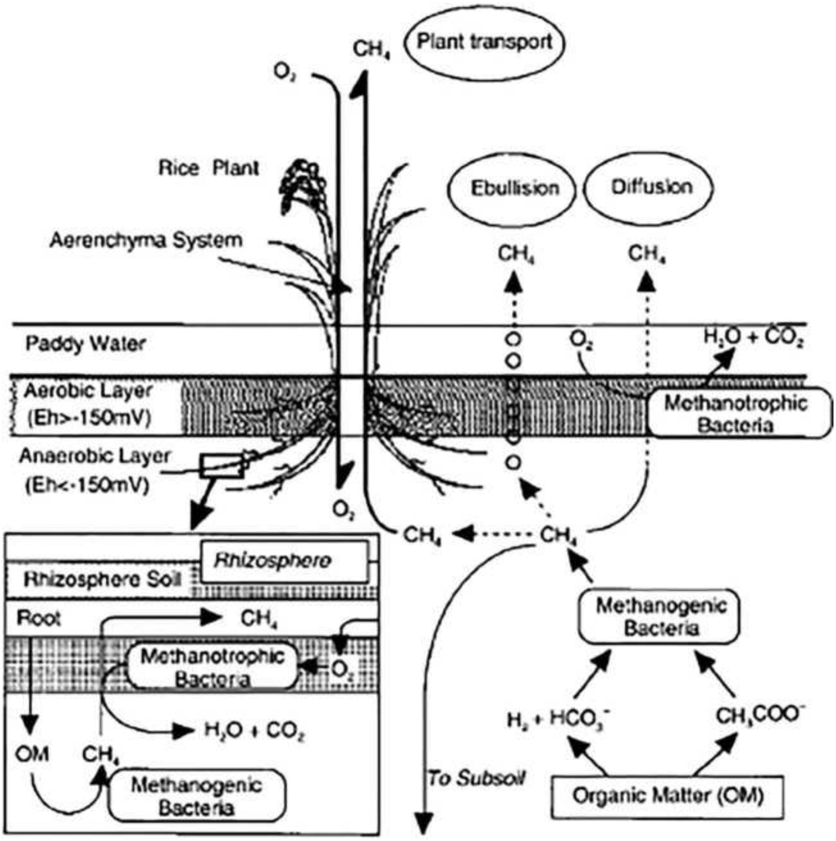

FIGURE 1 Production, oxidation and emission of CH4 in rice paddy fields.
Source: Conrad[3] and Knowles.[4]

temperate rice fields, more than 90% of CH_4 is emitted through plants,[5] while significant amounts of CH_4 may evolve by ebullition, in particular during the early part of the season in the tropical rice fields.[6] Therefore, it is concluded that possible strategies for mitigating CH_4 emission from rice cultivation can be made by controlling either production, oxidation, or transport processes.

Options for Mitigating CH_4 Emission

Water Management

Mid-season drainage (aeration)in flooded rice fields supplies oxygen into soil, resulting in a reduction of CH_4 production and a possible enhancement of CH_4 oxidation in soil.[7,8] A study using an automated sampling and analyzing system clearly showed that short-term drainage had a strong effect on CH_4 emission, as shown in Figure. 2. Total emission rates of CH_4 during the cultivation period were reduced by 42%–45% by short-term drainage practices compared with continuously flooded treatment.[9] These results indicate that improvement in water management can be one of the most promising mitigation strategies for CH_4 emission from rice fields. Increasing the rate of water percolation in rice fields by installing underground pipe drainage may also have an influence on CH_4 production and emission.

Soil Amendments and Mineral Fertilizers

The progress of soil reduction can be retarded by adding one of several electron acceptors in the sequential soil redox reactions. Sulfate is one of the most promising candidates for this strategy because it is commonly used as a component of mineral fertilizer and soil amendment. Field measurements have shown that CH_4 emission rate decreased by at most 55%–70% by application of ammonium sulfate or gypsum.[10,11]

Additions of other oxidants, such as nitrate and iron-containing materials, may influence CH_4 emission from rice fields. As well as adding oxidants, dressing paddy fields with other soils that contain a large amount of free iron and manganese may decrease CH_4 emission. Other chemical candidates are nitrification inhibitors and acetylene releasing materials.

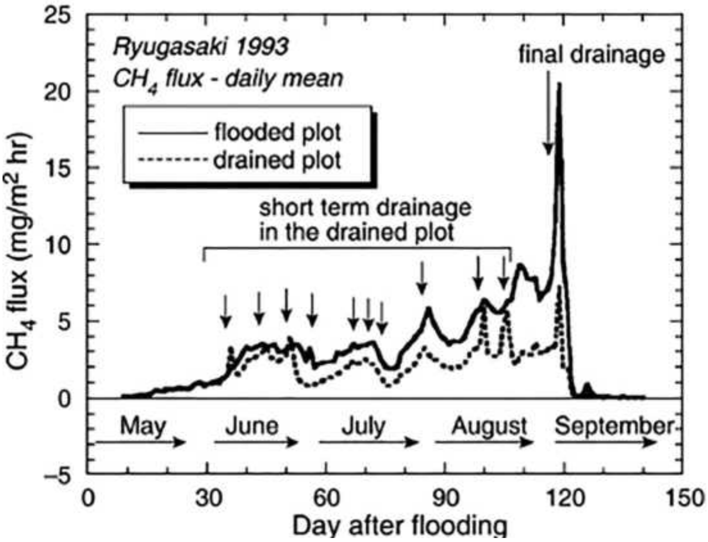

FIGURE 2 Effect of water management on CH_4 emission from a rice paddy field. The arrows indicate period of midseason drainage in the intermittent irrigation plot and the timing of final drainage in both of the plots.

Organic Matter Management

In rice cultivation, fresh organic matter and animal wastes are often applied as fertilizers. In the fields, a proportion of the biomass of previous crops and weeds remains in soils at the start of rice cultivation. Such organic matter is decomposed in soils and acts as a substrate for fermentation reactions. Many researchers have demonstrated that incorporation of rice straw and green manure into rice paddy soils dramatically increases CH_4 emission.[7,10,12] The impact of organic amendments on CH_4 emissions can be described by a dose–response curve which adopts correction factors for composted and fermented organic matter.[6] Mitigation of CH_4 emission requires that the quantities of organic amendments be minimized.

Field experiments also indicated that composted or fermented organic matter increased CH_4 emission much less than fresh organic matter, due to a lower content of easily decomposable carbon.[6,7] Therefore, stimulation of composting organic amendments appears to be a promising mitigation option. Plowing the fields during the fallow period and promoting aerobic degradation of organic matter is also likely to reduce CH_4 emission.

Others

Different tillage and cropping practices change the physical, chemical, and microbiological properties of the plow layer soil and may reduce CH_4 emission. These include deep tillage, no tillage, and flooded rice-upland crop rotation.

Selecting and breeding rice cultivars that emit lower CH_4 is a desirable approach because it is easy to adopt. There are four points to consider for selecting cultivars: 1) they should exude low levels carbon from their roots; 2) they should have a low level of CH_4 transport and a high level of CH_4 oxidation in the rhizosphere; 3) they should have a higher harvest index, in order to reduce organic matter input into soil after harvest; and 4) they should be suitable and have a high productivity when other mitigation options are performed.

Problems and Feasibility of the Options

If the above mitigation options could be applied to world's rice cultivation, global CH_4 emission from rice fields could decrease significantly. However, there are several formidable obstacles to adopting the mitigation options into local rice farming. Table 2 summarizes the problems and feasibility of the individual mitigation options along with the efficiency of the options.

Application of some options is limited to specific types of rice fields. In particular, altering water management practices may be limited to rice paddy fields where the irrigation system is well equipped. Long midseason drainage and short flooding may cause possible negative effects on grain yield and soil fertility. Improving percolation by underground pipe drainage requires laborious engineering work. The increased water requirement is another problem in the water management options because water is a scarce commodity in many regions.

Cost and labor are serious obstacles for applying each option to local farmers. Most of the mitigation options will decrease profitability and the farmer net returns in the short run. To overcome these obstacles, an effort to maximize net returns by joining CH_4 mitigation and increased rice production will be needed, as well as political support.

It is recognized that the mitigation options should not have any significant trade-off effects, such as decreased rice yield, a decline in soil fertility, or increased environmental impact by nitrogen compounds. The development of anaerobic conditions in soil by flooding decreases decomposition rates of soil organic matter compared with aerobic soils, resulting in soil fertility being sustained for a long time. Flooded rice cultivation shows very little growth retardation by continuous cropping. Some mitigation options may reduce these advantages of rice fields. Application of sulfate-containing fertilizer may cause a reduction in rice yield due to the toxicity of hydrogen sulfide. Mid-season aeration and soil amendments may induce nitrogen transformation resulting in enhanced N_2O emissions.[16,17]

TABLE 2 Evaluation of the Mitigation Options for Methane Emission from Fields

		Problem for Application

Petroleum: Hydrocarbon Contamination

Svetlana Drozdova
and Erwin
Rosenberg

Introduction

Historically, environmental analyses focused on monitoring compounds that pose a threat to humans and their environment. Petroleum hydrocarbon compounds are among them. Contamination of water, soil, and sediment samples by petroleum hydrocarbons is a common and severe environmental problem caused by improper handling, storage, transport, or use of petrochemical products or raw materials.

Petroleum products are the major source of energy for industry and daily life. Leaks and accidental spills occur regularly during exploration, production, refining, transport, and storage. In addition, natural processes can result in seepage of crude oil from geologic formations below the seafloor. The total input of crude oil and petroleum into the environment is estimated to be 1.3 million tons per year. To understand the potential effect of petroleum contaminations on the environment, it is important to understand the nature and distribution of sources and their inputs. Petroleum poses a range of environmental risks when released into the environment. Catastrophic and large-scale spills have a very severe physical impact in addition to the chemical pollution that they cause; chronic discharges and small releases can damage and eventually kill the exposed flora and fauna due to toxicity of many of the individual compounds contained in petroleum. Oil contamination in the environment is primarily assessed by measuring the chemical concentrations of petroleum products in the affected environmental compartment (e.g., sediment, biota, water).

This entry provides a discussion of the environmental relevance of petroleum hydrocarbons; the principal sources of petroleum contaminations in the environment; and the nature and composition of crude oil and petroleum products derived from it. The fate of petroleum hydrocarbons in the environment, possible effects from exposure to them, and their toxicity are discussed as well. The entry is concluded by an overview of analytical methods for determination of petroleum hydrocarbon contamination.

Petroleum Hydrocarbons and Their Environmental Relevance

Oil and gas resources are organic compounds, formed by the effects of heat and pressure on sediments trapped beneath the earth's surface over millions of years. The remains of animals and plants that lived millions of years ago in a marine environment were covered by layers of sand and silt over the years. Heat and pressure from these layers helped the remains turn into crude oil or petroleum.[1] The word "petroleum" means "rock oil" (from Greek: petra [rock] + Latin: oleum [oil])[2] or "oil from the earth." While ancient societies made some use of these resources, the modern petroleum age began less than a century and a half ago, when in 1859, Colonel Drake discovered oil in Oil Creek in Titusville, Philadelphia, United States. From that time on, the world's demand for fossil fuel and the production of oil have continuously increased. From the 1980s, in particular, after the second oil crisis of 1979, the petroleum business has developed into a high-technology industry. Advances in technology have greatly improved the ability to find and extract oil and gas and to convert them to efficient fuels and useful consumer products. About 100 countries produce crude oil. Russia, Saudi Arabia, the United States, Iran, and China are the top five producing countries in 2009 (Table 1).[3] In the United States, the oil and gas industry employs 1.4 million people and generates about 4% of U.S. economic activity. It is larger than the domestic automobile industry and larger than education and social services, the computer industry, and the steel industry combined.[4] At a refinery, different fractions of the crude oil are separated into useable petroleum products. Various sources of information provide a good overview of the different processes in petroleum refining.[5–7] Petroleum products are used worldwide for energy production, as fuel for transport, and as a raw material for many chemical processes. The United States is the biggest consumer of oil in the world (Table 1). Although there exist well-developed alternatives to the use of oil (particularly for energy production and transportation), our societies are still strongly dependent on oil, which is an environmental burden, an economic problem, and a political hazard. However, at the current time, the economic situation still favors the use of petroleum and petroleum products for these applications rather than its alternatives, which at the moment are not competitive from an economic point of view.

Petroleum poses a range of environmental risks when it is released into the environment (whether by catastrophic spills or through chronic discharges). In addition to the physical impact of large spills, the toxicity of many of the individual compounds contained in crude oils or petroleum products is significant. Information on how petroleum hydrocarbons enter and diffuse in the environment is abundant.[8,9] The sources of petroleum input to the environment, particularly to the sea, are diverse. They can be categorized effectively into four major groups, namely, natural seeps, petroleum extraction, petroleum transportation, and petroleum consumption.

Natural seeps are frequently encountered phenomena that occur when crude oil seeps from the geologic strata beneath the seafloor to the overlying water column as a natural process.[10] Recognized by geologists for decades as indicating the existence of potentially exploitable reserves of petroleum, these seeps release vast amounts of crude oil annually. Yet these large volumes are released at a rate low enough that the surrounding ecosystem can adapt and even thrive in their presence; which is not true in case of the catastrophic and accidental impact of a tanker or oil well spill. Natural processes are, therefore, responsible for over 45% of the petroleum entering the marine environment worldwide (Table 2).[11]

As result of human activities, about 700,000 tons of petroleum is released annually into the sea worldwide. Processes such as petroleum extraction, transportation, and consumption can cause soil and groundwater contamination in case of equipment failure or operation errors and other reasons. Petroleum extraction can result in release of both crude oil and refined products as a result of human activities associated with efforts to explore and produce petroleum. The nature and size of these releases are highly variable—see Table 3 for the largest oil spills observed until 2010[12]—and can include accidental spills of crude oil from platforms and blowouts such as that of the oil rig Deepwater Horizon in the Gulf of Mexico in April 2010 or slow chronic releases of water produced from oil- or gas- bearing formations during extraction. Under current industry practices, this "produced water" is treated to separate from crude oil and either injected back into the reservoir or discharged overboard. Produced water is

TABLE 3 Top 10 Oil Spills in the World as of 2010

	Incident	Location	Year	Type of Incident	Magnitude of Oil Spill (gallons)
1	Gulf War	Kuwait	1991	Oil spill due to war action and sabotage of oil drilling stations and pipelines, encompassing also the dumping of the charge of several oil tankers into the Persian Gulf by Iraqi troops during the Gulf War.	520,000,000
2	Deepwater Horizon	Gulf of Mexico	2010	Oil spill as a consequence of a methane blowout (which could not be prevented due to a technical problem) at the oil rig Deepwater Horizon, which caused an explosion and and the subsequent loss of the oil drilling platform. The well continued to leak for over 100 days.	172,000,000
3	Ixtoc I	Mexico	1979	After an unexpected blowout at the offshore oil rig Ixtoc 1 in the Gulf of Mexico, the platform exploded and collapsed. Oil escaped freely from the well for almost 1 year until the well could be capped.	138,000,000
4	Atlantic Empress/ Aegean Captain	Trinidad and Tobago	1979	Collision of two ships, the Aegean Captain and the supertanker Atlantic Empress, during a heavy storm in the Caribbean Sea. The Atlantic Empress exploded, sank, and lost its freight.	90,000,000
5	Fergana Valley/ Mingbulak	Russia	1992	Technical failure of an oil well in the Fergana Valley located between Kyrgyzstan and Uzbekistan from which oil blew out for a period of 8 months.	88,000,000
6	Nowruz Oil Field	Persian Gulf	1983	Collision of an oil tanker with an oil platform at the Nowruz Oil Field during the Iran–Iraq War. After the oil drilling platform collapsed, the wellhead was destroyed and leaked oil into the Persian Gulf for more than 6 months before being capped. A similar event at the same oilfield resulted directly form war action.	80,000,000
7	Castillo de Bellver	South Africa	1983	A fire at the tanker Castillo de Bellver caused the ship to drift and then break into two separate pieces. Relatively little damage was done to the South African coastline since the oil may have sunk into the sea or burned during the fire.	79,000,000
8	The Amoco Cadiz	France	1978	The crude oil carrier Amoco Cadiz ran aground off the French Atlantic coast and finally spilt into halves, whereby it lost its complete freight, which contaminated 200 km of the French coastline.	69,000,000
9	ABT Summer	Angola	1991	Following a fire aboard the oil tanker *ABT Summer*, it sank and all its freight either leaked to the sea or sank to the ground about 900 miles from the coast of Angola.	51,000,000
10	The MT Haven	Genova, Italy	1991	After unloading the oil tanker MT Haven, a fire broke out, followed by explosions after which the ship sank and continued to leak oil for 12 years.	45,000,000

Source: Adapted from Top 10 Worst Oil Spills.[12]

the largest single wastewater stream in oil and gas production. The amount of produced water from a reservoir varies widely and increases over time as the reservoir is depleted. Petroleum transportation can result also in releases of dramatically varying sizes of petroleum products (not just crude oil) from major incidents (mostly from tankers, such as the one in 1979 off the coast of Tobago, when two tankers collided and one of these, the Atlantic Empress, sank, losing all its freight) to relatively small operational releases that occur regularly, such as those from pipelines.

Releases that occur during the consumption of petroleum, whether by individual car and boat owners, non-tank vessels, or runoff from urban or industrial areas, are typically small but frequent and widespread and are responsible for the vast majority (70%) of petroleum introduced to the environment through human activity.

Because crude oil and petroleum products are a complex and highly variable mixture of hundreds to thousands of individual hydrocarbon compounds, characterizing the risks posed by petroleum-contaminated soil and water has proven to be difficult and inexact. It is very important to have an understanding of the toxicology, analytical science, environmental fate and behavior, risk, and technological implications of petroleum hydrocarbons in order to interpret, evaluate the risk of, and make decisions about the hazardous effect to and ensure the appropriate protection of the environment.

General Chemical Composition Features of Crude Oils and Petroleum Products

Crude oil is an extremely complex mixture of several thousands of different compounds; its compositions and physical properties vary widely depending on the source from which the oils are produced, the geologic environment, and location in which they migrated and from which they are extracted. The nature of the refining processes has an effect on crude oil compositions as well. As indicated in Table 4, petroleum and petroleum products contain primarily hydrocarbons, heteroatom compounds, and relatively small concentrations of (organo)metallic constituents.[13,14] The complexity of petroleum and petroleum products increases with carbon number of its constituents, so it is impossible to identify all components. Petroleum and petroleum products are typically characterized in terms of boiling range and approximate carbon number. Raw petroleum is usually dark brown or almost black, although some fields deliver a greenish or sometimes yellow petroleum. Depending upon the oil field and the way the petroleum composition was formed, the crude oil will also differ in viscosity. The composition of crude oil impacts certain physical properties of the oil, and it is these physical properties (e.g., density or viscosity) by which crude oils are generally characterized, classified, and traded. These physical properties can be used to classify crude oils as light, medium, or heavy. The American Petroleum Institute (API) gravity[15] is a measure of the specific gravity of a petroleum liquid compared with water (API = 10).

TABLE 4 Main Constituents of Petroleum Hydrocarbons and Representative Examples

Petroleum Hydrocarbon Compounds						
Aliphatics/Alicyclics				Aromatics		
Saturated hydrocarbons		Unsaturated hydrocarbons				
Alkanes(paraffins)	Cycloalkanes	Alkenes (olefins)	Alkynes (acetylenes)	Benzene and alkylbenzenes (BTEX)	Polynuclear aromatics (PAH)	Heterocyclic compounds
Single carbon bonds, straight and branched structure	Straight and cyclic structure	One or more double carbon bonds, straight, branched, or cyclic	One or more triple carbon bonds, straight, branched, or cyclic	Single aromatic ring or with attached functional group	Two or more aromatic rings fused together, can be with attached functional group	Aromatic ring structures with one or more heteroatom (N, S, O) in the ring
C_nH_{2n+2}	C_nH_{2n}	C_nH_{2n}	C_nH_{2n-2}			
 				 		n-Decane 3-Methylnonane	Cyclohexane	1-Octene	1-Hexyne	Benzol Toluene	Naphthalene	Pyrrole

Light oils are defined as having an API < 22.3, heavy oils are those with API > 31.1, and medium oils have an API gravity between 22.3 and 31.1.

Regardless of the complexity, petroleum compounds can be separated into two major categories: hydrocarbons and non-hydrocarbons. Hydrocarbons (compounds composed solely of carbon and hydrogen) comprise the majority of the components in most petroleum products and are the compounds that are primarily (but not always) measured as total petroleum hydrocarbons (TPH).[16] The nonhydrocarbon components are heterocyclic hydrocarbons (compounds containing heteroatoms such as sulfur, nitrogen, or oxygen in addition to carbon and hydrogen). These heterocyclic hydrocarbons are typically present in oils at relatively low concentrations and can be found in most refined motor fuels as they are concentrated in the heavier fractions and residues during refining. Most organic nitrogen hydrocarbons in crude oils are present as alkylated aromatic heterocycles, mostly with a pyrrolic structure. Crude oils also contain small amounts of organometallic compounds (of nickel, vanadium, and other metals up to atomic number 42, with the exception of rubidium and niobium) and inorganic salts. Although, depending on the analytical method, sulfur-, oxygen-, and nitrogen-containing compounds are sometimes included in the value reported as TPH concentration, they do not fall under the definition of petroleum hydrocarbons in the strict sense.[16]

Depending on the structure of petroleum hydrocarbons, the individual compounds are grouped into aliphatic(saturated and unsaturated) hydrocarbons and aromatics. Saturated hydrocarbons are the major class of compounds found in crude oil. The common names of these types of compounds are alkanes and isoalkanes or, as used in petroleum industry, paraffins and isoparaffins, respectively. Unsaturated hydrocarbons have at least one multiple bond (double bond [alkenes] or triple bond [alkynes]), and they are typically not present in crude oil but can be formed during the cracking process. Aromatic hydrocarbons are based on the benzene ring structure and are further categorized depending on the number of rings. Benzene rings are very stable and therefore persistent in the environment, and particularly, the mono- and polycyclic aromatic compounds can have toxic effects on organisms. Aromatic hydrocarbons with one benzene ring and with one or more side chains are alkyl benzenes and include benzene; toluene; ethylbenzene; and o-, p-, and m-xylenes (BTEX). This class of compounds has significant water solubility and is more mobile in the environment. Polycyclic aromatic hydrocarbons (PAHs) are aromatic compounds with two or more fused aromatic rings. Occurrence of PAH compounds in oils is dominated almost completely by the C1- to C4-alkylated homologues of the parent PAH, in particular, for naphthalene, phenanthrene, dibenzothiophene (a sulfur-containing aromatic heterocycle), fluorine, and chrysene. These alkylated PAH homologues form the basis of chemical characterization and identification of oil spills.[17,18] A typical crude oil may contain 0.2% to more than 7% total PAHs. Of the hydrocarbon compounds common in petroleum, PAHs appear to pose the greatest toxicity to the environment.

Different crude oil sources usually have a unique hydrocarbon composition.[19,20] The actual overall properties of each different petroleum source are defined by the percentage of the main hydrocarbons found within petroleum as part of the petroleum composition. The percentages for these hydrocarbons can vary greatly. It gives the crude oil a quite-specific compound personality depending on geographic region. The typical percentage of hydrocarbons (although covering very wide ranges) is as follows: paraffins (15%–60%), naphthenes (30%–60%), aromatics (3%–30%), and asphaltenes making up the remainder. Furthermore, due to differences in refining technologies and refinery operating conditions, each refining process has a distinct impact on the hydrocarbon composition of the product.

Refined petroleum products are primarily produced through distillation processes that separate fractions from crude oil according to their boiling ranges. Production processes may also be directed to increase the yield of low-molecular-weight fractions, reduce the concentration of undesirable sulfur and nitrogen components, and incorporate performance-enhancing additives. Therefore, each petroleum product has its unique, product-specific hydrocarbon pattern. The petroleum products are composed of both aliphatic and aromatic hydrocarbons in a range of molecules that include C6 and greater. The different classes of compounds contained in various petroleum products are summarized in Table 5.[20,21] The main products are gasoline (benzene), naphtha/solvents, jet fuels, kerosene, diesel fuel, and lubricating (motor) oils. Due to the variety of components in petroleum, they are typically characterized using the boiling range of the mixture and the carbon number rather than individual components. For example, diesel is a fraction with boiling points between 200°C and 325°C and is represented as C10–C22.

While a physical property such as boiling range may establish the initial product specification, other finer specifications define their ultimate use in certain applications. A lighter, less dense, raw petroleum composition with a composition that contains higher percentages of hydrocarbons is much more profitable as a fuel source. On the other hand, other denser petroleum compositions with a less flammable level of hydrocarbons and containing higher levels of sulfur are expensive to refine into a fuel and are therefore more suitable for plastics manufacturing and other uses. In contrast to the ever-increasing demand, the world's reserves of light petroleum (light crude oil) are severely depleted, and refineries are forced to refine and process more and more heavy crude oil and bitumen.

Petroleum fractions are among the most complex samples an analyst can face in terms of the number of compounds present. The characterization of petroleum fractions is typically done by gas chromatography (GC). As can be seen in Figure 1, the petroleum products contain such a large number of hydrocarbon constituents that complete chromatographic separation is not possible. Even then, GC remains the most informative analytical technique, providing both quantitative information (deduced from the total signal recorded in a chromatogram) and qualitative information, which derives from the fact that the retention times in the chromatograms can be correlated with the boiling points of the compounds contained in the petroleum. To illustrate the complexity of chemical composition of petroleum products, Figure 2 shows the chromatograms for six different petroleum products, including a crude oil with API of 18.7 and the BAM (Bundesanstalt für Materialprüfung, Berlin) petroleum hydrocarbon standard. The BAM standard K-010 is a certified reference material for the determination of mineral hydrocarbons, which is a synthetic mixture of a diesel and a lubricating oil. It is evident that these six samples are very different according to their carbon ranges. The difference is clearly seen from the comparison of their chromatograms. The volatile fuel with a content of hydrocarbons with less than 10 C atoms (benzene and premium gasoline) has the majority of its constituents at the beginning of chromatogram (Figure 2c). The peaks in the chromatogram of diesel are shifted to the retention time window where hydrocarbons from C10 to C22 are eluted (Figure 2d). In turn, the chromatogram of motor oil shows a characteristic "bump" (because the fraction of saturated alkanes is very small) situated in the

TABLE 5 Overview of Petroleum Products with Respect to Boiling Point Ranges, Approximate Carbon Number, and Average Percentage Amount of Aliphatic and Aromatic Compounds

		Fractions				Hydrocarbons	
	Boiling Range	<C7 (% w/w)	C7–C10 (% w/w)	C10–C40 (% w/w)	>C40 (% w/w)	Aliphatic	Aromatic
Statfjord C (39.1)[a]		11.6	18.1	56.6	13.7		
Crude oil (API = 18.7)		0.9	3.0	63.2	32.8		
Grane[a]							
Normal benzene[b]	40–200°C	~100 (C5–C12)				~70%	20%–50%

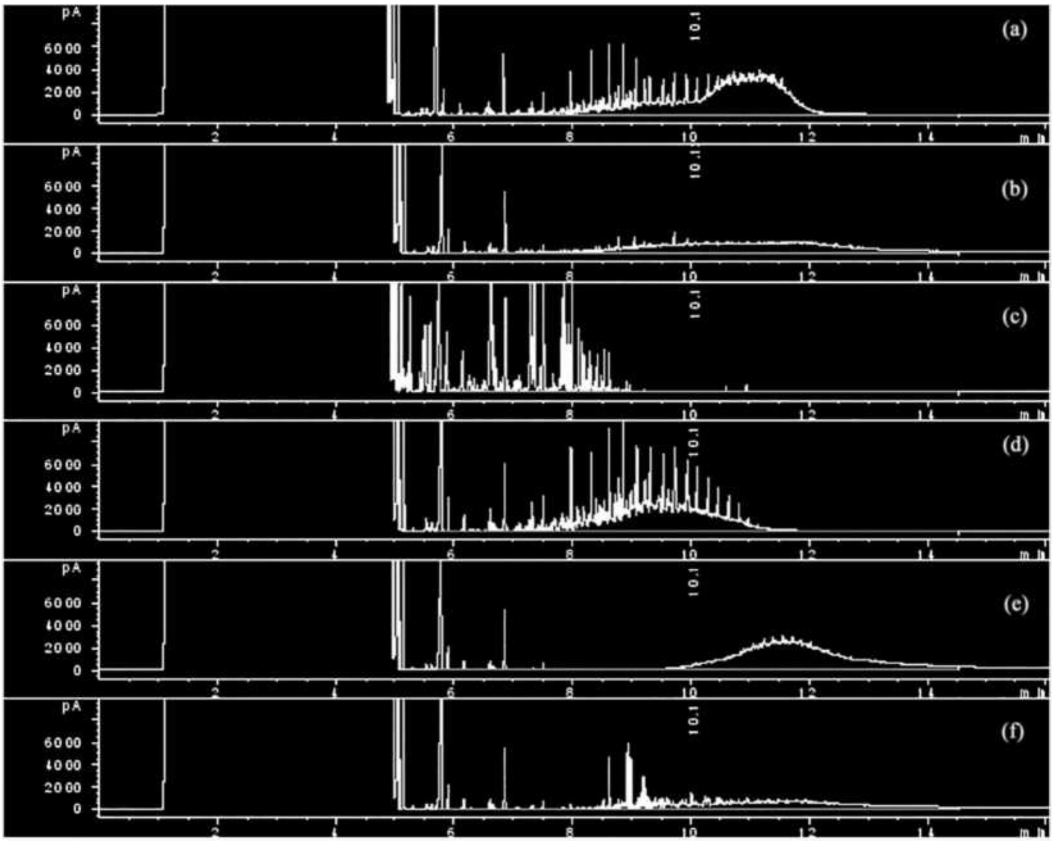

FIGURE 2 Comparison of chromatograms of different oil samples: (a) BAM; (b) crude oil (API = 18.7); (c) gasoline; (d) diesel; (e) motor oil; and (f) heavy heating oil with the same concentration (20 ppm oil in water) obtained by GC-FID method

region where heavier hydrocarbons C20–C40 are eluted (Figure 2e). Thus, GC- based methods provide important qualitative information, which in the ideal case even allows the assignment of the source of contamination. This is proven by the comparison of chromatograms of different oil samples (Figure 2).

Fate of Petroleum Hydrocarbons in the Environment

The effects of petroleum hydrocarbons entering the environment are a complex function of the magnitude and the rate of release; the nature of the released petroleum (its physicochemical properties and, in particular, the amount of toxic compounds it may contain); and the affected geographical, hydrogeological, and biological ecosystem. The fate of petroleum-type pollutants in the environment has been investigated in many studies.[22] Complex transformation and degradation processes of oil in the environment start from its first contact with the atmosphere, seawater, and soil. They depend on the physical properties (volatility, solubility, etc.), as well as on the chemical properties (chemical composition) of the oil. While the former are responsible for transport, or diffusion of the petroleum hydrocarbons in the environment, the latter are responsible for their chemical, photo-, and microbial degradation. The main processes affecting the environmental fate of petroleum hydrocarbons after their release to the environment are thus their volatilization, dissolution/dispersion and emulsification in water, adsorption to soil, oxidation, destruction, and biodegradation.[23,24] In addition to the parameters that characterize the oil's composition, reactivity, and toxicity, the environmental conditions, i.e., the meteorological and hydrological factors, also play an important role in the fate of petroleum hydrocarbons.

When petroleum hydrocarbons are released to the water column, certain fractions will float on top and form thin surface films. This process is controlled by the viscosity of the oil and the surface tension of water. A spill of 1 ton of oil can disperse over a radius of 50 m in 10 min, forming a slick 10 mm thick. Later, it spreads, gets thinner, and covers an area of up to 12 km^2.[11] It should be pointed out that much of the environmental and ecological damage caused by oil spills actually is due to this oil film that covers the surface of the sea, or the coastline, thus physically impairing birds and other animals and causing suffocation of fish as oxygen will not permeate the oil layers to a sufficient degree anymore. In the first days after the spill, the volatile compounds from oil evaporate. Only a small proportion of the hydrocarbon constituents of petroleum products are significantly soluble in water. Dissolution takes more time compared with evaporation, considering that most oil components are soluble in water only to a limited degree (although the degradation products typically are more polar and thus more soluble). Other heavier fractions (up to 10%–30%) will accumulate in the sediment at the bottom of the water, which may affect bottom-feeding fish and organisms. This happens mainly in the narrow coastal zone and shallow waters, where water is intensively mixing.

Crude oil released to the soil may percolate and reach the groundwater. Because petroleum has a lower specific gravity than water, free (undissolved) product and most dissolved contamination are usually concentrated near the top of the groundwater.[25] This may then lead to a fractionation of the original complex mixture, depending on the chemical properties of the compound. Some of these compounds will evaporate, while others will dissolve into the groundwater and be diffused from the release area. Other compounds will adsorb to soil or sediments and will remain there for a long period of time, while others will be metabolized by organisms found in the soil.[26,27]

While evaporation and dissolution redistribute the oil, photochemical oxidation and bacterial degradation transform it. Where crude oil is exposed to sunlight and oxygen in the environment, both photooxidation and aerobic microbial oxidation take place. The photochemical oxidation of hydrocarbons is dependent upon ultraviolet (UV) radiation and will therefore occur only in the upper surface layers. The aromatic hydrocarbons absorb UV radiation with high efficiency and are transformed mainly into hydrogen peroxides. Alkanes are much less efficient in absorbing UV radiation, and only small quantities are transformed by this process. The final products of oxidation (hydroperoxides, phenols, carboxylic acids, ketones, aldehydes, and others) usually have increased water solubility and toxicity. Where oxygen and sunlight are excluded in anoxic environments, anaerobic microbial oxidation takes place.[28,29]

Generally, saturated alkanes are more quickly degraded by microorganisms than aromatic compounds; alkanes and smaller-sized aromatics are degraded before branched alkanes, multiring and substituted aromatics, and cyclic compounds.[30,31] Polar petroleum compounds such as sulfur- and nitrogen-containing species are the most resistant to microbial degradation. Complex structures (e.g., branched methyl groups) and the stability of hydrocarbons decrease the rates of mineralization, which are likely a consequence of the greater stability of carbon–carbon bonds in aromatic rings than in straight-chain compounds. Emulsification also provides greater surface area for microorganisms to attach.

It has been shown in experiments that *n*-alkanes are among the most biodegradable hydrocarbons, and therefore, they are easily broken down and preferentially depleted from soil samples.[32] Also, it has been proven in simulation experiments of the biodegradation of two different samples of crude petroleum (paraffinic and naphthenic type) that microbial cultures that were isolated as dominant microorganisms from the surface of a wastewater canal of an oil refinery (most abundant species: *Phormidium foveolarum,* filamentous Cyanobacteria [blue-green algae] and *Achnanthes minutissima,* diatoms, algae) show a strongly differentiated degradation behavior with clear preference for the degradation of *n*-alkanes and isoprenoid aliphatic alkanes.[33] As can be seen in Figure 3, the largest degree of biodegradation was achieved in a medium containing the base nutrients $Ca(NO_3)_2.4H_2O$, $K_2HPO_4.7H_2O$, KCl, $FeCl_2$, and K_2SO_4, at pH ≈ 8 and exposed to light. Biodegradation activity is somewhat lower with the same medium in the dark. With a medium containing not only the nutrient broth but also organic compounds (tryptone, yeast extract, glucose, at pH ≈ 7), degradation occurs at a much lower rate, especially without light.

When crude oil or petroleum products are accidentally released to the environment, they are immediately subjected to a variety of weathering processes that lead to compositional changes and to the depletion of certain hydrocarbon compounds. Weathering processes include all previously mentioned physicochemical processes, such as dissolution, evaporation, photooxidation, polymerization, adsorptive interactions between hydrocarbons and the soil, and some biological factors. Furthermore, due to the fact that the degree of biodegradation is different for different types of petroleum hydrocarbons and varies depending on their nature, the weathering rate also depends on the type of petroleum contaminant. If we thus observe in the analysis of petroleum hydrocarbon contaminants changing patterns of hydrocarbons with time, this may be either due to the segregation of the oil according to the physical properties or due to the action of bacteria and microorganisms. As these are able to degrade only certain classes of compounds, or at least they exhibit a strong preference for some over other compounds, characteristic changes of the hydrocarbon pattern will result, as observed by GC (Figure 3).

Possible Toxic Effects from Exposure to Petroleum Hydrocarbons

As it was discussed earlier, crude oil and petroleum products are complex mixtures of groups of compounds. Many of the compounds are apparently benign, but many others are known to have toxic effects. Due to petroleum hydrocarbon toxicity, spilled hydrocarbons pose a threat that affects not only the sea and land but also the lakes, rivers, and groundwater and can be harmful for animals and human health.

Much of what is known about the impacts of petroleum hydrocarbons comes from studies of catastrophic oil spills and chronic seeps. Large oil spills usually receive considerable public attention because of the obvious environmental damage, oil-coated shorelines, and dead or moribund wildlife, including, in particular, oiled seabirds and marine animals. The acute toxicity of petroleum hydrocarbons to marine organisms is dependent on the persistence and bioavailability of specific hydrocarbons. The exposure to them may alter an organism's chances for survival and reproduction in the environment, and the narcotic effects of hydrocarbons on nerve transmission are a major biological factor in determining the ecologic impact of any release. Marine birds and mammals may be especially vulnerable to oil spills. In addition to acute effects such as high mortality, chronic, low-level exposure to hydrocarbons may affect reproductive performance and physiological impairment of seabirds and some marine mammals as well.[11] Petroleum contamination may also cause unfavorable impacts on nearby plants and animals. Plants growing in contaminated soils or water may die or appear distressed.

In turn, natural seeps, leaking pipelines, and production discharges release small amounts of oil over long periods of time, resulting in chronic exposure of organisms to oil and oil chemical compounds. The lower-molecular-weight compounds are usually the more water-soluble components of a product, and hence, attention has also been paid to the water-soluble fractions of petroleum and related products. Concentrations in the environment are usually comparatively low, and chronic effects are usually more significant.[26] The persistence of some compounds such as PAH in sediments, especially in urban areas, is also an example of chronic pollution and toxicity.

Nowadays, humans can be exposed to petroleum hydrocarbons through ingestion of contaminated drinking water and soil residues; inhalation of vapors and airborne soils; and contact of contaminants with skin (dermal exposure) from many sources, including gasoline fumes at the pump, spilled crankcase oil on pavement, chemicals used at home or work, or certain pesticides that contain petroleum hydrocarbon components as solvents. Most petroleum hydrocarbon constituents will enter the bloodstream rapidly when inhaled or ingested. Incorporated petroleum hydrocarbons are widely distributed by the blood throughout the body and quickly are metabolized into less harmful compounds. Others may be degraded into more harmful chemicals. Even other compounds are distributed by the blood to other parts of the body and do not readily break down but are accumulated instead in fat tissue. The resorption of petroleum compounds through dermal tissue is slower; that is why direct exposure of the skin to petroleum hydrocarbons is generally harmless when exposure is only occasional and of short duration.

Studies on animals have shown effects on the lungs, central nervous system, liver, kidney, developing fetus, and reproductive system from exposure to petroleum compounds, generally after breathing or swallowing the compounds. Health impacts of exposure to petroleum contamination may include lung irritation, headaches, dizziness, fatigue, diarrhea, cramps, and nervous system effects. Benzene and other chemicals found in petroleum products have been determined to be carcinogenic (cause cancer). More information regarding toxicity of petroleum chemicals is available, for example, from the Agency for Toxic Substances and Diseases Registry (ATSDR), an agency of the U.S. Department of Health and Human Services,[34] or from the European Chemicals Agency.[35]

Oil products are complex mixtures of hundreds of chemicals, with each compound having its own toxicity characteristics. There are many difficulties associated with assessing the health effects of such complex mixtures with regard to hazardous waste site remediation. This means that the traditional approach of evaluating individual components is largely inappropriate. Toxicity information is in the best case available for the pure product; however, once a petroleum product is released to the environment, it changes its composition as a result of weathering. These compositional changes may be reflected in changes in the toxicity of the product.

One approach for assessing the toxicity of oil products is to use toxicity information from studies conducted on the whole product. A second approach is to identify and quantify all components and then consider their toxicities. This approach produces data that theoretically could be compared with the known toxicity of each compound. The impracticality of this approach stems from its high analytical cost and the lack of toxicity data for many of the component chemicals found in hydrocarbon mixtures. A third approach is to consider a series of hydrocarbon fractions and determine appropriate tolerable concentrations and toxicity specific for those fractions. A number of groups have examined such an approach, but the most widely accepted and internationally used are the ones developed by the Total Petroleum Hydrocarbons Criteria Working Group (TPHCWG) and the Massachusetts Department of Environmental Protection (MA DEP) in the United States, although they have been subject to adjustments in many cases. For example, in the United Kingdom, the TPHCWG approach is modified and extended to consider heavier hydrocarbon fractions. It has been developed as part of the Environment Agency's[36] environment sciences program and published in documents related to petroleum hydro- carbons.[37]

The MA DEP introduced in 1994 the concept of petroleum hydrocarbon size-based fractions for use in evaluating the human health effects of exposure to complex mixtures of hydrocarbons[38,39] and provided oral toxicity values for each of the fractions. The toxicity value assigned for each fraction is used in dose–response evaluations. Cancer risks or hazard amounts are subsequently summed across the fractions to get the total values. The TPHCWG has developed and published a series of five monographs[16,40–42] detailing the data on petroleum hydrocarbons and, in addition, has developed tolerable intakes for a series of total hydrocarbon fractions. The TPHCWG independently identified largely similar groupings of hydrocarbon fractions with somewhat different toxicity values in 1997. Of the 250 individual compounds identified in petroleum by the TPHCWG, toxicity data were available for only 95. Of these 95, the TPHCWG concluded that there were sufficient data to develop toxicity criteria for only 25.

As there are differences in toxicity between different hydrocarbon compounds, it is impossible to accurately predict toxic effects of contamination for which only total hydrocarbon data are available. Health assessors often select surrogate or reference compounds (or combinations of compounds) to represent TPH so that toxicity and environmental fate can be evaluated. Correspondence dates relating the toxicologically derived hydrocarbon fractions and their toxicity values to the analytically defined reporting fractions (by MA DEP) are contained in Table 6 for ingestion and inhalation exposure. Inhaled or ingested volatile hydrocarbons have both general and specific effects. The toxicity values are represented as a reference dose (RfD), which is the U.S. Environmental Protection Agency's (EPA's) maximum acceptable oral dose of a toxic substance. Significant efforts have been undertaken by MA DEP to describe an approach for the evaluation of human health risks from ingestion exposure to complex petroleum hydrocarbon mixtures. The methods offered by MA DEP for determination of air-phase (APH), volatile (VPH), and extractable (EPH) petroleum hydrocarbons[43–45] are designed to complement and support the toxicological approach. The ranges of quantified hydrocarbons within each method and their reporting limits are shown in Table 7.

The components of petroleum can be generally divided into broad chemical classes: alkanes, cycloalkanes, alkenes, and aromatics. A review of Table 6 shows that a U.S. EPA RfD is available for only one alkane, *n*-hexane. In general terms, alkanes have relatively low acute toxicity, but alkanes having carbon numbers in the range of C5–C12 have narcotic properties, particularly following inhalation exposure to high concentrations, because of their relatively high volatility and low solubility in water. Repeated exposure to high

TABLE 6 Oral and Inhalation Toxicity Values by MA DEP for Petroleum Hydrocarbon Fractions and Individual Compounds Present in Petroleum Products

		Toxicity Value, RfD		
Carbon range	Compound	Inhalation mg/m^3	Oral mg/kg/day	Critical Effect
Aliphatic				
C5–C8		0.2	0.04	Neurotoxicity

concentrations, for example, of *n*-hexane (RfD, 0.06 mg/kg/day) may lead to irreversible effects on the nervous system. Hexane is considered to be the most toxic compound in the C5–C8 aliphatic fraction. No RfDs are available for other alkanes, nor for any cycloalkane or alkene. Alkenes exhibit little toxicity other than weak anesthetic properties. Alkanes and cycloalkanes are treated similarly and have similar toxic effects.

Aromatic compounds with less than nine carbon atoms (such as BTEX) are evaluated separately because the toxicity values for each are well supported and these compounds have a wide range of toxicity. However, most of the smaller aromatic compounds have low toxicity, with the exception of benzene, which is a known human carcinogen (RfD, 0.029 mg/kg/day). Most petroleum hydrocarbon mixtures contain very low concentrations of PAHs. The major concern regarding PAHs is the potential carcinogenicity of some of these. Benzo(*a*)pyrene and benz(*a*)anthracene are classified as probable human carcinogens. Benzo(*a*)pyrene is normally considered to be the most potent carcinogenic PAH, but the carcinogenic potency of most PAHs is not well characterized. In case of spills of petroleum products affecting water, PAHs are not usually a specific concern; however, this concern becomes more specific if these compounds are released into the soil due to a bioaccumulation of PAH in soil.

Different regulations and guidelines to protect public health have been developed. These public health statements tell as well about petroleum hydrocarbons and the effects of exposure. The U.S. EPA[46] identifies the most serious hazardous waste sites in the United States. The EPA lists certain wastes containing petroleum hydrocarbons as hazardous. It regulates certain petroleum fractions, products, and some individual petroleum compounds. General health and safety data are as well discussed by the Energy Institute,[7] which is the main professional organization for the energy industry within the United Kingdom that promotes the safe, environmentally responsible, and efficient supply and use of energy in all its forms and applications. The Occupational Safety and Health Administration and the Food and Drug Administration are other agencies that develop regulations for toxic substances in the United States. The information provided by all of them is regularly updated as more information becomes available. The Dutch National Institute for Public Health and the Environment (RIVM), has been involved in a number of studies on risk assessment for petroleum hydrocarbons which were commissioned by the Dutch government and the European Commission.[47] Also the U.K. Environment Agency, mentioned before, is the leading public body protecting and improving the environment in the United Kingdom, including protection from petroleum contaminations.

Total Petroleum Hydrocarbons and Analytical Methods for Determination of Petroleum Hydrocarbons in Environmental Media

Due to the compositional complexity of petroleum products, it is impossible to assess the extent of petroleum hydrocarbon contamination by directly measuring the concentration of each hydrocarbon contaminant. For this reason, at the present time, no single analytical method is capable of providing comprehensive chemical information on petroleum contaminants. Total petroleum hydrocarbon is one parameter and definition that is currently widely used for expressing the total concentration of nonpolar petroleum hydrocarbons in soil, water, or other investigated samples. In the United States, for example, there are no federal regulations or guidelines for TPH in general. Many states have standards for controlling the concentrations of petroleum hydrocarbons or components of petroleum products. These are designed to protect the public from the possible harmful health effects of these chemicals. Analytical methods are specified as well, many of which are considered to be methods for TPH. These generate basic information that is a surrogate for contamination, such as a single TPH concentration. Such data are not suitable for risk assessment. However, they are relatively quick and easy to obtain and can offer useful preliminary information.

The term TPH is widely used, but it is rarely well defined. In essence, TPH is defined by the analytical method—in other words, estimates of TPH concentration often vary depending on the analytical method used to measure it. Thus, the ATSDR defines the TPH as a term used to describe a broad family of several hundred chemical compounds that originally come from crude oil. In this sense, TPH is really a mixture of chemicals. As per the TPHCWG, TPH, also called “hydrocarbon index,” refers sometimes to mineral oil, hydrocarbon oil, extractable hydrocarbon, oil, and grease. The TPHCWG also says that the TPH measurement is the total concentration of the hydrocarbons extracted and measured by a particular method, and it depends on the analytical method used for determination. According to the MA DEP, the TPH is also a loosely defined parameter, which can be quantified using a number of different analyses, and this parameter is an estimate of the total concentration of petroleum hydrocarbons in a sample. Again, depending on the analytical method used to quantify TPH, the TPH concentration may represent the entire range of petroleum hydrocarbons from C9 to C36 or the sum of concentrations of a number of single compounds (for instance, BTEX) and groups of compounds (fractions, e.g., primarily aliphatics C9–C18, C19-C36, and aromatics C11–C20). Great improvements in the definition and analysis of TPH were finally introduced by the International Organization for Standardization (ISO)[48] in 2000, when it published the standard method ISO 9377-2:2000[49] for the quality control of water in which a method for the determination of the hydrocarbon oil index within the C10–C40 range in waters by means of GC is specified. The definition of “hydrocarbon oil index by GC-FID” was introduced, which defines the fraction of compounds extractable with a hydrocarbon solvent, boiling point between 36°C and 69°C, not adsorbed on Florisil, and which may be chromatographed with retention times between those of *n*-decane ($C10H22$) and *n*-tetracontane ($C40H82$). (Substances complying with this definition are long-chain or branched aliphatic, alicyclic, aromatic, or alkyl -substituted aromatic hydrocarbons.)

The TPHCWG and MA DEP evaluated the risk implications and arrived at the conclusion that TPH concentration data cannot be used for a quantitative estimation of the human health risk. The same concentration of TPH may represent very different compositions and very different risks to human health and the environment because the TPH parameter includes a number of compounds of differing toxicities and the health effects associated with exposure to particular concentrations of TPH cannot be determined. For example, two sites may have the same amount of TPH, but constituents at one site may include carcinogenic compounds while these compounds may be absent at the other site. If TPH data indicate that there may be significant contamination of environmental media, then fractionated measurements and the separate determination of BTEX compounds and PAHs are necessary so that potential risk to human health can be quantitatively assessed.[50] The hydrocarbon index is thus a good indicator of the (magnitude of the) relative contamination of oil; however, it will not be suitable to give a true representation of the actual concentration of TPH in the investigated sample. There are several reasons why TPH data do not provide the ideal information for investigated samples and do not establish target cleanup criteria. This is due to many factors including the complex nature of petroleum hydrocarbons, their interaction with the environment over time, and the non-specificity of some of the methods used. The scope of the methods used for TPH determination varies greatly. There are few, if any, methods that are capable of quantifying all hydrocarbons without interference from non-hydrocarbons. All methods are subject to interferences from non-hydrocarbons, some to a greater extent than others.

There are numerous established analytical methods that are available for detecting, measuring, or monitoring TPH and its metabolites. Analytical methods used for analysis of petroleum hydrocarbons in environmental media should provide a sufficient degree of robustness. At the current time, however, the correctness and precision of results for the petroleum hydrocarbon determination strongly depend on the proper choice of method and measurement parameters whose correct selection is left to the judgment of the analyst. Besides methods that measure the TPH concentration, two other types of methods can be distinguished. These are methods that measure the concentration of a group or fraction of petroleum compounds and methods that measure individual petroleum constituent concentrations. For product identification, the results of analyses of the petroleum groups or fractions can be useful because they separate and quantify different categories of hydrocarbons. Individual constituent methods quantify concentrations of specific compounds that might be present in petroleum-contaminated samples, such as BTEX and PAHs, which can be used to evaluate human health risk.

There are several basic steps related to the separation of analytes of interest from a sample matrix prior to their measurement, such as extraction, concentration, and cleanup. These steps are common to the analytical processes for all methods, irrespective of the method type or the environmental matrix. Each of these steps together with the sampling, which is also an important step in performing petroleum analyses, affects the final result and has a certain impact onto the measurement uncertainty.[51,52]

Sample taking and sample handling have been recognized as probably the most significant factors that contribute random errors and uncertainties in the analysis of offshore oil in produced water. There are some general guidelines available through a number of studies that have been carried out on this subject. To separate the analytes from the matrix, extraction is performed using one of the many available extraction methods. Heating of the sample or purging with an inert gas can be used in the analysis of volatile compounds; solid-phase extraction or extraction into a solvent is usually applied for water samples, the latter extraction method also being used for soil samples. For some types of solid samples, the extraction efficiency depends on the extraction method and time. However, ultrasonication and extraction by shaking are equally used for this purpose. It was demonstrated by some studies that extraction and cleanup are the most crucial steps in sample preparation procedures. According to the results. the most critical factors affecting TPH recovery are extraction solvent and type of cosolvent, extraction time, adsorbent and its mass, and the TPH concentration.[53] The results of a study where the occurrence of matrix effects in the gas chromatographic determination of petroleum hydrocarbons in soil was evaluated indicate that solid-phase extraction does not appear to be effective enough in removing interfering matrix components from the extract.[54]

Most of the methods for the determination of TPH involve a cleanup step using Florisil (a particular form of magnesium silicate) and sodium sulfate (anhydrous), which essentially aims at removing the polar, non-petroleum hydrocarbons of biological origin and remaining traces of water. It appears that the found hydrocarbon concentration strongly depends on the used cleanup technique. The efficiency of the cleanup procedure for removing polar compounds is not limited to heteroatomic substances like O-, N-, or Cl-containing compounds. Also, some hydrocarbons have a tendency to adsorb on Florisil, e.g., aromatic compounds with p- electrons or alkyl aromatics. The TPH recoveries after a cleanup procedure might depend on the composition of the oil investigated. Lower TPH recoveries may be expected for oils containing high concentrations of unsaturated hydrocarbons or PAHs. Also, lubricating oils often contain different amounts and types of (non-petrogenic) additives that may behave differently from the other compounds during the cleanup procedure.[55] The results demonstrate also that the ratio of Florisil amount and extract volume are of importance for the recovery of the purified extracts.[56]

The three most commonly used TPH testing methods include GC,[49,57–60] infrared absorption (IR),[61,62] and gravimetric analysis.[63–65] Conventional TPH methods are summarized in Table 8.

Methods based on solvent extraction followed by quantitative IR measurement (at a frequency of 2930 cm^{-1}, which corresponds to the stretching vibration of aliphatic CH2 groups) have been widely used in the past for TPH measurement because they are simple, quick, and inexpensive. However, the use of these methods has been discontinued, since the sale and use of Freons (required for the extraction of hydrocarbons from the sample) is no longer allowed, and Freons are generally phased out worldwide due to their ozone layer–destructing potential. Recently, a new IR-based method was introduced, based on Freon- free extraction. This method defines oil and grease in water and wastewater as the fraction that is extractable with a cyclic aliphatic hydrocarbon (for example, cyclohexane) and measured by IR absorption in the narrow spectral region of 1370–1380 cm^{-1} (which corresponds to the excitation frequency of the symmetrical deformation vibration of CH_3 groups) using mid-IR quantum cascade lasers.[62] The method also considers the volatile fraction of petroleum hydrocarbons, which is lost by gravimetric methods that require solvent evaporation prior to weighing, as well as by solventless IR methods that require drying of the employed solid-phase material prior to measurement. Similarly, a more complete fraction of extracted petroleum hydrocarbon is accessible by this method as compared with GC methods that use a time window for quantification, as petroleum hydrocarbons eluting outside these windows are also quantified. On the other hand, IR-based methods hardly provide any information on the chemical composition of the oil or the presence or absence of other relevant compounds (aromatics, PAHs). In contrast, they even detect compounds that are not typically considered as TPH, such as surfactants, which also may absorb IR radiation due to the presence of CH bonds. However, this statement is only partially true, since it depends mainly on the cleanup whether the IR method determines also compounds other than the TPH.

Gravimetric-based methods are also simple, quick, and inexpensive; they measure anything that is extractable by a solvent, not removed during solvent evaporation, and capable of being weighed. Consequently, they do not offer any selectivity or information on the type of oil detected. Gravimetric-based methods may be useful for oily sludges and wastewaters at high(er) concentrations but are not suitable for measurement of light hydrocarbons (less than C15), which will be lost by evaporation below 70–85°C.

Gas chromatography–based methods are currently the preferred laboratory methods for TPH measurement because they detect a broad range of hydrocarbons, they provide both sensitivity and selectivity, and they can be used for TPH identification as well as quantification. The potential of GC for producing information on the product-specific hydrocarbon pattern has been long recognized by researchers in the field of petroleum hydro-carbon analysis. [66–68]

Currently, there are several standard methodologies based on GC for different types of samples (water, soil, wastes). The ISO has published the standard ISO 93772:2000 for the quality control of water and specifies a method for the determination of the hydrocarbon oil index within the C10–C40 range in waters by means of GC. The method is suitable for surface water, wastewater, and water from sewage treatment plants and allows the determination of the hydrocarbon oil index in concentrations above 0.1 mg/L. Due to systematic differences, which became evident between the results from the DIN ISO method and those from the IR-based method, the GC-based method was subsequently modified.[69,70] As a result, the modified version of DIN ISO 9377-2:2000, the OSPAR (Oslo–Paris commission) reference method,[58] was published in 2005 and taken into force as a reference method in the field of petroleum production in January 2007. The OSPAR reference method is applicable for the determination of dispersed oil content in produced water and other types of wastewater discharged from gas, condensate, and oil platforms. It also allows the determination of the dispersed mineral oil content in concentrations above 0.1 mg/L and includes the determination of certain hydrocarbons within the C7–C10 range, with the TEX (toluene, ethylbenzene, and *o*-/*p*-/*m*-xylene) compounds being reported separately.

TABLE 8 Summary of Common TPH Methods

Analytical Method	Method Name	Matrix	Scope of Method	Carbon Range	Approximate Detection Limits	Advantages	Limitations	Reference
GC based	DIN ISO 9377-2:2000	Water	Solvent (hydrocarbon) extraction, cleanup using Florisil, evaporation, 1 µL injection, GC-FID	C10-C40	0.1 mg/L	Detects broad range of hydrocarbons; provides information (e.g., a chromatogram) for identification	Does not quantify below C10; chlorinated compounds can be quantified as TPH	[49]
	OSPAR (2007)	Water	n-Pentane extraction, cleanup using Florisil, 50 µL injection, GC-FID	C7–C40 + TEX compounds	0.1 mg/L	Does not need preconcentration step; detect broad range of hydrocarbons and polar hydrocarbons; provide information for identification	Does not quantify below C7	[57]
	DIN ISO 16703:2005–12	Soil	Acetone/n-heptane extraction, cleanup using Florisil, evaporation, GC-FID	C10–C40	10 mg/kg	Detects broad range of hydrocarbons; provide information (e.g., a chromatogram) for identification	Does not quantify below C10; chlorinated compounds can be quantified as TPH	[58]
	DIN EN 14039:2004	Wastes	Acetone/n-heptane extraction, cleanup using Florisil, evaporation, GC-FID	C10–C40	10 mg/kg			[59]
IR based	EPA 418.1 (1991/1992)	Water, soil	Freon extraction, silica gel treatment to remove polar compounds	Most hydrocarbons with exception of volatile and very high hydrocarbons	1 mg/mL in water, 10 mg/kg in soil	Technique is simple, quick, and inexpensive	Freon is banned now; low sensitivity; lack of specificity; prone to interference; provides quantitation only	[62]
	ASTM D7678-11 (2011)	Water, wastewater	Solvent (cyclic aliphatic hydrocarbon) extraction, cleanup using Florisil, IR Absorption in the region of 1370–1380 cm^{-1} (7.25–7.30 mm)	Most hydrocarbons with volatile	0.5 mg/mL	Technique is simple, very quick; a more complete fraction of extracted petroleum hydrocarbon is accessible		[61]

TABLE 8 (*Continued*) Summary of Common TPH Methods

Analytical Method	Method Name	Matrix	Scope of Method	Carbon Range	Approximate Detection Limits	Advantages	Limitations	Reference
Gravimetry	EPA 413.1 (1979) ASTM D4281–95(2005)el	Most appropriate for wastewater, sludge, sediment	Freon extraction, solvent evaporation	Anything that is extractable (with exception of volatiles which are lost)	5 mg/mL in water, 50 mg/kg in soil	Technique is simple, quick, and inexpensive	Freon is banned now; low sensitivity; lack of specificity not suitable for low boiling fractions; prone to interference (organic acids, phenols, and other polar hydrocarbons); provides quantitation only	[63,65]
	EPA 1664 (1999)	Most appropriate for water and wastewater	n-Hexane extraction, silica gel treatment to remove polar compounds, solvent evaporation	Anything that is extractable (with exception of volatiles which are lost)	5 mg/mL	Technique is simple, quick, and inexpensive	Low sensitivity; lack of specificity not suitable for low boiling fractions; prone to interference; provides quantitation only	[64]

Gas chromatography–based methods are based on the extraction of water samples with a nonpolar (hydrocarbon) solvent, the removal of polar substances by cleanup with Florisil, and capillary GC measurements using a nonpolar column and a flame ionization detector (FID), cumulating the total peak area of compounds eluted between *n*- decane (C10H22) and *n*-tetracontane ($C_{40}H_{82}$) for the DIN ISO 9377-2:2000 standard method and for the DIN ISO 16703:2005–12[59] standard method for soil samples. The OSPAR method was modified in order to include the determination of certain hydrocarbons with a boiling point between 98°C and 174°C (that is, from *n*-heptane to *n*-decane), with the TEX compounds being determined separately by integration and subtraction of their peak areas from the total integrated area. The GC-based methods usually cannot quantitatively detect compounds with a lower boiling point than *n*-heptane because these compounds are highly volatile and are interfered by the solvent peak. Furthermore, the EPA method 8240,[61] which is used to determine volatile organic compounds in a variety of waste matrices by GC/mass spectrometry (MS), exists. It can be used to quantitate most volatile organic compounds that have boiling points below 20°C and that are insoluble or slightly soluble in water. The estimated quantitation limit of the EPA 8240 method for an individual compound is approximately 5 μg/kg (wet weight) for soil/sediment samples, 0.5 mg/kg (wet weight) for wastes, and 5 μg/L for groundwater.

Gas chromatography–based methods are suitable for surface water, wastewater, and other types of wastewater discharged from gas, concentrate, and oil platforms and allow the determination of hydrocarbon oil concentration above 0.1 mg/L. To reach the required detection limit, the method according to DIN ISO 9377-2:2000 foresees preconcentration of the extracts by solvent evaporation, which bears the risk of losing the more volatile constituents of the sample. In contrast to this, the OSPAR method does not allow for any external apparatus for preconcentration, for which reason the GC must be equipped with an injection system that allows the injection of a volume of up to 100 μL of the extract. This is most easily realized with programmed-temperature vaporizer large-volume injectors. This technique can reduce the loss of volatile analytes, can increase sensitivity, and is a viable, fast, and automated alternative to an external preconcentration procedure.[71–73]

Petroleum products easily contain thousands of different compounds. Classical capillary GC cannot resolve such mixtures up to the level of individual compounds. A powerful analytical tool for separation of complex mixtures, such as petroleum hydrocarbons, is comprehensive two-dimensional GC (GC×GC or 2D-GC).[74–76] The use of 2D-GC with MS detection (GC×GC/MS) is expected to not only allow the separation of the various constituents of complex TPH samples but also to identify them based on MS detection (Figure 4b). It is known that a certain class of chemical compounds (a series of "homologues") forms a very distinct, clearly identifiable pattern in the two-dimensional space of the GC×GC separation. The diesel total ion (TIC) GC×GC/MS chromatogram, illustrated in Figure 4a, is characterized by very typical group-type patterns: saturated hydrocarbons, which present low second-dimension retention times, are followed by monocyclic and dicyclic aromatics; tri-and tetracyclic aromatics are the most retained on the secondary polar column.[77] Moreover, partial overlapping between chemical groups occurs, the monocyclic aromatics are situated in a rather narrow band, and the tri-and tetracyclic aromatics are hardly visible in the two-dimensional chromatogram. The analytical potential of such a two-dimensional system is great.

Conclusion

Due to the importance and widespread use of petroleum hydrocarbons for energy production, for transport, and as a raw material in the chemical industries, there are many routes for their inadvertent or accidental release into the environment. Thus, they do represent one of the most important sources of large-scale environmental pollution. While petroleum hydrocarbons also are introduced into the oceans from natural seeps, these continuous emissions of comparatively low intensity represent a less significant environmental problem since the resident flora and fauna have adapted to this continuous input of hydrocarbons and effects are limited to local scale. Large oil spills in contrast exceed the self-cleaning capacity

of the ecosystem, which cannot regenerate without human intervention to both physically and chemically immobilize, bind, and remove oil from the affected region. Although such techniques are available, large-scale oil spills always have caused severe damage to the environment, with the affected ecosystems recovering only slowly. Analytical methods are available for the qualitative and quantitative determination of the composition of oil samples and the assessment of pollution levels in various environmental compartments. Gas chromatographic techniques mostly have supplanted the former analytical standard method based on Freon extraction and mid-IR determination, but there is further research and development going on to develop either more powerful analytical methods—such as two-dimensional GC—or alternative detection methods, such as the ones based on mid-IR lasers as light sources.

Road-Traffic Emissions

Fabian Heidegger,
Regine Gerike,
Wolfram Schmidt,
Udo Becker, and
Jens Borken-Kleefeld

Introduction

The transport sector is a major contributor of air pollution and greenhouse gas emissions worldwide. Governments around the world are under pressure to deal with the consequences of climate change while also striving to meet growing transport demands. The prime challenge is to find and apply measures that reduce the environmental impact of transport, i.e., emissions (including air pollution, greenhouse gases, noise and vibration), land use, separation effects, and effects on landscape.

This chapter focuses solely on the topic of emissions, which includes energy consumption, air pollutants and greenhouse gases of road traffic and their measurements, as well as the possibility to model and influence the reduction of emissions via traffic planning measures, traffic management, or economic policy and user-related measures. Off-road emissions from vehicles are not included in this article, nor are upstream or downstream processes (e.g., well-to-tank emissions). Noise also contributes to road-traffic emissions but is not discussed here; however, it is important to note that the impact of noise can have major consequences on humans and animals.

Particularly in emerging economies, the aviation and road transport sectors have contributed considerably to the increase in emissions worldwide (although the latter sector has a high potential for emission reduction). The problems caused by road-traffic emissions can be separated into three categories:

- Climate Impact (mainly CO_2 emissions): In 2016, the transport sector produced around 8.0 $GtCO_2$ (25% of the total emissions that year), which measured 71% higher than those in 1990 (International Energy Agency 2018); 74% of those emissions were produced by road transport (International Energy Agency 2018).

- Major Share in Oil Consumption: With 92% of transport-final energy demand being composed of oil products, the transport sector is the least diversified energy end-use sector (International Energy Agency 2017). Hence, limited fossil fuel resources ensure a large share of mobility needs, especially in rural but also in urban areas today. Despite future energy efficiency gains and a wider application of electric cars, fuel needs will be higher in 2040 than they are today as a direct result of an increase in car use (International Energy Agency 2018).
- Air Pollutant Emissions: Many substances directly impact human health; in particular, there is high emission density in urban areas, which drives cities to develop solutions such as anti-pollution schemes.

Emissions are released in gaseous or particulate form into the atmosphere and are subject to physical and chemical transformation processes as well as to the influence of meteorological parameters during the transmission process (from the source to the place with pollution damage). Depending on the location, pollution damage has an effect on human health, vegetation, soil, water, building materials, and the climate. These substances can be grouped by the following impact categories (VDI 2019):

- Climate relevant substances (e.g., CO_2, CH_4, N_2O, black carbon)
- Substances contributing to ozone formation (e.g., NO_x, non-methane hydrocarbons [NMHC], carbon monoxide [CO])
- Eutrophying substances (e.g., NO_x, SO_2)
- Acidifying substances (e.g., NH_3, NO_x)
- Toxic substances (e.g., black carbon, heavy metals, polycyclic aromatic hydrocarbons, CO)
- Carcinogenic substances (e.g., black carbon, heavy metals, lead [Pb], aromatic hydrocarbons, e.g., benzene [C_6H_6], polycyclic aromatic hydrocarbons).

In the context of emissions and pollutants, the substances PM_{10} and NO_x (NO and NO_2) present the biggest problems in transportation. Particulate matter (PM) includes particles <10 μm in diameter (PM_{10}) as well as particles <2.5 μm in diameter ($PM_{2.5}$) (Pfäfflin 2018). PM occurs in incomplete combustion processes or due to abrasion and resuspension. PM may cause respiratory and cardiovascular diseases, and the smaller the size of the particle, the more dangerous it is to human health. NO_x is formed during high-temperature and high-pressure combustion processes and can lead to respiratory disorders, inflammation, and bronchitis. With long-term exposure, the number of heart attacks and fatalities as a result of respiratory disease significantly increases (Pfäfflin 2018).

Table 1 illustrates thresholds for nitrogen dioxide (NO_2), PM_{10}, and $PM_{2.5}$ in Europe. It is clearly visible that the guideline values of the WHO (World Health Organization) are substantially lower than the legally effective values of the European Union.

The European Union legislation directed toward creating a framework for the compliance of motor vehicles and their components limits the mass and number of particles, NO_x, and additional air pollutants, as well as greenhouse gases for vehicles (DIRECTIVE 2007/46/EC 2007), (REGULATION No

Source: According to (DIRECTIVE 2008/50/EC 2008) and (WHO 2006).

715/2007/EC 2007). Mainly CO_2 emissions are relevant regarding the direct climate impact of road transportation. As greenhouse gases do not cause local environmental damages or injuries to health, there is no need for local greenhouse gas thresholds. In 2009, the European Union introduced mandatory targets for average CO_2 emissions of 130 g CO_2/km for 2015 and 95 g CO_2/km for 2021 to be applied to each newly manufactured vehicle fleet (REGULATION No 333/2014/EU 2014).

Road vehicles are certified according to exhaust emission standards. In the United States, the Environmental Protection Agency (EPA) manages emission standards nationally. The European Union has its own set of emission standards, which all new vehicles must meet: The latest *Euro 6* targets passenger cars, light commercial vehicles, and motorcycles, and the *Euro VI* is for large goods vehicles and coaches (DIRECTIVE 2007/46/EC 2007), (REGULATION No 715/2007/EC 2007). Many Asian countries adopted these European emission standards; however, since the specified driving cycles, e.g., the WLTC (Worldwide Harmonized Light Vehicles Test Cycle), do not adequately represent real driving performance, the official limit values for air pollutants[1] and greenhouse gases (CO_2) are below actual driving emissions (although the vehicles fulfill the requirements of the test) (Hooftman et al. 2018). Therefore, the official exhaust thresholds cannot be used for a true and reliable emission calculation. In recent years, the topic of air pollution has received remarkable attention from the public, as well as from environmental and consumer organizations. Legal actions have been enforced upon vehicle manufacturers (e.g., Volkswagen, Daimler, Fiat, and Chrysler) for emission frauds (i.e., not complying with the limit thresholds of their vehicles) and upon cities and governments due to noncompliance with air quality standards.

Reliable emission projections/inventories combined with an integrated and systematic reduction of emissions—preferably in the form of pro-active prevention—are greatly needed. Substantial energy use and high levels of exhaust emissions are an unwanted outcome of transport demand; these are a consequence of many individual and non-individual interconnected processes. Mode choice and route choice, for example, are behaviors which could be adjusted rather quickly toward more sustainable options, while the implementation of change on the density of transportation networks, transportation planning, land use, and other economic factors would require an extensive amount of time and planning. In addition, emission factors (how much each vehicle emits per km [g/km or g/s]) and fuel use factors [l/km] of the vehicles, depending on, for example, vehicle type choice, topography, and driving behavior, are influencing coefficients for exhaust emissions.

This chapter is organized as follows: “Modeling of Road-Traffic Emissions” section gives an overview of energy consumption, vehicle propulsion technologies, default parameters of emission calculation, and types of emissions; “Potential Influences on Emission Reduction and Their Impacts” section introduces the modeling of road-traffic emissions by presenting different approaches and model types, followed by an example of an emission model and validation measures of emissions; and “Conclusion” section is dedicated to the potential influences for emission reduction and their impact, which can also be found in anti-air pollution schemes and climate action plans of cities and countries.

Energy Consumption and Types of Emissions

Default Parameters for Emission Calculation

Figure 1 summarizes the default parameters (all boxes on top) for determining road-traffic emissions. Colored (straight) arrows indicate effects to the type of emissions (all boxes in the middle); for example, the roughness of road surface will have an impact on abrasion and resuspension emissions. Moreover, vehicle fleet composition and traffic mileage affect the sum of all traffic emissions (box at the bottom). Resultant effects are shown as black (arcuated) arrows which close the circuit in a mutually reinforcing manner: An increase in the release of emissions directly affects climate change and meteorological conditions, just as

---

[1] True notably for NO_x (from diesel cars), but not necessarily for other regulated pollutants.

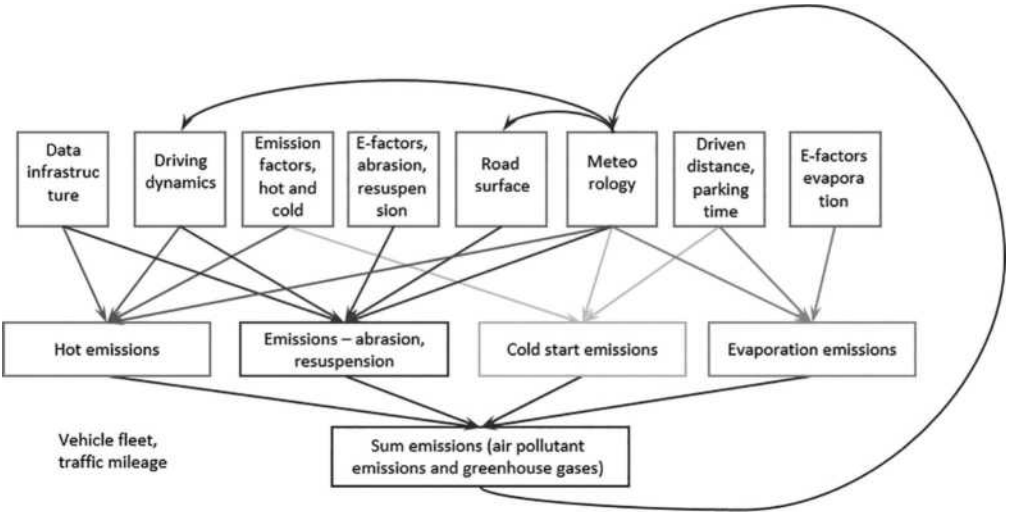

FIGURE 1 Default parameters (all boxes on top) for determining road-traffic emissions with resultant effects.

weather conditions affect driving dynamics (driving behavior) and road surfaces. Though not shown in Figure 1, emissions from trains, ships, airplanes, power stations and industry, domestic fuels and small businesses, mobile sources, agriculture, and biogenic sources are also part of the circuit.

Basics of Driving Dynamics

A vehicle moves or accelerates by converting externally added energy (fuel, electricity) into kinetic energy. When braking, kinetic energy is transferred to thermal energy. Some vehicle concepts are also able to recuperate and store electric energy for subsequent vehicle movement.

The level of energy consumption of a vehicle is dependent on the kinetic energy demand (to overcome driving resistances) as well as on the degree of efficiency of the engine and the use of auxiliary units such as air conditioning or lighting.

Kinetic energy demand arises from vehicle parameters and traffic situations (Pfäfflin 2018). Vehicle parameters include

- Acceleration Resistance: Overcoming vehicle mass inertia (including loading) and rotating masses (wheels, gearboxes, engine)
- Air Resistance: Force of displacement depending on vehicle size, drag coefficient, and speed of the vehicle
- Rolling Resistance: A result of tire contact with the road, the inner frictional resistance, and the weight force
- Gradient Resistances: Dependent on vehicle mass and topography.

During low speeds or stop-and-go traffic situations, the energy demand for the acceleration of vehicle mass is the decisive parameter. With a constant driving speed, rolling resistance and air resistance—especially at higher speeds—are the dominating factor for energy demand.

Energy Conversion in the Vehicle

As previously mentioned, kinetic energy is generated in either a combustion or an electric engine. Electric engines have a higher degree of efficiency than combustion engines. A hybrid vehicle obtains its energy from an electric engine and a fuel-based engine. Combustion engines are characterized by a cyclic, non-stationary, and non-optimal combustion process (Pfäfflin 2018). For a comparable vehicle type with similar engine power, the diesel engine has an advantage in terms of fuel consumption as compared to the gasoline engine. The spark ignition of the diesel leads to a more energy-efficient yield of fuel: This combustion process results in less fuel consumption and lowers CO_2 emissions; however, rising combustion temperatures lead to greater NO_x emissions.

Types of Emissions

The following is a list of the main types of emissions, divided by their components, as well as the chemical reactions in which they are released:

- Ammoniac (NH_3) and Dinitrogen (N_2O)—Released through catalytic converters
- Lead (Pb)—If the fuel contains lead
- Carbon Monoxide (CO) and Carbon Dioxide (CO_2)—During the combustion of fuel
- Hydrocarbons (HC)—During the combustion and evaporation of fuel
- PM (PM_{10}/$PM_{2.5}$)—In incomplete combustion or abrasion and resuspension
- Sulphur Dioxide (SO_2)—During the combustion of sulfurous fuel
- Nitrogen Oxide (NO_x)—During combustion process, especially from diesel engines.

There exist further emissions in road traffic, e.g., heavy metals, however, their effects on humans and the environment have yet to be sufficiently researched.

The following is a list of the main types of emissions, divided by point of origin:

- **Hot/Warm**

  These are emissions (CO, CO_2, NO_x, PM, HC, etc.) released when the engine and the exhaust reduction systems are hot, i.e., have reached their ideal operating temperature. Furthermore, hot emissions depend on traffic situations. Except for PM, hot/warm emissions have the highest share of total emissions on national inventories. Hot/warm emissions are given in units of [g/km].

- **Cold Start**

  When a vehicle has been parked for a minimum of 12 hours before the start of the engine, engine and exhaust reduction systems have reached cold start/ambient temperature; these technical systems are not at an ideal operating temperature. Upon start, an optimal operating temperature is first attained after a few kilometers. This produces cold-start supplement emissions, especially carbon monoxide (CO) and hydrocarbons (HC). Cold-start emissions are given as excess emissions (in [g/start]). A cool start arises in standstill times between 0.5 and 12 hours.

- **Abrasion and Resuspension**

  Abrasion from tires, brakes, clutch, and road surfaces are sources for non-exhaust particles (PMs). In addition, resuspension of generated and deposited particles from road surfaces occurs as a result of vehicle-induced airflow and wind. Technical improvements have reduced engine-based particles; thus, the emissions from abrasion and resuspension can exceed exhaust emissions.

- **Evaporation**

  Evaporative emissions in the form of HCs can be distinguished as follows:

  - Hot/warm soak emissions, given in [g/stop]—These emissions occur after switching off the engine when the engine is still hot or warm.
  - Diurnal evaporative emissions per vehicle given in [g/day].
  - Running losses—Generated as a result of vapor in the fuel tank during vehicle operation, given in [g/km].

Modeling of Road-Traffic Emissions

Overview of Approaches

In general, there are two different approaches for calculating road-traffic emissions for air pollutants and greenhouse gases: the top-down approach and the bottom-up approach. The selection of the suitable approach depends on the acceptable tolerance limit.

In the top-down approach, emissions are calculated based on "fuel sold" or "fuel used" (not including fuel exports to other countries) (European Environment Agency 2016). This approach is a simple means for calculating the (national) total quantity of emissions and is well suited for large-scale areas (in which the volume of fuel sold/fuel used within the country is known and inventoried), without, however, the use of temporal or spatial differentiation parameters or vehicle data. Moreover, the fuel-based approach is exact for CO_2 emissions (calculated from fuel quantity) but only approximate for some air pollutants.

All emission types for specific street sections as well as for partial or complete road networks on the meso- and microlevels can be calculated only with a bottom-up approach for all temporal and spatial differentiations on the basis of vehicle data, i.e., by means of (agent-based) traffic and emission models or by modeled vehicles. These two bottom-up approaches try to imitate or model driving behavior. Therefore, all the following remarks relate to the bottom-up approaches based on vehicle data only.

The bottom-up quantification of emissions can be implemented in different degrees. Potential spatial and temporal resolutions depend on the detail level of (available) input variables. Ericsson (2000) identifies cause–effect relationships (partly also interacting with each other) that influence variability of driving patterns: driver factors, vehicle factors, weather factors, traffic factors, street environment factors, and travel behavior factors (see Figure 2). Figure 2 allows a more detailed perspective into the top boxes of Figure 1 that can be used in a bottom-up approach.

Fontaras et al. (2017) add to Figure 2 driving style and vehicle maintenance (for driver factors), wind (for weather factors), aerodynamic and rolling resistance and auxiliary systems (for vehicle factors), road grade (for street environment factors), and none for travel behavior factors and traffic factors.

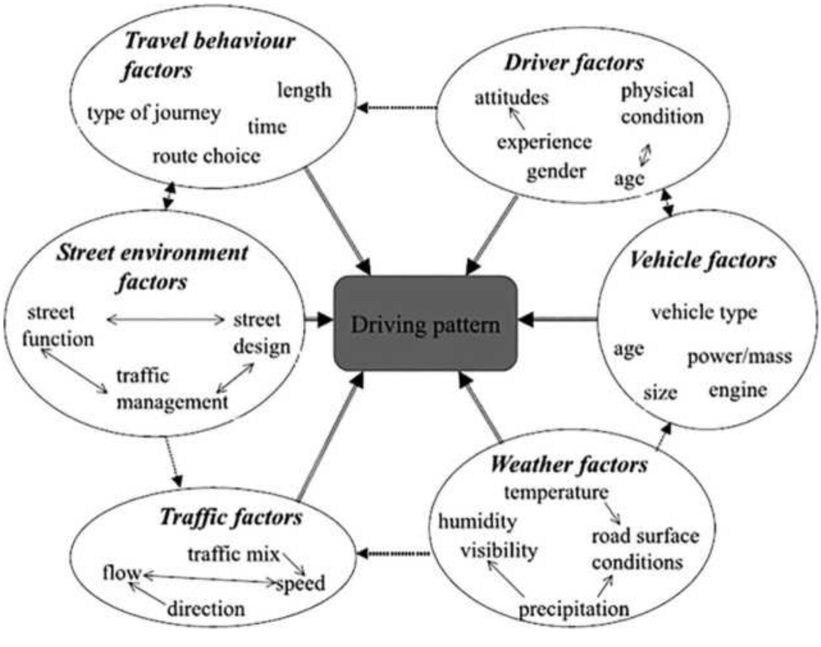

FIGURE 2 Cause–effect model of variability in driving patterns. [According to Ericsson (2000).]

Two technical possibilities for measuring emissions and one for modeling emissions are known. Emissions can be measured as a function of time or distance (known as emission factors):

- Either by a Portable Emission Measurement System (PEMS) at the exhaust of a test car that moves in traffic (exact, but costly)
- Or emissions can be determined in the laboratory with engine test facilities or chassis dynamometers. The necessary engine power to overcome driving resistances and the engine speed (according to a gearshift model) generate emission maps which allow for the calculation of emissions.

Emission models provide emission factors representative of vehicle classes/layers under specific driving situations. The model approach is ideal for the emission determination of large traffic networks, as it is less complex than individual measurements on each street. A traffic-supply model, a traffic-demand model, and an emission model are coupled. Data components for each model are discussed in the following sections.

Traffic-Supply Model

A traffic-supply model includes all infrastructure data of the road network (e.g., length of road sections, number of lanes, speed limits, gradients, traffic lights, and road surfaces). The result is a geo-referenced static traffic model allowing for the mapping of emissions back to their place of origin.

Traffic-Demand Model

The factors for the specification of driving dynamics (see Figure 2) are bundled in a traffic (demand) model. Traffic volume, traffic mileage (traffic volume multiplied by road section length), traffic flow, traffic composition, and traffic quality all serve as input variables for the energy demand of vehicles and emissions. Traffic volume is modeled either as Average Annual Daily Traffic (AADT) based on an average day of the year or in a higher temporal resolution with traffic flow by means of time series of a day, a week, or a year. Traffic flow is the number of vehicles which cross a specific road section over a certain period of time.

Traffic factors have to be quantified by indicators to make them useful for emission calculations in the study area. Ericsson (2000) identifies three parameter categories, which represent changes in driving patterns and have a high impact on fuel use and emissions:

- Level Indicators: Level measures describe, e.g., (average) speed, vehicle kilometers traveled, and number of vehicles. However, no information is given about variation or frequency of variation.
- Oscillation Indicators: Oscillation measures describe frequency, e.g., relative positive acceleration (RPA). RPA is defined as (see Eq. 1)

$$RPA = 1/x \int v * a^{+} \, dt \tag{1}$$

where x = total distance, v = speed, a^{+} = (positive) acceleration, and t = time.

- Distribution Indicators: Distribution measures indicate the distribution of a variable in a certain section, e.g., the percentage time share of acceleration ($a > 1.5\,\text{m/s}^2$).

According to Ericsson (2000), the five most important parameters for fuel consumption are

- Relative positive acceleration
- Number of accelerations per 100 m
- Percentage of time with $a > 1.5\,\text{m/s}^2$
- Percentage of time with $-2.5\,\text{m/s}^2 < a < -1.5\,\text{m/s}^2$
- Percentage of time with $v < 15$ km/h.

Data sources for quantifying traffic factors can be traffic detectors, radar, video detection, Floating car data (FCD), short-time counting, traffic messages, and data from police and traffic models with origin–destination matrices and assignment processes.

Traffic-Emission Model Types

The literature encompasses two general bottom-up approaches for calculating vehicle emissions by means of a traffic model: the macroscopic modeling approach with aggregated network parameters, which has rather low accuracy but enables faster computation of emission estimates, and the microscopic modeling approach with instantaneous vehicle emission rates, using either vehicle engine or vehicle speed/acceleration data (Jiang et al. 2018). According to Smit et al. (2010), there are five different types of traffic-emission models (see Table 2) with different input data and different interfaces between traffic volume and emission factors.

The first step for creating the model is to allocate road infrastructure data and traffic activity data into different categories (e.g., point sources, line sources, area sources) and into different temporal resolutions which refer back to each road section by means of geographical (interpolation) approaches and by assignment processes in traffic models. The second step is to select the emission factors of the model type that correspond as accurately as possible to the merged data of the road section. Subsequently, activity data (A) per road section are multiplied with specific emission factors (EF) per vehicle category, where E = emission (see Eq. 2):

$$E = A * EF \tag{2}$$

The total amount of emissions of a road network results in the sum of all mentioned vehicle emissions that are released on the road sections.

An emission model implies classed emission factors per substance, country, and year for all vehicle categories. These vehicle categories exist for the bottom-up approach (VDI 2019):

- Cars
- Light duty vehicles (≤ 3.5 tons permissible total weight, e.g. small buses, camper vans)
- Heavy duty vehicles (> 3.5 tons permissible total weight, e.g., trucks, truck trains, semitrailer trucks)
- Buses (regular buses, coaches)
- Motorized two-wheelers (motorcycles and mopeds)
- Per vehicle layer/segment: Vehicle category with the same propulsion technique and same size (mass or engine capacity) with the same emission performance to make emission calculation more manageable.

TABLE 2 Different Types of Traffic-Emission Models

Model Type	Input Data	Source	Example Models
Average speed models	Mean traveling speed	Traffic models or field measurements	COPERT, MOBILE or EMFAC
Traffic situation models	Vehicle kilometers traveled per traffic situation	Traffic models	ARTEMIS or HBEFA
Traffic variable models	Traffic-flow variables	Macroscopic and microscopic traffic models	TEE or Matzoros
Cycle variable models	Function of driving cycle variables at high resolution (seconds to minutes)	Obtained from vehicle movements (equipped with GPS) or microscopic traffic models	MEASURE or VERSIT+
Modal models	Function of driving cycle variables	Obtained via engine or vehicle operating models at the highest resolution (one to several seconds)	PHEM, CMEM, or VeTESS

Source: Own Representation Based on Smit, Ntziachristos, and Boulter (2010).

Vehicle-specific components depend predominantly on the following:

- Vehicle size (weight and motorization)
- Drive concept (induced engine [spark ignition engine], or autoignition [diesel engine], natural gas, hybrid)
- In-Engine technology-based reduction measures (e.g., exhaust gas recirculation [EGR]) or exhaust gas after-treatment systems (particulate traps, selective catalytic reduction [SCR], lean NO_x trap, three-way catalytic converter)
- Gear ratio
- Air resistance
- Rolling resistance of tires
- Vehicle conditions (age, mileage, maintenance).

Operational-specific components depend predominantly on the following:

- Engine and exhaust gas temperature
- Gear selection
- Operation of accessories (e.g., air conditioner, alternator)
- Cargo load
- Fuel quality
- Gradient of road
- Ambient temperature
- Height above sea level
- Driving behavior.

To manage the multiple variability of emission calculations, vehicles with similar technical attributes are summarized into the abovementioned vehicle categories with similar consumption and emission behavior, and then, emission factors are attached. The lowest level of detail are vehicle layers. Each vehicle is considered homogenous with respect to its emission characteristics and reasonably distinct from any other layer. Layer criteria are the abovementioned vehicle-specific components. The share of each vehicle layer in the vehicle category changes over time and place due to fleet modernization; therefore, the emission factors are updated yearly for the whole vehicle fleet. Traffic-mileage-related emission calculations need fleet compositions which are weighted accordingly, as average yearly traffic mileage may vary within the vehicle layers (e.g., cars with diesel engines have a higher traffic mileage than cars with gasoline engines).

The HBEFA Traffic Situation Model

The Handbook of Emission Factors for Road Transport (HBEFA) provides a traffic situation model which can be used for large-scale emission calculations while also taking driving dynamics into consideration.

HBEFA maps a comprehensive range of real driving specifications through 1190 classed driving cycles, simulated with the emission model Passenger Car and Heavy Duty Emission Model (PHEM). Kinematic parameters (velocity, percentage of standstill time, and RPA) are considered by traffic situations. They are differentiated by

- Area (urban area/rural area)
- Road type (motorway, arterial road, collecting roads, etc.)
- Speed limit
- Traffic conditions/levels of service (LOS): Fluent, dense, saturated, stop and go, etc.

HBEFA model generates emission factors for all current vehicle categories and concepts for different countries (Germany, Austria, Switzerland, Sweden, France, and Norway).

Figure 3 shows NOx emission factors for a HBEFA traffic situation with examples given for different vehicle categories, such as diesel cars, gasoline cars, light duty vehicles, heavy goods vehicles, and

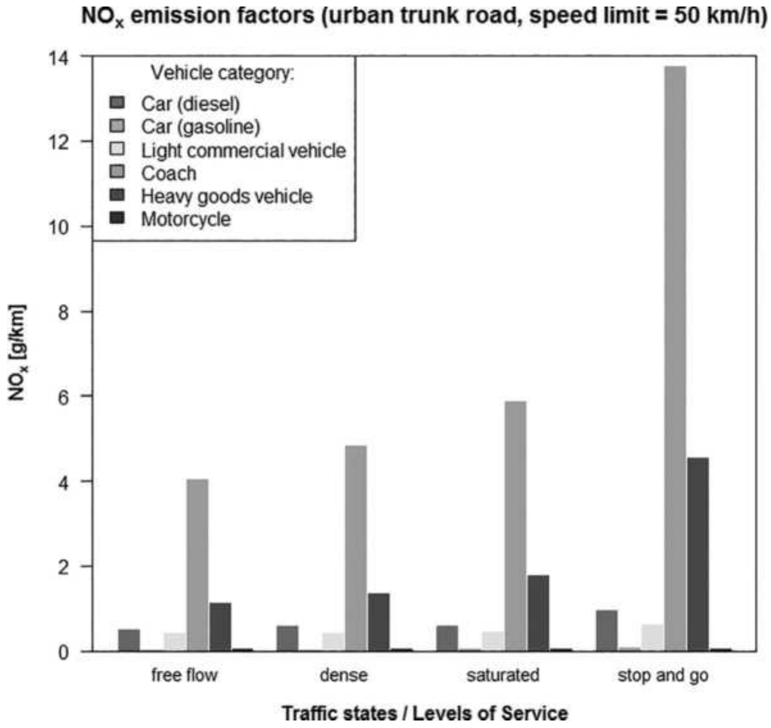

FIGURE 3 Emission factors produced by the HBEFA traffic situation model (urban area/speed limit = 50 km/h on a trunk road) for an average German car in 2019. (INFRAS 2017.)

motorcycles (all from the 2019 German vehicle fleet; ordered from left to right in figure 3), on an urban trunk road with speed limit = 50 km/h without gradient for different LOS (INFRAS 2017).

Validation of Emissions

According to Smit et al. (2010), the calculated emissions can be validated at different spatial scales (local, road, journey, area) by means of six different methods:

1. In *laboratory measurements*, driving conditions can be imitated under controlled parameters
2. *Onboard measurements* are able to test real driving conditions of a vehicle.
3. *Tunnel validation measures* at the tunnel entrance and exit, linked with tunnel features, e.g., tunnel airflow, cross-sectional areas, road length, and traffic density, measure emissions from a large sample of the on-road fleet.
4. Compared to the tunnel validation with relatively "controlled" conditions, *ambient concentration measurements* require results from combined emission and dispersion modeling (including background concentrations from households, industry, agriculture, and natural resources).
5. In the *remote sensing method*, an infrared/ultraviolet beam is directed from a pylon across the road to measure instantaneous ratios of various pollutants of a large sample of the fleet.
6. *Ambient mass balance studies* specify emission fluxes (kg/h) through the measurement of pollutant concentrations upwind and downwind of certain areas at different heights to compare these data with area-wide emission prognoses by the model for the same period.

In addition to the above methods, Poehler et al. (2019) use the *plume chasing method* to measure real vehicle emissions of a vehicle with a testing vehicle driven behind. The ratio of a pollutant (e.g., NO$_x$) to

CO_2 is independent from the dilution of the exhaust plume after correction of the background concentration. The ratio enables the calculation of the emission values of the vehicle.

Potential Influences on Emission Reduction and Their Impacts

As mentioned in "Energy Consumption and Types of Emissions" section, traffic demand and the resulting environmental impacts are embedded in complex interdisciplinary relationships. Therefore, systematic emission–reduction measurements, preferably implemented as pro-active prevention approaches, are needed—for example, by covering the dimensions of the four "E's". These include

- Engineering (e.g., technical reduction possibilities, traffic planning measures)
- Encouragement/Economy (e.g., pricing measures, incentives to change traffic behavior)
- Education (e.g., pedagogical and communicative measures, such as the promotion of environmentally-friendly modes)
- Enforcement (e.g., legislative measures, control, and monitoring).

The four "E's" merge in a bundle of vehicle-related, infrastructural, traffic-planning-related, traffic-management-related, and user-related measures, in which the impacts increase as more measures are implemented together (Schlag 1998).

Vehicle-Related Measures

Undesirable secondary outcomes emerge from combustion processes while driving. Their amount can be reduced by using high-quality fuel and in-engine technology as well as through the utilization of five different after-treatment systems of exhaust gases, as follows:

1. A *three-way catalytic converter* (for suction pipe gasoline engines) oxidizes the air pollutants carbon monoxide (CO), hydrocarbons (HC), and nitrogen oxides (NO_x) to CO_2 and inert N_2, if the exhaust temperature is sufficiently high.
2. An *oxidation catalytic converter* (for diesel engines and gasoline engines with direct injection) oxidizes HC, CO, and soluble particles.
3. *SCR* reduces nitrogen oxides with ammoniac (NH_3)—based on an aqueous urea solution—to nitrogen (N_2) and water (H_2O).
4. In *particulate reduction systems*, the exhaust gases flow over porous surfaces in open or closed filter systems.
5. *EGR* mixes exhaust gases back to the combustion chamber to reduce thermic NO_x (Pfäfflin 2018).

Infrastructural, Traffic Planning, Traffic Management-Related Measures

Traffic-planning measures—often coupled with traffic-management measures—reveal steering effects on traffic flows, which usually include, in addition to primary local (desired) impacts, secondary (unwanted) effects on the transportation system (e.g., induced traffic[2] [increasing traffic], spatial shift of traffic flows, etc.). Thus, traffic-planning measures are typically valued on a case-by-case basis. Often, the effectiveness of a planning measure is also dependent on framework conditions and the type of chosen implementation. Pfäfflin (2018) has outlined seven typical planning measures as follows:

1. *Measures of improvement of traffic efficiency/decongestion* include, for example, capacity expansions or construction of roundabouts (consider maximum thresholds of traffic volume) from an infrastructure perspective. From a traffic management perspective, traffic control centers can implement environmentally oriented traffic management based on the following:

---

[2] Hills (1996) explains the usage of this term in the context of transportation.

- Traffic models for an interpolation or prognosis of traffic scenarios and strategies
- Data archives to recognize traffic behavior patterns and causal relations
- Strategy management systems to run predefined strategies.

Traffic control centers use Intelligent Transportation Systems (ITS); these include sensor systems for traffic monitoring, devices for transfer systems for traffic incidents (e.g., road works, accidents, events), devices to control traffic flow (e.g., [virtual] variable message signs), and further information devices for transportation users. Further traffic management scenarios are optimization of traffic lights (green waves), ramp metering, dedicated lanes for vehicle with high occupancy (HOV lane), or high-occupancy toll lanes (HOT lanes), in which high-occupancy vehicles are without charge, and other vehicles are required to pay a variable, demand-adjusted fee.

All these measures lead—under the assumption of same boundary conditions—to an improvement in local traffic quality with less stop and go and, thus, less emissions; however, rebound effects must be considered. Lower travel times induce traffic (either from changed-route choice or from modal shift from public transport) which may lead to an increase in the total emissions in the network than before the implementation of the traffic planning measure.

2. *Construction of new bypass roads* leads to traffic shifts and/or induced traffic with a shift or increase of emissions. Dismantling of main through-roads reduces the risk of the abovementioned rebound effects.
3. *Access and transit prohibitions* restrict temporarily or permanently an entry of certain vehicle categories or vehicle groups to specified roads or areas, e.g., implemented as environmental zones or city-center tolls. An environmental zone can lead to an acceleration of vehicle-fleet modernization with less specific emissions—also outside of the environmental zone. In contrast, traffic shifts and a rise in vehicle kilometers traveled (due to longer trips to detour around the environmental zone) can lead to increased emissions.
4. *Parking management* includes the dismantling or creation of parking spaces as well as the establishment of parking guidance systems. Parking guidance systems reduce the emissions created by traffic in search of parking; yet, at the same time, the attractiveness of parking spaces has the counter effect of induced traffic (increasing traffic). Consistent parking-space management zones of sufficient size with homogenous prices will reduce variable attractiveness between parking options and, thus, avoid extended searches for parking.
5. The *reduction of permissible maximum speed* is a measure that does not directly affect emissions but rather driving behavior. A maximal reduction in emissions can be seen in the mid-speed range of 60–80 km/h. Emissions increase at faster speeds due to higher engine power demand; they also increase at speeds below 50 km/h as a result of external factors such as traffic control, traffic signal settings, and gradient. Therefore, an overarching statement concerning permissible maximum speed is not possible.
6. The *attraction of environmentally-friendly modes* includes modes of transportation with zero or less emissions than motorized traffic, e.g., walking, cycling, public transportation, or trains. Measures that increase attractiveness of these modes include a safe infrastructure for non-motorized traffic, an increase in network density and frequency, barrier-free vehicles, public relations (information and communication, marketing, consultations), educational measures (e.g., biking safety classes), carsharing, ridesharing, and intermodal mobility stations (mobility as a service). For the most part, reducing environmental impacts can only be achieved when pull measures are combined with push measures of motorized transportation (reduction of parking spaces, increase of parking prices, etc.).
7. *Measures without secondary effects to traffic quality and traffic volumes* include construction of noise-protection barriers for lowering emissions, planting vegetation, or installing photocatalytic surface coatings for the reduction of NO_2 concentrations. The reduction potential is very low compared to other measures.

User-Related Measures: Internalizing External Costs of Environmental Impact, Mobility Management, and Land Use Planning

The abovementioned traffic-planning measures have a predominantly local or regional impact on transportation. International policies must set incentives for all emission sectors to develop and implement a common cooperation strategy for reducing and eliminating emissions. This can be achieved through the realization of a climate-friendly legal framework which follows the *true-cost principle* (i.e., usage-related charges with no external effects on other regions, people, or time frames) combined with municipal and operational *mobility management* (a target-oriented approach for influencing individual mobility behavior by perceiving, revealing, and assessing mobility options for traffic prevention). A climate-friendly transportation policy and legislation also encourages the development of livable, green, and healthy cities / (small) towns composed of the following:

- Diversity: Buildings and public spaces serve multiple purposes, such as for employment, shopping, or recreation.
- Density: Critical for short distances and the (public) transit system, density concentrates trip origins or destinations, allowing for ride sharing to become practical as well as economical.
- Design: This provides an accessible, barrier-free, safe, and rewarding infrastructure with an easy-to-understand orientation system. Streets would not only have link functions (which minimize travel times) but also have place functions (which maximize the time traffic participants spend for social interaction in public spaces) (Cervero and Kockelman 1997).

A successive realization of the true-cost principle in transport with social compensation measures leads to traffic behavior changes, sustainability, and a shift toward eco-conscious transportation.

Conclusion

Transport emissions are a significant contributor to total emissions worldwide; in particular, road-traffic emissions have been increasing, and this trend will continue in the future. The substances PM_{10} and NO_x (NO and NO_2) present the greatest problems in transport, with the resultant CO_2 contributing directly to global warming. Fuel-based vehicles are the majority, but electric vehicles gain market shares. Emissions arise from combustion processes, abrasion, resuspension, and evaporation. Either the emissions can be measured with test vehicles or the emissions can be modeled with traffic and emission models for large networks. Several methods exist on different spatial scales to validate emissions. Emissions can be reduced most effectively with an integrated approach consisting of vehicle-related, infrastructural, traffic-planning-related, traffic-management-related, and user-related measures. (Rebound effects must also be considered.) Traffic and emission models can be used for environmentally oriented traffic management. A realization of the true-cost principle will support a shift toward eco-conscious transportation.

Delakowitz

Introduction

Regenerative resources like wind and solar energies, running and falling water (hydropower), biomass processed in some way and geothermic energy are in a position to replace crude oil, natural gas, coal, and uranium step by step depending on both technological innovations and political decisions. Here, technological innovations are not meant to require fundamental inventions to render some renewable resource useful for energy (electric current) "harvesting." Rather, this is about making existing technologies cheaper and overcoming specific material problems, like device corrosion and fast "blocking" of underground heat exchange pathways with geothermic energy, storage in an easy-to-handle form (methanol?) for both solar energy and biomass, or using less toxic and less brittle semiconductors in much thinner layers in photovoltaics [thin-film cells based on either copper indium dichalcogenides (chalcopyrites) or organic semiconductors].

Given the relativeness of time and the notorious "difficulty to make predictions which refer to the future," what does it say about classical fossil resources running out in the foreseeable future? Putting this into proper context means to distinguish between "reserve" and "resource": "reserve" just encompasses those deposits of energy carriers that are actually known and can be really accessed following both technical and economic criteria. In the pre-1973 world of %2.70 per barrel of crude oil (some $19 per ton), it would have been considered a fancy to try to extract oil from shales or sand and drill deep below the seafloor (now always performed in the Atlantic Ocean and the Mexican Gulf, off Brazil and Angola) or in remote arctic regions. Currently, the meaning of underground hard coal production or making access to very deep natural gas deposits is doubtful. While oil production from oil sands (Alberta Province, Canada) is now economically viable—but still an ecological disaster in a sensitive surrounding—other methods of accessing certain fossil resources will probably never be viable: it simply takes more energy to extract and process traces of ^{235}U dissolved in seawater than can be obtained from its fission afterwards. As the term "reserves" by definition ("share of total potential which can be mined and exploited economically reasonable by currently available technical means") includes both the present level of technology and current pricing, reserves are subject to changes other than due to ongoing prospection and exploitation. For example, when disregarding the environmental and safety issues associated with either kind of fossil energy carrier for this moment, both oil sands and shale gas are close to the lower limit of economic feasibility given the current crude and natural gas prices. However, available amounts are not settled with shale gas, not permitting to include it into the reserves, while oil sands—although a blueprint for ecological disaster—are economically and technically feasible to produce and hence are part of (Canada's and global) crude reserves. Matters are different once again if the technology to actually obtain energy from some fossil or far-spread reservoir around is not yet at hand or it is doubtful whether energy required to mine and concentrate that particular source might even exceed the energetic payback obtained thereafter: consider amounts/concentrations of deuterium, ^{6}Li, and ^{235}U in seawater. The former two (^{6}Li being a precursor to fusion "fuel" tritium) would combine to an inexhaustible source of energy if "only" net-energy-yield nuclear fusion would be at hand already, while there are just some 15 ng (!) of ^{235}U that can be actually extracted from 1 L of ocean water, providing a few hundred joules ($\approx 10^{-4}$ kWh) of electric energy in nuclear (now, fission) power plants thereafter. Even though the corresponding extraction was already demonstrated in Japan, using ion-exchange resins, the energy for producing the resins and running the device is so large that ocean-derived uranium is not a viable resource either and thus cannot be counted among the reserves.

"Resources," on the other hand, are those energy carriers either already discovered (not a single "elephant field" of crude oil was spotted after the 1960s anywhere in the world!) or *reasonably believed* to exist from geological arguments in Earth's crust, but cannot be exploited right now for either technological or economic reasons. Due to the difficulties and risks associated with drilling either below some 9 km underground or into active magma regions, most of the huge amounts of geothermic energy can never be actually used. Hence, for fossil resources as well, we are left with what is in the crust or the ocean (floor). Given this distinction, the residual economic lifetimes for traditional forms of energy carriers such as oil, natural gas, brown and hard coal, or uranium given in Figure 1 are obtained.

Energy Depletion of Fossil Fuels

Counting from year 2000 onwards, the German Federal Institute for Geosciences and Natural Resources estimated in 2002 that reserves of oil, natural, gas and uranium will last for just another 40 to 65 years. Reserves of both hard and brown coal will still last up to 200 years, whereas the resources of coal and gas and uranium are to last more than 200 years. Things are more critical with crude oil, reserves of which will be gone within 60 years while resources are estimated to last for 160 years at best. Data and predictions in Figure 1 do not cover and include the energy consumption of current growth regions [BRICS states like Brazil, Russia, India, China (PR), and other Latin American countries], leaving us with the

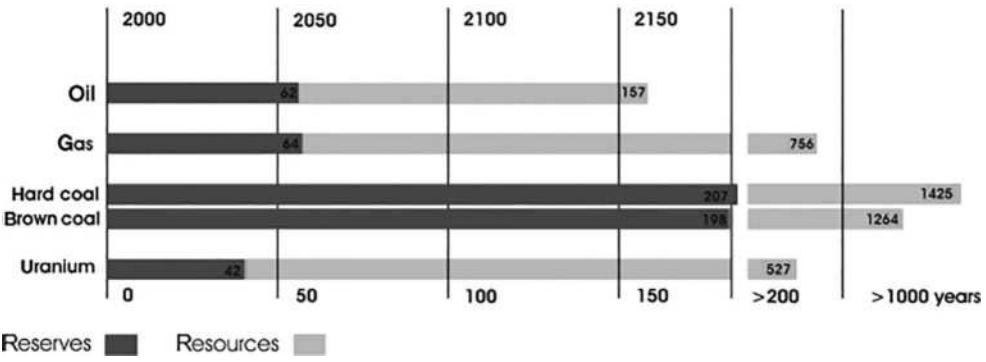

FIGURE 1 Predicted reserves/resources of fossil energy carriers from year 2000 onwards.
Source: German Federal Institute for Geosciences and Natural Resources, 2002.

conclusion that we are left with much less time to change our bases of energy supply altogether.[1–4] The resources of crude oil are much disputed. Apparently, most of the additional stockpiles—beyond established reserves still considered a few years ago—simply do not exist. Speculation on oil term in markets is considerably influenced by this insecurity of affairs while the big oil companies obviously produce an exaggerated picture of resources rather than make speculation go its way.

Another matter is the regional distribution of these reserves/resources all around the globe (Figure 2; Federal Institute for Geosciences and Raw Material Research.[5]): the problem is obvious with crude oil, and everybody is aware of it, but there are also biases/imbalances with hard coal. Considering the total energy stored in it, some 60% of it rests with brown or hard coal; the smaller part is included in liquid and gaseous hydrocarbons. Note that efficiencies of power plants differ considerably among these energy carriers, with hard coal and gas steam plants being superior to others ($\eta_{el} > 55\%$). Crude oil, which may be produced by current technologies, reasonably amounts to 6682 EJ, a little less than with natural gas (7136 EJ). 1000 EJ (exajoule) = 10^{21} J. Standard heats of formation of the compounds/mixture/combustion products involved are as follows:

CH_4	−50 kJ/mol
C (graphite)	zero [by definition (standard state of an element)]
"CH_2" (fraction of crude oil)	≈ −20 kJ/mol
CO_2	−394 kJ/mol
H_2O	−237 kJ/mol

Thus, 1 mol (44 g) of CO_2 produced from combustion of natural gas (CH_4, essentially), crude oil, and coal yields 818 kJ, 611 kJ, and 394 kJ, respectively. The annual global anthropogenic CO_2 output is of the order of gigatons (1015 g, Pg), with the atmosphere containing some 770 Pg of it now, considerably more than which is tied up in living biota (about 610 Pg). One gigaton of CO2 from hard coal, crude oil, and natural gas natural translates into somewhat less than 9, 13.9, and 18.6 EJ of thermal energy, respectively. Thus, actually combusting the above-estimated resources would leave us with some 50,000 gigatons, that is, 65 times (!) the present CO2 inventory of the atmosphere.

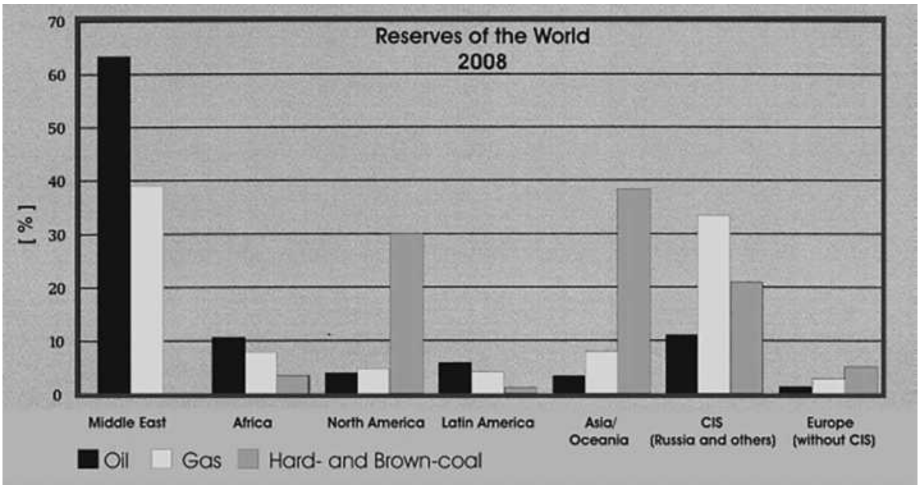

FIGURE 2 Estimate of the regional/continental distribution of oil/gas/coal reserves.[5] As for the Commonwealth of Independent States (former USSR except of Baltic states and Georgia), the biggest share is with just three of them: Russia (the current biggest oil producer in the world), Azerbaijan (both oil and gas), and Turkmenistan (almost gas only).

The total energy from conventional fossil energy carriers (resources combined) would be some 448,289 EJ, 97% of these resources being hard or brown coal. Besides the above-mentioned conventional energy carriers, there are substantial amounts of other energy carriers such as oil sands, oil shales, tars, and other kinds of the heaviest, most condensed oils, natural gas from dense storage sites, carbon deposits (adsorbed), or aquifer waters, plus gas (CH_4) hydrates on deep shelf (below some 350 m of seawater or in the uppermost sediments down there) reserves and resources that correspond to an energy equivalent of 2368 EJ and 116,270 EJ, respectively.[6]

Most industrial activities now depend on oil, as do almost all traffic systems, be it airplanes, ships, or cars. Oil getting scarce thus does not only cause prices to rise; there will also be ramifications on workforce in petrochemical branches and political implications. The largest share of oil (2005), some 742 billion barrels, is located in Central and Southern Asia (Bangladesh, Bhutan, India, Maldives, Nepal, Pakistan, Afghanistan, Sri Lanka, and parts of Iran).

Considering the global oil reserves according to British Petrol in 2005, this translates into 62% of global stockpiles, whereas North America commands just 5%, being one of the meta-regions scarcest in oil besides Asia/Pacific and Europe.

With oil getting scarce, a one-sided economic dependence on the Middle East poses increasing political risks, causing everybody to consider oil and gas resources located elsewhere and how they and additional geological goods might be obtained. Thus, there is a recent growing geopolitical interest in the Arctic region, which will become void of drifting ice during the next 20 or 30 years due to climate change. According to the U.S. Geological Survey Institute,[7] some 30% of natural gas and 13% of crude oil are located there. However, most of these are located far offshore [the remainder already exploited for decades in Russia (Taimyr Peninsula) and Alaska], with most of the gas belonging to the Russian Federation while oil is scattered among Canada, Alaska, and Greenland (still partly governed by Denmark). Though very large, experts say[7] that these deposits are not enough to consider relocation of most production activities from the Middle East. In addition, long transport distances (thus, costs) and still adverse weather and climate conditions pose grave problems. Everybody is still aware of what can happen with deep sea-based oil production considering the Deepwater Horizon catastrophe of April 2010, environmental concerns translating into larger political obstacles, higher insurance fees, and eventually less consumer acceptance.

That the so-called peak-oil level where global oil production has reached its maximum ever was already achieved in the beginning of the 21st century is evident from a depiction of development of oil production from 1930 until (predicted) 2050 (Figure 3): scarce oil means there will be no more cheap oil. Until the beginning of the 21st century, one barrel of oil commanded between $20 and a maximum

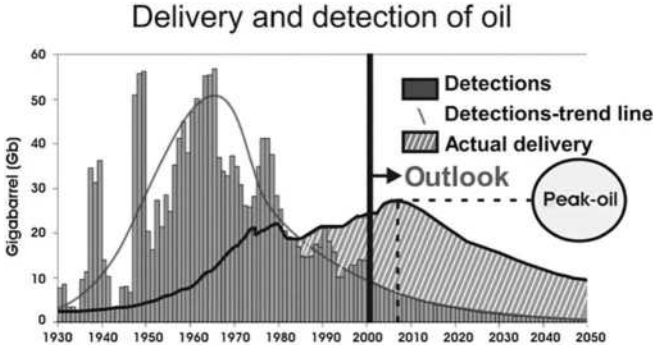

FIGURE 3 Oil findings and delivery rates from 1930 to 2050 with the outlook after Campbell (2006).[8] The delivery rate per year is calculated by the Association for Peak-Oil and Gas Studies, Germany. Data from ExxonMobil (2002). Peak oil: point of time when the maximum rate of global petroleum extraction is reached.

of \$40. The financial crisis made it (Brent) rise up to \$147 after 2007. Declining somewhat, it now (2011) stabilizes around \$100. In the long term, it is more likely to increase again, having severe drawbacks on economic conditions in industrialized countries especially.

Figure 1 tells us that hard and brown coal reserves are to last another about 200 years, rendering coal-fired power plants most attractive if it were not for coal being one of the most polluting sources of energy. Combustion of coal produces plenty of CO2, and therefore, it contributes to the anthropogenic part of greenhouse effect warming of our atmosphere.

Climate Protection

CO_2 is one of the most prominent greenhouse gases in the atmosphere, contributing to heating the atmosphere and thus the Earth's surface.[10,11] There is both a natural and an anthropogenic (share of) greenhouse effect. CO_2, produced by animal respiration, wildfires, and volcanoes, is a natural (<300 ppm) component of the atmosphere, heating our planet from a radiation equilibrium ("blackbody") value of some −18°C to a global average of +15°C, that is, by a considerable 33°C.

A global increase of average atmospheric temperatures is now seen for decades, with Figure 4 displaying the distribution of this effect for 2000–2009 as compared to the reference time frame of 1951–1980. Satellite measurements by the NASA Earth Observatory showed the largest increases of the average temperature in the Arctic parts of the Northern Hemisphere, besides some parts of Antarctica. Between the beginning and the end of the 20th century, the average increase was 0.74 ± 0.18°C.

Time is imminent for rethinking energy production with a focus on sustainability in all ecological, economic terms and social acceptance. Man-made radiative greenhouse forcing is established for more than 20 years now. It causes enhanced glacier meltdown rates in the Arctic (Greenland actually turns green again), the Alps, and other mountainous regions, as well as sea level rising (both due to meltdown waters and to thermal expansion of warmed surface water), with more frequent droughts causing limnetic waters to evaporate often completely. We also would be urged and obliged to seriously think about what we are doing if, as some scientists still maintain to argue, this would be a

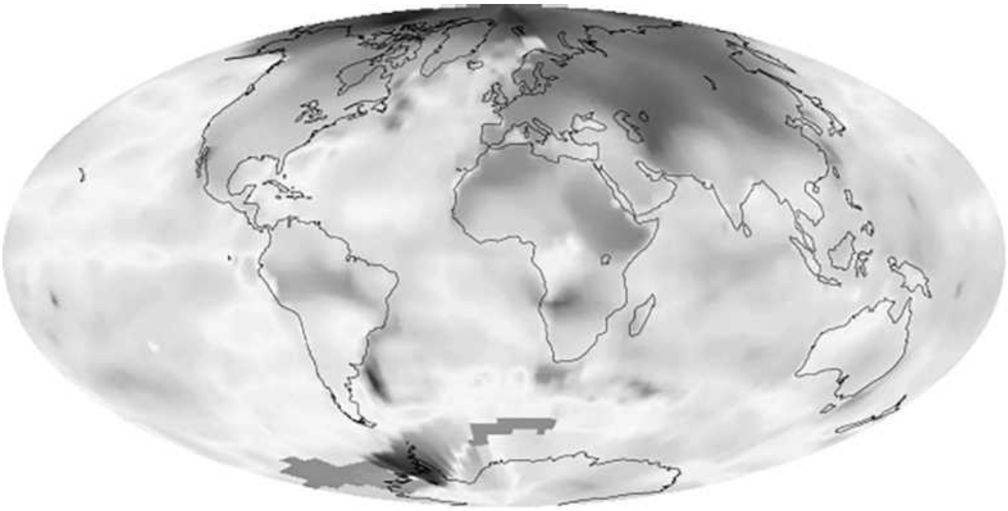

FIGURE 4 Regional distribution of relative greenhouse effect warming. The map shows the 10 years average (2000–2009) global mean temperature anomaly relative to the 1951–1980 mean. The largest temperature increases are in the Arctic and the Antarctic Peninsula. The darker the gray shades in the picture of NASA,[14] the larger the increase in local average temperatures.

normal climate excursion as occurred in the later Middle Ages. It does not take much proficiency in the natural sciences to acknowledge the problems associated with the industry emitting greenhouse gases[12] while striving to maintain and enhance our common well-being. The destruction of the environment concomitant with the exploitation of the developing Third World countries has already been an issue some 40 years ago, prompting the first Conference on the Human Environment at Stockholm (Sweden) on June 16, 1972, initiated and organized by the United Nations. Twenty years after, in 1992, the most comprehensive global conference on such issues ever held, the United Nations Conference on Environment and Development (UNCED), took place in Rio de Janeiro. One hundred years ago, Wilhelm Ostwald mentioned in his approach "Die Mühle des Lebens,"[13] "Do not waste energy, rather use it wisely," This is in opposite to the Kantian imperative at this time, and the first energetic step to a so-called sustainable chemistry of today.[15]

A total of 178 countries dedicated themselves to Agenda 21 to oblige the 118 more developed countries to embrace environmental restoration, preservation, and social development. Their aims are to meet the challenge of global warming, pollution, and biodiversity and to solve the interrelated social problems of poverty, health, and population. The Agenda 21 program furthermore encompasses constructing a network of "new and equitable global partnership through the creation of new levels of cooperation among States, key sectors of societies and people, while working towards international agreements which respect the interests of all and protect the integrity of the global environmental and developmental system."

In 1997, the World Climate Summit was held at Kyoto, Japan, focusing on the future climate protection policy and measures. The 158 states that had so far signed and ratified the Framework Convention on Climate Protection and 6 "observer states" had sent a total of almost 2300 delegates, plus another 3900 observers from non-governmental and other international organizations and 3700 journalists from global media, making up a total of close to 10,000.[16] The Kyoto process unleashed by this huge meeting now describes the attempts to maintain climate protection agreements beyond the Kyoto protocol running out in 2012 and to do so in a way that still is safeguarded by agreements of international law.

The industrialized states listed in Appendix 1 of the Kyoto Protocol agreed to reduce their collective greenhouse gas emissions by 5.2% from the 1990 levels by the year 2012. The common (purported) aim of the international community is to limit the increase of global average temperature within 2°C. By now, it has become most doubtful whether this "two-degree aim" can be kept at all. In addition, it was proven that even an aggressive forestation policy could not cope by photosynthetic absorption (assimilation) with the present upsurge of CO_2 produced. The progress made so far is modest at best, with real successes still to be waited for. The subsequent UN Climate Conference at Copenhagen (Denmark) in late 2009 saw just a communiqué of minimal consent without any mandatory aims in CO2 reduction although the "two-degree aim" was once again acknowledged to be worthwhile.

Role of Nuclear Power

The Fukushima (Japan) sequence of catastrophic events began on March 11, 2011 [the strongest earthquake ever recorded in Japan (Richter magnitude 9.1)], causing coolant pipes to break and starting a sequence of reactor core meltdowns in at least three adjacent nuclear power plants (NPPs). The area was then hit by a tsunami; any semblance of control of the preceding events was lost. Finally, the uncooled reactor systems exploded one after the other, releasing large amounts of radioactivity and visibly destroying reactor block 3. People reconsidered the risks of nuclear energy all over the world, although with grossly differing political consequences.

Now introduced into IAEA (International Atomic Energy Agency) accident level VII, the events at Fukushima were set equal to the Chernobyl disaster [April 1986, Ukraine (officially: Ukrainian Soviet Socialist Republic)] and considered worse than the explosion of a nuclear fission waste storage tank at Kyshtym in 1957 [near Chelyabinsk, Urals, then RSFSR (Russian Soviet Federative Socialist Republic), USSR (Union of Soviet Socialist Republic); level VI accident], which delivered very large amounts of

^{90}Sr [several EBq (exabecquerel: 10^{18} Bq)] that an area of some 15,000 km^2 had to be abandoned for any human use up to now. Japan is known to be tectonically most active, prompting the authorities and engineers to consider earthquakes up to Richter magnitude 7.9 in design. Two matters demand further consideration here:

a. What causes, e.g., main coolant pipes to break is acceleration and the mere amplitude of dislocation combined with inertia, that is, parameters rather covered by the "old-fashioned" Mercalli scale of earthquake intensity, with Mercalli 13 denoting accelerations larger than that of the Earth's gravity. Such quakes actually happened, e.g., the Easter quake of 1964 in Central Alaska (there is a very impressive movie showing cars and humans and even some homes losing contact with the ground during the quake). In contrast, Richter scaling gives the energy unleashed by a quake [or a landslide or an underground explosion (be it chemical or nuclear in origin)] in a logarithmic way: Depending on the depth of the epicenter, i.e., the amount of matter located above the vibrating or breaking sample of crustal matter, accelerations due to a given amount of tectonic energy can be quite different: the "fairly moderate" Haiti quake of February 2010 (Richter 7.1) became a real killer not because of its energy but since its epicenter was located just a few kilometers below the surface, producing a massive acceleration, thus aggravating the effects of non-adapted architecture. Inertia also is a matter of dislocation of the ground, which provides a kind of reference frame, physically speaking, to which any device that can vibrate, etc., will respond: this dislocation was about 2.5 m in Japan on March 11, 2011, that is, much larger than in the even stronger (more energetic) Chile 1960 (Richter 9.5) and Sumatra Christmas 2004 (Richter 9.3) earthquakes.
b. At least two NPPs, one of them in Japan, had already experienced earthquakes exceeding these limits of design: at Niigata (NW Japan) and at then Leninakan in Armenian Soviet Socialist Republic (SSR) in 1988. Hence, the design was obviously short of reasonable expectations [Central Europe, German, Swiss, and French NPPs next to the Upper Rhine Rift Valley do not take account of the fact that Basle City was almost completely destroyed by a quake in historic times (in 1356)].

The Fukushima earthquake was far stronger than this. The tragedy was worsened by a tsunami caused by this quake; it took thousands of lives in cities and villages near the coast, but most likely, the crucial damage to the Fukushima NPPs was caused by the earthquake, though the NPP area was inundated soon after. Certain radionuclides, mainly highly volatile ones were released; that core meltdowns had occurred was first contested and then confirmed by Japanese authorities only 2 1/2 mo later. These highly volatile radionuclides include ^{131}I, $^{134;137}$Cs and some noble gases, and traces of ^{132}Te but not Sr, Ba, and rare earth elements. Apparently, the temperatures during core meltdown did not yet suffice to vaporize alkaline earths or rare earth element compounds (cesium becomes highly volatile as a hydroxide, CsOH molecules sublimating as easily as NaOH and KOH do), neither did volatile chlorides form after NaCl from seawater pumped inside to cool the reactor cores solidified. Including those still missing, their whereabouts unaccounted for but unlikely still to be alive, there were some 23,000 fatalities due to the quake and tsunami, and several workers received massive radiation damages during cleanup, with a nuclear catastrophe still looming ahead. The number of people forced to abandon their homes and jobs (permanently) at Fukushima and Iitate provinces [40 km NW Fukushima (the NPP site, not the town of Fukushima)] is more than 80,000 now, that is, close to that of people who became homeless due to the Chernobyl accident. Responses from different countries were different: while politicians and citizens in certain countries started to abandon energetic uses of nuclear fission (Germany and Switzerland) or reaffirmed prior decisions of this kind [New Zealand, referendum in Italy with a 94% (2011) turnout, Belgium], others chose to keep a pronuclear course or even kept up decisions to build national first-ever NPPs (Poland).

On a global scale, the issue of nuclear energy is controversial in all developing countries, classical industrialized states, and "official" and "unofficial" nuclear-arms-possessing states. While the United States plans to commence building the first new NPPs after a moratorium of some third of a century,[17] Italy officially revoked the schedule to abandon nuclear energy adopted by a 1994 referendum (but only so in the old Berlusconi regime, the Monti administration being undecided on this issue), and the spring 2012 presidential election campaign in France triggered a broad discussion on the future of NPPs there for the first time. Several developing states extend their present NPP program apparently as a pretext to obtain more fissionable material for nuclear arms, like India and Iran, regardless of whether they signed the Non-Proliferation treaty (Iran), did not sign (India and Israel), or left the protocol some time later (North Korea). In "established" nuclear powers, on the other hand, NPP extension also is a means to get rid of excess amounts of weapons-grade or "special" nuclear fuels (United States, Russia, U.K.). The most interesting case is some 2 tons of ^{233}U left over from the thorium/uranium breeding cycle, which is/was used only in India for energy production and formerly in the United States for making arms. Now, the United States is left with a stockpile of this nuclide, a nuclide that actually would be usable by very-low-technology groups or states to produce "efficient" and reliable-yield warheads (different from that with any plutonium isotope [-mixture]!) and correspondingly must safeguard it to a level that would not be necessary with any other isotope—unless they "burn" it in reactors.

Hence, the ambiguity of nuclear technologies continues to influence decisions on introducing or maintaining it as an energy source, far beyond, and competing with, considerations of supply reliability (the number of states that provide/export significant amounts of uranium is considerably smaller than those that provide all natural gas, crude oil, and hard coal). Political decisions on increased or renewed use of nuclear energy in certain countries hence cannot be considered a signal that is globally significant, except for their drawbacks to the issue of proliferation.

The classical argument in favor of nuclear energy production is their releasing much less CO_2 as compared to oil, coal, or natural gas power plants, enabling economies to meet Kyoto ends more easily. For certain countries that produce nuclear fuels but command few other natural resources, there is the bonus of apparent independence; this includes Japan. In the EU, the Czech Republic presently is the only state to mine domestic uranium ores, globally large producers being differently organized and reliable in political terms [Australia, Canada, the United States, Kazakhstan, Niger, Gabon (Central Africa)].

Nuclear energy is rather "compact," a GW-class power plant taking a few hectares at most, which is important in countries as densely populated as Japan (or India, or Belgium), with Japan covering a total area hardly larger than that of Germany (372,000 km^2). Next to the United States (104) and France (59), Japan has the largest number of NPPs [53, from which 6 at Fukushima and 3 at another highly earthquake-prone site (scheduled for shutdown) must be subtracted; thus, effectively it is only 44] due to an experience from the 1970s: the OPEC oil crisis in 1973, rapidly increasing the prices of crude, of course hit all the already then industrialized countries except for those producing sufficient fossil fuels of their own (Canada, Australia) or relying on other sources mainly for different reasons (Norway, New Zealand, South Africa) but worst so in Japan: in fact, there were large-scale electricity shutdowns badly hurting Japan's economy. Hence, Japan—once again in its history—became eager for independent supply, planning to build yet more NPPs before Fukushima happened. By now, unlike France, Belgium, the United States, or formerly Lithuania, which obtains 60% or more of its electricity from NPPs, Japan's rate is 30%. During the period of Soviet dominance, Lithuania even had the largest NPP in the world, a 2400 MW$_{el}$ plant at Ignalina (now Visaginas) of the notorious (Chernobyl) RbmK (*reaktor bolshoy moshchnosti kanalniy:* high-power channel-type reactor) construction type. Relying on nuclear energy by >70% shortly after regaining independence, Lithuania had to close down this plant as a precondition for joining the EU, as Bulgaria had with Kozloduy. Now, Lithuanians plan to erect a new, similarly huge NPP at the same site next to the border triangle with Latvia and Belarus to supply all of the three Baltic states even though Latvia is now the EU's champion in regenerative energy supply, producing almost 40% of its (admittedly rather limited) demand mainly from hydropower, wind, and some biomass use, and suffers from financial crisis (much like Ireland and Greece but less perceived to do so since they still maintain their own currency, the Lat). Figure 5 shows the global pattern of distribution of NPPs that is almost complete [note that there are 1) considerable differences in electric outputs of individual plants and 2) some plants were primarily meant to produce radionuclides rather than electricity, although they

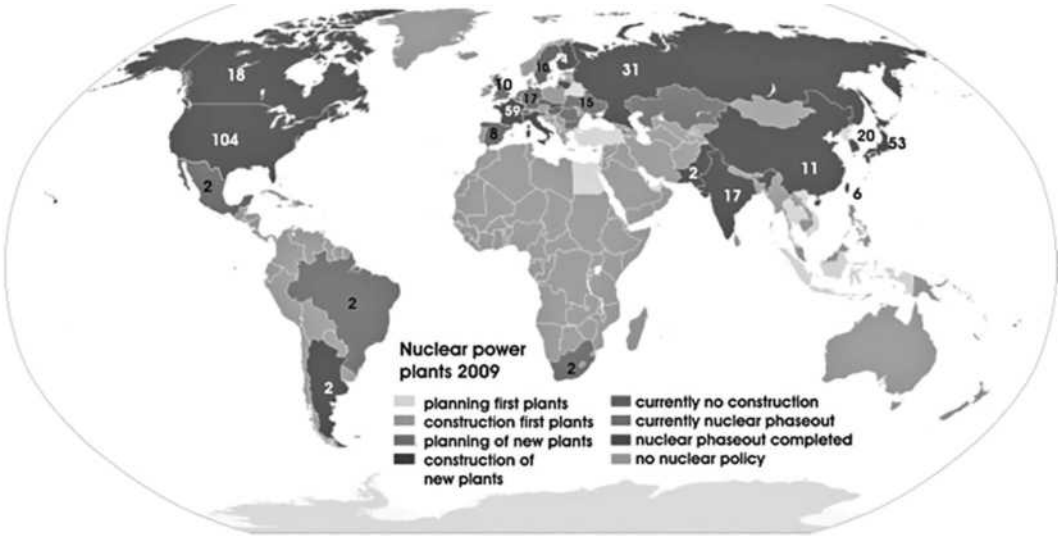

FIGURE 5 Nuclear power worldwide in 2009 (the figure was transferred from Wikipedia; the number of nuclear power plants has been added by collecting information separately by Wikipedia). The number of nuclear power plants is not complete.

are connected to the public current grids (e.g., Dimona in Southern Israel)]. The total number is about 450 NPPs.

As shown above (Figure 1), uranium reserves are to last for just another about 30 years from now (2011), adding another problem to safety concerns and disposal of radioactive wastes (see below) associated with nuclear (fission) energy. The increase in prices during the last 5 years even relatively surpassed that of oil, the process probably going on as demands for uranium did not yet reduce considerably on a global scale after Fukushima. Figure 6 shows a map indicating the 10 most prolific uranium-mining countries (by 2008).

Let us turn to the third issue associated with nuclear energy: radioactive wastes, which are produced by all nuclear fission, then located in "used" (irradiated) fuel rods, neutron impact on non-fissionable ^{238}U, and on construction materials from Zircaloy to concrete, and their first decay products, sometimes dissolved in activated wastewaters including dissolution residues (nitric acid) in nuclear fuel reprocessing (now banned in both the United States and Germany), must be disposed of and stored until radioactive towards stable products is essentially complete. A fuel rod in an NPP is a metal (Zr mainly) tube filled with cylindrical sintered pellets of UO2 or some mixture of UO2 and PuO2; metal alloys or other compounds (carbide UC2, hydride UH3) are used in minireactors only. After a while, a fuel rod is "spent," reducing the ^{235}U content from the original 3.5% to some 1.3% while 1–1.5% of plutonium—most of it fissionable also—were produced from ^{238}U in situ. Although use could be continued by further pulling out the control rods that absorb excess neutrons, it would be no longer safe to work with such rods. Thus, they are replaced, usually a third of them every year or so. The "spent" rods are stored for several decades, usually next to "their" reactor to get rid of the highly active short-lived isotopes of high yields, e.g., $^{141;144}$Ce and $^{103;106}$Ru and ^{91}Y, then either processed or put to a final depository (if there is one, by now only in Finland).

The case is not at all settled; there are no operating final deposit sites but only such ones meant to contain (withhold) the waste for a few decades. Obviously, radioactive waste solutions were discarded into the open sea or rivers both after accidents and routinely during nuclear reprocessing [Windscale/Sellafield (U.K.) and La Hague (France), Mayak near Chelyabinsk (Russian Federation)], not to mention simply dumping entire discarded reactors from nuclear-powered submarines into the sea, with or without the rest of the vessels … What can be done responsibly with nuclear waste instead?

FIGURE 6 The 10 states (dark gray) that produced the largest amounts of uranium ores (in 2008). Besides the spatially largest states outside of South America and except for China and India, most are located in Western Africa, including Gabon (Central Africa) whose ultra-high-grade (>60% U) deposits at Oklo and neighboring sites gave rise to natural reactors some 2 billion years ago (map from Wikipedia.de).

The periods of time over which radionuclides from fission reactors must be stored and safeguarded are outright unimaginable and far beyond any other time frame of political or economic planning: there are nuclides with half-lives of several million years (^{94}Nb, ^{129}I, ^{237}Np); thus, they will create a danger for 10^7 year or the like. With ^{237}Np (tons of which currently exist) and ^{243}Am (americium, tens of kilograms of which exist), there is an additional problem: during very long storage, enriched samples of either nuclide will spontaneously turn into fissionable materials (^{233}U and ^{239}Pu, respectively), causing heat and neutron release to increase after millennia.

Here are some examples:

Uranium	^{238}U	4.468 billion years
Uranium	^{235}U	704 million years
Iodine	^{129}I	15 million years
Neptunium	^{237}Np	2.144 million years
Plutonium	^{239}Pu	24,110 years

While actinides [from the third, protactinium (Pa, $Z = 91$) onwards] generally are extremely chemotoxic, this does only matter for long-lived nuclides like the natural uranium isotopes, ^{237}Np, $^{242;244}$Pu, or $^{247;248}$Cm. In the other cases, say at $T_{1/2} \leq 10^5$ years for α emitters with negligible spontaneous fission shares, radiotoxicity, i.e., the effects caused by particles of ionizing radiation emitted during decay, prevails even against this chemotoxicity. Among these nuclides, $^{239;240}$Pu (which are produced together in a reactor given there is substantial irradiation of a uranium sample) are peculiar in their radiotoxicity but are rather long lived as they do reside in the body at very sensitive points: the marrow and mucosa around or in bones and liver, while radioactive ("hot") particles may be inhaled and reside in the lung, exposing it to radiation. Note that some 6 tons (!) of ^{239}Pu that escaped fission during nuclear bomb tests were spread up into the stratosphere as an aerosol that still keeps on being deposited ("fallout") apart from some other transuranic nuclides: from analyses of fallout composition, 1100 kg of ^{240}Pu and substantial amounts of $^{241;243}$Am (produced in nuclear weapons containing ^{241}Pu or ^{242m}Am as fissionable nuclides, which have much smaller critical masses with fast neutrons than all $^{233;235}$U and ^{239}Pu) are determined. Estimated amounts of the latter are 25 kg ^{241}Pu, 70 kg of its decay daughter ^{241}Am, and 2.5 kg ^{238}Pu [most of it from breakup of a RIG (radioisotope thermoelectric generator) during re-entry in a 1960s space probe mission; data calculated from Breban et al.[18] Besides this, there are natural contributions of plutonium in the biosphere: some 5 kg of ^{244}Pu is still left over from the origins of the solar system owing to its 83-milion-year half-life and trace amounts (<1 g) of ^{238}Pu from the double-β-decay branch of ^{238}U. Most fallout radioactivity is still due to ^{241}Pu ($T_{1/2} = 14$ years), but this is less destructive in radiotoxicological terms because it does undergo β-decay, rather than α-decay, followed by each comparable activities of $^{239;240}$Pu and ^{241}Am ($T_{1/2} = 433$ years). This compromises sensitive tissues.

Cancer rates, e.g., bone skin sarcomas and their metastases, will thus increase after a Super-GAU (German: *größter anzunehmender Unfall* means worst case, meltdown) if plutonium is released, like in the 1951 Mayak accident (Russian Federation) or after a Pu-based nuclear fission bomb was destroyed 1) in an airplane crash at Thule (Greenland) in 1968 or 2) by mis-ignition ("fizzle") in the *Hardtack Quince* test (explosion yield but 0.02 kt TNT) at Runit Island, Enewetak Atoll (now some part of Republic of Marshall Islands) in 1958. Both latter events spread several kilograms each of ^{239}Pu over a very restricted area, which made effectively cleaning it impossible. The doubtful results of (2 out of 5) nuclear bomb tests in Pakistan (1998) and the first one in North Korea (2006)—neither yet precluding burst of Pu and fission products to the surface though these were underground test "fizzles"—must be added to this list. Runit Island (Pacific Ocean) is now used as a dumpsite for highly contaminated materials from nearby test craters, the hole capped by a concrete dome of some 100 m diameter. This is the gravest possible kind of catastrophe from an ecological and ecotoxicological point of view, going beyond even what happened at Fukushima or Chernobyl. The environment, including groundwater, is so polluted that access is strongly impeded for centuries or even longer.

As with Chernobyl and the Bikini Atoll test site, animals and plants apparently adapted to the harsh radiological conditions there. Starting soon after the Chernobyl accident, researchers noted that diverse animals (including wolves, foxes, lynx, moose, hares, and many kinds of birds)—and some humans—returned to the off-limits area around Chernobyl, including the so-called Red Forest and the decontamination lake. Among these, there are species that try to avoid man, prompting them to invade an area where there are (almost) no humans left behind. In addition, biodiversity is lower than in comparable areas, brain sizes tend to be reduced in both mammals and birds, and there are other malformations, tumors, and evidence of genetic alterations.[19] Likewise, there are lots of aquatic life in Bikini Atoll [except for the crater basin of the largest ever U.S. test, *Castle Bravo* (1954, some 15 MT)], but once again, there is reduced biodiversity.

At least since 9/11 some 10 years ago, but actually ever since the first threat to attack a NPP by a flying passenger airplane abducted before (in 1972 over Oak Ridge, Tennessee) citizens and public authorities of countries which make use of nuclear fission power: while older NPPs—all over the world—must be considered to be improperly protected against even the impact of a smaller airliner there is virtually none anywhere to withstand the perpendicular impact of a fighter plane. The jet engine compressor axle in a military plane is about 3–3.5 m long, made of dense metals such as niobium alloys, then hitting a concrete ($\rho \approx 2.8$ g/cm^3) shell at about the speed of sound. This will suffice to penetrate some 10 m (!) of concrete, as compared to an actual containment thickness of less than 2 m. In addition, global warming and eutrophication combine to increase the likelihood that river or ocean water cooling can no longer be taken for granted in summer at least: in 2003, rivers became so warm all over Central Europe (probably related to global warming) that NPPs from France to Lithuania had to be shut down for many weeks. In the same summer, cooling water entries at the Russian Sosnovy Bor plant were blocked by algae excessively growing in the adjacent Bight of Helsinki. Either problem is likely to occur more often in the future.

Transmutation[20,21] is discussed as a means of faster disposal of fissiogenic radionuclides, exposing the nuclide mixture obtained by fuel reprocessing to a high-energy proton beam. Fission products that are distinguished by a considerable excess of neutrons in their nuclei hence are brought closer to stability while actinides will either undergo fission directly or produce at least nuclides of much shorter lifetimes. It is completely unsettled and doubtful whether this can be done on a scale of tons of material.

Rethinking in the Way for Ecological Economics

The previous entry was mainly concerned with the problems of conventional and nuclear energy sources from an economic, ecological, and political point of view, which will challenge us more and more in the near future. There are several quite different—and mutually independent— reasons to switch to alternative,[4,22–251] that is, regenerative, resources of energy, including resources of fossil fuels becoming scarce(r), constraining greenhouse gas emissions, and striving for geopolitical risk management (spreading suppliers among most diverse regions and political systems, if you are not in a position to produce the materials related to your energy demands domestically). Although there are numerous incentives, this transformation will take several decades not only on a global scale but also in national dimensions, and it depends on both economic interest positions and technical innovations. While wind energy is, at present, technically "ripe," the size of rotors being no longer limited by mechanical problems with generators, etc., exposed to vibrations and bending along a horizontal axis, but by the size of available cranes required to erect them (maximum: some 200 m rotor diameter, 7–9 MW peak power), and photovoltaic devices that reasonably benefit from technologies of semiconductor processing—which is now advanced much beyond anything that would ever be required in solar energy conversion—becoming a large-scale-business as well [the combined area of highly integrated chips that make it to the market in computers and numerous other devices (some 70 of them alone in a common car) annually is in the square kilometer region also], extracting energy from the oceans actually still takes an engineer's ingenuity to make it reasonably work. For solar energy, the "surviving" technical innovation challenges are restricted to thin-layer and organic semiconductor systems and to conversion/storage in a convenient chemical storage form, like methanol.

The following part of this entry will deal with both those energy forms already present on the global market for energy conversion devices, plus a discussion of how energy can be harvested from the open sea, keeping in mind which will be the challenges for Germany or Italy who both decided either to abandon (D) the use of nuclear energy until 2022 or not to restart it (I). This prompts the question whether redesigning the energy supply of a medium-sized highly industrialized country, including consumers which are really demanding, within some 10 years, merits further consideration which is added, too.

Globally View of Renewable Energy

Available energy resources are "renewable" when they are sustainable and environmentally benign (which need not coincide) if

- They renew themselves in the short term by itself (e.g., biomass).
- Their use does not contribute to the depletion of the source (e.g., wind, sun, water).
- They do not have an impact on the environment.

Sustainability in that sense means a triad related to ecology, economy, and social affairs. Figure 7 gives an overview of different energy sources like sun, wind, water, geothermal energy, and biomass for the establishment of technical supported renewable energies.[4,22,24,26,27]

In 2010, the Global Status Report on Renewable Energies[28] was published, parts of which are now to be quoted. In its preface, El Ashry (UN Foundation) already noted more than a hundred states to have political agendas or strategies in 2010 in favor of spreading and widening the use of renewable energy sources, about a doubling from just 55 five years before. In 2009, the largest increases were observed with wind power and photovoltaics, investing some $150 billion into extending capacities and producing and implementing renewable energies vs. only $30 billion in 2004. Except sometimes for advancement of nuclear energy, more money is allocated into capacities and growth of renewable energy sources than into fossil types. By reaching substantial shares of energy input (particularly in some less-populated countries like Denmark, Latvia, or Mongolia), renewable energies did have a turning point, which renders them significant, as they also address the problems of climate change. As implied before, acceptance and broad

FIGURE 7 Renewable energy sources: onshore and offshore wind power, biomass, solar power, geothermal, hydropower. (a) Onshore wind turbines located outside of Palm Springs, California (photograph: Wikipedia, Tim1337); (b) sugar cane is a major supplier of biomass, which is used either as food or as energy supplier (photograph: Wikipedia, Culture sugar cane, Avaré, Sao Paulo. José Reynaldo da Fonseca, 2006); (c) newly constructed offshore windmills on the Thornton Bank, 28 km offshore, on the Belgian part of the North Sea (photograph: Wikipedia, Hans Hillewaert, 2008); (d) photovoltaic array near Freiberg (Germany) (photograph: Wikipedia, I, Eclipse.sx); (e) Krafla Geothermal Station (2006), North Iceland (photograph: Wikipedia, Mike Schiraldi); (f) Grand Coulee Dam is a hydroelectric gravity dam on the Columbia River in the U.S. state of Washington. It is the largest electric-power-producing facility in the United States (photograph: Wikipedia, (http://users.owt.com/chubbard/gcdam/html/photos/exteriors.html) U.S. Bureau of Reclamation). Larger dams are located in Russia, Brazil, and China.

application of renewables are not (no longer) restricted to highly developed industrialized countries but extend to developing nations now displaying more than half of implemented and operating renewable energy supply systems. However, it remains to be seen as to how far this is actually in favor of domestic development, better situations especially in rural areas, or larger autonomy towards globalized oil and coal markets or is another blueprint for export of goods to the North: growing sugar cane and oil palms for biofuel exports in Brazil or Indonesia threatens local primary forests if not even the food supply there. The Desertec blueprint (http://www.desertec.org) for producing lots of hydrogen from solar sources in Northern Africa revives existing supplier roles with countries like Algeria once again.

Figure 8 gives a more precise idea of the present relevance of renewables, their share being some 19% of total in 2008. Share of final energy means: at the point of end use, as electricity, heat, and directly used fuels. This method counts all forms of electricity equally, regardless of origin. The European Commission adopted this method in 2007 when setting the EU target of a 20% renewables share of energy by 2020. Thus, it could be called the "EC method."[29] This includes all traditional sources of biomass energy carriers (biogas, ethanol, wood, etc.), large hydropower plants, and the "novel" kinds of renewables such as small-scale hydropower plants, modern biomass sources, wind and solar energy, geothermics, and biofuels. To be exact, it should be noted that some of the "modern" ones actually are rather old, from small-scale water mills also delivering electricity up to biofuels [Rudolf Diesel demonstrated his engine to be run with peanut oil fuel already at the 1900 World Fair (EXPO) at Paris].

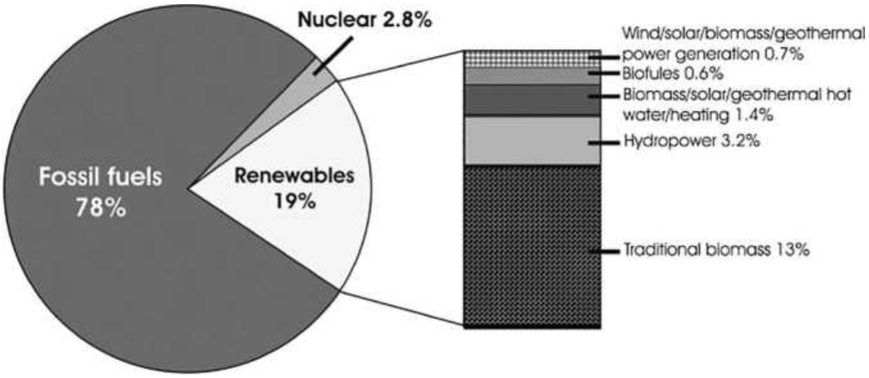

FIGURE 8 Global final energy consumption of conventional and renewable energy in 2008 after REN 21 (2010). Also consider footnote 327 of REN 21 (2010).[28]

Most of these 19% (13%, i.e., relatively 70% among the renewables) rests with traditional biomass used for cooking and heating. This, however, is subject to some change and even cutbacks, especially because there is virtually no possible firing wood (not even small branches) left over around (and this is to say, up to 50–70 km from the outer edge of “informal suburban settlements”!) megacities[30] all over developing and threshold countries, causing to replace with more advanced (e.g., solar cooking devices) or at least more efficiently use these resources. Hydropower represents 3.2% (17% out of renewables) and is growing modestly but from an already advanced level. The other renewable energies contribute 2.7% (relative share: some 14%) and undergo very fast growth in both industrialized and certain developing countries.

In developing countries, renewable energies have a particular role in national support and corresponding policies as well, contributing to their present share of renewable energy capacities of more than 50% [but compare this to both their share of global population, which, including the BRICS (Brazil, Russia, India, China) states except Russia, is >80%, on one hand, and their share of global energy consumption, on the other hand]. China now leads in several indicators of market growth. Among suppliers of wind energy, India now ranks No. 5 globally, owing to its substantial expansion of biogas and photovoltaic capacities especially in the countryside (India also plans to install another 15 NPPs owing to its being populated as densely as, e.g., Belgium or the Netherlands in total and citing growing industrial energy demands). Brazil is now a key supplier of ethanol from sugar cane, adding to other kinds of biomass and wind power in its renewable energy portfolio. Concerning the complete array of renewable energy sources, Argentina, Costa Rica, Egypt, Indonesia, Kenya, Tanzania, Thailand, Tunisia, Uruguay, and others boast high growth rates, often even surpassing their sometimes impressive gross economic growth rates.

In a nutshell, the geographical distribution and political significance of renewable energies have considerably been altered in favor of near-global distribution and application. As compared to quite a few countries in the 1990s, there are at least 82 countries presently operating wind power plants. As for manufacturing these devices, production was relocated from Europe to Asia, with the largest shares in China, India, and South Korea, which additionally become more devoted to renewable energy applications. China not only is the “production yard” of the world for conventional items including consumer electronics but also made, in 2009, 40% of PV devices (from solar cells to complete panels with control and DC/AC converter units), 30% of the world’s wind power plants, and even 77% of solar-driven water-heating collectors. All over Latin America, countries like Argentina, Brazil, Colombia, Ecuador, and Peru increase their production, including exports of biofuels, additionally investing in other kinds and technologies of renewable energies. More than 20 countries in the “Solar Belt” of the Middle, Northern, and sub-Saharan Africa are involved in renewable energy markets.

Large economic gains and considerable further technological changes are to be achieved from this state of affairs and developments beyond the principal players of the highly developed world such as the European Union (EU), the United States, Australia, Canada, or Japan. With renewable energies gaining a truly global footage and application area, there is internationally growing confidence into renewable energies being less susceptible towards perturbations by either political turnovers or market changes such as financial crises than "classical" energy carriers (which readily, like other raw materials, become an item of speculation undergoing tremendous price level oscillations in such conditions).

Another impetus to renewable energy development—as to every other kind of large-scale technical innovation—is its inherent potential to create entire new industries (or at least create vast uncharted fields of opportunities for existing technical branches) and thus millions of new workplaces. In photovoltaics, much larger amounts of semiconductor-grade to medium-purity silicon, SiH_x, and GaAs are used than in integrated (chip) solid-state microelectronics (e.g., GaAs chips are applied in cellphones), whereas technologies required to obtain control of a large rotating propeller in changing conditions, originally developed for helicopters, now increase reliability and output of wind power systems. Creating new workplaces is, by the way, the positive, friendly side of the "dual-use" problem: both engineers and blue-collar technicians who were mainly concerned with development and production of arms systems had to strive to save and "humanize" their workplaces after the Cold War came to an unanticipatedly happy end around 1990; these highly skilled metal workers and engineers at Kiel harbor (Germany) then started to focus on wind power plants (with rotor techniques borrowed from military helicopters) and integrated current-heat support systems (using diesel engines originally designed for tank propulsion to consume and convert plant and waste oils to produce some 1 MW each of electricity and heat). Hence, although not creating environmentally benign branches from scratch, this "Arbeitskreis für Alternative Produktion" (workgroup planning alternative production) and similar endeavors in U.S., British, Australian, and French arms enterprises effectively increased the array of possible customers much beyond the state (i.e., department of defense and sometimes police forces) and in the same turn reduced political-military dependences even though most of the respective employers did not really like the idea of employees considering what should (better) be produced on their own.

This is part of the ethical issues and bonuses associated with alternative energy production: there is a considerable bonus in terms of both workplace safety and numbers of workers required to install and run 1 GWel of alternative energies as compared to fossil and nuclear types; besides, there are fewer risks associated with making PV devices than with coal or uranium mining for the miners themselves, counting and comparing, for example, mine accidents and cancer fatalities per MWy. In 2009, there were an estimated three million workforce directly related and devoted to renewable energies, about half of them concerned with biofuels, and many more than this in branches indirectly connected with renewables (Table 1).

What are the recent performances of renewable energies as of 2009 (Figure 9, source: REN 21[28])? For the second consecutive year, in 2009, in both the United States and the EU, the newly installed renewable energy capacities exceeded those of combined conventional fossil energies and nuclear power. Renewables accounted for 60% of newly installed power capacity in Europe in 2009, and nearly 20% of annual power production.

Christopher Flavin (Worldwatch Institute) pointed out in his entry "Renewable Energy at the Tipping Point" within the REN 21[28] report that China's recent leader role in producing wind rotors and photovoltaic devices just gives proof of the political prerogatives in favor of renewable energy exploitation, including both laws and funding, to be successful. Although there were initial problems, the important reforms in China starting with the national legislation on renewable energies of 2005 caused fast and efficient development there. China since then increased its efforts to become a leading innovative power as well as key producer of renewable energy technologies.

Table 2 shows the five countries that are the most important players concerning renewable energies, as of 2009.

TABLE 1 Jobs Worldwide from Renewable Energy (REN 21[28] with Added Information from the United Nations Environment Programme Report 2010)

Industry	Estimated Jobs Worldwide	Selected National Estimates
Biofuels	>1,500,000	Brazil, 730,000 for sugar cane and ethanol production
Wind power	>500,000	Germany, 100,000; United States, 85,000; Spain, 42,000; Denmark, 22,000; India, 10,000
Solar hot water	~300,000	China, 250,000
Solar PV	~300,000	Germany, 70,000; Spain, 26,000; United States, 7,000
Biomass power	–	Germany, 110,000; Unites States, 66,000; Spain, 5,000
Hydropower	–	Europe, 20,000; United States, 8,000; Spain, 7,000
Geothermal	–	Germany, 9,000; United States, 9,000
Solar thermal power	~2,000	Spain, 1,000; United States, 1,000
Total	>3,000,000	

Note: Further information about the evaluation of the data are reported in REN 21,[28] p. 75, note 226. The table is incomplete.

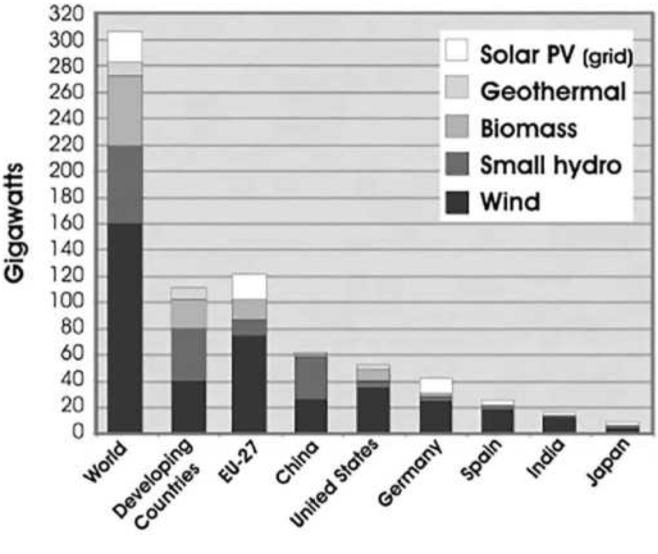

FIGURE 9 Renewable power capacities in 2009 without inclusion of large-scale hydropower: Developing World, European Union, and Top Six Countries (REN 21 2010).[28]
Note: Only includes small hydropower <10MW.

Owing to the well-known variabilities of renewable energy output, which are due to weather, time of day, and longer-period (tidal power plants) periodic or aperiodic changes, there are much larger theoretical (peak power output) renewable energy technical potentials than average yields. The present (as of end of 2009) capacity of a global 1.23 TW (1230 GW) that now constitutes just more than 25% of total electric generating capacity worldwide thus is considerably larger than the actual share/contribution of produced electricity.

What about Ocean-Related Energy [Waves, Ocean Currents, Tidal Power Plants, Osmotic Energy Conversion, Ocean Thermal Energy Conversion (OTEC)]?

The power associated with flowing water is impressive and has motivated people to use it many centuries ago in mills located at running creeks and rivers. It was an obvious idea to extend this technique to tapping ocean currents, like the Gulf current, as well as tidal water flows[31] that can reach speeds much above those seen in most rivers [e.g., some 6 m/sec (11 knots/hr) along the Welsh coast of the Atlantic

TABLE 2 The Five Countries That Are the Most Important Players concerning Renewable Energies [as of 2009[28]]

	#1	#2	#3	#4	#5
Annual amounts in 2009					
New capacity investment	Germany	China	United States	Italy	Spain
Wind power added	China	United States	Spain	Germany	India
Solar PV added (grid connected)	Germany	Italy	Japan	United States	Czech Republic
Ethanol production	United States	Brazil	China	Canada	France
Biodiesel production	France/Germany		United States	Brazil	Argentina
Existing capacity as of end of 2009					
Renewables' power capacity (including only small hydro)	China	United States	Germany	Spain	India
Renewables' power capacity (including all hydro)	China	United States	Canada	Brazil	Japan
Wind power	United States	China	Germany	Spain	India
Biomass power	United States	Brazil	Germany	China	Sweden
Geothermal power	United States	Philippines	Indonesia	Mexico	Italy
Solar PV (grid connected)	Germany	Spain	Japan	United States	Italy

Ocean (rather than perpendicular to it)], providing concentrated energy as flow speeds are close to those in air (wind), with water being 800 times as dense; thus, a rotor of equal diameter exposed to a water flow of equal speed delivers 800 times as much power [or the same power at $\sqrt[3]{(1/800)}$. this speed, i.e., some 10.8%]. Basins that are filled with water at maximum level differences of a few meters are commonplace in electric storage (in German: Pumpspeicherwerk), with the same being offered by tidal changes of ocean and estuary water levels [the largest tides are seen in river mounds, e.g., River Severn (Wales) or River Rance (France, Normandy) at some 10 m], and not just after pumping water into them by electrical power obtained otherwise, but for free twice a day (actually even 4 times daily using differences of either levels).

Concerning periodical filling and uncharging of storage basins connected to flowing water turbines, there is but one large power plant (240 MW_{el}) in the world still connected to the French grid back in 1967. It is located at La Rance in the mounding of River Rance, next to the famous island Mont St. Michel (Figure 10).

FIGURE 10 Aerial photograph of the world's biggest tidal power station. The Rance Tidal Power Station is located at La Rance (NW France) in the mounding of River Rance, next to the famous island Mont St. Michel.
Source: Photograph: Wikipedia.

Here, the tidal water level differences are far larger than the global average of about 3.5 m (isolated ocean basins, such as the Black Sea and the Baltic Sea, and even the Mediterranean Sea, tend to lack any significant tides, e.g., average tides in the Baltic Sea are some 20 cm); the minimum tidal heights required for a meaningful operation of a tidal power plant are estimated to be some 5 m.[32] Obviously, the gain of energy from a basin of given size interacting with the tide flows increases by the square of tidal water level changes: the amount of water flowing in and out is proportional to tidal height and so is the energy gain from a given mass of water flowing through the turbines. Now being operated for more than 40 years (it was connected to the French grid in 1967), effects from this plant and its overall performance can be well evaluated:

- Local tidal height decreased from some 14 m (!) to <8 m due to deposition and relocation of sediments.
- Corrosion is an issue, requiring both to avoid combination of different alloys in the construction to exclude galvanic effects in seawater, and active electrochemical protection measures.
- There were some ecological side effects concerning distributions of limnetic and marine fishes in and on either side of the basin, with the power plant shifting the limits of marine and limnetic populations of fishes somewhat downstream into the estuary. The turbines rotate so slowly that both fishes and squids can pass through them without being hurt, much unlike classical running-water power plants.
- Actual average output to the grid is some 540 GWh/yr, which is an average of 62 MW, about 25% of nominal power production.

Nevertheless, the La Rance plant remained unique, being the only large-scale plant existing, although sites having even higher tidal heights such as Bay of Fundy (Canada, up to 19 m) were used for yet smaller installations.

Waves[33] may be destructive, but their energy can also be technically exploited, e.g., with transducers based on either bending of some part of the device [hydraulically or by piezoelectric (piezoelectricity means electricity resulting from applying pressure, squeezing) devices]. Other devices employ either systems operating on periodically compressing and expanding air by by-passing volumes in a volume (some hollow metal or concrete bunker) under which the waves pass through and pass this air over a rotating turbine or using the alternating flow directions of water or directly converting the water level oscillation into electricity by electromagnetic induction.

It is estimated that one can gain some 15 kW_{el} (130,000 kWh/yr) from a single meter of coastline around the North Sea, which is comparable to the gain earned by covering about 1 km of land behind this shoreline by photovoltaics in the same climate (this sounds stunning if not paradoxical but consider the width of the seas where the waves could gain energy before from wind rather efficiently converting solar energy). So far, wave energy converters were constructed at Western ocean coasts in the Northern Hemisphere, including SW Norway (Toftestallen, near Bergen), the northernmost Scotch coast, open to the Atlantic Ocean and Oregon. A most straightforward way to convert mechanical movements into electricity, besides piezoelectric techniques, is by magnetic induction. A buoy is towed to the seafloor, with a magnetic shaft tethered to it, while the floating part of the buoy contains some induction coil that hence moves up and down around the shaft within the magnetic field produced by the latter, directly producing an alternating current even though its voltage and frequency still have to be adjusted.

Of course, such interferences with natural water flows may alter and affect the ecological situation in estuaries especially; in the best cases, using both tidal and wave energy reduces coastal erosion.

Less obvious sources of energy associated with ocean and shoreline,[34] respectively, include the temperature difference between surface waters and the deep sea (particularly in the tropics, except for the Red Sea and its annexes like the Gulf of Aqaba/Eilat), some 25–30°C there and the gradient in salt content and, thus, the osmotic pressure difference of some 26 bar between the ocean and freshwater from rivers and creeks running into it (the latter being identical to have this water falling through a Pelton turbine from about 260 m of height).

At a surface temperature of some 300–305°K in tropical waters, the Carnot (most efficient heat engine) maximum efficiency would be about 8%–10%. Usually, in OTEC plants, ammonia is used as a heat-transferring working medium; actual efficiencies are about 3% due to long hoses required to exchange hot and cold waters. Rather than steep cliffs selected earlier, OTEC plants are now located on either ships or floating constructions much like those employed in crude oil production. Given the problems associated with coral bleaching due to surface waters exceeding 30°C, some larger use of the OTEC technology should even provide a real ecological bonus while mixing nutrients between deep and surface waters might cause problems of eutrophication.

The osmotic pressure of some solution is about the pressure that would be exerted if the same concentration of dissolved entities (i.e., ions from, say, $MgCl_2$ solutions, to be counted individually, hence producing 3 times the osmotic pressure in water or acetonitrile than if dissolved in non-ionizing solvent like a long-chain alcohol); 1 M/kg of solvent (here water) hence is equivalent to a gas compressed to 1 M/L, which is tantamount to a pressure of some 24 bar at 20°C. A unimolar $MgCl_2$ solution in water would thus produce an osmotic pressure of more than 70 bar, while the corresponding value for seawater—which is 0.55 M NaCl solution to a first approximation—is about 26 bar [the actual value for Norway is a little smaller because of 1) the water being colder and 2) some dilution by the very freshwater discharges into the Fjord site used, which is rather remote from the open ocean].

Before dreaming of what the latter source could deliver when passing but substantial parts of the freshwater flows of giant rivers like River Amazon, Mississippi, Yangtzekiang (China's largest river), Kongo, or the Siberian rivers like Yenisei through such devices, be reminded of some problems that are not yet solved. The only demonstration plant existing so far is located at a creek mounding into a fjord in Norway, producing some 3–4 kW of electric power since November 2009. There are three quite different kinds of converting osmotic potentials into electricity:

- Using a water-permeable yet pressure-proof membrane (this is done in Norway). The saltwater content of this closed membrane volume is going to absorb pure water from the freshwater passed along outside (i.e., in the mounding of the river). Due to the osmotic pressure, the water level inside will increase considerably, allowing to pass it over a falling-water turbine and produce electricity eventually. This process is a somewhat periodical one: as the saltwater gets diluted during the process, you need to discard it into the ocean sooner or later and refill the chamber with "pure" (3.5% salt) ocean water. By now, electric power output is about $1\,W/m^2$ of membrane interface area; the aim is to achieve $5\,W/m^2$ soon.
- Electrochemical settings using the diffusion potential: concentration differences leveled off by diffusion create electric potentials even though no redox reactions are involved in charge transfer. Likewise, second-type electrochemical cells draw upon concentration potentials: an electrode made of combined silver and AgCl (both solid and mixed among each other) will adjust its potential according to the concentration level of chloride ions. This can be used both in analytical chemistry and for producing electric currents from chloride solutions that differ in concentration (freshwater typical values being 1–2 mM/L as opposed to 0.55 M/L in seawater, giving an open-cell voltage of 150–170 mV).
- Theoretically speaking, the zeta (electrokinetic) potential could also be used in osmotic energy conversion: by osmotic pressure differences forcing water through some membrane, or a column filled with a packed solid, it will produce an electrical potential difference between either side of the interface. This potential is due to selective adsorption of cations or anions onto a typically charged particle, charging being caused by oxide/ hydroxide particles (say, wet alumina) behaving as an acid (adsorbing hydroxide) or base (adsorbing protons) depending on local pH, co-sorbents, and material (point of zero zeta potential). Then, the other, non-adsorbed ions will be passed through along the solvent, and a potential of typically half a V forms. The effect is reversible (electrokinetic water pumping).

The problems are with membrane stability and, more generally, also affecting electrochemical systems, clogging of the interfaces by biomass (mainly phytoplankton) or even mineral concretions. The Norwegian success terminated a history of decades of failed experiments on osmotic power production.

Things became a little different—and better, rather more advanced—because of OTEC. The first plant ever of this kind was constructed by French Georges Claude (1870–1960) at the coast of Cuba back in the late 19th century. OTEC devices are simple thermal power plants using rather small T differences, more like a steam engine compared to turbines, coal-fired plants, or internal combustion engines.

The global distribution of chances for this way of harvesting is solar energy indirectly (having hot water from insolation in the tropics while cooling is provided by Arctic or Antarctic undercurrents at some 1000–2000 m of depth).

Eventually, there can be integrated offshore energy parks making use of almost all the energy sources discussed above combined on, or beneath, a tethered floating island.

Geothermal Energy

For many decades, *geothermal* energy[35,36] has been well established for heating purposes in countries like Iceland, New Zealand, and several developing countries in Central America such as El Salvador. Although electrical uses, with geothermal (fumarole) vapors directly run through a steam turbine, were first tried in Italy more than a century ago (at Larderello in 1904, delivering about 200 W), corrosion and clogging problems remain severe until this day. The obvious reason is the "contamination" of fumaroles with both clogging agents like boric acid and hydrolyzable volatile metal chlorides, besides the large shares of corrosive gaseous acid precursors like SO_2, HCl, and HF. Thus, one has to create a primary heat exchange cycle directly exposed to these corrosive items, as well as a secondary one linked to the heat/mechanical/electrical conversion systems, much like in NPPs and mainly for the same reasons (if not even worse here), and worse, due to the rather small heat difference, this decreases total efficiency of conversion. When obtaining the vapor from underground wells drilled several kilometers into the Earth's crust rather than operating close to active volcanoes, clogging of drilling holes or rock fractures required to circulate some operating medium also remains critical. Hence, it is safe to predict that geothermics will remain more concerned with heating (houses, swimming pools, etc.,) than with electricity production in the near future as well.

Wind Power

Wind power now is an established source of energy, with average production costs per energy unit (e.g., cent per kilowatt-hour) coming close to those by conventional (fossil) energy sources.[37–40] In certain countries, the share of wind power in total electricity production exceeds 20% (Denmark, Mongolia), and there is a broad international consensus that state subsidies are no longer required nor given to enhance the rate of implementation. Rather, as with all kinds of renewable energies that are subject to considerable periodic (sunlight) or non-periodic changes of supply, the optimum strategy of storage becomes imminent. Hence, electrolysis of water (and possibly secondary production of methane or methanol) by "excess" wind power (excesses being produced by mismatches with the grid also), storage of H_2 or CH_3OH, and use of the latter energy carriers in either vehicles or stationary fuel cells connected to the electric grid are gaining importance.

The size of individual plants is limited by the necessity to erect them and thereby place 100-ton items more than 100 m above the ground within millimeter precision, that is, by size of the available cranes. The largest wind power systems thus now have 200 m rotor diameter and deliver some 8 MW while arrays of them ("wind parks") can produce outputs in the size of classical power plants and NPPs both on- and offshore. However, in either case, interactions with local fauna may become significant.

Solar

Solar energy is the key source of almost all the biological and meteorological processes operating on Earth.[41,42] Semiconductor solid-state devices allow for a remarkably efficient exploitation of this source, with an additional role for thermal processes that latter rely on focusing and, thus, on non-scattered sunlight, that is, on clear skies. These thermal processes include production of fuels by cycles involving zinc or cerium oxides as well as metallurgical transformations.

Solar thermal power plants, augmented by natural gas or biogas combustion during night and other dark times, are now realized in a scale of hundreds of megawatts, while photovoltaics in 2011 first yielded an all-year average of more than 2000 MW (2 GW) electrical output in Germany (some 3% of total current). The price breakdown in production and processing of semiconductors (which need not be that pure or advanced than with electronic microdevices) supports the "boom" furthermore, regardless of fast cuts in state subsidies paid for supplying PV current to the public grid in all the EU member countries now.

When considering very large plants such as in the Desertec initiative, the increase of radiation absorption however becomes likely to influence the performance of solar parks by itself: large volumes of heated air will rise right above the plants, causing an increased dust advection to the panels as well as clouds to form on their top (both sailplane pilots and birds of prey look for typical kinds of clouds to spot regions of upwind over hotter surface areas!). High-yield photovoltaics by thin-layer solar cells [a few micrometers' total thickness, unlike 0.3–0.5 mm with polycrystalline SiH_x ("blue silicon")] demands rare (e.g., In) and/or highly toxic (Cd, As, Se, Te) elements, causing problems in all mining, processing them and eventually abandoning old PV devices when their performance sharply decreases after several decades.

Biomass

Biomass can be used in a variety of ways as a source of energy, with combustion of wood and vegetable or animal oils for both heating and illumination purposes dating back as far as the Stone Age.[43,44] More recently, plant oils were introduced into internal combustion engines (first with peanut oil; diesel, 1900), while other engines were fed with either wood distillates (containing mainly CH_3OH and acetone besides H_2 and CO) or ethanol produced by microbial activity, much after steam engines had been powered by either wood, wood-processing residues (e.g., sawdust), or peat to replace hard coal (which is biogenic in itself, of course).

Conversion methods of brown coal—lignite—by hydrogenation, gasification (steam gas process), and liquefaction can also be readily applied to biomass, including less obvious representatives of biomass such as sewage sludge (chiefly containing heterotrophic bacteria), and then mostly even take less vigorous conditions in terms of all temperature, H_2 pressure (3–10 bar rather than hundreds of bars), and needed catalysts. Finally, motivated by the fact that biomasses, especially scrap biomasses, became an item of fuel production (and waste treatment/compaction) once again, the very former coal liquefaction plants in, e.g., South Africa are now used for this purpose. Regionally, in Germany, success and economic performance were poorer, however.

Using scrap or digestible waste fractions relieves an ethical problem from the competition among food/fodder and "energy plants" for the same agrarian areas, but even after avoiding this, one must bear in mind the poor area productivity of photosynthesis—the only economically viable source of biomass energy carriers in a large scale—which typically is 0.5% or a few kilograms of reduced $C/m^{2}*a$, i.e., far short of photovoltaics. While there will be a role in waste processing, a large-scale use of biomass for energy purposes such as in Brazil poses a lot of difficult problems, including ecological ones associated with monocultures, possible fertilization/eutrophication, and high water requirements.

Renewable Energy in Germany and the Planned Nuclear Exit

Concerning its gross domestic product (GDP), Germany is the largest national economy in Europe and No. 4 in the world. In 2009, it was second in export and third in import values. Like with the GDP, Germany ranks No. 4 in energy consumption [measured in fossil fuel (hard coal) mass equivalents (BTU: British thermal unit)] but just No. 21 among the energy producers in the world).[46] The intention of the Federal Government of Germany in fulfilment of Kyoto Protocol obligations is a reduction of greenhouse gas production of about 40% by 2020 and up to about 80%–95% reduction by 2050. Quite recently, the greenhouse gas issue and the risk of NPPs (disaster of Fukushima in 2011) were aggravated by the decision to abandon nuclear energy use in Germany in the early 2020s. Figure 11 shows the fuel mix in 2010 and the aimed fuel mix in 2050 in Germany, which mainly will be supplied by wind and solar power.

By steadily replacing fossil energy sources with renewables, the share of the latter will increase, even allowing for a slight increase in energy consumption (which, in Germany, like most other highly developed countries, is rather constant for decades now, notwithstanding a slight decrease in population happening soon). Hydropower is fully established now except for reactivation of very small local plants, many of which had been in operation since the early 20th century. Hence, the present 3% share will remain almost the same; 35% from photovoltaics corresponds to an average output of some 23 GW, which, in our climates, is tantamount to an introduced peak power of 130–150 GW, more than twice that what now is funneled into the entire grid by all kinds of power plants. Dealing with this excess energy on sunny summer afternoons, possibly by chemical storage (water electrolysis, then linked to fuel cells), remains to be figured out. The total area required to produce this amount of PV electricity is about 1000 km^2 [<0.3% of Germany's total area (356,000 km^2) and <10% of the fields on which "energy plants" are now grown (>12,000 km^2 are covered with rape alone)], even assuming no further improvement in today's Si hydride polycrystallinic or $CuIn(S; Se)_2$ thin-layer solar cells (some 13% efficiency).

Growth and Booming Region Ems-Axis, Lower Saxony (NW Germany)

The previous entries dealt with the global-scale relevance of renewable energies. Besides the environmental issue, there are both economic and social surpluses produced by creating novel workplaces.

This can turn a formerly "just" agrarian region into some diversified boom area as will be shown by the example of the so-called River Ems-Axis (Lower Saxony, Northwestern Germany). For more than a decade now, the region keeps increasing its workforce by 3% per year—no "Mc jobs" but fully qualified jobs that produce social security and modest earnings, with >10,000 enterprises that keep expanding and creating new jobs one year after another. The regional motto reads: "Powerful, innovative and ready to achieve by unconventional solutions—these are our region's benchmarks."

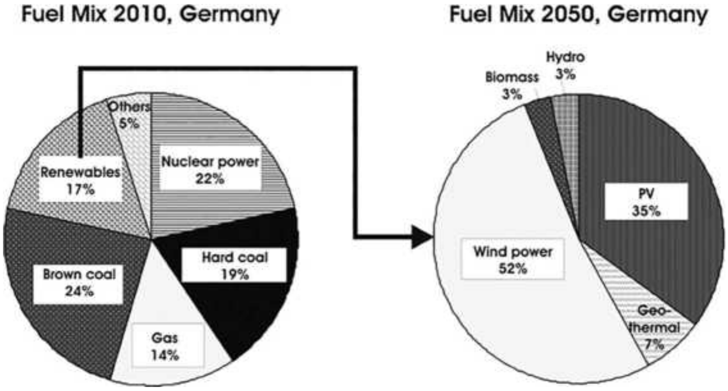

FIGURE 11 Energy mix contributions in Germany in 2010 and the probable future in 2050.[45]

As the Ems-Axis is located next to the North Sea, maritime-related activities are prominent by locating shipyards, shipping companies, and wind power plant producers, among suppliers of other renewable energies. This model region was created through a combination of prudent political support, improvement of infrastructures, synergy among regionally active enterprises, and finally the support of the public. It is located near the Dutch border in Central Europe, making use of already existing East-West connections, and, in addition, links the North Sea shores to the German megalopolis Ruhr district, which is the most populated part of the most populated and economically prolific *Bundesland* of Germany. The Ems-Axis includes the counties Wittmund, Aurich, Leer, Emsland, Grafschaft Bentheim, and Emden City with its large harbor (see Figure 12).

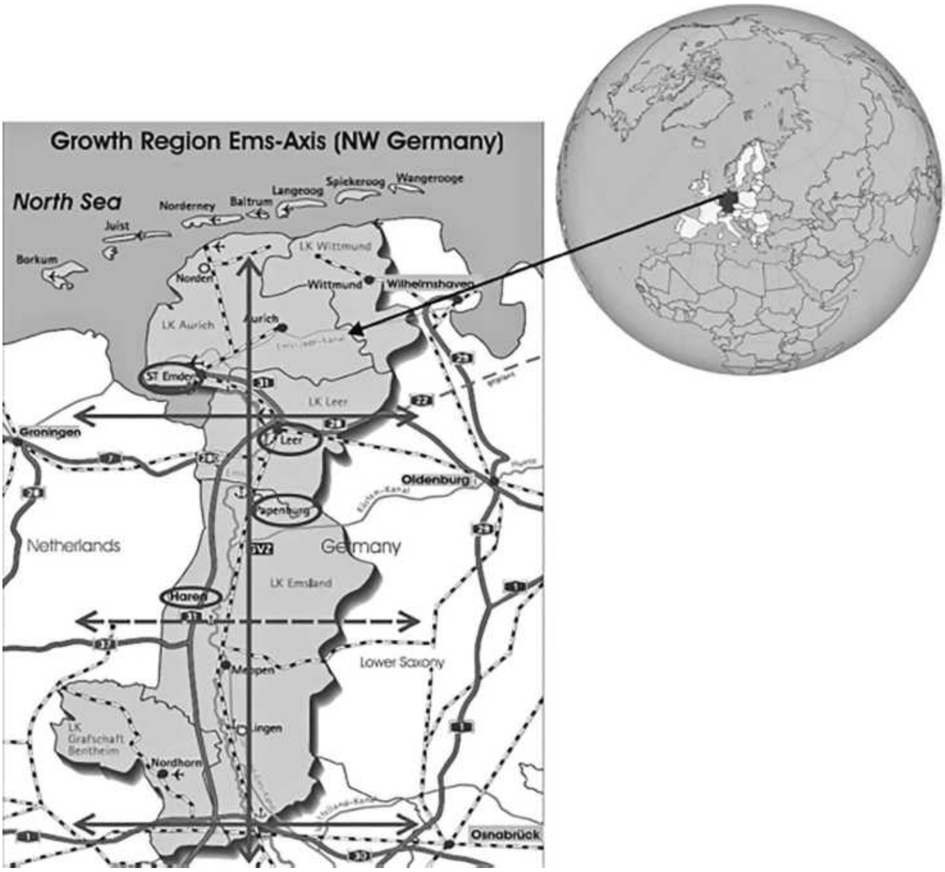

FIGURE 12 The growth region Ems-Axis in Northwestern Germany. This figure shows the excellent infrastructure that will imminently cause new enterprises to settle and expand here. The East-West and South-North highways (motorways) are marked with Nos. 7, 28, 30, 31, and 37, while rivers and channels for ship travel are marked medium gray. These are the River Ems, which is deep and wide enough to permit economically meaningful transportation by ship, and the Dortmund–Ems channel, which extends almost parallel to it. Railway tracks are outlined in black and white. Framed: the cities of Leer and Haren/Ems are among the most important locations for ship owners all over Germany. In Papenburg, there is the Meyer shipyards, among the largest in Europe and moreover the one producing the biggest ships (passenger and cruise ships). Other notable shipyards located next to the shore at Emden recently rather switched to producing wind power plants. The Ems-Axis is distinguished by intense economic activities covering all energy supply, integrated maritime activities, agriculture, and tourism; processing plastics and metals; building vehicles and machines; and providing logistical infrastructure.

Source: The main figure of the Ems-Axis is modified after http://www.emsachse.de. The figure on the right is from Wikipedia, TUBS.

There are six permanent workgroups concerned with energy, integrated maritime economy, tourism, production of plastics items, vehicles and machines, and finally logistics to initiate and run projects. It is the aim of these workgroups and the economic region to make Ems-Axis an independent axis along which economic, travel, and transport activities will organize. This implies strengthening economy-related infrastructure and creating networks for regional economy.

The cities of Haren and Leer combine to be the second-largest shipowner's site in Germany. A total of 750 ships are run from here, making these two special and significant players in running ship travel and dockyards and providing additional maritime goods and items, together with Papenburg. The existing travel infrastructure allows to process materials inshore and, using local logistics, build huge ocean liners such as that for Disney Cruise Line (340 m long and 37 m wide, 128,000 tons, can accommodate 2500 passengers) at Papenburg's Meyer dockyards (Figure 13). The latter commands the world's most advanced instrumentation and facilities for building ships, its workforce being about 2500.

One should mention that there is minimal required bureaucracy used to acquire these infrastructures. This enabled Motorway 31—a crucial North-South connection—to be completed years ahead of planning, with the region providing the required funds itself by joint and coordinated action. Another ambitious project was Euroharbour Emsland at Haren (operated jointly with nearby Meppen city), the construction of which began in 2007. In August 2011, construction of the plant of ENERCON wind power devices began here. ENERCON is the manufacturer of the most advanced wind rotors (the actual propellers), producing blades that are aimed to deliver 3 MW per unit at the Emsland Euroharbour site. The principal administrative person *(Landrat)* of the largest of the involved counties and cities of Ems-Axis, Emsland itself, uses to call this a "pro-climate climate," stressing that currently, an impressive 82% of the energy consumed in the county are derived from renewable energy. The location of Euroharbour, the 24,000-population town of Haren, even boasts a 100% renewable electric current production. Among the renewables, wind is most important for the Ems-Axis region. With the shore nearby and little terrain roughness, it is most suited to create onshore wind plants; thus, NW Germany outcompetes the southern parts of the country in this respect.

Yet, there are also offshore wind power parks in the region now. In 2010, the first one in German domestic waters, "Alpha Ventus," was erected and connected to the grid. As for crucial parts of wind power technology, BARD Energy at Emden both produces rotor blades specifically designed for offshore application (there are special criteria to withstand salt corrosion, impact of water drops on the fastly moving blades, etc.,) and likewise constructs entire power plants at offshore sites (Figure 14).

Suffice this to show features of the booming Ems-Axis economic region, which additionally sports, for example, the Transrapid (maglev) testbed at Lathen, and notably a big plant at Werlte, which will be the first in the world to convert excess wind power energy via hydrogen and hydrogenation of CO_2 into methane for energy storage purposes (to be combined with natural gas CH_4 and biogas). With regard to issues of energy use efficiency and extending the amount of renewable energy supply, the Ems-Axis consortium stated in May 2011:

FIGURE 13 Meyer shipyards at Papenburg (NW Germany). The largest dock is incredibly 504 m long. Right figure: Norwegian Jewel in front of the 70 m tall Meyerwerft Hall.

"Partners in growing region Ems-Axis consider big chances for local and regional economy to be obtained from making energy supply a cornerstone of economical politics. Simultaneously they respond to their environmental responsibility by making energy use more efficient and increasing the share of renewable energy sources.

Growing region Ems-Axis is capable of becoming a model (blueprint) energy supply region for the future. Concerning Germany, this region both has the largest concentration of wind power plants and is the site of globally active producers of wind power devices. In addition, renewable energy is earned here from all biomass, sun and geothermal resources. So there is a bandwidth of competence in energy supply which yields new impetus to the region by enhanced cooperation and thus advantages in competition which in turn once more improves the economic performance of the local enterprises".

More pieces of information on the Ems-Axis region, including pertinent enterprises, can be obtained via http://www.emsachse.de.

Conclusion

The present mix of renewable resources used in both thermal and electrical energy delivery represents a superposition of both technical problems still to be overcome (the less so) and political decisions, many of which are made in favor of protecting the respective domestic industries for both producing energies and the very power plants required to obtain and convert them: this partly is a quite reasonable and, to some extent, even responsible industrial policy. Now, there are "old" energy sources, exploitation of which has become so costly that it is worthwhile only in certain most simple conditions, including hard coal and, in another way, oil sands. This statement refers to all economic costs of exploitation, ecological side effects (as well as cultural ones such as destruction of villages and first-nation settlements in favor of open pits), and risk production causes to the workers. The renewables make it to the market step by step with their increasing ability to compete economically and the perspective to relieve old dependences, in addition to avoiding the above risks by offering genuine technical alternatives.

Of course, this might produce problems for countries that have virtually nothing else to offer to today's global markets than their fossil energy carriers, including uranium, but not to some of the "big shots" in fossil fuel mining—highly industrialized countries such as the Unites States, Canada, Australia, and Russia. Apparently, however, there is no convincing perspective of sustainable development by which the common population might benefit from exploitation of fossil energy carriers alone for countries such as Niger in Western Africa (uranium) or Yemen in the Middle East (oil). Other large uranium suppliers like Gabon (West Central Africa) or Kazakhstan (Central Asia/ Eastern Europe) have a more diversified supply portfolio. Several of the Arab oil-producing countries are very aware of what might happen to them, their regimes, their population, and their common welfare (which is often truly restricted to some indigenous minorities) when oil continues to get scarce, and there are cautionary economic examples of countries, societies, and national economies running out of the single, principal minable resource the entire economy was based on, such as the tiny South Pacific Republic of Nauru (phosphate) and Bolivia in Central South America (tin, silver).

Nevertheless, the exchange of our joint economic basis for energy production appears feasible globally within some 50 years from now. It remains to be seen whether this is fast enough both to control climate effects from fossil combustion within acceptable limits and to reorganize completely our strategies of personal transportation while avoiding yet more catastrophes like those in Chernobyl or Fukushima [as well as the failure of a hydropower plant in Longarone (Friaul, NE Italy) which took some 2000 lives in 1963]. Besides this, nuclear power plants—like other technical systems—can run into operation states where they almost or entirely escape control. If a catastrophic accident then can be avoided due to self-regulation or simply luck, it is by no means satisfying or consoling that, e.g., nuclear reactors arrived at states that were not even known to their own operators for extended periods of time (like in Forsmark, Sweden, in 2006), let alone these people would be able to influence it anymore.

The future awaits us but is notoriously hard to predict, but we should take chances, even severe ones, if we decide either way, and we should be aware that doing nothing is tantamount not only to taking chances but also pursuing ways that we know for sure to be not sustainable, not even in the shorter term.

Acknowledgments

We are deeply thankful to the thousands of comments given by colleagues, students, friends, and especially opposite thinking people during attractive and highly motivating discussions during the past decades. For intensive support during the preparation of this entry, we would like to thank Prof. Michael Tomaschek, University of Applied Sciences Emden/Leer.

This entry corresponds in parts with chapter 4.4 (Energy—One of the Biggest Challenges of the 21st Century) of the textbook by Fraenzle, S., Markert, B., and Wuen-schmann, S. (2012) on an "Introduction to Environmental Engineering" published by Wiley/VCH, Weinheim.

Energy and Environmental Security

Muhammad Asif

Introduction

The economies of all countries, and particularly of the developed countries, are dependent on secure supplies of energy. Energy security means consistent availability of sufficient energy in various forms at affordable prices. These conditions must prevail over the long term if energy is to contribute to sustainable development. Owing to the pivotal role of energy in the modern age, energy security is at the heart of national and international energy policies across the world.

The global environmental scene has changed dramatically over the last century. Global warming and its consequent climatic changes driven by human activities, in particular the production of greenhouse gases (GHGs), directly impact the environment. The environmental security to a certain extent is linked with the energy security as there is an intimate relationship between energy and environment. The production and use of all energy sources results in undesirable environmental effects, which vary based on the health of the existing ecosystem, the size and health of the human population, energy production and consumption technology, and chemical properties of the energy source or conversion device. A shorthand equation for the environmental impacts of energy production and use has been provided by Solomon:[1]

$$I = PAT$$

where I is the environmental impact, P is the size of the human population, A is the affluence of the population (e.g., per capita income and/or energy use), and T is the technology (e.g., energy efficiency, emission rate of air and water pollution). A comparison of different types of energy systems in terms of CO_2 emissions is provided in Table 1.[2]

The energy resources, presently being consumed in the world, can be broadly classified into three groups: fossil fuels, nuclear power, and renewable energy. Fossil fuels contribute to more than 80%

TABLE 1 Comparison of CO_2 Emissions from Different Energy Systems

Type of Power Plant	Fuel/Type of Energy	CO_2 (kg/kWh)
Steam power plant	Lignite	1.04–1.16
Steam power plant	Hard coal	0.83
Gas power plant	Pit coal	0.79
Thermal power plant	Fuel oil (heavy)	0.76
Gas turbine power plant	Natural gas	0.58
Nuclear power plant (pressurized water)	Uranium	0.025
Thermal power plant	Natural gas	0.45
Solar thermal power plant	Solar energy	0.1–0.15
Photovoltaic power plant	Solar energy	0.1–0.2
Wind power plant	Solar/wind energy	0.02
Hydroelectric power plant	Hydropower	0.004

of world's total energy supplies and are mainly classified into the following three types: coal, oil, and natural gas. It is the set of fossil fuels that primarily bond the environmental security with energy security. Global warming—the predominant threat to environmental security—to a great extent is a consequence of fossil fuel consumption. As the two issues go side by side, their potential solutions would also be closely related.

Energy and Sustainable Development

Energy is at the heart of the existence of present-day societies. The accomplishments of civilization have largely been achieved through the increasingly efficient and extensive harnessing of various forms of energy to extend human capabilities and ingenuity. Providing adequate and affordable energy is essential for eradicating poverty, improving human welfare, and raising living standards worldwide. The per capita energy consumption is an index used to measure the socioeconomic prosperity in any society—the human development index (HDI) of a country has strong relationship with its energy prosperity.[3] A direct correlation between the access to electricity and the economic well-being in a range of countries, for example, is indicated in Figure 1.[4] Throughout the course of history, with the evolution of civilizations, the human demand for energy has continuously swallowed. Of present, key factors driving the growth in energy demand include increasing human population, modernization, and urbanization.

Poverty, hunger, disease, illiteracy, and environmental degradation are among the most important challenges facing the world. Poor and inadequate access to secure and affordable energy is one of the crucial factors behind these issues. Electricity, for example, is vital for providing basic social services such as education and health, water supply and purification, sanitation, and refrigeration of essential medicines. Electricity can also be helpful in supporting a wide range of income-generating opportunities. Access to electricity remains to be a serious issue in developing countries as around 13% of the world's population—do not have access to it yet.[5] As of 2017, around 3 billion people rely on traditional biomass, including wood, agricultural residues, and dung, for cooking and heating. More than 99% of people without electricity live in developing regions, and four out of five live in rural areas of South Asia and sub-Saharan Africa.[6,7]

There is a global consensus that the provision of secure, affordable, and socially acceptable energy services is a prerequisite for eradicating poverty in order to achieve the Millennium Development Goals (MDGs). The Earth Summit 2002 strongly urged the nations to "Take joint actions and improve efforts to work together at all levels to improve access to reliable and affordable energy services for sustainable development sufficient to facilitate the achievement of the MDGs, including the goal of halving the proportion of people in poverty by 2015, and as a means to generate other important services that mitigate poverty, bearing in mind that access to energy facilitates the eradication of poverty." United

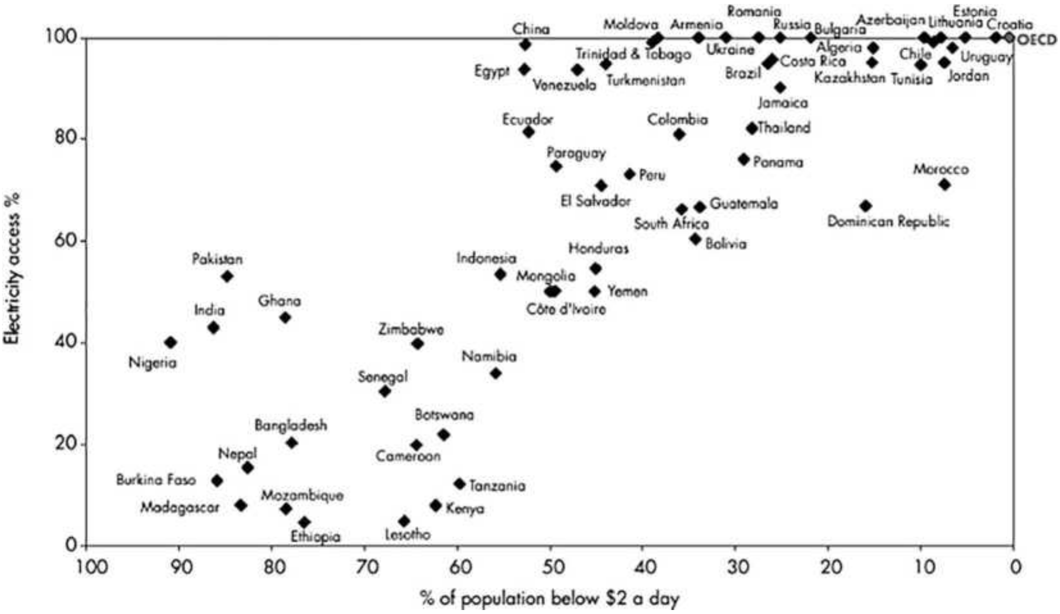

FIGURE 1 Relationship between economic prosperity and availability of electricity.

Nations also acknowledged that "without increased investment in the energy sector, the MDGs will not be achieved in the poorest countries."

With the growing world population and people's innate aspirations for improved life, a central and collective global issue in the new century is to sustain socioeconomic growth within the constraints of the Earth's limited natural resources while at the same time preserving the environment. This target—sustainable development—can only be met by ensuring energy sustainability.

Energy Security

Energy has attained the status of an indispensable strategic commodity, and ensuring its availability is one of the important responsibilities of governments across the world. Failure to ensure robust provision of interruption-free and affordable energy may result into serious financial and social problems. Breach of energy security is also prone to lead to national instability. A great number of countries in the world, particularly the industrialized mature economies, have placed energy security on top of their national policies. The high degree of multidisciplinary interdependency among nations makes energy security vital from both national and international perspectives. German Foreign Minister Frank-Walter Steinmeier emphasizes this fact by stating that maintaining global security in the 21st century will "inseparably also be linked to energy security."[8] At their summit in Brussels in March 2007, the European Union (EU) leaders adopted a road map, the highlight of which was "Energy is what makes Europe tick. It is essential, then, for the European Union to address the major energy challenges facing us today and in future." Similarly, the 2006 G8 summit held in St. Petersburg had energy security on top of its agenda ahead of issues such as education, health, trade, environment, and terrorism.[9] The seventh sustainable development goal (SDG) by the United Nations—ensure access to affordable, reliable, sustainable, and modern energy—is all about energy security.[5]

Owing to a great degree of dependency upon oil and gas, the international energy market generally gauges the energy security in terms of secure supplies of these two commodities. The balance of evidence suggests that the present international energy market is vulnerable to different types of security risks. Energy security risks can be broadly classified into two categories: first, man-made— international geopolitical and geostrategic conflicts resulting into military attacks and wars, and sabotage and terrorist activities on relatively smaller scale; and second, natural— depletion of fossil fuel reserves, floods, fires, and earthquakes.

Risk Assessment

As with the supply of any commodity, the security of energy supply depends on the availability, size, and location of the energy reserves. The availability and the size of the reserves and their location then determine the supply line: the exploitation, transportation, and utilization arrangements. Conversely, the security of the exploitation, transportation, and utilization arrangements then determines the security of energy supplies. Using a very simple model, the major components of the risk can be identified:

- The number of potential disruptive events
- The probability that, given a potential disruptive event, the supply line will be successfully disrupted
- The potential consequences of such a disruption.

The contingency strategy could have three possible prongs. In order to minimize the risk, the number of potential disruptive events must be made as low as possible. Similarly, the probability that such an event will result in disruption must also be minimized. Finally, contingencies must be in place to successfully survive such a disruption.

The effects of human errors can be minimized by proper education and training of the operators, and by ergonomically suitable design. Energy companies have always strived to achieve this but failed spectacularly on a number of occasions, such as Windscale in the U.K., Chernobyl in the Ukraine, or Three Mile Island in the United States, and most recently Fukushima in Japan. However, based on past experience, the probability of human error can be estimated with relative accuracy. Determining the probability of sabotage or a military attack is difficult, since it depends upon various political and economic considerations. Nevertheless, it can be observed that such events are more frequent in unstable countries with many unresolved internal and external conflicts. Finally, the probability and severity of the natural events can be, once again, estimated for various locations, based on geographical, geological, and historical data.

In order to minimize the subsequent disruptions, or the effect of the potentially disruptive events, defense systems or protection and safeguards systems are employed. These systems have been well developed, and in order to maximize their effectiveness, they use the principles of defense in depth, redundancy, and diversity. All energy companies are geared to deal with human errors and natural events, but problems can be encountered when dealing with sabotage or military attacks. To minimize the impact of sabotage and military attacks, security services must be called for assistance. These services are generally able to deal with these problems domestically in countries without serious internal and external conflicts. However, in countries with serious internal and external conflicts, either the internal security forces can be ineffective, particularly in remote locations, or their loyalty can be divided. In these cases, the governments sometimes require security support from other countries, which, while improving the defenses, may make the internal conflicts worse and lead to an increasing frequency of attacks. Hence, stable countries, where the probability of an initial attack is already low, can, generally, protect their installations, but countries, with significant internal and external conflicts, where the probability of an initial attack is already high, cannot, generally, protect their installations.

All developed countries have contingency plans in place to deal with the effects of supply disruptions in the form of strategic sock reserves. These plans used to be based on the diversity of the energy supplies and the availability of strategic stocks. Due to the reliance on oil and natural gas by the developed countries, the principle of diversity of energy supplies holds less and less. All developed countries now deal with the potential problems primarily by having strategic reserves of oil supplies. By definition, the strategic reserves would be only available for certain activities and a certain period of time. This selectivity and time limit would provide a serious blow to the economies of the developed countries, if the reserves had to be used for a significant period of time.

Many of the world's leading oil-producing countries such as Iraq and Nigeria are politically unstable. The Middle East region as a whole has quite a volatile geopolitical situation and has experienced frequent conflicts over the last 100 years. There are serious reservations regarding security of oil; production and supply channels of many countries are regarded as the legitimate targets of radical elements because of various internal and external conflicts.

Getting oil from the well to the refinery and from there to the service station involves a complex transportation and storage system. Millions of barrels of oil are transported every day in tankers, pipelines, and trucks. This transportation system has always been a possible weakness of the oil industry, but it has become even more so in the present volatile geopolitical situation, especially in the Middle East region. The threats of global terrorism have made the equation more complex. Tankers and pipelines are quite vulnerable targets. There are approximately 4000 tankers employed, and each of them can be attacked in the high seas and more seriously while passing through narrow straits in hazardous areas. Pipelines, through which about 40% of the world's oil flows, are no less vulnerable, and due to their length, they are very difficult to protect. This makes pipelines potential targets for terrorists. In recent years, there have been an increased number of pipeline sabotages in different countries particularly Nigeria and Iraq, sending shockwaves in international energy markets.

Depleting Oil Reserves

A combination of constrained production capacity and growing fears of a rapid depletion of oil reserves in the world is also an important factor that has been playing its behind-the-scene role in pushing oil prices. In recent years, global oil infrastructure particularly with regard to extraction and refining capacity has been stretched to its limits. The production capacity of various oil-rich countries in the world, such as Iraq and Venezuela, has also been curtailed. The aspect of depleting oil reserves, despite its critical role, for various reasons, is not being publicly accepted by the market forces.

The world's ultimate conventional oil reserves are estimated at 2,000 billion barrels. This is the amount of production that would have been produced when production eventually ceases. The demand for oil has grown rapidly over the last few decades as shown in Table 2.[10] The surging demand for oil has already stretched the production to its limits—in mid-2002, there were more than 6 million barrels per day of excess production capacity, but by mid-2003, the daily excess capacity was below 2 million barrels, which further skewed to less than 1 million barrels by 2006.[11]

Different countries are at different stages of their reserve depletion curves. Some, such as the United States, are past their midpoint and are in terminal decline, whereas others are close to midpoint such as U.K. and Norway. However, the five major Gulf producers—Saudi Arabia, Iraq, Iran, Kuwait, and United Arab Emirates—are at an early stage of depletion and can exert a swing role, making up the difference between world demand and what others can supply.

The expert consensus is that the world's midpoint of reserve depletion will be reached when 1,000 billion barrels of oil have been produced—that is to say, half the ultimate reserves of 2,000 billion barrels. It is estimated that around 1,000 billion barrels have already been consumed and 1,000 billion barrels of proven oil reserves are left in the world.[12] According to BP statistical review of oil reserves in 2017, the reserve-to-production ratio for North America, South and Central America, Europe, Asia Pacific, Middle East, and Africa was 12, 48, 13, 32, 120, and 62, respectively. The reserve-to-production ratio for the whole world is reported to be equal to 52 years.[13] In the backdrop of a continuous growth in oil demand—as according to the U.S. Department of Energy, by 2025 the global daily demand could be as much as 110 barrels/day—the global reserves are actually going to run out much quicker than 42 years.[14]

A growing number of opinions among energy experts suggest that global oil production will probably peak sometime during this decade as indicated in Table 3.[15] A siren call regarding energy

TABLE 2 Growth in World Oil Demand

Year	World Population (million)	Average Daily Oil Demand (million barrels/day)	World Average per Capita Consumption (barrels/yr)
1965	3310	31.23	3.65
1968	3520	39.04	4.05

security was also raised in a recent speech made by the British Ambassador to the United States, Sir David Manning. He eloquently puts forward the case thus: “The International Energy Agency predicts that, if we do nothing, the global oil demand will reach 121 million barrels per day by 2030, up from 85 million barrels today. That will require increasing production by 37 million barrels per day over the next 25 years, of which 25 million barrels per day has yet to be discovered. That is, we’ll have to find four petroleum systems that are each the size of the North Sea. Production from existing fields is dropping at about 5% per year.” Only one barrel of oil is now being discovered for every

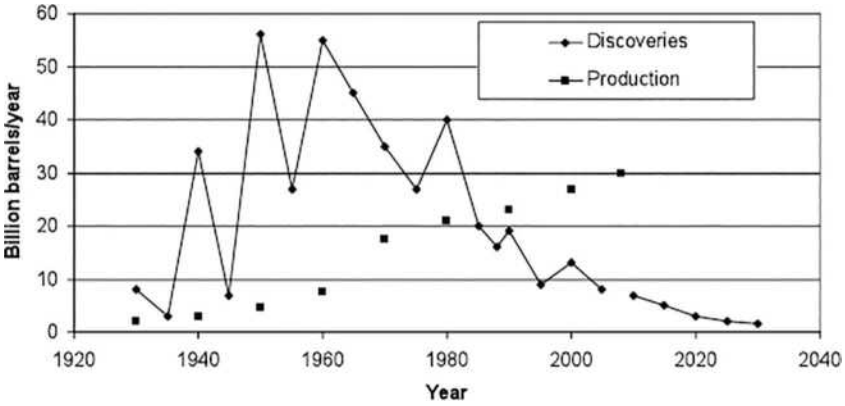

FIGURE 2 An overview of global oil discoveries and production.

four consumed as highlighted in Figure 2. Globally, the discovery rate of untapped oil peaked in the late 1960s. Over the past decade, oil production has been falling in 33 of the world's 48 largest oil-producing countries, including 6 of the 13 members of OPEC (Organization of the Petroleum Exporting Countries).[16]

Concerns over Security of Supplies from the Middle East

Oil and gas are jointly contributing to around 56% of the present global energy requirements. In terms of existence, both oil and gas are extremely localized by their very nature. Vast majority of their resources are found in relatively confined regions. For example, almost 88% of the world oil reserves exist within ten countries. Middle East is the oil headquarters of the world, holding almost 48% of the global oil as highlighted in Figure 3.[13] The situation with natural gas is even more intense. Statistics indicate that of the remaining known gas reserves in the world, equivalent to 6260 trillion cubic feet (tcf), around 57% are shared by only three countries: Russia, Iran, and Qatar, as shown in Figure 4.[17]

Middle East has been under the limelight for its vast oil reserves for nearly a century now. By the 1950s, it had established its standing as the oil-rich region of the world—its oil reserves were equal to the rest of the world's combined and double the U.S. reserves.[18] For the last six decades, Middle East

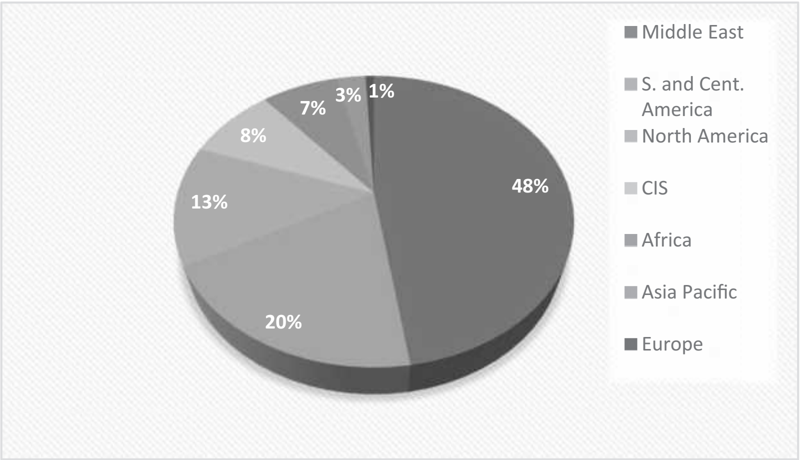

FIGURE 3 Remaining oil reserves in the world, 2017.

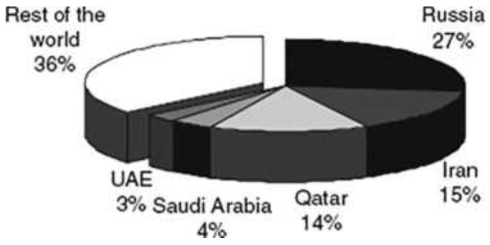

FIGURE 4 Remaining natural gas reserves in the world, 2009.

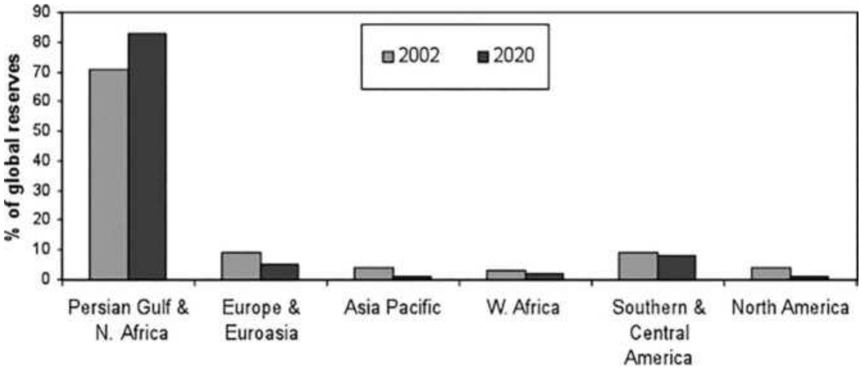

FIGURE 5 Growing share of Middle Eastern oil reserves.

has been the source of abundant and cheap oil that propelled the economic growth of the world over this period. In 2006, it produced about 28% of the world's total oil. During the same year, the region exported 18.2 million barrels of oil per day. Besides oil, the region also has huge reserves (2509 tcf) of natural gas, accounting for 41% of total proven world gas reserves.[19]

The importance of the Arabian Gulf countries is several-fold. The oil and gas reserves in non-Middle East countries are being depleted more rapidly than those of Middle East producers. If production continues at the present rate, many of the largest, non-Middle Eastern producers in 2002, such as Russia, Mexico, United States, Norway, and Brazil, will cease to be relevant players in the oil market in less than two decades. At that point, the Middle East will be the only major reservoir of abundant crude oil—within 20 years or so, about four-fifths of oil reserves could be in the hands of the Middle Eastern countries as shown in Figure 5.[11] The role of the region in future oil supplies of the world is thus going to become even more prominent.

Global Warming

Since the industrial revolution, human activities have resulted in a sharp rise in the concentration of GHGs in the Earth's atmosphere. The GHGs such as carbon dioxide (CO_2), nitrous oxide (N_2O), methane (CH_4), ozone (O_3), sulfur hexafluoride (SF_6), hydrofluorocarbons (HFCs), and perfluorocarbons (PFCs) are widely considered to be the root cause of a rapid increase in the atmospheric temperature, a phenomenon recognized as global warming. As a consequence of global warming, the climatic patterns of the earth are experiencing wide-ranging changes that are having numerous and far-reaching implications for the planet. The concentration levels of GHGs in the atmosphere are usually described in terms of carbon dioxide equivalent (CO_2e). Estimates suggest that since the advent of the industrial revolution, the level of GHGs in the atmosphere has grown from 280 parts per million (ppm) CO_2e to 430 ppm CO_2e.

Scientific circles believe that in order to avoid catastrophic implications, the level should be limited to 450–550 ppm CO_2e.[20] The growing concentration of GHGs in the atmosphere has increased the global average temperature. Some estimates suggest that the global temperature has increased by 0.8°C since the industrial revolution. The rise in the atmospheric temperature leads to the melting of glaciers and ice sheets, which, in turn, increases the sea level. According to the Intergovernmental Panel on Climate Change (IPCC), over the last century, the global sea level has increased at a rate of around 2 mm/yr. Estimates also indicate that the sea level rose twice as much between 1993 and 2003 as in the previous three decades.[21]

Global warming and climate change lead to a pattern of more frequent and more intense weather events such as floods, storms, droughts, heat waves, diseases, and loss of habitat. These events affect people across the world and result into huge casualties. According to the World Health Organization (WHO), as many as 160,000 people die each year from the side effects of climate change, and the numbers could almost double by 2020. These side effects range from malaria to malnutrition and diarrhea that follow in the wake of floods, droughts, and warmer temperatures.[22] Evidence suggests that the weather-related disasters have quadrupled over the last two decades. According to Oxfam, from an average of 120 disasters a year in the early 1980s, there are now as many as 500, with the rise to be attributed to unpredictable weather conditions caused by global warming. The year 2007 saw floods in South Asia, across the breadth of Africa and Mexico, which affected more than 250 million people. Devastating floods in 2010 affected a similar magnitude of people in China and Pakistan alone.[23] Statistics also suggest that over the last 25 years, the number of people affected by disasters has risen by 68%, from an average of 174 million a year from 1985 to 1994 to 254 million a year from 1995 to 2004.[24]

Climate change is responsible for huge economic consequences. Between the 1960s and the 1990s, the number of significant natural catastrophes such as floods and storms rose nine-fold, and the associated economic losses rose by a factor of nine. Figures indicate that the economic losses as a direct result of natural catastrophes over 5 years between 1954 and 1959 were $35 billion, while between 1995 and 1999, these losses were around $340 billion.[25] Natural catastrophes associated with global warming killed more than 190,000 people in 2004, twice as many as in 2003, with an economic cost of $145 billion. The August 2005 Hurricane Katrina was responsible for taking more than 1,000 human lives. Hurricane Katrina caused at least $125 billion in economic damage and could cost the insurance industry up to $60 billion in claims. That is significantly higher than the previous record-setting storm, Hurricane Andrew in 1992, which caused nearly $21 billion in insured losses in today's dollars.[26] Katrina shut down large portions of oil and gas production in the Gulf of Mexico at a time when worldwide energy output was already stretched thin. While the storm's impact was most acute in the United States, it also sent fuel costs higher around the globe, squeezing consumers in Europe and Asia.[27] It has been reported that since the advent of the 20th century, natural disasters such as floods, storms, earthquakes, and bushfires have resulted in an estimated loss of nearly 8 million lives and over $7 trillion of economic loss.[27]

The scale and intensity of global warming are set to increase in the 21st century. Global mean temperature is forecast to rise by between 1°C and 4.5°C by 2100, with best estimates somewhere between 2°C and 3°C. All projections produce rates of warming that are greater than those experienced in the last 10,000 years. Sea level is projected to rise by about 50 cm by 2100 (with a range of 20–90 cm).[11,28] Temperature and sea level changes will not be globally uniform. Land areas, particularly at high latitudes, will warm faster than the oceans, with a more vigorous hydrological cycle potentially affecting the rate and scale of various extreme events such as drought, flood, and rainfall. Impacts on natural and semi-natural ecosystems, agriculture, water resources, human infrastructure, and human health are subject to many uncertainties, but all will be subject to stresses that will exacerbate stresses from other sources such as land degradation, pollution, population growth and migration, and rising per capita exploitation of natural resources. Global warming is also set to have colossal ramifications on biodiversity—Stern Report suggests that a warming of even only 2°C could leave 15–40% species facing extinction.[20]

Global Warming Threats for Developing Countries

Although global warming is a threat to the whole planet, its intensity is not uniformly distributed. It is the low-lying and small island countries that are being hit harder. Most of them are actually poor and developing countries. It is feared that several hundred million people in densely populated coastal regions—particularly river deltas in Asia—are threatened by rising sea levels and the increasing risk of flooding. It is estimated that more than one-sixth of the world's population live in areas affected by water sources from glaciers and snow pack that will very likely disappear.[29] The number of people at risk of flooding by coastal storm surges is projected to increase from the current 75 million to 200 million by 2080, when sea levels may have risen by more than 1 ft. In the United Nation's list of countries under severe threat by global warming, Bangladesh is at the top. Being a low-lying and densely populated country, Bangladesh would be worst hit by any rise in the sea level. Coastal areas would experience erosion and inundation due to intensification of tidal action. A rise in seawater would enable saline water to intrude further inland during high tides. Destruction of agricultural land and loss of sweet water fauna and flora could also occur. The shoreline would retreat inland, causing changes in the coastal boundary and coastal configuration. The process will also shrink the land area of Bangladesh. Worst scenarios suggest that by the year 2050, one-third of the country could be under water, making more than 70 million people homeless.[30] For small island developing states (SIDSs), global warming poses an enormous set of challenges for their livelihood, safety, and security. Since most of the infrastructure in these countries is on the coast, the damage from consequent erosion and flooding is likely to be hugely burdensome for their already fragile economies. Owing to their smaller land area compared to other countries, they cannot afford to lose land due to surging sea level. For some, for example, Maldives, it threatens their very existence.

The health-related implications of global warming are also expected to be more formidable for developing countries. The WHO estimates that global warming is already causing about 5 million extra cases of severe illness a year. By 2030, however, the number of climate-related diseases is likely to more than double, with a dramatic increase in heat-related deaths caused by heart failure, respiratory disorders, the spread of infectious diseases, and malnutrition from crop failures. Countries with coastlines along the Indian and Pacific oceans and sub-Saharan Africa would suffer a disproportionate share of the extra health burden. According to WHO experts, many of the most important diseases in poor countries, such as diarrhea and malnutrition, are highly sensitive to climate. Also, that the health sector is already struggling to control these diseases and climate change threatens to undermine these efforts.[31]

One of the significant heartbreaks of global warming is that developed and industrialized countries are acutely responsible for the phenomenon, but the heavier price is to be paid by the poor and developing nations. For example, the average value of the per capita energy consumption—an index to measure the contribution towards global warming—in industrialized and developed countries is almost six times greater than that in developing countries. In 2007, the former U.S. Vice President Al Gore, in his famous work on global warming, heavily criticized the United States for turning a blind eye on the issue of global warming. According to him, the U.S. stance on the Kyoto Protocol is unfavorable despite the fact that it alone is responsible for more than 30% of the world GHG emissions. He concludes that a U.S. citizen emits nearly six times greater amount of carbon as compared to the world average emission as indicated in Figure 6, whereas compared to African or South Asian countries such as Pakistan, India, and Bangladesh, the per capita carbon emission in the United States is around 22 times higher.[32] Figure 7 provides a relationship between carbon dioxide emissions and gross national income (GNI) of a range of developing and developed countries. It can be seen that China has a substantially higher emission rate compared to other countries. Australia, Canada, and the United States also have a significantly higher emission rate in comparison with other developed countries. According to the World Wildlife Fund (WWF), in terms of eco-footprint, an index of sustainability, the excessive consumption of natural resources by the developed countries is imposing serious implications on the ecosystem of the planet.[33] These pieces of evidence indicate that the responsibility of the disturbance in the global ecosystem, also

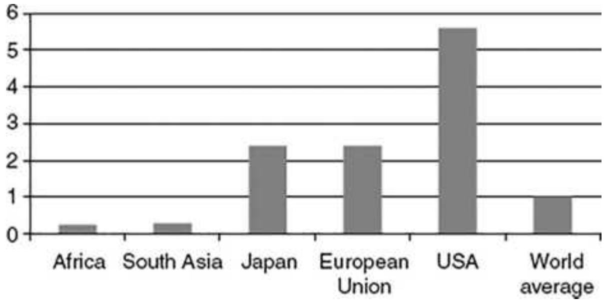

FIGURE 6 Annual per capita carbon emission in tons.

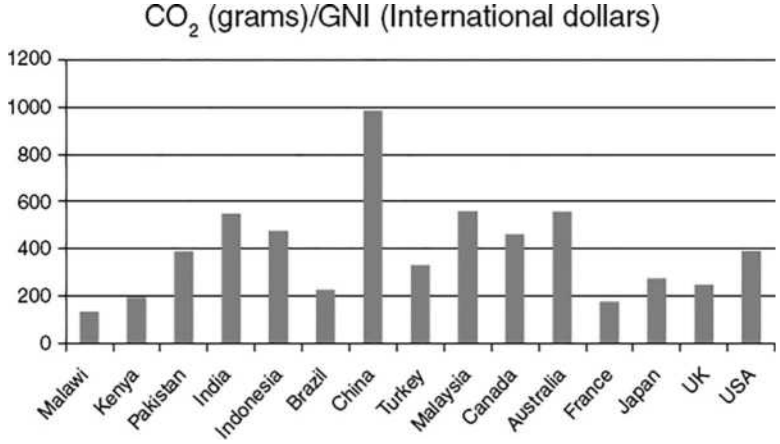

FIGURE 7 The per capita values of grams of carbon dioxide emitted for each international dollar of GNI in various countries.

leading to the phenomenon of global warming and climate change, to a great extent rests on the shoulders of the developed and industrialized countries of the world.

In the backdrop of the trajectory of the issue, the Kyoto Protocol urges the industrialized countries to reduce their collective emissions of GHGs by 5.2% compared to the year 1990. However, compared to the emission levels that would be expected by 2010 without the Protocol, this target represents a 29% cut. The goal is to lower overall emissions of six GHGs—carbon dioxide, methane, nitrous oxide, sulfur hexafluoride, HFCs, and PFCs—calculated as an average over the 5-year period of 2008–2012. National targets range from 8% reductions for the EU and some others to 7% for the United States and 6% for Japan. The developing countries of the world have been spared any emission reduction obligations not only in the Kyoto Protocol but also in its predecessor accords such as Agenda 21. According to Professor Jonathan Patz, it is incumbent on those countries bearing the greatest responsibility for climate change to show moral leadership. He goes on to say: "Those least able to cope and least responsible for the GHGs that cause global warming are most affected. Herein exists an enormous global ethical challenge."[34] On similar lines, Sir Nicholas Stern acknowledges that the developed countries should realize their responsibility towards addressing global warming. He concludes that climate change is the greatest and widest-ranging challenge mankind has ever faced. All countries will be affected by climate change, but the poorest countries will suffer earliest and most. Loss of biodiversity is another inevitable consequence—more than 40% of the species are likely to face extinction. He further urges that climate change should be fully integrated into development policy, and rich countries should honor pledges to increase support through overseas development assistance.[20]

To tackle global warming, a radical change in human attitude towards the environment and consumption of natural resources is required. A major shift in energy consumption practices—from the reliance on currently employed environmentally dangerous resources to the environmentally friendly ones—would be imperative to attain sustainable development. To safeguard the future of coming generations, the world thus has to move towards low-carbon energy systems.

Renewable Energy

Renewable energy as the name implies is the energy obtained from natural resources such as wind power, solar energy, hydropower, biomass energy, and geothermal energy. Renewable energy resources have also been important for humans since the beginning of civilization. Biomass, for example, has been used for heating, cooking, and steam production; wind has been used for moving ships; both hydropower and wind have been used for powering mills to grind grains. Renewable energy resources are abundant in nature and have the potential to provide energy services with zero or almost zero emissions. Renewable energy is acknowledged as a vital and plentiful source of energy. Technically, renewable energy resources have enormous potential and can meet many times the present world energy demand. However, due to their intermittent nature, they have to be used in conjunction with other energy resources. They can enhance diversity in energy supply markets, secure long-term sustainable energy supplies, and reduce local and global atmospheric emissions. They can also provide commercially attractive options to meet specific needs for energy services (particularly in developing countries and rural areas), create new employment opportunities, and offer possibilities for local manufacturing of equipment.

Renewable energy's favorable dimensions in terms of resources availability, reducing cost trends, and environmental friendliness are propelling its rapid growth.[35,36] Technological advancements and supportive policy frameworks have also played a vital role in the rapid growth of renewable energy application around the world.[37–39] In 2017, renewable energy technologies received a cumulative investment of $280 billion. At the end of the year, the global installed capacity of renewables stood at 2,195 GW. Renewables contributed to over 26% of the world's total electricity supplies.[40] Overall, renewables accounted for an estimated 70% of net additions to global power capacity in 2017. Solar photovoltaic (PV) made up led the renewables march, making up nearly 55% of the newly installed renewable power capacity in the year. Wind power and hydropower with respective shares of 29% and 11% account for most of the remaining capacity additions. Renewable energy technologies are becoming competitive with conventional power systems—in 2017, solar PV and wind power projects received bids as low as $30/MWh. Since 2010, the global weighted average levelized cost of electricity (LCOE) of utility-scale solar PV has dropped by over 73%.[35]

Conclusions

The world faces stringent energy and environmental challenges. Fossil fuels, contributing to more than 80% of global energy supplies, interlink the security of energy and environment. The present energy scenario has a number of concerns including depletion of fossil fuel reserves, surging energy prices, geopolitical conflicts in fossil-fuel-rich regions, and emission of GHGs. The emission of GHGs leads to environmental insecurity by contributing to global warming. The intensity of the global warming concerns can be gauged from the fact that the average atmospheric temperature is forecasted to rise by as much as 4.5°C during the 21st century compared to a 0.8°C increment since the industrial revolution. Global warming and the consequent sea level rise—which could be up to 50 cm over the same period—would have catastrophic implications for natural and seminatural ecosystems, agriculture, water resources, human infrastructure, and human health. Even the very existence of some of the small island countries is under threat. Energy and environmental security is thus absolutely vital for sustainable development. The world needs to shift to energy resources that are more reliable, affordable, secure, and environmentally friendly. Renewable energy is one possible solution that can significantly help address the energy and environmental security concern.

Energy Commissioning: New Buildings

Janey Kaster

Introduction

This entry provides an overview of commissioning—the processes one employs to optimize the performance characteristics of a new facility being constructed. Commissioning is important to achieve customer satisfaction, optimal performance of building systems, cost containment, and energy efficiency, and it should be understood by contractors and owners.

After providing an overview of commissioning and its history and prevalence, this entry discusses what systems should be part of the commissioning process, the benefits of commissioning, how commissioning is conducted, and the individuals and teams critical for successful commissioning. Then the entry provides a detailed discussion of each of the different phases of a successful commissioning process, followed by a discussion of the common mistakes to avoid and how one can measure the success of a commissioning effort, together with a cost-benefit analysis tool.

The purpose of this entry will be realized if its readers decide that successful commissioning is one of the most important aspects of construction projects and that commissioning should be managed carefully and deliberately throughout any project, from predesign to postacceptance. As an introduction to those unfamiliar with the process and as a refresher for those who are, the following section provides an overview of commissioning, how it developed, and its current prevalence today.

Overview of Commissioning

Commissioning Defined

Commissioning is the methodology for bringing to light design errors, equipment malfunctions, and improper control strategies at the most cost-effective time to implement corrective action. Commissioning facilitates a thorough understanding of a facility's intended use and ensures that the design meets the intent through coordination, communication, and cooperation of the design and installation team. Commissioning ensures that individual components function as a cohesive system. For these reasons, commissioning is best when it begins in the predesign phase of a construction project and can in one sense be viewed as the most important form of quality assurance for construction projects.

Unfortunately, there are many misconceptions associated with commissioning, and perhaps for this reason, commissioning has been executed with varying degrees of success, depending on the level of understanding of what constitutes a "commissioned" project. American Society of Heating, Refrigerating and Air-Conditioning Engineers (AHSRAE) guidelines define commissioning as: the process of ensuring that systems are designed, installed, functionally tested, and capable of being operated and maintained to perform conformity with the design intent … [which] begins with planning and includes design, construction, startup, acceptance, and training, and is applied throughout the life of the building.[4] However, for many contractors and owners, this definition is simplified into the process of system startup and checkout or completing punch-list items.

Of course, a system startup and checkout process carried out by a qualified contractor is one important aspect of commissioning. Likewise, construction inspection and the generation and completion of punch-list items by a construction manager are other important aspects of commissioning. However, it takes much more than these standard installation activities to have a truly "commissioned" system. Commissioning is a comprehensive and methodical approach to the design and implementation of a cohesive system that culminates in the successful turnover of the facility to maintenance staff trained in the optimal operation of those systems.

Without commissioning, a contractor starts up the equipment but doesn't look beyond the startup to system operation. Assessing system operation requires the contractor to think about how the equipment will be used under different conditions. As one easily comprehended example, commissioning requires the contractor to think about how the equipment will operate as the seasons change. Analysis of the equipment and building systems under different load conditions due to seasonal conditions at the time of system startup will almost certainly result in some adjustments to the installed equipment for all but the most benign climates. However, addressing this common requirement of varying load due to seasonal changes most likely will not occur without commissioning. Instead, the maintenance staff is simply handed a building with minimal training and left to figure out how to achieve optimal operation on their own. In this seasonal example, one can just imagine how pleased the maintenance staff would be with the contractor when a varying load leads to equipment or system failure—often under very hot or very cold conditions!

Thus, the primary goal of commissioning is to achieve optimal building systems performance. For heating, ventilation, and air-conditioning (HVAC) systems, optimal performance can be measured by thermal comfort, indoor air quality, and energy savings. Energy savings, however, can result simply from successful commissioning targeted at achieving thermal comfort and excellent indoor air quality. Proper commissioning will prevent HVAC system malfunction—such as simultaneous heating and cooling, and overheating or overcooling—and successful malfunction prevention translates directly into energy savings. Accordingly, energy savings rise with increasing comprehensiveness of the commissioning plan. Commissioning enhances energy performance (savings) by ensuring and maximizing the performance of specific energy efficiency measures and correcting problems causing excessive energy use.[3] Commissioning, then, is the most cost-effective means of improving energy efficiency in commercial buildings. In the next section, the two main types of commissioning in use today—acceptance-based and processed-based—are compared and contrasted.

Acceptance-Based vs. Process-Based Commissioning

Given the varied nature of construction projects, contractors, owners, buildings, and the needs of the diverse participants in any building projection, commissioning can of course take a variety of forms. Generally, however, there are two types of commissioning: acceptance-based and process-based. Process-based commissioning is a comprehensive process that begins in the predesign phase and continues through postacceptance, while acceptance-based commissioning, which is perceived to be the cheaper method, basically examines whether an installation is compliant with the design and accordingly achieves more limited results.

Acceptance-based commissioning is the most prevalent type due to budget constraints and the lack of hard cost/benefit data to justify the more extensive process-based commissioning. Acceptance-based commissioning does not involve the contractor in the design process but simply constitutes a process to ensure that the installation matches the design. In acceptance-based commissioning, confrontational relationships are more likely to develop between the commissioning agent and the contractor because the commissioning agent and the contractor, having been excluded from the design phase, have not "bought in" to the design and thus may be more likely to disagree in their interpretation of the design intent.

Because the acceptance-based commissioning process simply validates that the installation matches the design, installation issues are identified later in the cycle. Construction inspection and regular commissioning meetings do not occur until late in the construction/installation phase with acceptance-based commissioning. As a result, there is no early opportunity to spot errors and omissions in the design, when remedial measures are less costly to undertake and less likely to cause embarrassment to the designer and additional costs to the contractor. As most contractors will readily agree, addressing issues spotted in the design or submittal stages of construction is typically much less costly than addressing them after installation, when correction often means tearing out work completed and typically delays the completion date.

Acceptance-based commissioning is cheaper, however, at least on its face, being approximately 80% of the cost of process-based commissioning.[2] If only the initial cost of commissioning services is considered, many owners will conclude that this is the most cost-effective commissioning approach. However, this 20% cost differential does not take into account the cost of correcting defects after the fact that process-based commissioning could have identified and corrected at earlier stages of the project. One need encounter only a single, expensive-to-correct project to become a devotee of process-based commissioning.

Process-based commissioning involves the commissioning agent in the predesign through the construction, functional testing, and owner training. The main purpose is quality assurance—assurance that the design intent is properly defined and followed through in all phases of the facility life cycle. It includes ensuring that the budget matches the standards that have been set forth for the project so that last-minute "value engineering" does not undermine the design intent, that the products furnished and installed meet the performance requirements and expectation compliant with the design intent, and that the training and documentation provided to the facility staff equip them to maintain facility systems true to the design intent.

As the reader will no doubt already appreciate, the author believes that process-based commissioning is far more valuable to contractors and owners than acceptance-based commissioning. Accordingly, the remainder of this entry will focus on process-based commissioning, after a brief review of the history of commissioning from inception to date, which demonstrates that our current, actively evolving construction market demands contractors and contracting professionals intimately familiar with and expert in conducting process-based commissioning.

History of Commissioning

Commissioning originated in the early 1980s in response to a large increase in construction litigation. Owners were dissatisfied with the results of their construction projects and had recourse only to the courts and litigation to resolve disputes that could not be resolved by meeting directly with their contractors. While litigation attorneys no doubt found this satisfactory approach to resolving construction project issues, owners did not, and they actively began looking for other means to gain assurance that they were receiving systems compliant with the design intent and with the performance characteristics and quality specified. Commissioning was the result.

While commissioning enjoyed early favor and wide acceptance, the recession of the mid-1980s placed increasing market pressure on costs, and by the mid-to late 1980s it forced building professionals to reduce fees and streamline services. As a result, acceptance-based commissioning became the norm, and process-based commissioning became very rare. This situation exists in most markets today; however, the increasing cost of energy, the growing awareness of the global threat of climate change and the need to reduce CO2 emissions as a result, and the legal and regulatory changes resulting from both are creating a completely new market in which process-based commissioning will become ever more important, as discussed in the following section.

Prevalence of Commissioning Today

There are varying degrees of market acceptance of commissioning from state to state. Commissioning is in wide use in California and Texas, for example, but it is much less widely used in many other states. The factors that impact the level of market acceptance depend upon

- The availability of commissioning service providers
- State codes and regulations
- Tax credits
- Strength of the state's economy[1]

State and federal policies with regard to commissioning are changing rapidly to increase the demand for commissioning. Also, technical assistance and funding are increasingly available for projects that can serve as demonstration projects for energy advocacy groups. The owner should investigate how each of these factors could benefit the decision to adopt commissioning in future construction projects.

Some of the major initiatives driving the growing market acceptance of commissioning are:

- Federal government's U.S. Energy Policy Act of 1992 and Executive Order 12902, mandating that federal agencies develop commissioning plans
- Portland Energy Conservation, Inc.; National Strategy for Building Commissioning; and their annual conferences
- ASHRAE HVAC Commissioning Guidelines (1989)
- Utilities establishing commissioning incentive programs
- Energy Star building program
- Leadership in Energy Environmental Design (LEED) certification for new construction
- Building codes
- State energy commission research programs

Currently, the LEED is having the largest impact in broadening the acceptance of commissioning. The Green Building Council is the sponsor of LEED and is focused on sustainable design—design and construction practices that significantly reduce or eliminate the cradle-to-grave negative impacts of buildings on the environment and building occupants. Leadership in energy efficient design encourages sustainable site planning, conservation of water and water efficiency, energy efficiency and renewable energy, conservation of materials and resources, and indoor environmental quality.

With this background on commissioning, the various components of the commissioning process can be explored, beginning with an evaluation of what building systems should be subject to the commissioning process.[5]

Commissioning Process

Systems to Include in the Commissioning Process

The general rule for including a system in the commissioning process is: the more complicated the system is the more compelling is the need to include it in the commissioning process. Systems that are required to integrate or interact with other systems should be included. Systems that require specialized trades working independently to create a cohesive system should be included, as well as systems that are critical to the operation of the building. Without a commissioning plan on the design and construction of these systems, installation deficiencies are likely to create improper interaction and operation of system components.

For example, in designing a lab, the doors should be included in the commissioning process because determining the amount of leakage through the doorways could prove critical to the ability to maintain critical room pressures to ensure proper containment of hazardous material. Another common example is an energy retrofit project. Such projects generally incorporate commissioning as part of the measurement and verification plan to ensure that energy savings result from the retrofit process.

For any project, the owner must be able to answer the question of why commissioning is important.

Why Commissioning?

A strong commissioning plan provides quality assurance, prevents disputes, and ensures contract compliance to deliver the intended system performance. Commissioning is especially important for HVAC systems that are present in virtually all buildings because commissioned HVAC systems are more energy efficient.

The infusion of electronics into almost every aspect of modern building systems creates increasingly complex systems requiring many specialty contractors. Commissioning ensures that these complex subsystems will interact as a cohesive system.

Commissioning identifies design or construction issues and, if done correctly, identifies them at the earliest stage in which they can be addressed most cost effectively. The number of deficiencies in new construction exceeds existing building retrofit by a factor of 3.[3] Common issues that can be identified by commissioning that might otherwise be overlooked in the construction and acceptance phase are: air distribution problems (these occur frequently in new buildings due to design capacities, change of space utilization, or improper installation), energy problems, and moisture problems.

Despite the advantages of commissioning, the current marketplace still exhibits many barriers to adopting commissioning in its most comprehensive and valuable forms.

Barriers to Commissioning

The general misperception that creates a barrier to the adoption of commissioning is that it adds extra, unjustified costs to a construction project. Until recently, this has been a difficult perception to combat because there are no energy-use baselines for assessing the efficiency of a new building. As the cost of energy continues to rise, however, it becomes increasingly less difficult to convince owners that commissioning is cost effective. Likewise, many owners and contractors do not appreciate that commissioning can reduce the number and cost of change orders through early problem identification. However, once the contractor and owner have a basis on which to compare the benefit of resolving a construction issue earlier as opposed to later, in the construction process, commissioning becomes easier to sell as a win–win proposal.

Finding qualified commissioning service providers can also be a barrier, especially in states where commissioning is not prevalent today. The references cited in this entry provide a variety of sources for identifying associations promulgating commissioning that can provide referrals to qualified commissioning agents.

For any owner adopting commissioning, it is critical to ensure acceptance of commissioning by all of the design construction team members. Enthusiastic acceptance of commissioning by the design team will have a very positive influence on the cost and success of your project. An objective of this entry is to provide a source of information to help gain such acceptance by design construction team members and the participants in the construction market.

Selecting the Commissioning Agent

Contracting an independent agent to act on behalf of the owner to perform the commissioning process is the best way to ensure successful commissioning. Most equipment vendors are not qualified and are likely to be biased against discovering design and installation problems—a critical function of the commissioning agent—with potentially costly remedies. Likewise, systems integrators have the background in control systems and data exchange required for commissioning but may not be strong in mechanical design, which is an important skill for the commissioning agent. Fortunately, most large mechanical consulting firms offer comprehensive commissioning services, although the desire to be competitive in the selection processes sometimes forces these firms to streamline their scope on commissioning.

Owners need to look closely at the commissioning scope being offered. An owner may want to solicit commissioning services independently from the selection of the architect/mechanical/electrical/plumbing design team or, minimally, to request specific details on the design team's approach to commissioning. If an owner chooses the same mechanical, electrical, and plumbing (MEP) firm for design and commissioning, the owner should ensure that there is physical separation between the designer and commissioner to ensure that objectivity is maintained in the design review stages. An owner should consider taking on the role of the commissioning agent directly, especially if qualified personnel exist in-house. This approach can be very cost effective. The largest obstacles to success with an in-house commissioning agent are the required qualifications and the need to dedicate a valuable resource to the commissioning effort. Many times, other priorities may interfere with the execution of the commissioning process by an in-house owner's agent.

There are three basic approaches to selecting the commissioning agent:

Negotiated—best approach for ensuring a true partnership
Selective bid list—preapproved list of bidders
Competitive—open bid list

Regardless of the approach, the owner should clearly define the responsibilities of the commissioning agent at the start of the selection process. Fixed-cost budgets should be provided by the commissioning agent to the owner for the predesign and design phases of the project, with not-to-exceed budgets submitted for the construction and acceptance phases. Firm service fees should be agreed upon as the design is finalized.

Skills of a Qualified Commissioning Agent

A commissioning agent needs to be a good communicator, both in writing and verbally. Writing skills are important because documentation is critical to the success of the commissioning plan. Likewise, oral communication skills are important because communicating issues uncovered in a factual and nonaccusatory manner is most likely to resolve those issues efficiently and effectively. The commissioning agent should have practical field experience in MEP controls design and startup to be able to identify potential issues early. The commissioning agent likewise needs a thorough understanding of how building structural design impacts building systems. The commissioning agent must be an effective facilitator and must be able to decrease the stress in stressful situations. In sum, the commissioning agent is the cornerstone of the commissioning team and the primary determinant of success in the commissioning process.

At least ten organizations offer certifications for commissioning agents. However, there currently is no industry standard for certifying a commissioning agent. Regardless of certification, the owner should carefully evaluate the individuals to be performing the work from the commissioning firm selected. Individual experience and reputation should be investigated. References for the lead commissioning agent are far more valuable than references for the executive members of a commissioning firm in evaluating potential commissioning agents. The commissioning agent selected will, however, only be one member of a commissioning team, and the membership of the commissioning team is critical to successful commissioning.

Commissioning Team

The commissioning team is composed of representatives from all members of the project delivery team: the commissioning agent, representatives of the owner's maintenance team, the architect, the MEP designer, the construction manager, and systems contractors. Each team member is responsible for a particular area of expertise, and one important function of the commissioning agent is to act as a facilitator of intrateam communication.

The maintenance team representatives bring to the commissioning team the knowledge of current operations, and they should be involved in the commissioning process at the earliest stage, defining the design intent in the predesign phase, as described below. Early involvement of maintenance team representatives ensures a smooth transition from construction to a fully operational facility, and aids in the acceptance and full use of the technologies and strategies that have been developed during the commissioning process. Involvement of the maintenance team representatives also shortens the building turnover transition period.

The other members of the commissioning team have defined and important functions. The architect leads the development of the design intent document (DID). The MEP designer's responsibilities are to develop the mechanical systems that support the design intent of the facility and comply with the owner's current operating standards. The MEP schematic design is the basis for the systems installed and is discussed further below. The construction manager ensures that the project installation meets the criteria defined in the specifications, the budget requirements, and the predefined schedule. The systems contractors' responsibilities are to furnish and install a fully functional system that meets the design specifications. There are generally several contractors whose work must be coordinated to ensure that the end product is a cohesive system.

Once the commissioning team is in place, commissioning can take place, and it occurs in defined and delineated phases—the subject of the following section.

Commissioning Phases

The commissioning process occurs over a variety of clearly delineated phases. The commission plan is the set of documents and events that defines the commissioning process over all phases. The commissioning plan needs to reflect a systematic, proactive approach that facilitates communication and cooperation of the entire design and construction team.

The phases of the commissioning process are:

Predesign
Design
Construction/installation
Acceptance
Postacceptance

These phases and the commissioning activities associated with them are described in the following sections.

Predesign Phase

The predesign phase is the phase in which the design intent is established in the form of the DID. In this phase of a construction project, the role of commissioning in the project is established if process-based commissioning is followed. Initiation of the commissioning process in the predesign phase increases acceptance of the commissioning process by all design team members. Predesign discussions about commissioning allow all team members involved in the project to assess and accept the importance of commissioning to a successful project. In addition, these discussions give team members more time to assimilate the impact of commissioning on their individual roles and responsibilities in the project. A successful project is more likely to result when the predesign phase is built around the concept of commissioning instead of commissioning's being imposed on a project after it has been designed.

Once an owner has decided to adopt commissioning as an integral part of the design and construction of a project, the owner should be urged to follow the LEED certification process, as discussed above. The commissioning agent can assist in the documentation preparation required for the LEED certification, which occurs in the postacceptance phase.

The predesign phase is the ideal time for an owner to select and retain the commissioning agent. The design team member should, if possible, be involved in the selection of the commissioning agent because that member's involvement will typically ensure a more cohesive commissioning team. Once the commissioning agent is selected and retained, the commissioning-approach outline is developed. The commissioning-approach outline defines the scope and depth of the commissioning process to be employed for the project. Critical commissioning questions are addressed in this outline. The outline will include, for most projects, answers to the following questions:

What equipment is to be included?
What procedures are to be followed?
What is the budget for the process?

As the above questions suggest, the commissioning budget is developed from the choices made in this phase. Also, if the owner has a commissioning policy, it needs to be applied to the specifics of the particular project in this phase.

The key event in the predesign phase is the creation of the DID, which defines the technical criteria for meeting the requirements of the intended use of the facilities. The DID document is often created based in part upon the information received from interviews with the intended building occupants and maintenance staff. Critical information—such as the hours of operation, occupancy levels, special environmental considerations (such as pressure and humidity), applicable codes, and budgetary considerations and limitations—is identified in this document. The owner's preference, if any, for certain equipment or contactors should also be identified at this time. Together, the answers to the critical questions above and the information in the DID are used to develop the commissioning approach outline. A thorough review of the DID by the commissioning agent ensures that the commissioning-approach outline will be aligned with the design intent.

With the commissioning agent selected, the DID document created, and the commissioning approach outline in place, the design phase is ready to commence.

Design Phase

The design phase is the phase in which the schematics and specifications for all components of a project are prepared. One key schematic and set of specifications relevant to the commissioning plan is the MEP schematic design, which specifies installation requirements for the MEP systems. As noted, the DID is the basis for creating the commissioning approach outline in the predesign phase. The DID also serves as the basis for creating the MEP schematic design in the design phase. The DID provides the MEP designer with the key concepts from which the MEP schematic design is developed.

The completed MEP schematic design is reviewed by the commissioning agent for completeness and conformance to the DID. At this stage, the commissioning agent and the other design team members should consider what current technologies, particularly those for energy efficiency, could be profitably included in the design. Many of the design enhancements currently incorporated into existing buildings during energy retrofitting for operational optimization are often not considered in new building construction. This can result in significant lost opportunity, so these design enhancements should be reviewed for incorporation into the base design during this phase of the commissioning process. This point illustrates the important principle that technologies important to retrocommissioning should be applied to new building construction—a point that is surprisingly often overlooked in the industry today.

For example, the following design improvements and technologies should always be considered for applicability to a particular project:

- Variable-speed fan and pumps installed
- Chilled water cooling (instead of DX cooling)
- Utility meters for gas, electric, hot water, chilled water, and steam at both the building and system level
- CO_2 implementation for minimum indoor air requirements

This list of design improvements is not exhaustive; the skilled commissioning agent will create and expand personalized lists as experience warrants and as the demands of particular projects suggest.

In addition to assisting in the evaluation of potential design improvements, the commissioning agent further inspects the MEP schematic design for:

- Proper sizing of equipment capacities
- Clearly defined and optimized operating sequences
- Equipment accessibility for ease of servicing

Once the commissioning agent's review is complete, the feedback is discussed with the design team to determine whether its incorporation into the MEP schematic design is warranted. The agreed-upon changes or enhancements are incorporated, thus completing the MEP schematic design.

The completed MEP schematic design serves as the basis on which the commissioning agent will transform the commissioning-approach outline into the commissioning specification.

The commissioning specification is the mechanism for binding contractually the contractors to the commissioning process. Expectations are clearly defined, including:

- Responsibilities of each contractor
- Site meeting requirements
- List of the equipment, systems, and interfaces
- Preliminary verification checklists
- Preliminary functional-performance testing checklists
- Training requirements and who is to participate
- Documentation requirements

- Postconstruction documentation requirements
- Commissioning schedule
- Definition for system acceptance
- Impact of failed results

Completion of the commissioning specification is required to select the systems contractor in a competitive solicitation. Alternatively, however, owners with strong, preexisting relationships with systems contractors may enter into a negotiated bid with those contractors, who can then be instrumental in finalizing the commissioning specification.

Owners frequently select systems contractors early in the design cycle to ensure that the contractors are involved in the design process. As noted above, if there are strong, preexisting relationships with systems contractors, early selection without a competitive selection process (described in the following paragraph) can be very beneficial. However, if there is no competitive selection process, steps should be taken to ensure that the owner gets the best value. For example, unit pricing should be negotiated in advance to ensure that the owner is getting fair and reasonable pricing. The commissioning agent and the MEP designer can be good sources for validating the unit pricing. The final contract price should be justified with the unit pricing information.

If the system selection process is competitive, technical proposals should be requested with the submission of the bid price. The systems contractors need to demonstrate a complete understanding of the project requirements to ensure that major components have not been overlooked. Information such as the project schedule and manpower loading for the project provide a good basis from which to measure the contractor's level of understanding. If the solicitation does not have a preselected list of contractors, the technical proposal should include the contractor's financial information, capabilities, and reference lists. As in the negotiated process described above, unit pricing should be requested to ensure the proper pricing of project additions and deletions. The review of the technical proposals should be included in the commissioning agent's scope of work.

A mandatory prebid conference should be held to walk the potential contractors through the requirements and to reinforce expectations. This conference should be held regardless of the approach—negotiated or competitive— used for contractor selection. The contractor who is to bear the financial burden for failed verification tests and subsequent functional-performance tests should be reminded of these responsibilities to reinforce their importance in the prebid meeting. The prebid conference sets the tone of the project and emphasizes the importance of the commissioning process to a successful project.

Once the MEP schematic design and commissioning specification are complete, and the systems contractors have been selected, the construction/installation phase begins.

Construction/Installation Phase

Coordination, communication, and cooperation are the keys to success in the construction and installation phase. The commissioning agent is the catalyst for ensuring that these critical activities occur throughout the construction and installation phase.

Frequently, value engineering options are proposed by the contractors prior to commencing the installation. The commissioning agent should be actively involved in the assessment of any options proposed. Many times, what appears to be a good idea in construction can have a disastrous effect on a facility's long-term operation. For example, automatic controls are often value engineered out of the design, yet the cost of their inclusion is incurred many times over in the labor required to perform their function manually over the life of the building. The commissioning agent can ensure that the design intent is preserved, the life-cycle costs are considered, and the impact on all systems of any value engineering modification proposed is thoroughly evaluated.

Once the design aspects are complete and value engineering ideas have been incorporated or rejected, the submittals, including verification checklists, need to be finalized. The submittals documentation is prepared by the systems contractors and reviewed by the commissioning agent. There are two types of submittals: technical submittals and commissioning submittals. Both types of submittals are discussed below.

Technical submittals are provided to document the systems contractors' interpretation of the design documents. The commissioning agent reviews the technical submittals for compliance and completeness. It is in this submittal review process that potential issues are identified prior to installation, reducing the need for rework and minimizing schedule delays. The technical submittals should include:

- Detailed schematics
- Equipment data sheets
- Sequence of operation
- Bill of material

A key technical submittal is the testing, adjusting, and balancing submittal (TAB). The TAB should include:

- TAB procedures
- Instrumentation
- Format for results
- Data sheets with equipment design parameters
- Operational readiness requirements
- Schedule

In addition to the TAB, other technical submittals, such as building automation control submittals, will be obtained from the systems contractors and reviewed by the commissioning agent.

The commissioning submittal generally follows the technical submittal in time and includes:

- Verification checklists
- Startup requirements
- Test and balance plan
- Training plan

The commissioning information in the commissioning submittal is customized for each element of the system.

These submittals, together with the commissioning specification, are incorporated into the commissioning plan, which becomes a living document codifying the results of the construction commissioning activities. This plan should be inspected in regular site meetings. Emphasis on the documentation aspect of the commissioning process early in the construction phase increases the contractors' awareness of the importance of commissioning to a successful project.

In addition to the submittals, the contractors are responsible for updating the design documents with submitted and approved equipment data and field changes on an ongoing basis. This update design document should be utilized during the testing and acceptance phase.

The commissioning agent also performs periodic site visits during the installation to observe the quality of workmanship and compliance with the specifications. Observed deficiencies should be discussed with the contractor and documented to ensure future compliance. Further inspections should be conducted to ensure that appropriate corrective action has been taken.

The best way to ensure that the items discussed above are addressed in a timely manner is to hold regularly scheduled commissioning meetings that require the participation of all systems contractors. This is the mechanism for ensuring that communication occurs. Meeting minutes prepared by the commissioning agent document the discussions and decisions reached. Commissioning meetings should be coordinated with the regular project meetings because many participants in a construction project need to attend both meetings.

Typical elements of a commissioning meeting include:

- Discussing field installation issues to facilitate rapid response to field questions
- Updating design documents with field changes
- Reviewing the commissioning agent's field observations
- Reviewing progress against schedule
- Coordinating multicontractor activities

Once familiar with the meeting process, an agenda will be helpful but not necessary. Meeting minutes should be kept and distributed to all participants.

With approved technical and commissioning plan submittals, as installation progresses, the contractor is ready to begin the system verification testing. The systems contractor generally executes the system verification independently of the commissioning agent. Contractor system verification includes:

- Point-to-point wiring checked out
- Sensor accuracy validated
- Control loops exercised

Each of the activities should be documented for each control or system element, and signed and dated by the verification technician.

The documentation expected from these activities should be clearly defined in the commissioning specification to ensure its availability to the commissioning agent for inspection of the verification process. The commissioning agent's role in the system verification testing is to ensure that the tests are completed and that the results reflect that the system is ready for the functional-performance tests. Because the commissioning agent is typically not present during the verification testing, the documentation controls how successfully the commissioning agent performs this aspect of commissioning.

In addition to system verification testing, equipment startup is an important activity during this phase. Equipment startup occurs at different time frames relative to the system verification testing, depending on the equipment and system involved. There may be instances when the system verification needs to occur prior to equipment startup to prevent a catastrophic event that could lead to equipment failure. The commissioning agent reviews the startup procedures prior to the startup to ensure that equipment startup is coordinated properly with the system verification. Unlike in verification testing, the commissioning agent should be present during HVAC equipment startup to document the results. These results are memorialized in the final commissioning report, so their documentation ultimately is the responsibility of the commissioning agent.

Once system verification testing and equipment startup have been completed, the acceptance phase begins.

Acceptance Phase

The acceptance phase of the project is the phase in which the owner accepts the project as complete and delivered in accordance with the specifications, and concludes with acceptance of the project in its entirety. An effective commissioning process during the installation phase should reduce the time and labor associated with the functional-performance tests of the acceptance phase.

Statistical sampling is often used instead of 100% functional-performance testing to make the process more efficient. A 20% random sample with a failure rate less than 1% indicates that the entire system was properly installed. If the failure rate exceeds 1%, a complete testing of every system may need to be completed to correct inadequacies in the initial checkout and verification testing. This random sampling statistical approach holds the contractor accountable for the initial checkout and test, with the performance testing serving only to confirm the quality and thoroughness of the installation. This approach saves time and money for all involved. It is critical, however, that the ramifications of not meeting the desired results of the random tests are clearly defined in the commissioning specifications.

The commissioning agent witnesses and documents the results of the functional-performance tests, using specific forms and procedures developed for the system being tested. These forms are created with the input of the contractor in the installation phase. Involvement of the maintenance staff in the functional-performance testing is important. The maintenance team is often not included in the design process, so they may not fully understand the design intent. The functional-performance testing can provide the maintenance team an opportunity to learn and appreciate the design intent. If the design intent is to be preserved, the maintenance team must fully understand the design intent. This involvement of the maintenance team increases their knowledge of the system going into the training and will increase the effectiveness of the training.

Training of the maintenance team is critical to a successful operational handover once a facility is ready for occupancy. This training should include:

- Operations and maintenance (O&M) manual overview
- Hardware component review
- Software component review
- Operations review
- Interdependencies discussion
- Limitations discussion
- Maintenance review
- Troubleshooting procedures review
- Emergency shutdown procedures review

The support level purchased from the systems contractor determines the areas of most importance in the training and therefore should be determined prior to the training process. Training should be videotaped for later use by new maintenance team members and in refresher courses, and for general reference by the existing maintenance team. Using the O&M manuals as a training manual increases the maintenance team's awareness of the information contained in them, making the O&M manuals more likely to be referenced when appropriate in the future.

The O&M manuals should be prepared by the contractor in an organized and easy-to-use manner. The commissioning agent is sometimes engaged to organize them all into an easily referenced set of documents. The manuals should be provided in both hard-copy and electronic formats, and should include:

- System diagrams
- Input/output lists
- Sequence of operations
- Alarm points list
- Trend points list
- Testing documentation
- Emergency procedures

These services—including functional-performance testing, training, and preparing O&M manuals—should be included in the commissioning plan to ensure the project's successful acceptance. The long-term success of the project, however, is determined by the activities that occur in the postacceptance phase.

Postacceptance Phase

The postacceptance phase is the phase in which the owner takes beneficial occupancy and forms an opinion about future work with the design team, contractors, and the commissioning agent who completed the project. This is also the phase in which LEED certification, if adopted, is completed. Activities that usually occur in the acceptance phase should instead occur in the postacceptance phase. This is due to constraints that are not controllable by the contractor or owner. For example, seasonal changes may make functional-performance testing of some HVAC systems impractical during the acceptance phase for certain load conditions. This generally means that in locations that experience significant seasonal climate change, some of the functional-performance testing is deferred until suitable weather conditions exist. The commissioning agent determines which functional-performance tests need to be deferred and hence carried out in the postacceptance phase.

During the postacceptance phase, the commissioning agent prepares a final commissioning report that is provided to the owner and design team. The executive summary of this report provides an overall assessment of the design intent conformance. The report details whether the commissioned equipment and systems meet the commissioning requirements. Problems encountered and corrective actions taken are documented in this report. The report also includes the signed and dated startup and functional-performance testing checklists.

The final commissioning report can be used profitably as the basis of a "lessons learned" meeting involving the design team so that the commissioning process can be continuously improved and adaptations can be made to the owner's commissioning policy for future projects. The owner should use the experience of the first commissioned project to develop the protocols and standards for future projects. The documentation of this experience is the owner's commissioning policy. Providing this policy and the information it contains to the design and construction team for the next project can help the owner reduce budget overruns by eliminating any need to reinvent protocols and standards and by setting the right expectations earlier in the process.

Commissioning therefore should not be viewed as a onetime event but should instead be viewed as an operational philosophy. A recommissioning or continuous commissioning plan should be adopted for any building to sustain the benefits delivered from a commissioning plan. The commissioning agent can add great value to the creation of the recommissioning plan and can do so most effectively in the postacceptance phase of the project.

Figure 1 depicts the information development that occurs in the evolution of a commissioning plan and summarizes the information presented in the preceding sections by outlining the various phases of the commissioning process.

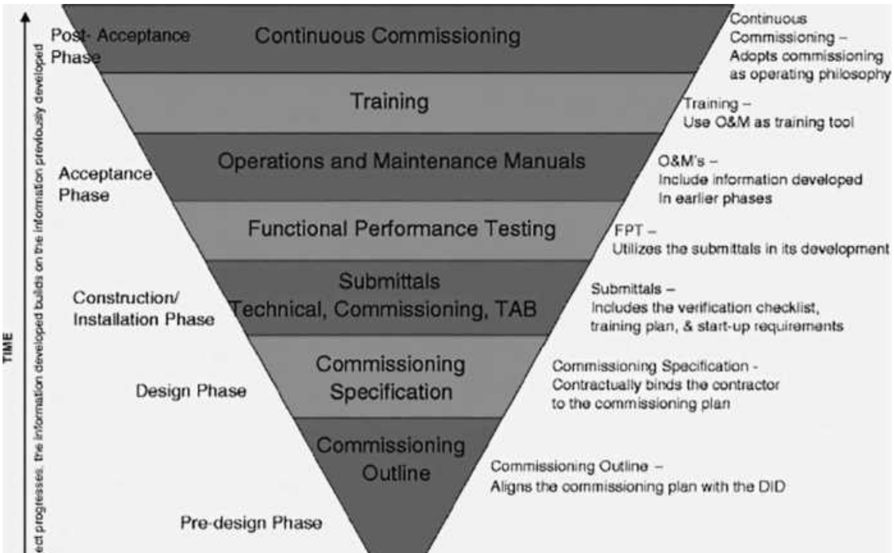

FIGURE 1 The commissioning plan.

With this background, the reader is better positioned for success in future commissioning projects and better prepared to learn the key success factors in commissioning and how to avoid common mistakes in the commissioning process.

Commissioning Success Factors

Ultimately, the owner will be the sole judge of whether a commissioning process has been successful. Thus, second only to the need for a competent, professional commissioning agent, keeping the owner or the owner's senior representative actively involved in and informed at all steps of the commissioning process is a key success factor. The commissioning agent should report directly to the owner or the owner's most senior representative on the project, not only to ensure that this involvement and information transfer occur, but also to ensure the objective implementation of the commissioning plan—a third key success factor.

Another key success factor is an owner appreciation— which can be enhanced by the commissioning agent—that commissioning must be an ongoing process to get full benefit. For example, major systems should undergo periodic modified functional testing to ensure that the original design intent is being maintained or to make system modification if the design intent has changed. If an owner appreciates that commissioning is a continuous process that lasts for the entire life of the facility, the commissioning process will be a success.

Most owners will agree that the commissioning process is successful if success can be measured in a cost/benefit analysis. Cost/benefit or return on equity is the most widely used approach to judge the success of any project. Unfortunately, the misapplication of cost/benefit analyses has been the single largest barrier to the widespread adoption of commissioning. For example, because new construction does not have an energy baseline from which to judge energy savings, improper application of a cost/benefit analysis can lead to failure to include energy savings technologies—technologies the commissioning agent can identify—in the construction process. Similarly, unless one can appreciate how commissioning can prevent schedule delays and rework by spotting issues and resolving them early in the construction process, one cannot properly offset the costs of commissioning with the benefits.

Fortunately, there are now extensive studies analyzing the cost/benefit of commissioning that justify its application. A study performed jointly by Lawrence Berkeley National Laboratory; Portland Energy Conservation, Inc.; and the Energy Systems Laboratory at Texas A&M University provides compelling analytical data on the cost/benefit of commissioning. The study defines the median commissioning cost for new construction as $1 per square foot or 0.6% of the total construction cost. The median simple payback for new construction projects utilizing commissioning is 4.8 years. This simple payback calculation does not take into account the quantified nonenergy impacts, such as the reduction in the cost and frequency of change orders or premature equipment failure due to improper installation practices. The study quantifies the median nonenergy benefits for new construction at $1.24 per square foot per year.[3]

While the primary cost component of assessing the cost/benefit of commissioning lies in whether there was a successful negotiation of the cost of services with the commissioning service provider, the more important aspect of the analysis relates to the outcomes of the process. For example, after a commissioning process is complete, what are the answers to these questions?

Are the systems functioning to the design intent?
Has the owner's staff been trained to operate the facility?
How many of the systems are operated manually a year after installation?

Positive answers to these and similar questions will ensure that any cost/benefit analysis will demonstrate the value of commissioning.

To ensure that a commissioning process is successful, one must avoid common mistakes. A commissioning plan is a customized approach to ensuring that all the systems operate in the most effective and efficient manner. A poor commissioning plan will deliver poor results. A common mistake is to use an existing commissioning plan and simply insert it into a specification to address commissioning. Each commissioning plan should be specifically tailored to the project to be commissioned.

Also, perhaps due to ill-conceived budget constraints, commissioning is implemented only in the construction phase. Such constraints are ill conceived because the cost of early involvement of the commissioning agent in the design phases is insignificant compared with the cost of correcting design defects in the construction phase. Significant cost savings can arise from identifying design issues prior to construction. Studies have shown that 80% of the cost of commissioning occurs in the construction phase.[2] Also, the later the commissioning process starts, the more confrontational commissioning becomes, making it more expensive to implement later in the process.[2] Therefore, adopting commissioning early in the project is a key success factor.

Value engineering often results in ill-informed, last-minute design changes that have an adverse and unintended impact on the overall building performance and energy use.[3] By ensuring that the commissioning process includes careful evaluation of all value engineering proposals, the commissioning agent and owner can avoid such costly mistakes.

Finally, the commissioning agent's incentive structure should not be tied to the number of issues brought to light during the commissioning process, as this can create an antagonistic environment that may create more problems than it solves. Instead, the incentive structure should be outcome based and the questions outlined above regarding compliance with design intent, training results, and postacceptance performance provide excellent bases for a positive incentive structure.

Conclusion

Commissioning should be performed on all but the most simplistic of new construction projects. The benefits of commissioning include:

- Optimization of building performance
  —Enhanced operation of building systems
  —Better-prepared maintenance staff
  —Comprehensive documentation of systems
  —Increased energy efficiency
  —Improved quality of construction
- Reduced facility life-cycle cost
  —Reduced impact of design changes
  —Fewer change orders
  —Fewer project delays
  —Less rework or postconstruction corrective work
  —Reduced energy costs
- Increased occupant satisfaction
  —Shortened turnover transition period
  —Improved system operation
  —Improved system reliability

With these benefits, owners and contractors alike should adopt the commissioning process as the best way to ensure cost-efficient construction and the surest way to a successful construction project.

Energy Sources: Renewable versus Non-Renewable

Marc A. Rosen

Introduction

Energy can exist in many forms and be converted from form to form by energy-conversion technologies. Society and the people within it use energy carriers (often simply referred to as energy), which are produced from energy sources, in all aspects of living.

A basic understanding of renewable energy and non-renewable energy is provided in this entry. Renewable energy includes the energy received directly and indirectly from the sun as well as energy derived from other natural forces. Non-renewable energy includes non-renewable energy resources as well as energy forms that do not exist naturally but are produced by people. The main types of renewable energy are listed in Table 1, and the main types of non-renewable energy are listed in Table 2. All of these have been studied extensively.[1–10]

From the breakdown of renewable and non-renewable energy in Tables 1 and 2, it is clear that energy resources are often categorized into two groups: (1) those generally acknowledged to be finite and non-renewable and therefore not sustainable over the long term (e.g., fossil fuels, peat, uranium) and (2) those generally considered renewable and therefore sustainable over the relatively longer term (e.g., sunlight, wind, tides, falling water). Wastes (convertible to useful energy forms through, for example, waste-to-energy incineration facilities) and biomass fuels are also sometimes viewed as renewable energy sources.

In this entry, energy forms, sources, and carriers are explained. Renewable energy and non-renewable energy are discussed, and energy-conversion technologies are described. Then, energy use and factors

TABLE 1 Types of Renewable Energy

- Direct solar radiation
- Solar-related energy*
  - Water based
    - Hydraulic energy (falling and running water, including large and small hydro)
    - Wave energy
    - Ocean thermal energy (from temperature difference between surface and deep waters of the ocean)
  - Air based
    - Wind energy
  - Land based
    - Biomass (where the rate of use does not exceed the rate of replenishment)
    - Geothermal energy (ambient)
  - Non-solar-related energy
  - Geothermal energy (internal heat of the earth)
  - Tidal energy (from gravitational forces of the sun and moon and the rotation of the earth)

*As explained in the text, fossil fuels are originally solar energy, but with a very long time lag for their transformation. So technically, they are solar-related energies. But for practical purposes, fossil fuels are non-renewable, so they are not listed in this table.

TABLE 2 Types of Non-Renewable Energy

- Energy sources
  - Fossil fuels
    - Conventional
      - Coal
      - Oil
      - Natural gas
    - Alternative
      - Oil shales
      - Tar sands
      - Peat
  - Non-fossil fuels
    - Uranium
    - Fusion material (e.g., deuterium)
    - Wastes (which can be used as energy forms or converted to more useful energy forms)
- Energy currencies
  - Work
  - Electricity
  - Thermal energy
    - Heat (or a heated medium such as hot air, steam, exhaust gases)
    - Cold (or a cooled medium such as cold brine, ice)
  - Secondary chemical fuels
    - Conventional
      - Oil products (e.g., gasoline, diesel fuel, naphtha)
      - Synthetic gaseous fuels (e.g., from coal gasification)
      - Coal products (e.g., coke)
    - Non-conventional
      - Methanol
      - Ammonia
      - Hydrogen

in energy selection are discussed. Finally, efficiencies for energy use are presented, along with measures to improve energy efficiency.

Forms, Sources, and Carriers of Energy

Energy comes in a variety of forms, including fossil fuels (e.g., coal, oil, natural gas), fossil fuel-based products (e.g., gasoline, diesel fuel), uranium, electricity, work (e.g., mechanical energy in a rotating engine shaft), heat, heated substances (e.g., steam, hot air), and light and other electromagnetic radiation.

Energy sources (sometimes called primary energy forms) are found in the natural environment. Some are available in finite quantities (e.g., fossil fuels, fossil fuel-containing substances such as oil sands, peat, and uranium). Some energy resources are renewable (or relatively renewable), including sunlight (or solar energy), falling water, wind, tides, geothermal heat, wood, and other biomass fuels (provided the growth rate exceeds or meets the rate of use). Energy sources are often processed from their raw forms prior to use.

Energy carriers (sometimes called energy currencies) are the energy forms that we transport and use, and include some energy sources (e.g., fossil fuels) and processed (or secondary) energy forms (e.g., gasoline, electricity, work, heat). The processed energy forms are not found in the environment.

The distinction between energy carriers and sources is important. Energy carriers can exist in a variety of forms and can be converted from one form to another, while energy sources are the original resource from which an energy carrier is produced. Misunderstanding sometimes results between energy sources and carriers because some energy sources are also energy carriers. For example, hydrogen is an energy carrier, not an energy source, and can be produced from a wide range of resources using various energy-conversion processes (e.g., water electrolysis, reforming of natural gas, coal gasification). In this way, hydrogen energy is analogous to electricity. Nevertheless, hydrogen is often erroneously referred to as an energy source, especially in discussions of its potential future role as a chemical energy carrier to replace fossil fuels.

Renewable Energy

Renewable energy includes the solar radiation incident on the earth and the energy forms that directly result from that radiation. Renewable energy also includes the energy supplied by other natural forces, such as gravitation and the rotation of the earth. The types of renewable energy are summarized in Table 1. It is this energy that makes possible the existence of ecosystems, human civilizations, and life itself.

Solar Energy

Direct solar radiation is the main type of renewable energy.[11] The daily energy output of the sun is 8.33×10^{25} kWh, of which the earth receives 4.14×10^{15} kWh. At any instant, the rate of solar energy reaching the earth is 1.75×10^{17} W, which is about 20,000 times greater than the total energy-use rate of the world. Solar radiation can be converted directly to electricity in photovoltaic devices. Also, solar energy can be collected as heat and used for thermal processes such as space and water heating or concentrated for use for in high-temperature heating and thermal electricity generation.

Most of the energy that enters the system of the earth and its atmosphere eventually exits to space. This concept can be demonstrated by considering the earth–sun energy balance (see Figure 1). A general energy balance

$$\text{Energy input} - \text{Energy output} = \text{Energy accumulation}$$

can be applied to the earth when

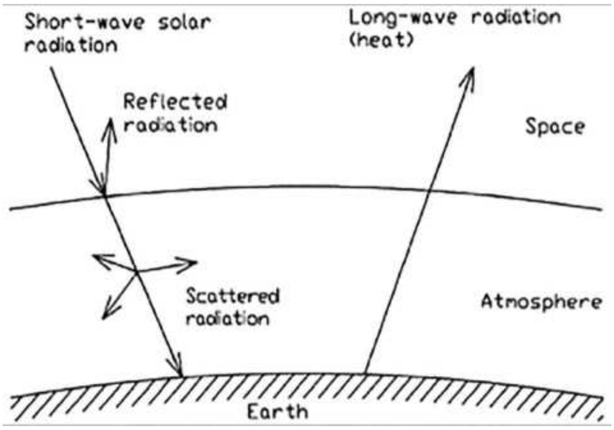

FIGURE 1 Earth–sun energy balance.

- The energy input is the short-wave solar radiation entering the atmosphere.
- The energy output is the long-wave radiation exiting the atmosphere to space.
- The energy accumulation term is the increase in energy of the earth and its atmosphere.

The main implication of this global energy balance is that since the average temperature of the earth is relatively constant, the energy accumulation term is zero. Therefore, the energy output is equal to the energy input for the planet.

Global warming is caused by a disruption in the earth–sun energy balance. The main cause of global warming is increased releases of atmospheric "greenhouse gases" that absorb radiation in the 8–20 μm region. When greenhouse gas concentrations increase in the atmosphere, energy output from the earth and its atmosphere (Figure 1) is reduced while energy input remains constant. Thus, the energy accumulation term becomes positive, leading to an increase in the average temperature of the earth. Eventually, if concentrations of greenhouse gases in the atmosphere stabilize at new levels, the energy balance is re-established but at some higher average planetary temperature.

Solar-Related Energy

Several types of renewable energy are a consequence of solar radiation. These can be loosely arranged into water, air, and land groupings. Some forms of solar-derived energy are more common, for reasons of practicality, economics, and environmental impact.

Water-Based Solar-Related Energy. The most common solar-related energy is hydraulic energy, which includes falling and running water in natural settings such as rivers and waterfalls. Large-scale hydroelectric generating installations are common. Most economically utilizable hydraulic resources have already been developed. Recently, interest in the potential uses of small-scale hydro has grown. Other forms of solar-related energy involve water. Wave energy systems that take advantage of the motion of waves have been proposed, although the potential contribution from wave energy is relatively small. Ocean thermal energy arises from the temperature difference between surface and deep waters of the ocean. This temperature difference can be utilized to drive a heat engine, and several ocean thermal energy-conversion (OTEC) devices have been tested.

Land-Based Solar-Related Energy. Biomass energy includes wood and other forms of plants and organic matter. Biomass can act as a fuel itself or can be converted into more desirable fuels. Several fast-growing trees have been identified as good candidates for biomass energy production. Biomass energy is only a renewable resource when the rate at which it is used does not exceed the rate at which it is replenished. Another form of solar-related energy that involves land is ambient geothermal energy. This is the energy at ambient temperatures in the ground near the surface, which is maintained predominantly by solar radiation and ambient air temperatures. This ambient energy can be used for heating and/or cooling, especially in conjunction with technologies like heat pumps.

Air-Based Solar-Related Energy. Wind energy is used extensively in some countries (e.g., Denmark) for electricity generation. Its use is growing in recent years, making it more widespread than even a decade ago.[12]

Non-Solar-Related Energy

The main types of renewable energy in this category are geothermal energy,[13] which exists as a consequence of the internal heat of the earth, and tidal energy, which is attributable to the gravitational forces of the sun and moon and the rotation of the earth. Both of these energy sources have been used in limited ways.

Non-Renewable Energy

Non-renewable energy, often called secondary energy, includes both energy resources that are available in limited quantities and not renewable and energy forms produced by humankind.[2–7,13] Different types of non-renewable energy are summarized in Table 2. Non-renewable energy is related to the level of technological development of a society.

Two main categories exist for non-renewable energy:

- Energy resources that are not renewable. The most common of these are fossil fuels, which are the basis of the economy for most industrialized countries. In addition to conventional fossil fuels, there exist alternative fossil fuels such as oil shales, tar sands, and peat. Other non-renewable energy resources include uranium and fusion material (e.g., deuterium).
- Energy currencies not existing naturally. This category of non-renewable energy encompasses energy currencies that do not exist naturally. They include such basic energy forms as work, electricity, and thermal energy. The latter can be either heat or a heated medium like steam or cold water.

At this point, a note on the non-renewability of fossil fuels is necessary for clarity and comprehensiveness. Fossil fuels are originally solar energy, but with a very long time lag for their transformation. Thus, considering the origin of fossil fuels, they could in theory be listed in Table 1 along with other solar-related energies. The non-renewability of fossil fuels deals with the lengthy time lag as well as the unique conditions on Earth that permit the creation of biomass at a much faster rate than its decomposition. Thus, fossil fuels are for practical purposes non-renewable, so they are not listed in Table 1.

Thermal energy in the form of heat or cold can be transported to users over long distances in district heating and/or cooling systems. District heating systems use centralized heating facilities to produce a heated medium that is transported to many users connected along a district heating network. For example, buildings in the cores of many cities are often connected by pipes through which hot water or steam flows to provide space and water heating. Similarly, district cooling involves the central production of a cold medium, which is transported to users through a piping network to provide cooling. Many cities and industrial parks utilize such district energy systems.

Wastes, which include recovered materials and energy that would otherwise be discarded, are also sometimes considered as an energy source in the category of non-renewable energy. Wastes can be used directly as energy forms or converted to more useful forms. Waste materials and waste heat can be recovered for utilization both within a facility and in other facilities where they are needed. For example, waste heat from hot gases (e.g., stack gases) and liquids (e.g., cooling-water discharges) can sometimes be recovered. Also, material wastes can be used in waste-to-energy incineration facilities, which burn garbage to provide heat and to generate electricity. Utilizing such wastes offsets the need for further supplies of external energy.

Non-renewable energy also includes secondary chemical fuels. Some conventional ones include oil-derived products such as gasoline, diesel fuel, and naphtha, as well as synthetic gaseous fuels (e.g., from coal gasification) and coal products (e.g., coke). The types of non-conventional chemical fuels proposed are numerous and include methanol, ammonia, and hydrogen.

Life Cycle Considerations

As many types of non-renewable energy can be produced from energy resources or converted from other types of energy, it is important to understand and consider all the steps in the entire life cycle of an energy product. The following life stages are usually included in assessments:

- Extraction or collection of raw energy resources
- Manufacturing and processing of the desired energy form(s)
- Transportation and distribution of the energy to users
- Energy storage
- Use of the energy to provide services and tasks
- Recovery and reuse of output energy that would otherwise be wasted (e.g., waste heat recovery)
- Recycling of wastes from any of the above steps
- Disposal of final wastes (e.g., materials such as stack gases and solid wastes including ash).

For example, the life cycle of a general energy form may involve the following chain of events:

Raw resource → Finished resource → Energy product → Waste → Waste disposal

Two or more types of energy can be simultaneously produced in some systems. For example, cogeneration is a process that usually refers to the combined generation of electricity (or work) and heat (or a heated medium). Trigeneration refers to an extended cogeneration process in which cooling is provided as a third product.

Some examples of the different life cycles for electricity generation methods from a range of energy sources are presented in Table 3. In that table, methods based on fossil fuels and non-fossil resources are considered. In addition, electricity generation from different energy sources via a less conventional technology, fuel cells, is considered in Table 4. All processes in Tables 3 and 4 include equipment disposal as a final step in the life cycle, although that step is not shown.

TABLE 3 Life Cycles for Selected Energy Sources and Methods for Electricity Generation

Method and Energy Source	Energy-conversion Processes in the Life Cycle
Fossil fuel-based methods	
Natural gas	Extraction via gas well → Transport → Processing → Natural gas-fired power plant
Coal	Coal mining → Transport → Processing → Coal-fired power plant
Oil	Extraction via oil well → Transport (tanker or pipeline) → Refining → Oil-fired power plant
Non-fossil-based methods	
Nuclear	Uranium mining → Transport → Processing → Nuclear power plant
Hydro	Hydraulic turbine
Wind	Wind generator
Solar (thermal)	Solar energy collection → Thermal power plant
Solar (non-thermal)	Solar photovoltaic panels

TABLE 4 Life Cycles for Electricity Generation from Various Energy Sources Using Fuel Cells

Energy Source	Energy-conversion Processes in the Life Cycle
Fossil fuels	Fossil-based hydrogen production → Fuel cell
Non-fossil energy sources	Hydrogen production → Fuel cell
High-temperature heat (e.g., solar)	Hydrogen production via thermochemical cycle → Fuel cell

Energy Use

Energy use involves the production of useful energy forms through energy-conversion processes, as well as energy transportation, distribution and storage, and the utilization of energy resources and processed forms of energy to provide services and perform tasks.

Energy-Conversion Technologies

Desired energy carriers are produced from energy sources, or converted from one form to another, using energy-conversion technologies. The energy-conversion technology appropriate in a given instance depends on the initial (or source) and final (or desired) energy forms. Conventional energy-conversion technologies include hydroelectric, fossil fuel, and nuclear generating stations; oil refineries; engines and motors; and heaters.[14–16] Some examples of less conventional energy-conversion technologies include fuel cells, solar photovoltaics, and high-efficiency and/or clean technologies for fossil fuels (e.g., combined-cycle systems).[4,17,18] Some energy-conversion technologies yield more than one product (e.g., cogeneration). Various technologies for electricity generation are listed in Tables 3 and 4.

A major energy-conversion process is combustion, which drives furnaces, engines, transportation vehicles, etc., and which can be expressed for a hydrocarbon fuel as

$$\text{Hydrocarbon fuel} + \text{Air}\left(\text{mainly } O_2 \text{ and } N_2\right) \rightarrow CO_2 + H_2O + N_2 + \text{Other substances}$$

The other substances are leftover reactants and other reaction products. The reaction for stoichiometric combustion (i.e., complete combustion with a balanced amount of reactants and no reactions that yield other products) of a general hydrocarbon (C_mH_n) in air (treated as only nitrogen and oxygen) can be written as

$$C_mH_n + (m + n/4)(O_2 + 3.76N_2) \rightarrow m\,CO_2 + n/2H_2O + 3.76\,(m + n/4)N_2$$

Here, m and n are variables that take on different values for different hydrocarbons (e.g., in approximate terms, $m = 1$ and $n = 4$ for natural gas, which is mainly methane, $m = 1$ and $n = 2$ for oil, $m = 1$ and $n = 1$ for typical coal, and $m = 1$ and $n = 0$ for pure carbon). Several important points stem from these expressions. First, carbon dioxide is an inherent product of the combustion of any carbon-containing fuel. Generally, the only way to avoid carbon dioxide emissions is to eliminate the use of carbon-based fuels (e.g., by using hydrogen as a fuel). Second, if insufficient oxygen is available (or if mixing is poor or reaction time short), the carbon will often only partially combust, yielding CO. Third, excess air (over stoichiometric) is usually used to improve fuel burnup, often lowering combustor efficiencies since some of the fuel energy must go towards heating the excess air. Fourth, often the fuel is not a pure hydrocarbon and contains other substances, e.g., sulfur. Sulfur combusts, yielding heat, and reacts to sulfur dioxide.

Energy Selection

Energy selection involves choosing both energy carriers and sources. The selection often depends on the energy service to be provided and the energy-conversion technologies available. Some energy selections involve energy or fuel substitution (e.g., heating with natural gas rather than electricity).

To prevent environmental impact, energy sources are usually preferred, which are renewable and cause relatively lower environmental impacts.[19–23] By extension, preference is also placed on energy sources and carriers that can be used with higher efficiency and more environmentally benign energy-conversion technologies (e.g., boilers having low emissions of nitrogen oxides, NO_x).[9,24,25]

Renewable energy sources (Table 1), usually being derived from sunlight or solar-derived sources (e.g., wind, waves), are sustainable. A major barrier to renewable energy sources is that they are usually more costly to use than non-renewable energy sources such as fossil fuels, although this observation is not true in some niche applications.

Environmental Considerations

The use of fossil fuels leads to combustion emissions. Problematic pollutants are generally lower for fuels having higher hydrogen-to-carbon atomic ratios, so natural gas is more benign than oil, which is more benign than coal. There are no emissions during normal operation of nuclear power facilities except the spent fuel, which remains radioactive for many years. Although falling and running water, derived from solar energy, drive hydroelectric generation, flooding of lands sometimes occurs. The use of renewable energy is relatively benign, but resources are required to build the relevant energy-conversion technologies and large land tracts are often needed (e.g., for solar collectors or wind generators). In all assessments of environmental impact, adoption of a life cycle perspective is critical.

Energy Efficiency and Other Measures of Merit for Energy Use

Many efficiencies can be defined for energy use. Other measures are also often used to assess the merit of energy use relative to other criteria. One important measure is energy intensity, which reflects the energy use per some unit of output, e.g., energy consumption per monetary unit of gross domestic product for a country or region. Since they deal with raw materials, primary processing industries (e.g., petroleum/coal production, chemicals production, primary metals) generally have higher energy intensities than intermediate and secondary processing industries, which, although they come in a wide variety of forms, tend to deal with more finished products.

Numerous methods and technologies exist for improving energy efficiency:

Use of High-Efficiency Devices. Energy efficiency can generally be increased via high-efficiency versions of energy intensive devices (e.g., home appliances, furnaces, air conditioners, motors, boilers). New lighting fixtures (including bulbs, reflectors, diffusers, and ballasts), for instance, have significantly higher efficiencies and longer lives than older equipment. Lighting efficiency can also be increased by task lighting (i.e., directing light where it is needed), reducing lighting to levels adequate for the human eye and the nature of the facility, and using timers, dimmers, and occupancy sensors.

Energy Leak and Loss Prevention. Energy losses are associated with energy leaks. Approaches to avoid such energy leaks include (1) applying leak-prevention technologies and methods (e.g., sealing leaks in storage vessels and pipelines and insulating to reduce undesired heat flows) and (2) inspecting periodically to detect leaks and initiate appropriate actions.

Application of Advanced and Integrated Energy Systems. Many advanced energy systems feature increased efficiencies compared to conventional technologies. Efficiency can also be increased by advantageously integrating energy systems so that wastes become inputs to other processes. Waste-recovery and waste-to-energy plants normally increase efficiency by offsetting some of the need for external energy. Cogeneration and trigeneration are often more efficient than separate processes for the individual products. Compared to the alternative of each facility having its own heating and/ or cooling plant, district heating and/or cooling often provide increased efficiency and reduced environmental impact because many efficiency-improvement and environmental control measures are possible in centralized, large-scale facilities. Attempts have been made to optimize regional heat markets and systems.[26]

Improved Monitoring, Control, and Maintenance. Energy efficiency can be improved through better monitoring, control, and maintenance of operations, so that performance degradation from design specifications is avoided. Computer systems allow automated acquisition of frequent and widespread readings and diagnostic evaluations. The life span of energy equipment can be increased through diligent maintenance (e.g., cleaning, lubricating, calibrating, tuning, regular testing, periodic overhauling, replacing consumable items regularly).

Improved Matching of Energy Supplies and Demands. Rather than supply an energy form of a level that greatly exceeds that required for a specific energy demand, it is usually more efficient to supply an energy form of a better matched level. For instance, better matching can often be achieved for heat-transfer flow temperatures (e.g., for space heating at about 22°C, a heat supply of perhaps 40°C could be sufficient, rather than furnace combustion gases at hundreds of degrees). Thus, industrial waste heat and low-temperature cogenerated heat can satisfy some heating needs.

Energy Storage. Sometimes, available energy supply exceeds demand, and the energy is not utilized. [27,28] At times, the supply is not controllable (e.g., sunlight may be available for heating during the day whether or not it is needed), while in other cases, the supply may not be easily alterable (e.g., the waste heat from a factory). Energy storage can improve system efficiency by storing energy between times when it is available and needed.

Improved Building Envelopes. The energy efficiency of a building can be improved by increasing insulation to reduce heat infiltration in summer and heat loss in winter, applying weather stripping and caulking to reduce air leakages, and utilizing advanced and high-efficiency windows. The latter reduce heat losses by using multiple glazings that are sometimes separated by insulating gases or a vacuum, electronic and photosensitive windows that automatically reflect or absorb excessive sunlight, low-emissivity window coatings that increase a window's resistance to heat loss, and efficient window shades that adjust themselves using photosensitive sensors to block excessive sunlight while permitting natural room lighting.

Use of Passive Strategies to Reduce Energy Use. Passive, as opposed to active, methods can be used to reduce energy use. The following are some examples: adjusting design temperatures such as those used for space heating in winter and space cooling in summer; shutting energy devices during periods of non-use and using timers to control operating hours; using daylight harvesting to reduce artificial lighting needs; applying "free cooling" by using cool outdoor air when it is available to cool warm indoor spaces, rather than active air conditioning; using solar radiation to heat buildings by exploiting the thermal storage capacity of buildings; and locating trees, windows, and window shades so as to keep buildings cool during summer.

Use of Exergy Analysis. Exergy analysis is used to improve and optimize the efficiency and performance of energy and other systems and processes.[1,13,29–31]

Energy Sustainability

Achieving appropriate energy technologies, resources, and efficiencies can help in efforts to make energy systems more sustainable, in terms of environmental protection as well as economic and social development.[32] Energy sustainability requires appropriate energy sources and carriers, efficiencies, and environmental protection, in addition to other needs.[33,34] Efforts to achieve energy sustainability greatly support efforts to achieve overall sustainability,[35] and contribute significantly to attaining the United Nations Sustainable Development Goals for 2015–2030.[36]

Example

Many examples can illustrate the methods and technologies described in the section "Energy Efficiency and Other Measures of Merit for Energy Use" for improving energy efficiency. Here, we focus on the use of high-efficiency lighting. New fixtures have significantly higher efficiencies and longer lives than older equipment. Several operating parameters for various types of lighting are shown in Table 5. For example, the efficiencies for some light sources (in lumens of light delivered per watt of electricity consumed) are as follows: incandescent (10–30), mercury (20–55), fluorescent (20–60), high-pressure sodium (50–130), and low-pressure sodium (80–155). Thus, the same amount of light can be delivered with high-efficiency lighting using much less than 20% of the electricity required for an incandescent bulb. Lighting using

TABLE 5 Operating Parameters for Various Types of Lighting

	Normalized Light Output (lumens/W)			Normalized Electricity Use for Lighting (W/lumens)			Increase in Normalized Light Output (%)[a]	Decrease in Normalized Electrical Use (%)[a]
Lighting Type	Mean	Lower Range	Upper Range	Mean	Upper Range	Lower Range		
Incandescent	20	10	30	0.050	0.100	0.033	0	0
Mercury	38	20	55	0.026	0.050	0.018	90	48
Fluorescent	40	20	60	0.025	0.050	0.017	100	50
High-pressure sodium	90	50	130	0.011	0.020	0.0080	350	78
Low-pressure sodium	118	80	155	0.0085	0.013	0.0065	490	83

[a] Changes are relative to incandescent lighting and based on mean values.

light-emitting diode (LED) technology is capable today of over 100 lumens per watt, and some prototypes have demonstrated the ability to achieve 200 and even 300 lumens per watt.

On a regional or national level, the savings can be significant. Since lighting is a significant energy consumer, accounting for about 20% of U.S. electrical energy use, the use of high-efficiency lighting across the United States could reduce that country's electricity consumption by 18% (i.e., 90% of the 20% of electricity use attributable to lighting). Of course, cost and other considerations limit the implementation of high-efficiency lighting.

Note that other measures to increase lighting efficiency could reduce the electricity used for lighting further. If, for instance, electricity use for lighting is reduced by an additional 5% through application of (1) timers, dimmers, and occupancy sensors to turn lights off when rooms are unoccupied; (2) reduced lighting intensities; and (3) task lighting, then electricity use in the United States could be reduced by 19% (i.e., 95% of the 20% of electricity use attributable to lighting).

Conclusion

Categorizing energy forms as renewable energy and non-renewable energy allows for improved understanding of energy systems. Renewable energy and non-renewable energy are important in societies, particularly since they affect many facets of life and living standards. These energy categories and their applications are described in this entry, as are energy forms, sources, carriers, and technologies; energy use; energy selection and efficiencies; and efficiency-improvement measures.

Energy: Physics

Milivoje M. Kostic

Introduction: From Work to Heat to General Energy Concept

Energy is a fundamental concept indivisible from matter and space, and energy exchanges or transfers are associated with all processes (or changes), thus indivisible from time. Actually, energy is "the building block" and fundamental property of matter and space, thus a fundamental property of existence. Energy transfer is needed to produce a process to change other system properties. Also, among all properties, energy is the only one that is directly related to mass and vice versa: $E = mc^2$ (known in some literature as *mass energy,* or mass-energy equivalence; the c is the speed of light in a vacuum); thus, mass and energy are interrelated. Mass and energy are a manifestation of each other and are equivalent; they have a holistic meaning of *mass* energy.[1,2]

Energy moves cars and trains, and boats and planes. It bakes food and keeps it frozen for storage. Energy lights our homes and plays our music. Energy makes our bodies alive and grow, and allows our minds to think. Through centuries, people have learned how to use energy in different forms in order to do work more easily and live more comfortably. No wonder that energy is often defined as *ability to perform work,* i.e., as a potential for energy transfer in a specific direction (displacement in force direction), thus achieving a purposeful process, as opposed to dissipative (less-purposeful) energy transfer in the form of heat. The above definition could be generalized as: "energy is providing existence, and if exchanged, it has the ability to perform change."[3,4]

Any and every material system in nature possesses energy. The structure of any matter and field is "energetic," meaning active; i.e., photon waves are traveling in space, electrons are orbiting around an atom nucleus or flowing through a conductor, atoms and molecules are in constant rotation, vibration,

TABLE 1 Material System Structure and Related Forces and Energies

Particles	Forces	Energies

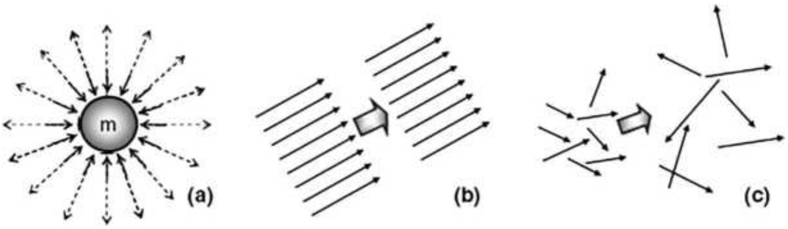

FIGURE 1 Different types of energy. (a) Potential gravitational and electromagnetic radiation. (b) Organized energy as work transfer. (c) Disorganized thermal energy as heat transfer.

or random thermal motion, etc., (see Table 1 and Figure 1). Thus, energy is a property of a material system (simply referred here as *system*) and, together with other properties, defines the system equilibrium state or existence in space and time.

Energy in transfer (E_{transfer}) is manifested as work (W) or heat (Q) when it is exchanged or transferred from one system to another, as explained next (see Figure 2).

Work

Work is a mode of energy transfer from one acting body (or system) to another resisting body (or system), with an acting force (or its component) in the direction of motion, along a path or displacement. A body that is acting (forcing) in motion-direction in time is doing work on another body that is resisting the motion (displacement rate) by an equal resistance force, including inertial force, in opposite direction of action. Energy transfer is a forced-displacement interaction between inertial material systems, in effect accelerating the reacting mass-energy sink system (i.e., its structure) at the expense of decelerating

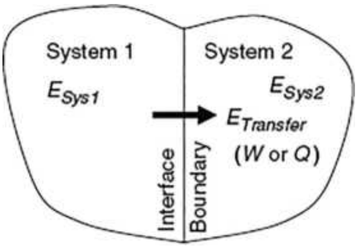

FIGURE 2 Energy as material system property and energy transfer from one system to another.

an acting-source system structure. The acting body (energy source) is imparting (transferring away) its energy to the resisting body (energy sink), and the amount of energy transfer is the work done by the acting onto the resisting body, equal to the product of the force component in the motion direction multiplied with the corresponding displacement, or vice versa (force multiplied by displacement component in the force direction, see Figure 3). If the force ($\vec{F}$) and displacement vectors ($d\vec{s} = d\vec{r}$) are not constant, then integration of differential work transfers from initial (1) to final state (2), defined by the corresponding position vectors $\vec{r}$, will be necessary (see Figure 4).

Work is a directional energy transfer. However, it is a scalar quantity like energy and is distinctive from another energy transfer in the form of *heat,* which is due to random motion (chaotic or random in all directions) and collisions of system molecules and their structural components.

Work transfer cannot occur without existence of a resisting body or system, or without finite displacement in the force direction. This may not always be obvious. For example, if we are holding a heavy weight or pushing hard against a stationary wall, there will be no work done against the weight or wall (neglecting their small deformations). However, we will be doing work internally due to the contraction and expansion of our muscles (thus force with displacement), thus converting (spending) a lot of chemical energy via muscle work and then dissipating it into thermal energy and heat transfer (sweating and getting tired).

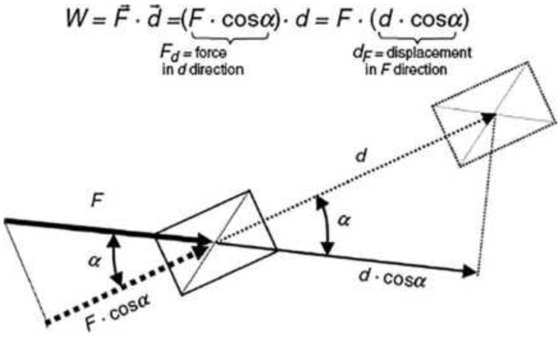

FIGURE 3 Work, force, and displacement.

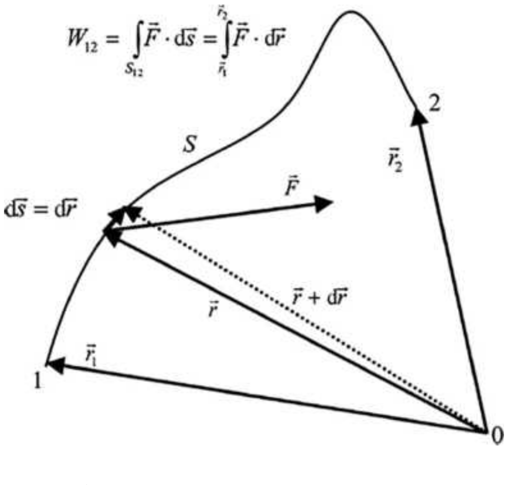

FIGURE 4 Work along arbitrary path.

Heat

Heat is another mode of energy transfer from one system at a higher temperature to another at a lower temperature due to their temperature difference. Fire was civilization's first great invention, long before people could read and write, and wood was the main heat source for cooking and heating for ages. However, true physical understanding of the nature of heat was discovered rather recently, in the middle of the 19th century, thanks to the development of the kinetic theory of gases. Thermal energy and its transfer as heat are defined as the energy associated with the random motion of atoms and molecules. The prior concept of heat was based on the *caloric* theory proposed by the French chemist Antoine Lavoisier in 1789. The caloric theory defines heat as a massless, colorless, odorless, and tasteless, fluid-like substance called the *caloric* that can be transferred or "poured" from one body into another. When caloric was added to a body, its temperature increased and vice versa. The caloric theory came under attack soon after its introduction. It maintained that heat is a substance that could not be created or destroyed. Yet it was known that heat can be generated indefinitely by rubbing hands together or from mechanical energy during friction, like mixing or similar. Finally, careful experiments by James P. Joule (1843) quantified correlation between mechanical work and heat, and thus put the caloric theory to rest by convincing the skeptics that heat was not the caloric substance after all. Although the caloric theory was totally abandoned in the middle of the 19th century, it contributed greatly to the development of thermodynamics and heat transfer. Actually, if conversion of all other energy types to heat (thermal energy "generation" from all types of "phlogistons") is included, i.e., conservation of energy in general, then caloric theory will be valid in general as stated by Clausius.[5]

Heat may be transferred by three distinctive mechanisms: conduction, convection, and thermal radiation (see Figure 5).[6] Heat conduction is the transfer of thermal energy due to interaction between the more energetic particles of a substance, like atoms and molecules (thus at higher temperature), and the adjacent, less energetic ones (thus at lower temperature). Heat convection is the transfer of thermal energy between a solid surface and the adjacent moving fluid, and it involves the combined effects of conduction and fluid motion. Thermal radiation is the transfer of thermal energy due to the emission of electromagnetic waves (or photons), which are products of random interactions between energetic electron shells of substance particles (thus related to the temperature). During those interactions, the electron shell energy level is changed, thus causing emission of photons, i.e., electromagnetic thermal radiation.

Joule's experiments of establishing equivalency between work and heat paved the way to establish the concept of internal thermal energy, to generalize the concept of energy, and to formulate the general law of energy conservation. The total internal energy includes all other possible but mechanical energy types or forms, including thermal, chemical, and nuclear energies. This allowed extension of

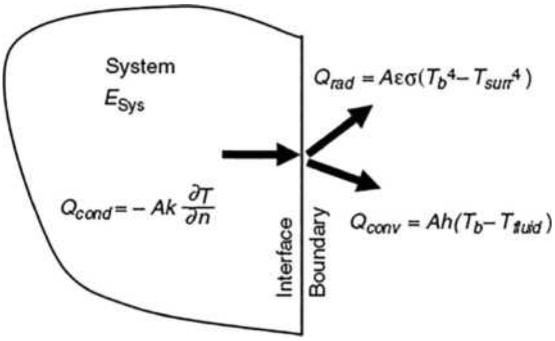

FIGURE 5 Heat as energy transfer by (a) conduction, (b) convection, and (c) radiation is due to difference in temperature.

the well-established law of mechanical energy conservation to the general law of energy conservation, known as the *first law of thermodynamics,* which includes all possible energy forms that a system could possess, and heat and all types of work as all possible energy transfers between the systems. The *law of energy conservation* will be elaborated later.

Energy

Energy is fundamental property of a physical system and refers to its potential to maintain a system identity or structure and to influence changes with other systems (via forced interaction) by imparting work (forced directional displacement) or heat (forced chaotic displacement/motion of a system's molecular or related structures). Energy exists in many forms: electromagnetic (including light), electrical, magnetic, nuclear, chemical, thermal, and mechanical (including kinetic, elastic, gravitational, and sound), where, for example, electromechanical energy may be kinetic or potential, while thermal energy represents overall potential and chaotic motion energy of molecules and/or related microstructure.[3,7,8]

Energy, Work, and Heat Units

Energy is manifested via work and heat transfer, with corresponding Force × Length dimension for work (N·m, kg_f·m, and lb_f·ft, in SI, metric, and English system of units, respectively), and the caloric units, in kilocalorie (kcal) or British thermal unit (Btu), the last two defined as heat needed to increase a unit mass of water (at reference state: specified pressure and temperature) for one degree of temperature in their respective units. Therefore, the water specific heat at reference state is 1 kcal/(kg °C) = 1 Btu/(lb °F) by definition, in metric and English system of units, respectively. It was demonstrated by Joule that 4187 Nm of work, when dissipated in heat, is equivalent to 1 kcal. In his honor, 1 N·m of work is named after him as 1 joule, or 1 J, the SI energy unit, also equal to electrical work of 1 W·s = 1 V·A·s. The SI unit for power, or work rate, is watt, i.e., 1 J/s = 1 W, and also corresponding units in other system of units, like Btu/hr, etc. Horsepower is defined as 1 HP = 550 lb_f·ft/sec = 745.7 *W*. Other common units for energy, work, and heat are given in Table 2.

Energy Forms and Classifications: Energy Transfer versus Energy Property

Any and all changes or processes (happening in space and time) are caused by energy exchanges or transfers from one substance *(system* or *subsystem)* to another (see Figure 2). A part of a system may be considered as a subsystem if energy transfer within a system is taking place, and inversely, a group of interacting systems may be considered as a larger isolated system, if they do not interact with the rest of the surroundings. Energy transfer may be in organized form (different types of work transfer due to different force actions) or in chaotic disorganized form (heat transfer due to temperature difference).

TABLE 2 Typical Energy Units with Conversion Factors

Energy Units	J	kWh	Btu
1 joule (J)	1	2.78×10^{-7}	9.49×10^{-4}
1 kilowatt hour (kWh)	3.6×10^{6}	1	3.412×10^{3}
1 kilocalorie (kcal = Cal = 1000 cal)	4187	1.19×10^{-3}	3.968
1 British thermal unit (Btu)	1055	2.93×10^{-4}	1
1 pound-force foot ($lb_f \cdot ft$)	1.36	3.78×10^{-7}	1.29×10^{-3}
1 electron volt (eV)	1.6×10^{-19}	4.45×10^{-26}	1.52×10^{-22}
1 horsepower × second (HP · s)	745.7	2.071×10^{-4}	0.707

Energy transfer into a system builds up energy potential or generalized force (called simply potential for short, like pressure, temperature, voltage, etc.) over energy displacement (like volume, entropy, charge, etc.). Conversely, if energy is transferred from a system, its energy potential is decreased. That is why net energy is transferred from a higher to a lower energy potential until the two equalize, due to virtually infinite probability of equipartition of energy over system microstructure, causing system equilibrium; otherwise, virtually impossible singularity of energy potential at infinite magnitude would result.[4]

There are many forms and classifications of energy (see Table 3), all of which could be classified as *microscopic* (or internal within a system microstructure) and/or *macroscopic* (or external as related to the system mass as a whole with reference to other systems or fields). Furthermore, energy may be "quasi-potential" (associated with a system equilibrium state and structure, i.e., system property) or "quasi-kinetic" (energy in transfer from one system or one structure to another, in the form of *work* or *heat*).

Every material system state is an equilibrium potential "held" by forces (space force fields); i.e., the forces "define" the potential and state—action and reaction; otherwise, a system will undergo dynamic change (in time) or quasi-kinetic energy exchange towards another stable equilibrium. Atoms (mass) are held by atomic and electromagnetic forces in small scale and by gravity in large scale (see Figure 1a); otherwise, mass would disintegrate ("evaporate" or radiate into energy) like partly in nuclear reactions—*nuclear* energy and/or electromagnetic radiation. Molecules are held by electrochemical bonding (e.g., valence) forces (chemical reactions—*chemical* energy). Liquids are held by latent intermolecular forces (gas condensation, when kinetic energy is reduced by cooling—*latent thermal* energy). Solids are held by "firm" intermolecular forces (freezing/fusing/solidification when energy is further reduced by cooling—*latent thermal* energy again). *Sensible thermal* energy represents intermolecular potential energy and energy of random molecular motion and is related to the temperature of a system. "Holding" potential forces may be "broken" by energy transfer (e.g., radiation, heating, high-energy particle interactions, etc.). States and potentials are often "hooked" (i.e., stable) and thus need to be "unhooked" (or to "be broken") to overcome existing "threshold" or equilibrium, like in igniting combustion, starting nuclear reaction, etc.

As stated above, energy transfer can be directional (purposeful or organized) and chaotic (dissipative or disorganized). For example, mass in motion (*mechanical kinetic* energy) and electron in motion (*electrical kinetic* energy) are organized kinetic energies (Figure 1b), while *thermal* energy is disorganized chaotic energy of motion of molecules and atoms (Figure 1c). System energy may be defined with reference to position in a force field, like *elastic potential* (stress) energy, *gravitational potential* energy, or *electromagnetic* field energy. There are many different energy forms and types (see Table 3). We are usually not interested in (absolute) energy level, but in the change of energy (during a process) from an initial state (*i*) to a final state (*f*), and thus zero reference values for different energy forms are irrelevant, and often taken arbitrarily for convenience. The following are basic correlations for energy changes of several typical energy forms, often encountered in practice: motion kinetic energy ($E_K = KE$) as a function of system velocity (V); potential elastic deformational, e.g., pressure or spring elastic energy ($E_{\text{Pdeff}} = E_{\text{Pp}} = E_{\text{Ps}}$), as a function of spring deformation displacement (x); gravitational potential energy ($E_{\text{Pg}} = PE_{\text{g}}$) as a function of gravitational elevation (z); and sensible thermal energy ($E_{\text{U}} = U$) as a function of system temperature (T):

$$\Delta E_k = \frac{1}{2} m\left(V_{\text{f}}^2 - V_{\text{i}}^2\right) \qquad \Delta E_{\text{Ps}} = \frac{1}{2} k\left(x_{\text{f}}^2 - x_{\text{i}}^2\right) \tag{1}$$

$$\Delta E_{\text{Pg}} = mg\left(z_{\text{f}} - z_{\text{i}}\right) \qquad \Delta E_{\text{U}} = mc_{\text{v}}\left(T_{\text{f}} - T_{\text{i}}\right)$$

If the reference energy values are taken to be zero when the above initial (i) variables are zero, then the above equations will represent the energy values for the final values (f) of the corresponding variables. If the corresponding parameters, spring constant k, gravity g, or constant-volume specific heat c_v, are not constant, then integration of differential energy changes from initial to final state will be necessary.

TABLE 3 Energy Forms and Classifications

Energy										
Scale							Type		Transfer (release)	
							Kinetic (Motion)		Kinetic (Motion)	
MACRO/External (mass Based)	MICRO/Internal (structure Based)	Energy Form (energy Storage)		Energy Process	Potential (state of field)	Directional[a]	Chaotic dissipative	Work[b] Directional[a]	Heat Dissipative	
		Mechanical								
x		—Kinetic	$mV^2/2$	Acceleration			X		X	
x		—Gravitational[c]	mgz	Elevation		X			X	
	x	—Elastic	$kx^2/2$ or $PV = mP/\rho$	Deformation		X			X	
		Thermal	U_{th}							
	x	—Sensible	$U_{th} = mc_{avg}T$	Heating				X		X
	x	—Latent	$U_{th} = H_{latent}$	Melting Evaporation		X				X
	x	Chemical	U_{ch}	Chemical reaction		X				X
	x	Nuclear	U_{nucl}	Nuclear reaction		X				X
		Electrical	E_{el}							
	x	—Electro kinetic	V(It) or $LI^2/2$	Electro-current flow			X		X	
	x	—Electrostatic	$(It)^2/(2C)$	Electro-charging		X			X	
		Magnetic	E_{magn}	Magnetization		X			X	
	x[d]	Electromagnetic	E_{el_mag}	Radiation			X[d]	X[e]	X	

[a] Electromechanical kinetic energy type (directional/organized, the highest energy quality) is preferable since it may be converted to any other energy form/type with high efficiency.
[b] All processes (involve energy transfer) are to some degree irreversible (i.e., dissipative or chaotic/disorganized).
[c] Due to mass position in a gravitational field.
[d] Electromagnetic form of energy is the smallest known scale of energy.
[e] Thermal radiation.

Energy transfer via work *W* (net-out), and heat transfer *Q* (net-in), may be expressed for reversible processes as product of related energy potentials (pressure *P*, or temperature *T*) and corresponding energy displacements (change of volume *V* and entropy *S*, respectively), i.e.:

$$W_{12} = \vec{F} \cdot \vec{d} = \left[\underbrace{\left(P \cdot A\vec{n} \right) . \vec{d}}_{\Delta V} \right] = P \cdot V_{12} = \Bigg| \underbrace{\int_{V1}^{V2} P \cdot dV}_{P \neq \text{const}} \tag{2}$$

$$Q_{12} = T \cdot \Delta S_{12|T \neq const} = \int_{S1}^{S2} T \cdot dS \tag{3}$$

Note, in Eq. 2, that force cannot act at a point but is distributed as pressure (P) over some area A (with orthogonal unit vector $\vec{n}$), which when displaced will cause the volume change ΔV. Also, note that it is custom in some references to denote heat transfer "in" and work transfer "out" as positive (as they appear in the above equations and a heat engine). In general, "in" (means "net-in") is negative "out" (means "net-out") and vice versa.

In general, energy transfer between systems is taking place at the system boundary interface and is equal to the product of energy potential or generalized force and the corresponding generalized displacement:[7–9]

$$\begin{aligned}\delta E_{\text{Transfer}} &= \delta Q_{\text{netIN}} - \left[\sum \delta W_{\text{netOUT}}\right] \\ &= \delta Q_{\text{netIN}} + \left[\sum \delta W_{\text{netIN}}\right] \\ &= T\text{d}s + \left[\underbrace{-PdV}_{\text{COMPR.}} + \underbrace{\sigma dA}_{\text{STRETCHING.}} + \underbrace{\tau d(A \cdot s)}_{\text{SHEARING.}}\right] \\ &\quad + \underbrace{Vdq}_{\text{CHARGING}} + \underbrace{\vec{E} \cdot d(V\vec{P})}_{\text{POLARIZATION}} \\ &\quad + \underbrace{\mu_\circ \vec{H} \cdot d(V\vec{P})}_{\text{MAGNETIZATION}} + \underbrace{\cdots}_{\text{ETC.}}\end{aligned} \tag{4}$$

where the quantities after the last equal sign are temperature and entropy; pressure and volume; surface tension and area; tangential stress and area with tangential displacement, voltage, and electrical charge; electric field strength and volume-electric dipole moment per unit volume product; and permeability of free space, magnetic field strength, and volume-magnetic dipole moment per unit volume product, respectively.

The total system energy stored within the system, as energy property, is:

$$E_{\text{Sys}} = \underbrace{E_K + E_{Pg} + E_{P\text{deff.}}}_{E_{\text{Mechanical}}} + \underbrace{\underbrace{E_{\text{Uth}}}_{\text{Thermal}} + E_{\text{Ch}} + E_{\text{Nucl}} + E_{\text{EI}} + E_{\text{Magn}} + \underbrace{\cdots}_{\text{Etc.}}}_{\text{Internal(total)}} \tag{5}$$

where the quantities after the equal sign are kinetic, potential gravitational, potential elastic deformational, thermal, chemical, nuclear, electric, magnetic energies, etc.

First Law of Energy Conservation: Work-Heat-Energy Principle

Newton formulated the general theory of motion of objects due to applied forces (1687). This provided for concepts of mechanical work, kinetic and potential energies, and development of solid-body mechanics. Furthermore, in absence of non-mechanical energy interactions, excluding friction and other dissipation effects, it is straightforward to derive (and thus prove) energy conservation, i.e.:

$$\underbrace{\int_{s1}^{s2} F_s \text{d}s}_{W_{\text{Fs}}} = \int_{s1}^{s2} \left(\underbrace{\frac{\text{d}V_s}{\text{d}t}}_{a_s} \right) \text{d}s = \int_{s1}^{s2} \left(\underbrace{m \frac{\text{d}V_s}{\text{d}s} \left\{ \frac{\text{d}s}{\text{d}t} \right\}}_{V_s} \right) \text{d}s$$

$$= \int_{V_1}^{V_2} mV_s \mathrm{d}V_s = \underbrace{\frac{1}{2}m\left(V_2^2 - V_1^2\right)}_{KE_2-KE_1}$$

$$\underbrace{\left(E_{\text{Transfer}} = W_{Fs}\right)}_{\text{work-energy transfer}} = \underbrace{\left(KE_2 - KE_1 = E_2 - E_1\right)}_{\text{energy transfer}} \tag{6}$$

The above correlation is known as the *work-energy principle*. The work-energy principle could be easily expended to include work of gravity force and gravitational potential energy as well as elastic spring force and potential elastic spring energy.

During a free gravity fall (or a free bounce) without air friction, for example, the potential energy is being converted to kinetic energy of the falling body (or vice versa for free bounce) and at any time the total mechanical energy (sum of kinetic and potential mechanical energies) is conserved, i.e., stays the same (see Figure 6). The mechanical energy is also conserved if a mass freely vibrates on an ideally elastic spring, or if a pendulum oscillates around its pivot, both in the absence of dissipative effects, like friction or non-elastic deformation. In general, for work of conservative forces only, the mechanical energy, E_{mech}, for N isolated systems is conserved since there is no dissipative conversion into thermal energy and thus no heat transfer, i.e.:

$$E_{\text{mech}} = E_K + E_{pg} + E_{Ps} = \sum_{i=1}^{N}\left(\frac{1}{2}mv^2 + mgz + \frac{1}{2}kx^2\right) = \text{const} \tag{7}$$

The mechanical work-energy concept could also be expended to fluid motion by inclusion of elastic-pressure force and potential elastic-pressure energy (referred to in some references as flow work; however, note that elastic- pressure energy is a system property while flow work is related energy transfer; see the *Bernoulli* equation below). For flowing or stationary fluid without frictional effects, the mechanical energy is conserved, including fluid elastic- pressure energy, $PV = mP/\rho$ (where V is volume, whereas v is used for velocity here), as expressed by the Bernoulli or hydrostatic equations below (see also Figure 7).[3]

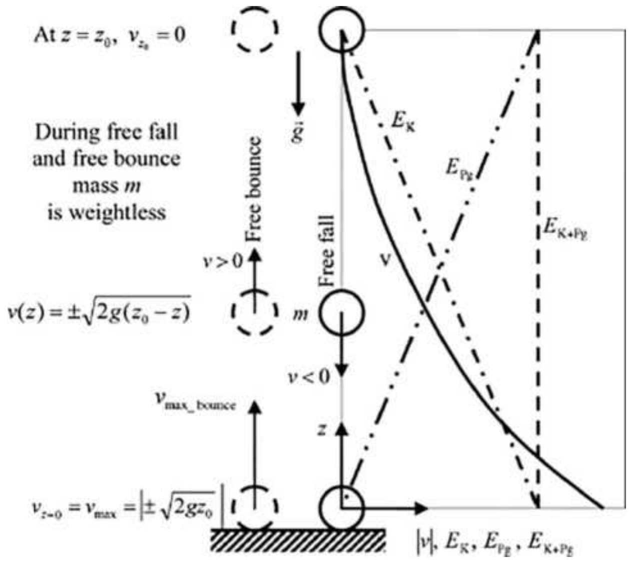

FIGURE 6 Energy and work due to conservative gravity force.

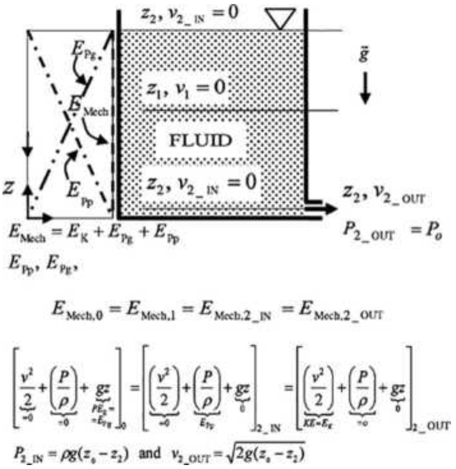

FIGURE 7 Conservation of fluid mechanical energy: Bernoulli equation, hydrostatic equation, and Torricelli's orifice velocity.

$$\frac{E_{\text{Mech}}}{m} = \frac{1}{m}\left(E_K + E_{Ps} + E_{Pg}\right) = \underbrace{\frac{v^2}{2} + \frac{P}{\rho} + gz}_{\substack{\text{Bernoulli}\\ \text{equation}}}\Bigg|_{v=0} = \underbrace{\frac{P}{\rho} + gz}_{\substack{\text{Hydrostatic}\\ \text{equation } (v=0)}} = \text{const.} \tag{8}$$

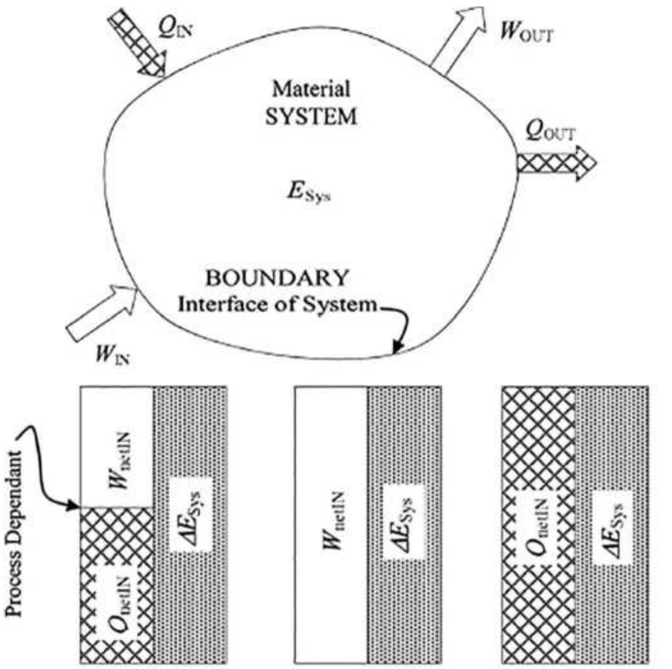
Work against inertial and/or conservative forces (also known as internal, or volumetric, or space potential field) is path independent, and during such a process, the mechanical energy is conserved. However, work of nonconservative, dissipative forces is process path dependent and part of the mechanical energy is converted (dissipated) to thermal energy (see Figure 8a).

When work of non-conservative (dissipative) forces, W_{nc}, is exchanged between N isolated systems, from an initial (i) to final state (f), then the total mechanical energy of all systems is reduced by that work amount, i.e.:

$$W_{nc,\, i\to f} = \left(\sum_{i=1}^{N} E_{\text{mech},\, i}\right)_i - \left(\sum_{i=1}^{N} E_{\text{mech},\, i}\right)_f \tag{9}$$

Regardless of the traveled path (or displacement), the work against conservative forces (like gravity or elastic spring in above cases) in absence of any dissipative forces will depend on the final and initial position (or state) only. However, the work of non-conservative, dissipative forces (W_{nc}) depends on the traveled path since the energy is dissipated during the force displacement, and mechanical energy will not be conserved but in part converted (via dissipation and heat transfer) into thermal energy. This should not be misunderstood with the total energy conservation, which is always the case, and it must include both work and heat transfer.

As already stated, there are many different types of work transfer into (or out of) a system that will change the corresponding energy form stored in the system (system properties). In addition to work, energy may be transferred as heat caused by temperature difference and associated with change of the thermal energy of a system. Furthermore, different forms of stored energy are often coupled so that one type of energy transfer may change more than one form of stored energy, particularly due to inevitable dissipative conversion of work to heat, i.e., to internal thermal energy. Conversely, heat and thermal



(a) Both Q and W
Work-Heat interaction
(process dependent)

(b) W only (No Q)
Work interaction
(adiabatic process)

(c) Q only (No W)
Heat interaction
(caloric process)

FIGURE 8 System energy and energy boundary interactions (transfers) for (a) arbitrary, (b) adiabatic, and (c) caloric processes.

energy may be converted into other energy forms. In the absence of a powerful nuclear reaction (conversion of mass into energy, $E = mc^2$, is virtually negligible), we then may assume that the mass and energy are conserved separately for an isolated system, a group of isolated systems, or for the Universe. Since the material system structure is of particulate form, then systems' interactions (collisions at different scale sizes) will exchange energy during the forced displacement— and similarly to the mechanical energy conservation—the totality of all forms of energy will be conserved[7,8] (also see Figure 8), which could be expressed as:

$$\underbrace{\sum_{\text{All } i\text{'s}} E_{i,\text{ Trans.}}}_{\text{BOUNDARY}} = \underbrace{\Delta E_{\text{Change}}}_{\text{SYSTEM}} \text{ or}$$

$$\underbrace{\sum_{\text{All } j\text{'s}} W_{j,\text{ netIN}} = \sum_{\text{All } k\text{'s}} Q_{k,\text{ netIN}}}_{\text{BOUNDARY}} \tag{10}$$

$$= \underbrace{\Delta E_{\text{netIncrease}}}_{\text{SYSTEM}} = \Delta E_{\text{Sys}}$$

Energy interactions or transfers across a system boundary, in the form of work, $W_{\text{netIN}} = \sum W_{\text{IN}} - \sum W_{\text{OUT}} = -\left(\sum W_{\text{OUT}} - \sum W_{\text{IN}}\right) = -\sum W_{\text{netOUT}}$, and heat, $Q_{\text{netIN}} = \sum Q_{\text{IN}} - \sum Q_{\text{OUT}}$, will change the system total energy, $\Delta E_{\text{Sys}} = E_{\text{Sys},\,2} - E_{\text{Sys},\,1}$. Different energy-type transfers are process (or process path) dependent, for the same ΔE_{Sys} change, except for special two cases: for adiabatic processes with work interaction only (no heat transfer, but fully irreversible, all work to heat generation) or for caloric processes with heat interaction only (no work transfer) (see Figure 8a–c). For the latter caloric processes without work interactions (no volumetric expansion or other mechanical energy changes), the internal thermal energy is conserved by being transferred from one system to another via heat transfer only, known as *caloric*. This demonstrates the value of the caloric theory of heat that was established by Lavoisier and Laplace (1789), the great minds of the 18th century. Ironically, the caloric theory was creatively used by Sadi Carnot (1824) to develop the concept of reversible cycles for conversion of caloric heat to mechanical work as it "flows" from high- to low-temperature reservoirs that later helped in dismantling the caloric theory. The caloric theory was discredited by establishing the "heat equivalent of work, e.g., mechanical equivalent of heat" by Mayer (1842) and experimentally confirmed by Joule (1843), which paved the way for establishing the *first law of energy conservation* and new science of *thermodynamics* (Clausius, Rankine, and Kelvin, 1850 and later). Prejudging the caloric theory now as a "failure" is unfair and unjustified since it made great contributions in calorimetry and heat transfer, and it is "valid" for caloric processes (without work interactions).[5] The coupling of work-heat interactions and conversion between thermal and mechanical energy are outside of the caloric theory domain and are further developed within the first and second laws of thermodynamics.

The first law of energy conservation for the control volume (CV, with boundary surface BS) flow process (see Figure 9) is:

$$\underbrace{\frac{d}{dt}E_{\text{CV}}}_{\substack{\text{RATE OF ENERGY}\\ \text{CHANGE IN CV}}} = \underbrace{\sum_{\text{BS}} \dot{Q}_{\text{netIN},\,i}}_{\substack{\text{BS TRANSFER}\\ \text{RATE OF HEAT}}} - \underbrace{\sum_{\text{BS}} \dot{W}_{\text{netOUT},\,i}}_{\substack{\text{BS TRANSFER}\\ \text{RATE OF WORK}}} + \underbrace{\sum_{\text{IN}} \dot{m}_j\left(e+Pv\right)_j}_{\substack{\text{ENERGY TRANSPORT}\\ \text{RATE WITH MASS IN}}} - \underbrace{\sum_{\text{OUT}} \dot{m}_K\left(e+Pv\right)_K}_{\substack{\text{ENERGY TRANSPORT}\\ \text{RATE WITH MASS OUT}}} \tag{11}$$

The first law of energy conservation equation for a material system in a differential volume per unit of volume around a point (x, y, z) in a flowing fluid is:[8]

$$\underbrace{\rho\frac{De}{Dt}}_{\text{energy change in time}} = \underbrace{-\vec{V}.(\nabla P)}_{\substack{\text{work rate}\\ \text{of normal pressure stresses}}} + \underbrace{\nabla.\left(\vec{V}.\tau_{ij}\right)}_{\substack{\text{work rate}\\ \text{of shearing stresses}}} + \underbrace{\nabla\cdot\left(k\nabla T\right)}_{\substack{\text{heat rate}\\ \text{via thermal conduction}}} \tag{12}$$

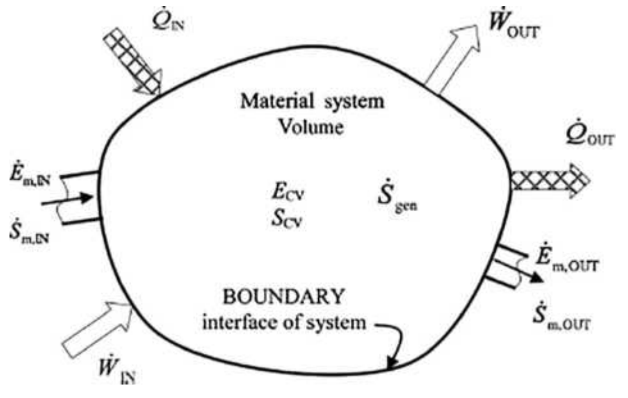


FIGURE 9 Control volume (CV) energy and entropy, and energy and entropy flows through the boundary interface of the CV.

Where $e = \hat{u} + \frac{\vec{V}^2}{2} + gz$.

Eq. 12 reduces after substitution, $\nabla \cdot \left(\vec{V} \cdot \tau_{ij}\right) = \vec{V}\left(\nabla \cdot \tau_{ij}\right) + \Phi$, and using the momentum equation, to:

$$\rho \frac{\mathrm{D}\hat{u}}{\mathrm{D}t} = -p\left(\nabla . \vec{V}\right) + \Phi_k + \Phi + \nabla \cdot \left(k \nabla T\right) \tag{13}$$

where $\Phi_k = k\left(\nabla \cdot \vec{V}\right)^2$ is the bulk-viscosity dissipation and Φ is the shear-viscosity dissipation function, which is the rate of mechanical work conversion to internal thermal energy for a differential volume per unit of volume, with [W/m^3] unit, given for Newtonian fluid as:

$$\begin{aligned} \Phi = \frac{\mathrm{d}\dot{W}_\Phi}{\mathrm{d}V} = &\left[\left(\frac{\partial u}{\partial x}\right)^2 \left(\frac{\partial v}{\partial y}\right)^2 \left(\frac{\partial w}{\partial z}\right)^2\right] \\ &+\mu\left[\left(\frac{\partial v}{\partial x} + \frac{\partial u}{\partial y}\right)^2 + \left(\frac{\partial w}{\partial y} + \frac{\partial v}{\partial z}\right)^2\right. \\ &\left.+\left(\frac{\partial u}{\partial z} + \frac{\partial w}{\partial x}\right)^2\right] - \frac{2}{3}\mu\left(\nabla \cdot \vec{V}\right)^2 \end{aligned} \tag{14}$$

The power or work rate of viscous dissipation (irreversible conversion of mechanical to thermal energy) in a control volume V is:

$$\dot{W}_\Phi = \int_V \Phi dV \tag{15}$$

Second Law of Energy Degradation: Entropy and Exergy

Every organized or directional kinetic energy will, in part or in whole (and ultimately in whole), disorganize/dissipate in all directions within the microstructure of a system (in time over its mass and space) into disorganized thermal energy. Entropy represents the measure of energy disorganization or random energy redistribution to smaller-scale structure and/or space, per absolute temperature level. Contrary to energy and mass, which are conserved in the universe, entropy is continuously generated (increased) due to continuous redistribution and disorganization of energy in transfer and thus degradation of the quality of energy ("spreading" of energy towards and over lower potentials in time until equipartitioned over system structure and space). Often, we want to extract energy from one system in order to purposefully change another system, thus to transfer energy in organized form (as work, the ultimate energy quality). No wonder that energy is defined as *ability to perform work,* and a special quantity, *exergy,* is defined as the maximum possible work that may be obtained from a system by bringing it to the equilibrium in a process with reference surroundings (called reference *dead state*). The maximum possible work will be obtained if we prevent energy disorganization, thus with limiting *reversible* processes where the existing non-equilibrium is conserved (but rearranged and could be reversed) within interacting systems. Since the energy is conserved during any process, only in ideal reversible processes will entropy (measure of energy disorganization or degradation) and exergy (maximum possible work with regard to the reference surroundings) be conserved, while in real irreversible processes, entropy will be generated and exergy will be partly (or even fully) destroyed or permanently lost. Therefore, conversion of other energy types in thermal energy or heat generation and transfer are universal manifestations of all natural and artificial (man-made) processes, where all organized potential and/or quasi-kinetic energies are disorganized or dissipated in the form of thermal energy, in irreversible and spontaneous processes.

Reversibility and Irreversibility: Energy Transfer and Disorganization, and Entropy Generation

Energy transfer (when energy moves from one system or subsystem to another) through a system boundary and in time is of kinetic nature and may be directionally organized as work or directionally chaotic and disorganized as heat. However, the net-energy transfer is in one direction only, from a higher to a lower energy potential, and the process cannot be reversed. Thus, *all processes are irreversible* in the direction of decreasing energy potential (like pressure and temperature) and increasing energy displacement (like volume and entropy) as a consequence of energy and mass conservation in the universe. This implies that the universe (as isolated and unrestricted system) is expending in space with entropy generation (or increase) as a measure of continuous energy degradation, i.e., energy redistribution and disorganization per unit of absolute temperature. It is possible in the limit to have an energy transfer process with infinitesimal potential difference (still from higher to infinitesimally lower potential, P). Then, if infinitesimal change of potential difference direction is reversed ($P + \mathrm{d}P \rightarrow P - \mathrm{d}P$, with infinitesimally small external energy, since $\mathrm{d}P \rightarrow 0$), the process will be reversed too, which is characterized by infinitesimal entropy generation, thus in the limit, without energy degradation (no further energy disorganization) and no entropy generation—thus achieving a limiting, ideal *reversible process*. Such processes at infinitesimal potential differences, called quasi-equilibrium processes, maintain the system space equilibrium at any instant but with incremental changes in time. The quasi-equilibrium processes are reversible and vice versa. In effect, the quasi-equilibrium reversible processes are infinitely slow processes at infinitesimally small potential differences, but they could be reversed to any previous state and forwarded to any future equilibrium state, without any "permanent" change to the rest of the surroundings. Therefore, the changes are "fully" reversible and, along with their rate of change and time, completely irrelevant, as if nothing is effectively changing—time is irrelevant as if it does not exist since it could be reversed (no permanent change and relativity of time). Since the real time cannot be reversed, it is a measure of permanent changes, i.e., irreversibility, which is, in turn, measured by entropy generation. In this regard, time and irreversible entropy generation are related.[2]

Entropy and the Second Law of Thermodynamics

Entropy is also a system property, which, together with energy, defines its equilibrium state and actually represents the system energy displacement or random energy disorganization (dissipation) per absolute temperature level over its mass and the space it occupies. Therefore, entropy as property of a system, for a given system state, is the same regardless whether it is reached by reversible heat transfer (Eq. 16) or irreversible heat or irreversible work transfer (caloric or adiabatic processes, Eq. 17). For example, an ideal gas system entropy increase will be the same during a reversible isothermal heat transfer and reversible expansion to a lower pressure (heat-in equal to expansion work-out), as during an irreversible adiabatic unrestricted expansion (no heat transfer and no expansion work) to the same pressure and volume, as illustrated in Fig. 10a and b, respectively.

If heat or work at higher potential (temperature or pressure) than necessary is transferred to a system, the energy at excess potential will dissipate spontaneously to a lower potential (if left alone) before a new equilibrium state is reached, with entropy generation, i.e., increase of entropy (energy degradation per absolute temperature level). A system will "accept" energy if it is transferred at minimum necessary (infinitesimally higher) or higher potential with regard to the system energy potential. Furthermore, the higher potential energy will dissipate and entropy increase will be the same as with minimum necessary potential, like in reversible heating process, i.e.

$$dS = \frac{\delta Q}{T} \text{ or } S = \int \frac{\delta Q}{T} + S_{\text{ref}} \tag{16}$$

However, source entropy will decrease to a smaller extent over higher potential, thus resulting in overall entropy generation for the two (or all) interacting systems, which may be considered as a combined isolated system (no energy exchange with the rest of the surroundings). The same is true for energy exchange between different system parts (could be considered as subsystems) at different energy potentials (non-uniform, not at equilibrium at a given time). Energy at higher potential (say, close to boundary within a system) will dissipate ("mix") to parts at lower energy potential with larger entropy increase than decrease at higher potential, resulting in internal irreversibility and entropy generation, i.e., energy "expansion" from higher potential over more mass and/or space with lower potential. Entropy is not only displacement for heat as often stated but also displacement for any energy dissipation (energy disorganization) and the measure of irreversibility. Examples are spontaneous heat transfer or throttling (unrestricted expansion) where "work potential" is lost ($W_{\text{pot, LOSS}}$), i.e., spontaneously converted (dissipated) in thermal energy, known as heat generation ($Q_{\text{gen}} = W_{\text{pot, LOSS}}$), resulting in entropy generation:

$$S_{\text{ref}} = \frac{Q_{\text{gen}}}{T} \geq \text{where } Q_{\text{gen}} = W_{\text{pot, LOSS}} \tag{17}$$

Eq. 17 may refer to the entropy generation rate at any instant within infinitesimal system or for the entropy generated during a larger process duration for an integral system. Therefore, entropy generation is the fundamental measure of irreversibility or "permanent change" that cannot be reversed, and therefore cannot be negative. This is true in general for closed and open processes and without any exception, thus representing the most general statement of the second law of energy degradation.[10]

However, there are two classical statements of the second law (both negative, about impossibility; see Figure 11).[7–9] One is the *Kelvin-Planck statement,* which expresses the never-violated fact that it is impossible to obtain work in a continuous cyclic process *(perpetual mobile)* from a single thermal reservoir (100% efficiency impossible, since it is not possible to spontaneously create non-equilibrium within the single reservoir in equilibrium), and the second is the *Clausius statement,* which refers to the direction of heat transfer, expressing the never-violated fact that it is impossible for heat transfer to take place spontaneously by itself (without any work input) from a lower- to a higher-temperature thermal reservoir: it is impossible to spontaneously create non-equilibrium. Actually, the two statements imply each other and thus are the same, as well as imply that all reversible cycles between the two temperature reservoirs (or all reversible processes between the two states) are the most (and equally) efficient with regard to extracting the maximum work out of a system or requiring the minimum possible work into the system (thus conserving the existing non-equilibrium).

Even though directionally organized energy transfer as work does not possess or generate any entropy (no energy disorganization, Figure 1b), it is possible to obtain work from the equal amount of disorganized thermal energy or heat if such process is reversible. There are two typical reversible processes where disorganized heat or thermal energy could be entirely converted into organized work, and vice versa. Namely, they are the following:[2]

1. Reversible expansion at constant thermal energy, e.g., isothermal-heating ideal-gas expansion ($\delta W = \delta Q$) (Figure 10a)
2. Reversible adiabatic expansion ($\delta W = -\mathrm{d}U$)

During a reversible isothermal heat transfer and expansion of an ideal-gas system (S) for example (Figure 10a), the heat transferred from a thermal reservoir (R) will reduce its entropy for ΔS_R

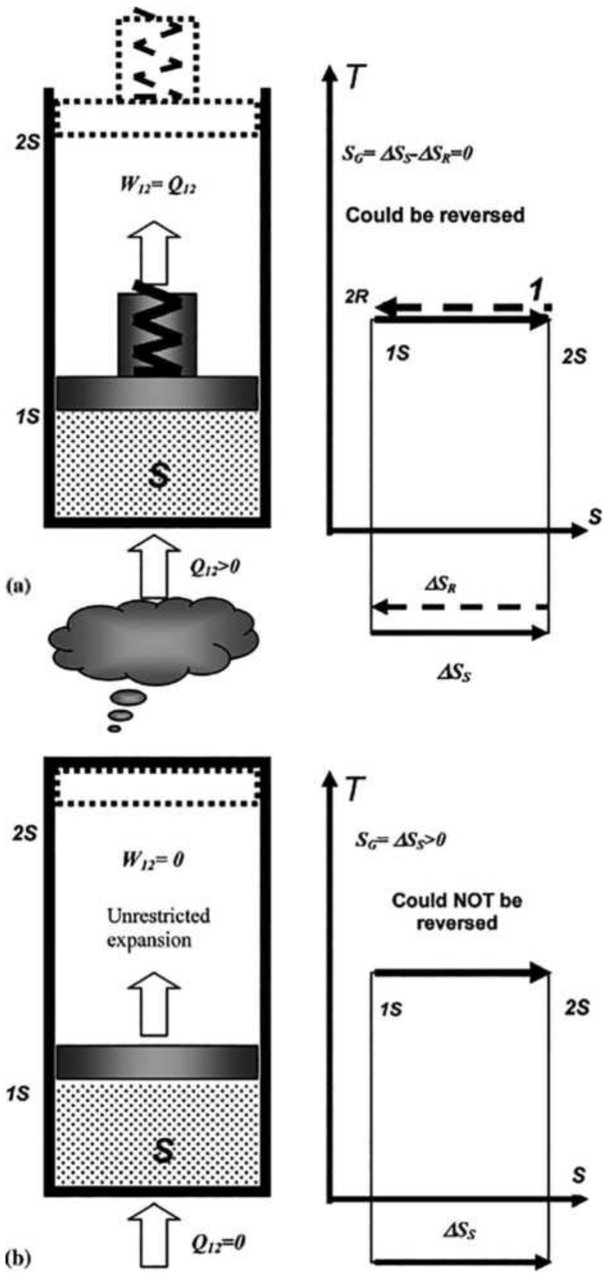

FIGURE 10 (a) Isothermal reversible heat transfer and restricted reversible expansion. (b) Adiabatic unrestricted irreversible expansion of the same initial system to the same final state (thus the same system entropy change).

magnitude, while ideal gas expansion in space (larger volume and lower pressure) will further disorganize its internal thermal energy and increase the gas entropy for ΔS_S, and in the process, an organized expansion work, equivalent to the heat transferred, will be obtained ($W_{12} = Q_{12}$). The process could be reversed, and thus, it is a reversible process with zero total entropy generation ($S_G = \Delta S_S - \Delta S_r = 0$). On the other hand, if the same initial system (ideal gas) is adiabatically expanded without any restriction (Figure 10b, thus zero expansion work) to the same final state, but without heat transfer, the system internal energy will remain the same but more disorganized over the larger volume, resulting in the same entropy increase as during the reversible isothermal heating and restricted expansion. However, this process cannot be autonomously reversed, since no work was obtained to compress back the system, and indeed the system entropy increase represents the total entropy generation ($S_G = \Delta S_S > 0$). Similarly, during reversible adiabatic expansion, the system internal thermal energy will be reduced and transferred in organized expansion work with no change of system entropy (isentropic process), since the reduction of disorganized internal energy and potential reduction of entropy will be compensated with equal increase of disorder and entropy in expanded volume. The process could be reversed back and forth (like elastic compression-expansion oscillations of a system) without energy degradation and entropy change, thus a reversible isentropic process. In reversible processes, energy is exchanged at minimum needed, not higher-than-needed potential, and isolated interacting systems as a whole do not undergo any energy-potential- related degradation/disorganization and with total conservation of entropy. The total non-equilibrium is conserved by reversible energy transfer within interacting systems, i.e., during reversible processes.

Heat Engines

Heat engines are devices undergoing thermomechanical cycles (converting thermal into mechanical energy), similar to the one in Figure 12, with mechanical expansion and compression network ($W = Q_h - Q_c$), obtained as the difference between the heat transferred to the engine from the

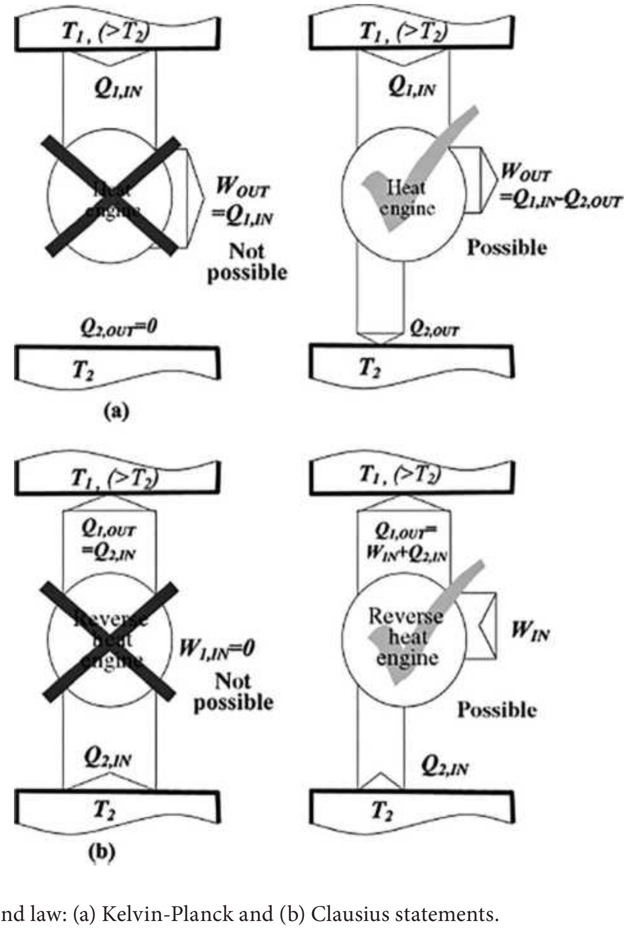

FIGURE 11 The second law: (a) Kelvin-Planck and (b) Clausius statements.

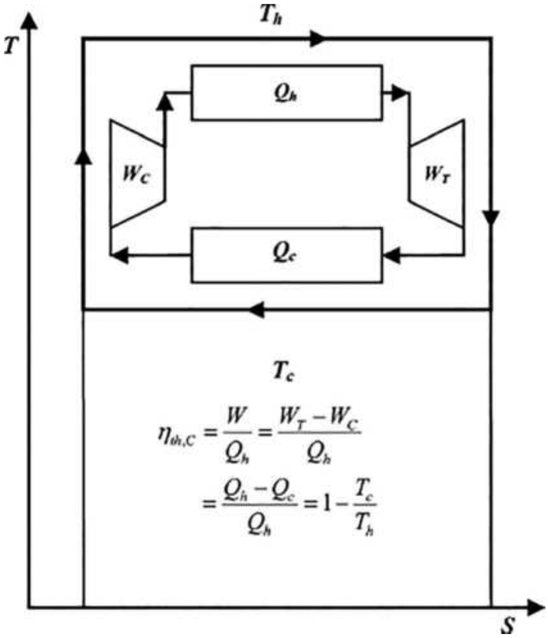

FIGURE 12 Heat engine ideal Carnot cycle.

high-temperature heat reservoir (at T_h) and rejected to a low-temperature (cold) heat reservoir (at T_c), thus converting part of the thermal energy into mechanical work. In a close-system cycle, the net-work-out is due to net-work of thermal expansion and thermal compression. Therefore, heat engine cycle cannot be accomplished without two thermal reservoirs at different temperatures, one at higher temperature to accomplish thermal expansion and work out, and another at lower temperature to accomplish thermal compression to initial volume and thus complete the cycle.[10]

The combustion process itself is an irreversible one, where chemical energy (electrochemical energy binding atoms in reactants' molecules) is chaotically released during combustion, i.e., converted in random thermal energy of products' molecules and cannot be fully converted into directional work energy. The *second law of thermodynamics* limits the maximum amount of work that could be obtained from thermal energy between any two thermal reservoirs at different temperatures, hot T_h and cold T_c, by using the ideal, reversible *Carnot cycle* (see Figure 12), with thermal efficiency given by Eq. 18. As an example, consider $T_c = 293$ K and $T_h = 2273$ K, then:

$$\eta_{\text{th, C\_ad}} = \frac{W}{Q_h} = \frac{Q_h - Q_c}{Q_h} = 1 - \frac{T_c}{T_h}\bigg|_{T_h = T_{\text{ad}} = 2273K,\ T_c = 293K} = 1 - \frac{293}{2273} = 87.1\% \tag{18}$$

where $W = W_T - W_C$ is the net-work of expansion, usually turbine (W_T) and compression (W_C) difference. The maximum efficiency is achieved if heat is supplied at the highest possible temperature, T_h, and released at the lowest possible temperature, T_c. However, both temperatures are limited by the fact that fuel combustion is performed using oxygen with ambient air, resulting in the maximum so-called adiabatic, stoichiometric combustion temperature, T_{ad}, which is for most fuels about 2000°C or 2273 K. A part of the heat supplied at high temperature, T_h, must be released to the surroundings at a low temperature of about $T_c = 20°\text{C} = 293$ K, which results in a Carnot efficiency of 87.1% (see Eq. 18 and Figure 12). However, the fuel heating value energy, $Q_{\text{HV}} = Q_{\text{ad\_var}}$, is not all available at the adiabatic temperature of the products but is distributed over their variable temperature range from an initial surrounding temperature before combustion, T_c, to a final adiabatic temperature, T_{ad}. For such a variable heat reservoir, a large number (infinite in the limit) of ideal Carnot engines operating at different temperatures (with $\mathrm{d}W = \mathrm{d}Q$) must be employed to achieve a reversible cycle, resulting in the variable- temperature Carnot cycle with the maximum possible combustion-products-to-work conversion efficiency:[1]

$$\eta_{\mathrm{th,\ Cvar\,max}} = \left.\frac{\ln\left(T_{\mathrm{ad}}/T_c\right)}{\left(T_{\mathrm{ad}}/T_c\right)-1}\right|_{T_{\mathrm{ad}}=2273K,\ T_c=293K} = 69.7\% \tag{19}$$

Eq. 19 is valid if the cyclic medium has constant specific heat; otherwise, integration will be required. Due to engine material property limitations and other unavoidable irreversibilities, it is impossible to reach the ideal Carnot efficiency. Different actual heat engines undergo similar but different cycles, depending on the system design. For example, internal combustion engines undergo the *Otto* cycle with gasoline fuel and the *Diesel* cycle with diesel fuel, while the steam and gas turbine power plants undergo the *Rankine* and *Brayton* cycles, respectively.[7,8] However, with improvements in material properties, effective component cooling and regeneration, and combining gas and steam turbine systems, the efficiencies above 50% are being achieved, which is a substantial improvement over the usual 30%–35% efficiency. The ideal Carnot cycle is an important reference to guide researchers and engineers to better understand limits and possibilities for new concepts and practical performance improvements of real heat engines.

The reversible Carnot cycle efficiency (Eq. 18) between the two thermal reservoirs does not depend on the cycling system, but only on the ratio of the absolute temperatures of the two reservoirs ($T = T_h$ and $T_{\mathrm{ref}} = T_{\mathrm{c}}$), known as Carnot cycle efficiency. Then, we may deduce the following ratio equality, where $Q = Q_h$ and $Q_{\mathrm{ref}} = Q_c$, i.e.:

$$\left.\frac{T}{T_{\mathrm{ref}}} = \frac{Q}{Q_{\mathrm{ref}}}\right|_{\mathrm{rev\ cycle}} \tag{20}$$

The above correlation, also known as the Carnot ratio equality, is much more important than what it appears at first. Actually, it is probably the most important equation in thermodynamics and among the most important equations in natural sciences.[10] Not only does Eq. 20 define the thermodynamic (absolute) temperature scale, which is independent of the substance of a thermometer, but it was also used by Clausius to deduce a fundamental property of matter, the entropy S, as well as the related process-equilibrium functions and correlations, and to quantify irreversibility (loss of work potential) and the far-reaching second law of thermodynamics.

The entropy balance equation for the control-volume flow process, complementing the related energy balance (Eq. 11, see Figure 9), is:[7–9]

$$\underbrace{\frac{\mathrm{d}}{\mathrm{d}t}S_{\mathrm{CV}}}_{\substack{\text{RATE OF ENTROPY}\\ \text{CHANGE IN CV}}} = \underbrace{\sum_{\mathrm{CS}}\frac{\dot{Q}_i}{T_i}}_{\substack{\text{CS TRANSFER}\\ \text{RATE WITH Q}}} + \underbrace{\sum_{\mathrm{IN}}\dot{m}_j S_j}_{\substack{\text{TRANSPORT}\\ \text{RATE WITH}\\ \text{MASS IN}}} - \underbrace{\sum_{\mathrm{OUT}}\dot{m}_k S_k}_{\substack{\text{TRANSPORT}\\ \text{RATE WITH}\\ \text{MASS OUT}}} + \underbrace{\dot{S}_{\mathrm{gen}}}_{\substack{\text{IRREVERSIBLE}\\ \text{GENERATION}\\ \text{RATE}}} \tag{21}$$

Exergy and the Second-Law Efficiency

Exergy, E_{X}, as described above, is defined as the maximum possible work (i.e., the work potential) that may be obtained from a system by bringing it to the equilibrium in a process with reference surroundings (called reference *dead state*). The maximum possible work will be obtained if we prevent energy disorganization, thus with limiting *reversible* processes where the existing non-equilibrium is conserved (but rearranged and could be reversed) within interacting systems. The specific exergy per unit of system mass, e_X, with reference to the surroundings with T_o, P_o, $V_o = 0$, and $z_o = 0$, is:[7]

$$e_x = \left(\breve{u} - \breve{u}_o\right) + P_o\left(\breve{v} - \breve{v}_o\right) - T_o\left(s - s_o\right) + \frac{1}{2}V^2 + gz \tag{22}$$

The specific exergy of a flowing fluid, used for control- volume analysis, in addition to Eq. 22 includes the so- called flow exergy, $(P - P_o)$, $\overset{\frown}{v}$ resulting in:

$$e_{xf} = \left(\breve{h} - \breve{h}_o\right) - T_o\left(s - s_o\right) + \frac{1}{2}V^2 + gz \tag{23}$$

where system state is defined by its specific properties (internal energy $\breve{u}$, enthalpy $\breve{h}$, specific volume $\breve{v}$, entropy s, velocity V, and elevation z, while 0th subscripted properties refer to the corresponding system properties in equilibrium with the surroundings (at T_o and P_o).

The exergy balance equation for the control-volume flow process, complementing the related energy and entropy balance (Eqs. 11 and 21, see Figure 9), is:[7,–9]

$$\frac{d}{dt}E_x = \sum\left(1 - \frac{T_o}{T_i}\right)\dot{Q}_{\mathrm{IN},\,i} - \left(\dot{W}_{\mathrm{out}} - P_o\frac{d}{dt}\dot{V}_{\mathrm{CV}}\right) + \sum_{\mathrm{in}}\dot{m}e_{xf} - \sum_{\mathrm{out}}\dot{m}e_{\mathrm{xf}} - \dot{E}_{\mathrm{X,\,LOSS}} \tag{24}$$

The destroyed or lost exergy ($E_{\mathrm{X,\,LOSS}}$), or irreversibility (I), is a measure of energy degradation causing entropy generation (S_{gen}), or vice versa (see Eq. 17), and represents the lost work potential ($W_{\mathrm{pot,\,LOSS}}$) with regard to reference or "dead" state (surroundings at T_o absolute temperature), as expressed by the following correlation:

$$I = W_{\mathrm{pot,\,LOSS}} = E_{\mathrm{X,\,LOSS}} = T_o S_{\mathrm{gen}} \geq 0 \tag{25}$$

The second-law efficiency is defined by comparing the real irreversible processes or cycles with the corresponding ideal reversible processes or cycles:

$$\eta_{\mathrm{II}} = \frac{E_{\mathrm{X,\,out}}}{E_{\mathrm{X,\,in}}} = 1 - \frac{E_{\mathrm{X,\,LOSS}}}{E_{\mathrm{X,\,in}}}, \text{ where } E_{\mathrm{X,\,LOSS}} = E_{\mathrm{X,\,in}} - E_{\mathrm{X,\,out}} \tag{26}$$

The second-law efficiency is true efficiency related to the "goodness" or quality of energy processes. For example, the ideal Carnot cycle has the second-law efficiency 100% as the best possible heat-engine conversion process, and the efficiency (quality) of the rejected heat to the surrounding is 0%; i.e., the rejected heat in an ideal cycle has no value at all; therefore, it is not a "waste energy" as usually presented but is a useful and necessary one for accomplishing the heat engine cycle. Many other misconceptions based on the first-law analysis are clarified using the second-law or exergy analysis.

Concluding Remarks: Energy Provides Existence and Is Cause for Change

Energy is the fundamental property of a physical system and refers to its potential to maintain a system identity or structure and to influence changes (via forced-displacement interactions) with other systems by imparting work (forced directional displacement) or heat (forced chaotic displacement/motion of a system's molecular or related structures). Energy exists in many forms: electromagnetic (including light), electrical, magnetic, nuclear, chemical, thermal, and mechanical (including kinetic, elastic, gravitational, and sound). Note that if all energy is literally expelled from a confined space, then nothing will be left (empty space). As long as any matter is left, it will contain energy—even at zero absolute temperature, the electrons will be orbiting around very energetic nucleus. Matter is and must be energetic, $E = mc^2$; thus, literally, "energy is everything"—no energy, nothing in the space. Mass and energy are a manifestation of each other and are equivalent; they have a holistic meaning of *mass energy*.

The philosophical and practical aspects of energy and entropy, including reversibility and irreversibility, could be summarized as follows:

- Energy is a fundamental concept indivisible from matter and space, and energy exchanges or transfers are associated with all processes (or changes), thus indivisible from time.
- Energy is "the building block" and fundamental property of matter and space, thus a fundamental property of existence. Any and every material system in nature possesses energy.
- For a given system state (structure and phase), addition of energy will spontaneously tend to randomly redistribute (disorganize, degrade, dissipate) over the system's finer microstructure and the space it occupies, called thermal energy, equalizing the thermal energy potential (temperature) and increasing the energy randomization per absolute temperature (entropy), and vice versa.
- Entropy is an integral measure of (random) thermal energy redistribution (due to heat transfer and/or irreversible heat generation due to energy degradation) within a system mass and/or space (during system expansion), per absolute temperature level. Entropy is increasing from a perfectly ordered (singular and unique) crystalline structure at zero absolute temperature (zero reference) during reversible heating (entropy transfer) and entropy generation during irreversible energy conversion (loss of work-potential to degraded thermal energy), i.e., energy degradation or random equipartition within system material structure and space per absolute temperature level. Energy and mass are conserved within interacting systems (all of which may be considered as a combined isolated system not interacting with its surrounding systems), and energy transfer (in time) is irreversible (in one direction) from a higher to a lower energy potential only, which then results in continuous generation (increase) of energy displacement, called entropy generation, which is a fundamental measure of irreversibility or permanent changes.
- Exergy refers to the maximum system work potential if it is reversibly brought to the equilibrium with reference surroundings; i.e., exergy is a measure of a system's non-equilibrium with regard to the reference system. Exergy is not conserved but is destroyed or lost during real irreversible processes commensurate to the related entropy generation.
- Reversible energy transfer is only possible as a limiting case of irreversible energy transfer at infinitesimally small energy potential differences, thus in quasiequilibrium processes, with conservation of entropy (no entropy generation). Since such changes are reversible, they are not permanent and, along with time, irrelevant.
- Non-equilibrium, i.e., non-uniform distribution of mass energy in space, tends in time to spontaneously and irreversibly redistribute over space towards a common equilibrium; thus, non-equilibrium cannot be spontaneously created. Therefore, all natural spontaneous or autonomous processes (proceeding by itself and without interaction with the rest of the surroundings) between systems in non-equilibrium have irreversible tendency towards a common equilibrium—and thus irreversible loss of the original work potential (measure of nonequilibrium), by converting other energy forms into the thermal energy accompanied with increase of entropy (randomized equipartition of energy per absolute temperature level). The spontaneous forced tendency of mass-energy transfer is due to a difference or nonequilibrium in space of the mass-energy space density or mass-energy potential. As mass energy is transferred from a higher to a lower potential, and thus conserved, the lower mass-energy potential is increased on the expense of the higher potential until the two equalize, i.e., until a lasting equilibrium is established. This explains a process tendency towards the common equilibrium and impossibility of otherwise (impossibility of spontaneous creation of non-equilibrium).[10]

In summary, energy provides existence and is cause for change. Energy is possessed (thus equilibrium property) by material systems and redistributed (transferred) between and within systems, due to systems' non-equilibrium, via forced- displacement interactions (process) towards the equilibrium (equipartition of energy over mass and space); thus, energy is conserved (the first law) but degraded (the second law). Finally, we may unify the two laws of thermodynamics as one *grand law of nature:* The universe consists of local material (mass energy) structures in forced equilibrium and their interactions via force fields. The forces are balanced at any time (including inertial—process rate forces), thus conserving momentum, while charges/mass and energy are transferred and conserved during forced displacement in space all the time, but energy is degraded (dissipated) as it is redistributed (transferred) from a higher to a lower non-equilibrium potential towards equilibrium (equipartition of energy).

Glossary

Energy: It is a fundamental property of a physical system and refers to its potential to maintain a material system identity or structure (force field in space) and to influence changes (via forced-displacement interactions, i.e., systems' restructuring) with other systems by imparting work (forced directional displacement) or heat (forced chaotic displacement/motion of a system's molecular or related structures). Energy exists in many forms: electromagnetic (including light), electrical, magnetic, nuclear, chemical, thermal, and mechanical (including kinetic, elastic, gravitational, and sound).

Energy conservation: It may refer to the fundamental law of nature that energy and mass are conserved, i.e., cannot be created or destroyed but only transferred from one form or one system to another. Another meaning of energy conservation is improvement of efficiency of energy processes so that they could be accomplished with minimal use of energy sources and minimal impact on the environment.

Energy conversion: A process of transformation of one form of energy to another, like conversion of chemical to thermal energy during combustion of fuels, or thermal to mechanical energy in heat engines, etc.

Energy efficiency: Ratio between useful (or minimally necessary) energy to complete a process and actual energy used to accomplish that process. Efficiency may also be defined as the ratio between energy used in an ideal energy-consuming process versus energy used in the corresponding real process, or vice versa, for an energy- producing process. Energy, as per the conservation law, cannot be lost (destroyed), but part of energy input that is not converted into "useful energy" is customarily referred to as "energy loss."

Entropy: It is an integral measure of (random) thermal energy redistribution (due to heat transfer or irreversible heat generation) within a system mass and/or space (during system expansion), per absolute temperature level. Entropy is increasing from a perfectly ordered (singular and unique) crystalline structure at zero absolute temperature (zero reference) during reversible heating (entropy transfer) and entropy generation during irreversible energy conversion (loss of work potential to thermal energy), i.e., energy degradation or random equipartition within system material structure and space per absolute temperature level.

Exergy: It is the maximum system work potential if it is reversibly brought to the equilibrium with reference surroundings; i.e., exergy is a measure of a system's nonequilibrium with regard to the reference system.

Heat: It is inevitable (spontaneous) energy transfer due to temperature differences (from a higher to a lower level), to a larger or smaller degree without control (dissipative) via chaotic (in all directions, non-purposeful) displacement/motion of system molecules and related microstructure, as opposed to controlled (purposeful and directional) energy transfer referred to as *work*.

Heat engine: It is a device undergoing thermomechanical cycle that partially converts thermal energy into mechanical work and is limited by the ideal *Carnot cycle* efficiency. The cycle mechanical expansion and compression net-work is obtained due to difference between heat transferred to the engine from a high-temperature heat reservoir and rejected to a low temperature reservoir, thus converting part of thermal energy into mechanical work.

Mechanical energy: It is defined as the energy associated with ordered motion of moving matter at a large scale (kinetic) and ordered elastic potential energy within the material structure (potential elastic), as well as potential energy in gravitational field (potential gravitational).

Power: It is the energy rate per unit of time and is related to work or heat transfer processes (different work power or heating power).

System (also *Particle* or *Body* or *Object*) refers to any arbitrarily chosen but fixed physical or material system in space (from a single particle to a system of particles), often called "closed system," which is subject to observation and analysis. System occupies a so-called system volume within its own enclosure interface or system boundary and thus separates itself from its surroundings, i.e., other surrounding systems.

Temperature: It refers to the average kinetic energy during thermal interaction of disordered microscopic motion of molecules and atoms. The concept of temperature is complicated by the particle internal degrees of freedom like molecular rotation and vibration and by the existence of internal interactions in solid materials, which can include the so-called collective molecular or atomic behavior. All of these phenomena could contribute to the kinetic energy during particle (thermal) interactions. When two objects are in thermal contact (i.e., interaction of random motion of their particles), the one that tends to spontaneously give away (lose) energy is at the higher temperature. In general, temperature is a measure of the tendency of an object to spontaneously exchange thermal energy with another object until their temperatures equalize, that is, until they achieve interacting particle kinetic energy equipartition (statistically equalize).

Thermal energy: It refers to the energy associated with the random, disordered motion of molecules and potential energy of intermolecular forces, as opposed to the macroscopic ordered energy associated with ordered "bulk" motion of system structure at a large scale, and excluding internal binding energy within atoms (nuclear) and within molecules (chemical).

Total internal energy: It refers to the energy associated with the random, disordered motion of molecules and intermolecular potential energy (thermal), potential energy associated with chemical molecular structure (chemical), and atomic nuclear structure (nuclear), as well as with other structural potentials in force fields (electrical, magnetic, elastic, etc.). It refers to the "invisible" microscopic energy on the subatomic, atomic, and molecular scale as opposed to "visible" mechanical, bulk energy.

Work: It is a type of controlled energy transfer when one system is exerting force in a specific direction and thus making a purposeful change (forced displacement) in the other systems. It is inevitably (spontaneously) accompanied, to a larger or smaller degree (negligible in ideal processes), by dissipative (without control) energy transfer referred to as *heat* (see above).

Energy: Renewable

John O. Blackburn

Introduction

Renewable energy is a category of energy supply that is receiving increasing attention in the United States. The term refers, of course, to energy sources that can be fully utilized without diminishing future supplies. The obvious contrast is with fossil fuels which, once used, are no longer available.

Renewable energy is certainly nothing new. Mankind lived on it almost exclusively until the industrial revolution in the 1700s. Falling water and wind provided mechanical energy for tasks like pumping water or grinding grain, while ships were propelled by wind. Wood fires provided heat for dwellings or for tasks like smelting metals.

This entry examines the various renewable energy resources in the United States and the status of conversion technologies. Because the largest two sources are also intermittent, integration into reliable supply systems is also examined. This turns out to be a less formidable task than it first appears to be.

Present energy end uses are examined in order to see how renewable sources might be deployed in a highly renewable energy future.

Renewable Energy Forms

Renewable energy comes in many forms, though most sources come directly or indirectly from solar radiation. Solar energy may be used directly as a source of heat as, for example, in heating water. It may also produce electricity, either directly in photovoltaic cells or by using concentrating collectors to produce steam for turbines. Wind energy, which is derived from solar energy, is now used almost exclusively to produce electricity, as is falling water. Winds over ocean waters produce waves, which are beginning to be harnessed as a source of electricity. Ocean currents or temperature differences between surface and deep waters also offer opportunities to extract useful energy.

Trees, crops, and other plant matter (referred to as "biomass" in the renewable energy literature) likewise represent stored solar energy. Half the world still uses wood as a fuel, while forest product industries in the industrial world use wood waste to produce process heat, steam, and electricity. Energy crops, trees, or even grasses could be grown. Fuel alcohols are now produced mostly from sugarcane and corn, and they are beginning to be produced from cheaper, more abundant cellulosic biomass materials, such as wheat straw or other waste products. Other biomass sources include animal manures and sewage, which can produce methane through anaerobic digestion. There are a few renewable sources of energy that do not derive from solar sources.

The moon's gravitational pull on the earth creates tidal movements of ocean waters. In some locations, the rise and fall of water levels is sufficiently great to generate electricity.

Heat generated from nuclear processes deep in the earth sometimes comes close enough to the surface to be captured as useful energy. When underground water is present as well, steam or hot water may be available for electricity generation.

The principal difference between age-old uses of renewable energy and the present possibilities is the availability of modern technologies with conversion efficiencies much higher than those previously available. Most importantly, all forms of renewable energy can be converted into electricity—the most versatile form of energy for human purposes.

Potential Renewable Resources in the United States

Solar radiation falling on the lower forty-eight states amounts to an estimated 44,000 quads (quadrillion Btu) annually—440 times the annual energy use for the nation.[1] Few other resources are found in such abundance. Windpower, the next most abundant renewable energy source, has an estimated electricity-generating potential of 10,000 billion kilowatt-hours in the United States, almost three times present annual electricity consumption.[2] This estimate is for on-shore wind turbines only; the additional offshore potential is large, but has not been as carefully estimated. Moreover, recent studies find the U.S. potential to be underestimated in quantity and in the number of areas with economic wind-generating potential.[3]

Hydroelectric facilities already generate 7%–8% of the nation's electricity, with another 3%–4% that might still be developed.[4] Geothermal resources that are suitable for electricity generation are found only in the western third of the United States, but they amount to 25,000 megawatts— enough to provide 25%–30% of that area's present electricity use. Geothermal heat is available to more of the nation, with a much larger potential.[5] The wave-generating potential has not yet been fully assessed in the United States. It appears to be substantial along the Pacific coast and the North Atlantic coast. Tidal power possibilities in the United States are limited to Alaska, Maine, and Washington.

As for biomass sources, U.S. forests and farms now produce materials with an energy content of some 14 quads. With energy crops, this could increase fourfold, according to estimates of the National Renewable Energy Laboratory.[6] Other recent estimates give a near-term potential of 19–20 quads over and above materials taken for food, feed, and forest products, given relatively minor modifications in farm and forestry practices.[7] The author gives a figure of 1 cent per kwh in Japan, but this calculation does not include amortization of the equipment or annual maintenance costs.

There is clearly no shortage of renewable energy. It comes in many forms and, with respect to solar radiation and windpower, in great abundance.

In order to be useful in human activities, renewable energy must be captured and converted into forms which are consistent with energy demands. Time gaps between availability and need must also be bridged. For these tasks, equipment that is reliable, durable, and affordable must be available.

Conversion Efficiencies

Conversion efficiencies for various forms of renewable energy vary considerably. The growth of trees and other plant life generally convert only 0.5%–1% of solar radiation into stored biomass energy, which can be used commercially. The fastest growing species in areas with long growing seasons (sugarcane, for example) convert 2%–3% of solar energy into recoverable energy.[8]

Other renewable technologies, fortunately, have much higher conversion ratios. Solar panels for heating water convert 40%–55% of the solar energy that falls on their surfaces to useful energy.[9] Crystalline silicon photovoltaic cells now on the market convert 11%–14% of solar radiation into electricity, lab models reach 33%, and nanotechnologies hold some promise of yet-higher figures.[10] It is these conversion efficiencies that facilitate the use of large quantities of renewable energy collected in a relatively small portion of a nation's total area.

State of Technologies: Costs

Technologies Now Fully Developed and Cost Competitive

Hydroelectricity has been competitive since the earliest days of grid electricity. Expansion in the United States is constrained by environmental considerations, though output can be expanded by repowering existing facilities or installing generators at small existing dams. Hydro capacity becomes extremely valuable in grids with high components of intermittent power from wind and solar sources because it enables them to operate over a considerable range without further backup.

Wind energy is competitive with conventional fuels in areas with good wind resources and its costs continue to fall.

Geothermal Electricity

This technology is now well established in suitable sites around the world. Initial capital costs are high, both for drilling into steam or hot water sources and for generating equipment. California has 2200 megawatts in operation, and new facilities are planned or under construction in several Western states.[11]

Biomass

About three quads are already used annually for energy in the United States. The forest products industries use 1.8 quads of wood and wood wastes for process heat and cogenerated electricity. Firewood heats three million homes and supplies some occasional heat to another 20 million. These uses are fully competitive with fossil fuels, as is methane collected from landfills.[12] Other biomass possibilities are listed in the following section.

Ocean Sources

A small number of tidal plants have been installed around the world, but none have been installed as of yet in the United States. Other technologies for using ocean energy, except for waves, are not under active development at this time.[13]

Technologies That Are Well Developed but Not Yet Fully Cost Competitive

Solar Water Heating

This is a relatively simple technology consisting basically of water pipes in a box covered with glass and painted black. Today's versions are, to be sure, much more sophisticated, with freeze-protection features to make the devices useable nationwide. Making costs competitive with present energy sources will be possible upon mass production and mass installation of the equipment, a feat long since accomplished in Israel.

Photovoltaic Electricity

Fifty years of research and development efforts have brought higher efficiencies and greatly reduced costs. Costs are still too high, by a factor of two or three, for photovoltaic electricity to be fully competitive on customer facilities in the United States. They are already competitive for users remote from a power grid or for utilities at peak summer hours.

Cost reductions in photovoltaic systems manufacturing are proceeding more slowly than anticipated in the 1980s and 1990s, while conventional generation, with which these systems compete, has shown declining inflation- adjusted cost, as well. Authoritative analyses in the 1980s projected cost reductions of photovoltaic modules and other system costs to about one dollar per peak watt (two dollars in 2005 prices), which implied Photovoltaic (PV) electricity costs of six to seven cents per kilowatt-hour.[14] Module prices have indeed declined to about $3.50 for volume purchases in 2005 (in current dollars).[15] Costs are not likely to fall significantly until some alternatives to the (now) standard silicon wafer are developed for volume production. Nonetheless, manufacturing costs have fallen below three dollars for modules.[16] With rapid market and manufacturing development, Japan can produce photovoltaic electricity at about 15 cents per kwh, competitive with (expensive) Japanese-delivered grid electricity.[17]

Photovoltaic equipment benefits from its potential location at the point of consumption, thus avoiding most of the costs of transmission and distribution. PV electricity, therefore, can be priced higher than electricity from central generating plants. Because there is already enough rooftop space to accommodate nearly any conceivable volume of photovoltaic power, site costs are avoided as well.

Other Biomass Sources

Subsidized fuel ethanol is made mostly from corn, but more abundant cellulose sources are beginning to be utilized. Scale economies and cost decreases with production experience should make this technology competitive in the next few years. Iogen, the Canadian producer of ethanol from wheat straw, estimates a price of $1.30 per gallon from a proposed plant in Idaho.[18] Economically feasible processes and equipment to produce methane from animal wastes are already available, but the technology is still not widely used.

Technologies for Which Further Development Is Required

Solar Industrial Process Heat

Development of equipment for these tasks received some attention in the late 1970s, but was abandoned after that as fuel prices declined. Industrial process heat requirements and insolation overlap considerably in the United States, so their potential remains to be exploited.[19] Further development awaits higher fossil fuel costs and some renewed research attention.

Wave Energy

Several small demonstration facilities now operate. The first full-scale commercial generation facilities are about to be installed in Portugal by British and Portuguese firms using British designs.[20]

Ocean Currents and Thermal Differences between Surface and Deep Ocean Waters

There is very little activity at present.

In summary, hydroelectric, wind, and geothermal electricity are fully cost-competitive with fossil and nuclear-generated electricity in areas with good resources. These areas are, respectively, three-quarters of the states for wind, all but three or four states for hydroelectricity, and the western third of the nation for geothermal. Biomass-based heat and electricity are likewise well-established sources and they are available in every state. Widespread market penetration of solar hot water systems awaits economies of mass production and mass installation. Biomass-based liquid fuel production is set to expand rapidly. Sales of photovoltaic equipment are rising rapidly, but still with subsidies and incentives. Cost reduction proceeds apace at about 4%–5% per year, while several promising new and potentially much cheaper versions are moving into production.

Solar industrial process heat is receiving little attention, though it probably will as oil and gas prices trend upward in coming decades.

Dealing with Intermittent Sources

Solar radiation and wind are the most abundant renewable energy sources, but they are also intermittent in nature. This feature raises issues of complementarity and energy storage. Utilities think of generating capacity in terms of baseload, intermediate, and peaking capacities. Because intermittent sources do not fit into any of these categories, they are likely to be relegated to marginal roles.

Inquiries that pose the question of usefulness in another way have produced much more favorable conclusions. Utilities are already accustomed to demand patterns that are subject to seasonal, daily, weather-related, and random fluctuations. Their supply sources, in contrast, can be turned on or off as they wish. The more fruitful approach in considering intermittent sources is to regard them as "negative demand"—the side which is already subject to variations. Models that start with actual hour-by-hour demand loads through the year and then subtract out wind or solar contributions, hour-by-hour, consistently show sizeable potential contributions from intermittent renewables without further backup. Needless to say, the presence of hydroelectric facilities or pumped storage units supports the ability to accommodate intermittent sources.

A simulation of the British electricity system showed that windpower, though not steadily available and not correlated with demand patterns, could still meet 25%–45% of system demand without additional backup, provided that the conventional components could be reconfigured to accommodate wind patterns.[21] A U.S. simulation found that in a system with demand patterns similar to those of most utilities, a grid with a substantial hydroelectric component could accommodate 50% of its outputs from intermittent renewable sources (i.e., wind and solar) and at costs no higher than those for conventional generation.[22] These are certainly counter-intuitive results, and they would need to be supplemented by modeling studies of other utilities. The findings, though, are consistent with experiences in Denmark and North Germany. Denmark now obtains 21% of its electricity from wind turbines, without evident problems of integrating this output into the national grid. German reports of strains on the grid seem to have more to do with transmission bottlenecks than generation sources.

Solar electricity has the advantage, for most utilities, of coinciding in availability with summer peaks in air-conditioning use. A recent New Jersey study found that photovoltaic generation would not only supply peak power (and thereby displace fuel generation) but 40%–70% of PV capacity would displace the capital costs of conventional generation, fractions which rose quickly in the presence of grid storage capacity.[23]

These results are so much at variance with traditional thinking in utility managements that time, experience, and external pressures will be required to bring solar and wind technologies into widespread use, even when they are cost-competitive. Therein lies the case for incentives and regulatory requirements, such as the renewable portfolio standards now found in 18 states. Expanding markets enable the solar and wind equipment manufacturers to scale up and further reduce costs, while the utilities gain actual operating experience with intermittent sources.

Moving toward an All-Renewable Energy Future

A consideration of energy futures in which renewable sources contribute most or all energy needs begins with an assessment of the quantity of energy that is likely to be needed, and its appropriate forms. As a starting point, one examines present energy sources and end uses in the economy, and then allows for increasing efficiencies. One must show that renewable resources are sufficient in quantity, quality and cost to provide for each of the end uses.

A word of caution is in order. It is much too easy to focus on energy supply, while neglecting the rich possibilities for improving energy efficiency in all end uses. One thus can miss the most economical opportunities for meeting energy demands because efficiency measures usually are less expensive than any new supplies, renewable or conventional. The reader is referred to the many entries in this encyclopedia that deal with the significant potential of increasing the efficiency with which energy is used.

TABLE 1 Fuel and Energy Use by Sector, United States, 2003 (Quadrillion Btus)

Sector	Fuel	Electricity	Total End Energy Use	Electricity Losses	Total Primary Energy	Fuel End Uses in Sector
Residential	7.2	4.4	11.5	8.7	21.3	Space heat
Commercial	4.3	4.1	8.4	9.2	17.6	Water heat Space heat
Transportation Industry Manufacturing	26.8	—a	26.8	0.1	26.9	Water heat Liquid fuel
Agriculture, Mining	15.8	3.4	19.2	7.7	26.9	Process heat
Construction	3.0	—a	3.0		3.0	
Feed stocks	3.0	—	3.0		3.0	
Total industry	21.8	3.4	25.2	7.7	32.9	
Total all sectors	60.1	11.9	72.0	26.7	98.7	

[a] Less than 0.1 quad.

Source: Adapted from Energy Information Administration (additional detail for industry from International Energy Agency, IEA Energy Statistics, 2003, Energy Balance Table for the United States).[25]

Present U.S. Energy Use

U.S. primary energy use is now running at about 100 quads per year and growing at about the same rate as population, unlike the growth pattern prior to 1973. Data for 2003 are shown in Table 1.

As the table indicates, primary energy use in the United States in 2003 was 98.7 quads. About 40% of this primary energy was used to generate electricity, and two-thirds (26.7 quads) of that was lost as waste heat in generation and transmission. End-use energy was thus 72 quads. Transportation and industry each take about one third of end-use energy, with the rest going to the residential and commercial sectors. In U.S. energy statistics, electricity losses are allocated to each of the sectors in order to see the primary energy demand occasioned by the activities of each sector.

Table 1 also lists the kinds of energy end-uses provided by fuels because these would have to be supplied from renewable sources in the absence of fuels. (Sector end- uses for electricity are not shown, since electricity is readily produced from renewable sources.) In the residential sector, for example, fuels are used mostly to heat space and water or, put differently, to provide low temperature (under 100 degrees centigrade) heat. A much smaller use of fuel is for cooking, which utilizes temperatures in the 100–250 degree centigrade range. Fuel use in the commercial sector is applied for similar purposes. Eighty percent of industrial energy use is in manufacturing, while 20% goes to mining, agriculture, and construction or is used for fuel-based feedstocks. Manufacturing end-use energy is 19 quads of which three to four quads is for refining petroleum.

Energy Efficiency Gains

All of these uses can be reduced with gains in energy efficiency, and some of them can be reduced significantly. Indeed, if the best practices already existing in building design and construction, lights, appliances, heating and cooling systems, vehicle mileage, and industrial processes were uniformly applied in the whole economy, end-use energy demands use would be 50%–70% lower, or in the 22–36 quad range—not the 72 quads shown in Table 1.[24] These potential reductions in energy use make renewable energy futures much more readily conceivable for high-income, high-output nations. Any energy supply system in a world of diminishing oil and gas output would be hard pressed to meet the energy demands of our present inefficient economy.

Adequacy of Renewable Resources

The questions for renewable energies then become:

1. In the United States, can renewable energy sources provide 22–36 quads, of which 6 to 9 or so would meet efficiency-reduced electricity demands, 3 to 5 quads would be used for heat in buildings, 7 to 10 quads or so would power the transportation sector, and 6 to 10 quads would be composed of fuels for industry?
2. If that can be shown, then can these sources provide for any continuing growth in the economy?
3. What technological developments are needed for this potential to be realized?

The adequacy of renewable energy sources, considered in gross, is easy to establish. Wind and solar resources alone provide these amounts of energy many times over. In addition, the "nonintermittent" renewable sources (biomass, hydroelectric, and geothermal resources) sum to another 17 quads at a minimum.

As to end-uses, 6 to 9 quads of electricity fall well under available sources, with storage capability being required only in areas lacking hydroelectric resources.

Space and water heat can be provided in part from direct solar sources, with the rest coming from biomass or perhaps electricity.

For those who envision a hydrogen-fueled transportation system, intermittent sources of renewable electricity are tailor-made. Hydrogen can be produced by electrolysis whenever solar or wind sources exceed grid demands. Liquid fuels from biomass are likely to be available, as well, especially with emerging technologies to produce liquid fuels from cellulosic materials.

Industrial process heat would come primarily from biomass sources, with some assistance from solar equipment or perhaps hydrogen produced from renewable electricity.

As to growth over time in energy demands over time, one can observe that economic growth in the United States, at least in per capita terms, is directed toward sectors that generally do not have high energy contents (services vs. basic commodities). If the United States is ever to reach a measure of sustainability with respect to its physical resource demands, its population must level off, as must that of any other nation seeking sustainability.

There are two major technological developments that remain to be achieved in order to make an all-renewable future attainable. The first is cost reductions in the manufacture and installation of photovoltaic systems and the second is the rapid commercialization and cost reduction in processes which make fuel ethanol from cellulosic materials, rather than foods. These developments are already well underway.

Space does not permit an extended analysis of these matters; this brief discussion is intended to establish, in general terms, that a largely or wholly renewable energy future is possible, given several decades to adjust. This view is not now widely accepted, yet it is certainly the most hopeful one for mankind in an age of diminishing fossil fuel resources.

Energy: Storage

Rudolf Marloth

Introduction

Although specific types of energy storage are introduced below, note that this encyclopedia has separate and detailed entries on batteries, compressed air storage, and pumped hydroelectricity. First, some definitions are given:

- Primary storage methods are designed for a single use. A regular flashlight cell is used once and discarded (NOT into landfill).
- Secondary storage methods allow energy to be stored and recovered repeatedly. Rechargeable flashlight cells are available.
- Renewable energy is endlessly available in nature. Wind and solar power are currently in the spotlight.

The greater part of the entry concerns secondary storage. Renewables and primary storage are discussed briefly. A glossary is included at the end of the entry.

Need for Storage

Depending upon the use, energy is stored for varying periods. The energy stored in the gas tank of an automobile is used over a period of about a week. Part of that energy is stored in the car's battery, to be used two or several times in a day.

Power companies use large-scale energy storage[1] to defer investment in new generation, transmission, and distribution facilities. It is useful for integration with renewables, for voltage and frequency regulation, for demand leveling, and in lieu of spinning reserves. Long-term energy storage might depend upon availability and the cost of transporting it, such as the pile of coal at a generating plant.

Rate payers can use energy storage for load leveling and to protect themselves from the vagaries of the grid. Large quantities of electric energy generated at night when utility rates are cheap are stored in order to be released in daytime when rates are high. Smaller quantities are stored indefinitely to keep critical or sensitive equipment running during power failures or surges, sometimes only for seconds or minutes, until backup generators can come on line. A small and isolated user might want to store irregular energy supplied by wind or sun rather than build a road, pipeline, or power line for access to conventional sources.

Example 1. Consider electric rates that are \$10.00/kW-mo and \$0.10/kWh during weekdays from noon to 6:00 P.M. and \$5.00/kW-mo and \$0.05/kWh during weeknights from midnight to 6:00 A.M. and on weekends. Making reasonable assumptions about on-peak and off-peak hours, calculate a benefit of this use of energy storage.

Solution. Using an average of 22 weekdays and 8 weekend days per month gives 132 hr/mo on-peak hours and 324 hr/mo off-peak hours. Storing energy over all the offpeak hours will reduce the demand contribution to the stored energy cost. Assuming 75% round-trip efficiency apportioned evenly between storage and recovery (86.6% each way) and spreading the demand cost cover each hour of use, the blended cost of stored energy is

$$\frac{\$5.00/\text{kW}-\text{mo}/324\text{hr/mo}+\$0.05/\text{kWh}}{0.866}=\$0.076/\text{kWh} \tag{1}$$

while the blended cost of recovered energy is

$$\frac{\$10.00/\text{kW}-\text{mo}/132\text{hr/mo}+\$0.10/\text{kWh}}{0.866}=\$0.20/\text{kWh} \tag{2}$$

Valuation Criteria

Energy storage methods can be evaluated by many different criteria, with importance depending upon the application. Possible criteria are first cost in \$/kWh, lifetime in cycles or hours, maintenance cost, energy density in kWh/lb, allowable depth of discharge, footprint in kWh/ft^2 and area in ft^2, reliability, and safety.

Storing Electricity

A journal entry[2] whose title implies the possibility of storing electric energy seems to allow in its content that, technically, one cannot. The methods cited require conversion and reconversion, with storage in any of several non-electric forms. For storage in batteries, electricity is converted to chemical energy. For flywheel storage, electricity is converted to rotational kinetic energy. In pumped hydroelectric storage, electricity is converted to gravitational potential energy. Compressed air and energy stored in springs are mechanical potential energy. Superconducting magnetic energy storage (SMES) is magnetic energy. The energy stored in a capacitor is in an electric field, so at least this can be called stored electric energy.

Renewable Energy

A distinction is commonly made between stored energy and renewable (natural) energy. Some might say that energy is "stored" in the wind or ocean waves where it is available to be converted into a more useful form. Others contend that at least some processing is required for energy to qualify as stored, for instance, oil from a well must be refined, transported, and stored in a tank. For another example of primary stored energy, sulfur, charcoal, and saltpeter are combined to make gunpowder. Other examples of renewable energy are waterfalls, sunlight, trees and other biomass (saw grass, bagasse, corn), and geothermal energy. The case of water behind a dam is not so simple.

However, once some of these resources are harvested, processed, transported, and deposited at the consuming site, they can be considered as primary stored energy. Yet another category of natural energy becomes available at unpredictable times, such as that in volcanoes, hurricanes and tornadoes, and falling trees. A fascinating example of this type[3] is the energy in rocks tumbling down the San Gabriel Mountains into the backyards of suburban Los Angeles.

Hydrocarbons (coal, oil, and gas) are not considered renewable because they require eons to form, and indeed, they are being used up much faster than they form.

Primary Storage

Primary storage involves extraction or manufacture and a storage site or vessel, for example: 1) coal mined, transported, and stored at a power plant; 2) gasoline in the fuel tank of an automobile; and 3) uranium ore mined and processed into pellets of fuel. Examples of manufactured products containing primary stored energy are gunpowder, candles, lamp oil, and, indeed, non-rechargeable flashlight batteries (cells). Taking this one step further, the energy used in manufactured durable goods is stored when the goods are inventoried. This has the advantage of a very low dissipation rate but the disadvantage of frozen capital.

Secondary Methods

Storing on the Grid

References to storage on the electric grid conjure visions of electrons running about on transmission lines, looking for a place to light. In fact, the term merely means storage facilities connected to the grid, and it is in vogue because the lack of such storage is an impediment to the development of renewable power.[4] The problem is the need for a stable supply of power combined with the erratic availability of renewables. The solution is threefold: 1) an extended grid from the sources to the users; 2) increased storage facilities to receive energy when available and to supply it when needed; and 3) improved controls to gain access to stored energy and/or to limit the demand by users.

Capacitors

The energy, E, stored in a capacitor is equal to

$$E = \frac{1}{2}CV^2 \tag{3}$$

where the capacitance, C, of a plate capacitor is equal to

$$C = \frac{\varepsilon A}{d} \tag{4}$$

where ε is the permittivity of the dielectric between the plates, V is the voltage across the plates, A is the area of each plate, and d is the distance between the plates.

Evidently then, a high-energy capacitor requires a high voltage, a high permittivity, and a large area-to-separation ratio.

Conventional electrostatic capacitors have two metal plates separated by a dielectric. Electrolytic capacitors[5] are made up of two aluminum foils. The anode foil is coated with aluminum oxide, Al_2O_3, and the cathode is the other foil with a spacer saturated with electrolyte facing the oxide layer. Many types of both aqueous and non-aqueous electrolytes have been used.

Electric double-layer capacitors (EDLCs), also known hyperbolically as supercapacitors or ultracapacitors, have, between the electrodes, two layers of a sponge-like material with a separator that takes the place of plates. The material is typically activated carbon, although carbon nanotubes are envisioned for the purpose. These materials have thousands as much area per volume as conventional dielectrics and the distance between charges is submicroscopic, thus making their capacitance and energy density that much greater than that of electrolytic capacitors. Because of the small spacing, the voltage is only 2–3 V.

A major use of EDLCs is in combination with batteries. While batteries store more energy, EDLCs can charge and discharge much faster. Thus the EDLC is used in cameras to supply the flash and in electric cars to assist in hill climbing and acceleration or to absorb braking energy.

Chemical Batteries

The lead–acid battery has several disadvantages. It is heavy, toxic, maintenance-intensive, and short-lived. However, the technology is well-developed, and the materials are inexpensive, and this trumps all the disadvantages. The positive electrode (cathode) is PbO_2, lead dioxide, the negative electrode (anode) is Pb, lead, and the electrolyte is sulfuric acid, H_2SO_4. The overall reaction is

$$PbO_2 + Pb + 2H_2SO_4 \leftrightarrow 2PbSO_4 + 2H_2O \tag{5}$$

moving to the right during discharge and to the left during charging. Thus both electrodes and the electrolyte are used up during discharge, forming lead sulfate and water. The reaction can be reversed by application of a reverse current at the electrodes. A half-reaction occurs at each electrode, with electrons being produced at the anode and absorbed at the cathode.

A large lead–acid battery test facility[6] was built by Southern California Edison in Chino, California, and went into operation in 1998. Four strings of series-wired cells were housed in each of two large buildings, with a smaller building in between to house the converter and controls. Each string consisted of 1032 two-volt cells tied in series to provide a nominal voltage of 2000 Vdc. The facility was programed for an 80% depth of discharge to provide 20.8 kAh, or 40 MWh plus the energy to run auxiliaries, primarily the air compressor and air handlers. Typical discharge cycles were 5 MW for 8 hr or 10 MW for 4 hr.

Compare these figures to those for an automotive SLI (starting, lighting, ignition) battery that has six 2V cells to provide 40 Ah or 480 Wh. The SLI battery is designed for high current for a short time and for shallow discharge, whereas a traction battery, e.g., a 6, 8, or 12V golf cart battery, is designed for deep discharge and power over long periods.

Compressed Air

In the compressed air energy storage (CAES) method,[7] air is stored at high pressure in an underground cavern for use in a gas turbine. Since a conventional gas turbine consumes about two-thirds of its fuel to compress air at the time of generation, the CAES method benefits by using electricity from the grid at off-peak times for use at on-peak times in lieu of the gas turbine compressor. One improvement to the basic method is a surface pond connected to the cavern that serves to keep the pressure in the cavern constant. When air is stored, water is displaced, and when air is withdrawn, water reenters. Second, between the compressor and the cavern is a thermal storage device to store the heat of compression. When the air is withdrawn, it is reheated.

Example 2. Compute the specific work required to compress air at 1 atm and 20°C to 50 atm in an adiabatic compressor having an isentropic efficiency of 80%. Assuming the air is stored at 20°C in a cavern of 200,000 m^3, what total work is required?

Solution. The specific work of compression is

$$w = \left(\frac{1}{\eta}\right)\left(\frac{k}{k-1}\right)RT_1\left[\left(\frac{P_2}{P_1}\right)^{\frac{k-1}{k}} - 1\right] = \left(\frac{1}{0.80}\right)\left(\frac{1.4}{0.4}\right)(0.287\text{kJ/kg}-\text{K})\left[(20+273)\text{K}\right]$$

$$\left[\left(\frac{50}{1}\right)^{\frac{1.4-1}{1.4}} - 1\right] = 758\text{kJ/kg} \tag{6}$$

$$m = \frac{P_2V_2}{RT_2} = \frac{50\left(101.3\ \text{kPa}\right)\left(2\times10^5\ \text{m}^3\right)}{\left(0.287\ \text{kPa}-\text{m}^3/\text{kg}-\text{K}\right)293\ \text{K}} = 1.20\times10^7\ \text{kg} \tag{7}$$

$$W = \frac{mw}{c_1} = \frac{\left(1.20\times10^7\ \text{kg}\right)\left(758\text{kJ/kg}\right)}{3.6\times10^6\ \text{kJ/MWh}} = 2530\ \text{MWh} \tag{8}$$

Flow Batteries

These batteries are so named because the electrolyte flows between the cell and a storage tank for each electrode. In the best-known flow battery the electrolyte is a solution of vanadium and sulfuric acid and the reaction is an oxidation-reduction reaction, hence the name vanadium redox battery[8] (VRB). The cathode electrolyte carries V^{5+} and V^{4+} ions, while the anode electrolyte carries V^{2+} and V^{3+} ions. The reactions during discharge are oxidation at the cathode

$$V^{4+} + V^{5+} + e^- \tag{9}$$

and reduction at the anode

$$V^{3+} + e^- \rightarrow V^{2+} \tag{10}$$

These reactions are reversed during charging. The electrodes are separated by a permeable ionic membrane to allow hydrogen ions to pass through to complete the circuit.

The electrodes do not take part in the reactions, so they do not deteriorate as in a lead–acid battery. The electrolyte can be recycled indefinitely, eliminating the problem of disposal. The battery can be fully discharged without damage, it can be discharged at high voltage, and it could be "instantly" recharged by replacing the electrolyte.

Flywheels

Originally, flywheels were used to regulate the speed of rotating machinery. By virtue of its large rotational inertia, the flywheel tended to oppose any tendency in the machine to slow down or speed up. Now flywheels are being used as energy storage devices.

Modern energy storage flywheels are massive rotating cylinders supported on stators by magnetically levitated bearings to eliminate bearing wear. The flywheel is operated in a low vacuum environment to reduce drag. Some of the key features of flywheels are low maintenance, long life, and inert material.

The choice of solid steel vs. composite rims is based on the system cost, weight, and size. Steel is denser (heavier) but composites can withstand much higher tip speeds. Actual delivered energy depends on the speed range of the flywheel as it cannot deliver its rated power at very low speeds.

The energy stored in a flywheel can be calculated as follows: The energy of translation of a particle of mass m and velocity v is $1/2mv^2$, so the energy of rotation of a particle of mass m and rotational speed ω rotating about a center at distance r is $1/2m(r\omega)^2$. For a group of particles all at distance R and totaling mass M, the rotational energy $1/2MR^2\omega^2$, is or $1/2I\omega^2$ where $I = MR^2$ is the rotational inertia (or moment of inertia). Therefore to maximize the stored energy, a flywheel should be heavy (large M), big (large R), fast (large ω), and have the mass concentrated at the outer rim (mass at R).

Flywheels are used to provide power to uninterruptible power supplies.[9] They pair well with batteries in this application, since flywheels are tolerant to frequent cycling (which batteries are not), and batteries can provide power for longer periods. Comparative advantages of flywheels over batteries are longer life, smaller footprint, less maintenance, and less stringent housing conditions. The main disadvantage of a flywheel is the short period in which backup power can be supplied because of the continuously decreasing speed of rotation. This can be overcome by introducing special circuitry, but this adds cost and complexity.

Example 3. Consider a modest-sized flywheel of 40 kg mass and 0.3 m diameter rotating at 5000 rpm. Find the stored energy. Assume all the mass to be located at the extremity.

Solution. The rotational speed is (5000 rev/min) (2π)/(60 sec/min) = 523.6 rad/sec. The kinetic energy in the wheel is (1/2) (40 kg) $(0.3\ \text{m})^2$ $(523.6\ \text{rad/sec})^2 = 493{,}500$ (kg-m/sec^2)-m (= N-m = J = W-sec). If only 10% of this energy is usable until the flywheel slows to an unacceptable speed, 49,350 W-sec is available, or about 5 kW for 10 sec until a longer-term backup can be brought on line.

Fuel Cells

Fuel cells are not properly an energy storage device, but an energy conversion device, since they take a continuous flow of materials and combine them to produce energy and heat. However, they have a certain analogy with chemical batteries. Fuel cells convert hydrogen and oxygen into electricity and heat. A fuel cell, like a battery, is made up of an anode, a cathode, and an electrolyte. A current is produced when hydrogen ionizes at the anode with the aid of a catalyst. The hydrogen ions pass through the electrolyte to the cathode, where they combine with oxygen to produce water. The electrons released at the anode travel through an electric circuit to the cathode. The overall reaction is

$$2H_2 + O_2 \rightarrow 2H_2O \tag{11}$$

Notice that the reaction only goes to the right, i.e., it is not reversible as in an energy storage device. As in a lead-acid battery, the half-reactions produce electrons at the anode and absorb them at the cathode.

Fuel cells use a variety of electrolytes, including phosphoric acid, molten carbonate, solid oxide, and a proton exchange membrane.

Pumped Hydroelectricity

In this method, water is pumped into an elevated reservoir, with the energy recovered when the water flows back down to a lower reservoir through a turbine generator. The reservoirs may be man-made or natural bodies of water. Reversible turbine/pumps reduce the equipment required. Pumped hydro is particularly advantageous in conjunction with gas- or coal-fired plants, first by demand leveling, allowing the thermal plant to run at its most efficient load, and second by responding quickly to fluctuations in demand, where a thermal plant cannot. Pumped hydro also has been found to pair well with wind power and its variations in availability. Of course pumped hydro can be used on a regular schedule of pumping at night when rates are cheap and recovering by day when rates are high. The energy stored, E, is the potential energy of position, $E = mgh$, where m is the mass of water, g is the acceleration due to gravity, and h is the difference in height between reservoirs. Conversion efficiency is good, with losses depending on efficiency of the motor/generator and pump/turbine, pipe friction, and evaporation/seepage. Dam failures notwithstanding, this method is generally safe. The essential requirement is a site where high and low reservoirs are naturally available or can be constructed at a reasonable cost.

Springs

The force, F, required to stretch or compress a linear spring is $F = kx$, where k is the spring constant and x is the change in length. The energy, E, stored is the integral of force over the change in length, $E = 1/2kx^2$. The torque, τ, required to twist a linear torsion spring is $\tau = k\theta$, where k is the spring constant and θ is the change in angle. The energy, E, stored is the integral of torque over the change in angle, $E = 1/2k\theta^2$.

Torsion springs are typically used in instruments in spiral form. A torsion pendulum is a heavy disk that rotates at the end of a wire in torsion.

It is interesting to note that a bolt is a spring, and the clamping force (i.e., the stored energy) is the stretch in the bolt times its spring constant.

Superconducting Magnets

SMES is the storage of a current, I, in a cryogenically cooled inductor with energy E equal to

$$E = \frac{1}{2} L I^2 \tag{12}$$

where the inductance of a coil, L, is equal to

$$L = \frac{\mu N^2 A}{X} \tag{13}$$

where μ is the permeability of the core, N is the number of turns in the coil, A is the cross-sectional area of the coil, and X is the length of the coil.

Evidently then, a high-energy SMES requires high current, a highly permeable core, many turns, and a large cross-sectional area-to-length ratio.

The energy is maintained without dissipation by cryo-genically cooling the coil.[10] Helium is used as a coolant because its freezing temperature is 4.2°C above absolute zero. The salient characteristic of SMES is fast response with extremely high power. Thus a prominent use would be to stabilize short-term faults in grid power. Advantages cited for this method of energy storage are high conversion efficiency because of low resistance losses, and low maintenance because of few moving parts.

Thermal Storage

A wag has suggested that the thermos bottle is the greatest invention of the human mind because it keeps hot things hot and cold things cold. How does it know? Three examples of thermal storage are discussed here: chilled water, regenerators, and Trombe walls.

The energy consumed by a chiller can be stored in the form of chilled water or ice in an insulated tank, usually as a play on varying electric rates. Water is an excellent medium for this since it is inexpensive but also because it has a high specific heat, giving a good energy-to-volume ratio. For instance, an energy-efficient chiller will operate at 0.5 kW/T, (T = ton) so that over 6 hr, a 100T chiller will make

$$(100\text{T})(12{,}000 \text{ Btu/hr} - \text{T})(6\text{hr}) = 7.2 \text{ MMBtu} \tag{14}$$

of cooling for

$$(0.5 \text{ kW/T})(100 \text{ T})(6 \text{ hr.}) = 300 \text{ kWh of electrity}$$

This energy can be stored by chilling water from 70°F to 35°F, which will require a volume of water equal to

$$\frac{7.2 \text{ MM Btu}}{(1 \text{ Btu/1 bm} - {}^\circ\text{F})(70 - 35{}^\circ\text{F})(62.41\text{bm/ft}^3)} = 3300\text{ft}^3 \tag{15}$$

which is equivalent to a cubical tank about 15 ft on a side. The energy would typically be recovered by running the chilled water through an air handler to provide air conditioning. Good insulation, the small temperature difference between the medium and the surroundings of the tank, and the relatively short storage time would keep the storage loss low.

A regenerator is a regenerative heat exchanger, in which energy is stored in the material of the heat exchanger itself. A regenerator cycles such that half of it is heated by hot flue or exhaust gases while cool combustion air is drawn in and heated in the other half. In the second half of the cycle, cool air enters through the previously heated material of the regenerator. For example, older industrial furnaces have two chimneys, where combustion air enters in one while flue gases heat the other. Then the paths are switched so that new air is heated as it descends the first, heated chimney. A newer type of regenerator is a slowly rotating heat wheel, with half of it being heated by exiting flue gas and the other half heating the incoming air. The paths of the intake and exhaust remain constant while the heat-storing element moves.

A Trombe wall[11] (after the engineer Felix Trombe who used it extensively) is a form of passive solar energy storage. It is most commonly used in small buildings in combination with other passive energy-saving methods. The wall is a south-facing thick construction of brick or concrete with a layer of glass on the outside and an air space between. The greenhouse effect allows solar radiation to heat the wall but blocks the longer-wavelength, lower-temperature radiation from the wall. The wall stores heat during the day and releases it into the living space at night. Vents with one-way flaps pierce the wall at the top and bottom, whereby cool air from the room enters the air space at the bottom, is heated, rises to the top of the space, and reenters the room through the top vent. The flaps block reverse flow.

Conclusion

Stored energy is considered here as involving some human activity, ruling out natural energy contained in the winds or the tides or the Earth's crust. Primary storage is advantageous when the energy source is cheap or available. A disadvantage of acquiring in advance of need is that energy leaks from the medium.

Most secondary methods involve converting from and to electrical energy, so the electric grid becomes a primary factor. The practice of "buy low, sell high" leads to storing energy during off-peak hours and recovering it during on-peak hours. The availability and location of renewables causes that energy to be transported from the source to the point of use and stored until most valuable. Finally, the grid is not completely reliable, so energy is stored to carry critical services through outages.

Since energy is lost in every round trip to and from a storage medium, ongoing efforts to improve conversion efficiencies are of great economic importance.

Glossary

Bagasse	the solid residue of a plant, e.g., sugarcane, after the juice has been extracted
Battery	a collection of chemical cell
Btu	British Thermal Unit, 1055 J or 778 ft-lbf
CAES	See Compressed Air Energy Storage
Chemical Cell	a unit that stores chemical energy and converts it from and electric energy
Chemical Energy	energy stored or released in a chemical reaction
Chiller	a mechanical device that cools a refrigerant in a thermodynamic cycle
Combustion	a chemical reaction that oxidizes fuel and releases thermal energy
Compressed Air Energy storage	large-scale secondary storage, used in gas turbines
Demand Leveling	what the power company does to reduce the peak demand
EDLC	electric double-layer capacitor

Energy	the capacity to do work, usual units Btu or kWh
Ethane	C_2H_6, a minor component of natural gas
Ethanol	C_2H_6O, ethyl alcohol, sometimes used as a component of automotive fuel
Ethanol	ethyl alcohol, grain alcohol, C_2H_5OH
Flow battery	a battery in which the electrolyte flows between the cell and a storage tank
Flywheel	a device that spins to store kinetic energy
Fuel Cell	an energy conversion device that generates energy from hydrogen and oxygen
Gasoline	primarily octane
Geothermal Energy	energy associated with heat in the Earth's crust
Heat Energy	more properly called thermal energy
Kinetic	energy associated with motion
Latent Energy	energy associated with a change in phase, also called latent heat
Load Leveling	what the rate payer does to reduce the peak demand
Mechanical	Energy kinetic or potential energy
Methane	CH_4, the main component of natural gas, 1000 Btu/ft3
MMBtu	million Btu
MMBtu/hr	million Btu per hour
Natural Gas	a mixture of hydrocarbon gases, primarily methane
Natural Energy	renewable energy
Octane	C_8H_{18}, the main component of gasoline
Potential Energy	energy associated with the position of a system or its component parts
Regenerator	an energy-storing heat exchanger
Renewable Energy	energy endlessly available in nature
Saw Grass	a sedge, with leaves having edges set with small sharp teeth, a source of ethanol
Sensible Energy	energy associated with a change in temperature, also called sensible heat
SMES	See superconducting magnetic energy storage
Superconducting Magnetic Energy Storage	energy stored by energizing (inducing a magnetic current in) a magnet
T	ton of cooling, 12,000 Btu/hr
Thermal Energy	sensible plus latent internal energy
Trombe Wall	a building component that stores heat from the sun

Fossil Fuel Combustion: Air Pollution and Global Warming

Dan Golomb

Introduction

Currently, fossil fuels supply about 86% of global primary energy consumption (39% oil, 24% coal, and 23% natural gas), providing energy for transportation, electricity generation, and industrial, commercial and residential uses. The air emissions of fossil fuel combustion are transported by winds and dispersed by atmospheric turbulence, eventually falling or migrating to the surface of the earth or ocean at various rates. While in the atmosphere, pollutants cause considerable harmful effects on human health, animals, vegetation, structures, and aesthetics.

In recent decades, it has become evident that rising levels of atmospheric carbon dioxide (and other greenhouse gases) have already warmed the earth's surface slightly. It is predicted that, with continuous and increasing use of fossil fuels, the warming trend will increase. Most of the increase in carbon dioxide levels is a direct consequence of fossil fuel combustion.

The goal of this entry is to describe the characteristics of fossil fuel-generated air pollutants, including carbon dioxide and other greenhouse gases, their transport and fate in the atmosphere, and their effects on human health, the environment, and global climate change.

Ambient and Emission Standards of Air Pollutants

Air pollutants, when they exceed certain concentrations, can cause acute or chronic diseases in humans, animals, and plants. They can impair visibility, cause climatic changes, and damage materials and structures. Regulatory agencies in most developed countries prescribe ambient standards (concentrations) for air pollutants. The standards are set at a level below which it is estimated that no harmful effect will ensue to human health and the environment. On the other hand, if the standards are exceeded, increased human mortality and morbidity, as well as environmental degradation, is expected. For example, in the United States, the Environmental Protection Agency (EPA) sets National Ambient Air Quality Standards (NAAQS) for six pollutants, the so-called criteria pollutants: carbon monoxide (CO), nitrogen dioxide (NO_2), ozone (O_3), sulfur dioxide (SO_2), particulate matter (PM), and lead (Pb). The standards are listed in Table 1. In the past, particulate matter was regulated regardless of size (the so-called Total Suspended Particles, TSP). Starting in 1978, particles were regulated with an aerodynamic diameter less than 10μm. This is called PM_{10}. In 1997, a new standard was introduced for particles with an aerodynamic diameter less than 2.5μm. This is called $PM_{2.5}$. The reason for regulating only small particles is that these particles can be lodged deep in the alveoli of the lungs, and hence are detrimental to our health, whereas the larger particles are filtered out in the upper respiratory tract. While there is a standard for lead concentrations in the air, this pollutant is no longer routinely monitored. With the phasing out of leaded gasoline in the 1970s, lead concentrations in the air steadily declined, and allegedly, in the United States, airborne lead no longer poses a health hazard. (Of course, lead in its other forms, such as in paint, pipes, groundwater, solder, and ores, is still a hazard.)

In addition, the EPA sets emission standards for stationary and mobile sources. Stationary sources include power plants, incinerators, steel, cement, paper and pulp factories, chemical manufacturers, refineries, and others. Mobile sources include automobiles, trucks, locomotives, ships, and aircraft. As an example, Table 2 lists the U.S. emission standards (New Source Performance Standards) for vfossil-fueled steam generators, which include large fossil-fueled power plants and industrial boilers that were constructed after 1970. The emission standards are set in terms of mass emitted per fuel heat input (g/GJ). However, in 1978, new regulations were implemented. Instead of numerical emission standards, EPA prescribed *emission control technologies,* the so-called best available control technologies (BACT), purporting to reduce emissions to a minimum with practical and economic pollution abatement devices. For example, current BACT for sulfur oxides is a "scrubber," usually employing a slurry of pulverized limestone ($CaCO_3$) counter-flowing to the flue gas that contains the sulfur oxides. For control of nitric oxides (NO_x), the current BACT is the low-NO_x-burner (LNB). Because the LNB reduces

TABLE 1 U.S. 2000 National Ambient Air Quality Standards (NAAQS)

Pollutant	Standard	Averaging Time
Carbon monoxide	9 ppm (10 mg/m^3)	8-h[a]
	35 ppm (40 mg/m^3)	1-h[a]
Lead	1.5 μg/m^3	Quarterly Average
Nitrogen dioxide	0.053 ppm (100 μg/m^3)	Annual (arithmetic mean)
Particulate matter (PM10)	50 μg/m^3	Annual[b] (arithmetic mean)
	150 μg/m^3	24-h[a]
Particulate matter (PM2.5)	15.0 pg/m^3	Annual[c] (arithmetic mean)
	65 μg/m^3	24-h[d]
Ozone	0.08 ppm	8-h[e]
Sulfur oxides	0.03 ppm	Annual (arithmetic mean)
	0.14 ppm	24-h[a]
	–	3-h[a]

[a] Not to be exceeded more than once per year.

[b] To attain this standard, the 3-year average of the weighted annual mean PM_{10} concentration at each monitor within an area must not exceed 50 μg/m^3.

[c] To attain this standard, the 3-year average of the weighted annual mean PM2.5 concentrations from single or multiple community-oriented monitors must not exceed 15.0 μg/m^3.

[d] To attain this standard, the 3-year average of the 98th percentile of 24-h concentrations at each population-oriented monitor within an area must not exceed 65 μg/m^3.

[e] To attain this standard, the 3-year average of the fourth-highest daily maximum 8-h average ozone concentrations measured at each monitor within an area over each year must not exceed 0.08 ppm.

TABLE 2 U.S. New Source Performance Standards (NSPS) for Fossil Fuel Steam Generators with Heat Input >73 MW

Pollutant	Fuel	Heat Input (g/GJ)
SO_2	Coal	516
	Oil	86
NO_2	Gas	86
	Coal (bituminous)	260
PM[a]	Coal (subbituminous)	210
	Oil	130
	Gas	86
	All	13

[a] PM, particulate matter. For PM emissions an opacity standard also applies, which allows a maximum obscuration of the background sky by 20% for a 6-min period.

Source: Data from EPA. Standards of performance for new stationary sources. Electric steam generating units. *Federal Register,* 45, February 1980, 8210–8213.

NO_x emissions only up to 50%, new sources may be required to employ more efficient NO_x-reducing technologies, such as selective catalytic reduction (SCR) or selective non-catalytic reduction (SNCR), based on ammonia or urea injection into the flue gas. For control of particulate matter, the current prescribed technology is the electrostatic precipitator (ESP). Because the ESP is not efficient in removing sub-micron and 1–2 pm particles, and in view of the new $PM_{2.5}$ standard, new sources may be required to install instead of an ESP a Fabric Filter (FF), also called a bag house. The FF consists of a porous fabric or fiberglass membrane that filters out efficiently the smallest particles, albeit at an increased cost and energy penalty compared to the ESP. The detailed description of the workings of these emission control technologies is beyond the scope of this entry; the reader is referred to the excellent handbooks on the subject.[1,2]

Table 3 lists the U.S. emission standards in units of mass emitted per length traveled (g/km) for passenger cars and light trucks for the different model years from 1968 to 1994. At present, the 1994 standards are still in effect. Notice that light truck standards are not as strict as those for light duty vehicles. This dichotomy is very controversial, because the light truck category includes sport utility vehicles (SUV), minivans, and pick-up trucks, which are mostly used for personal and not for cargo transport. Therefore, their emission standards ought to be equal to those for passenger cars. Until now, these vehicles captured the majority of sales in the United States. (With rising gasoline prices, this trend may be reversed.) The achievement of the emission standards relies on emission control technologies. For unleaded gasoline-fueled vehicles, the prevailing control technology is the three-way catalytic converter, which simultaneously reduces carbon monoxide (CO), nitric oxides (NO_x), and fragmentary hydrocarbon (HC) emissions. Unfortunately, the catalytic converter would not work on diesel-fueled vehicles, because the relatively high sulfur and particle emissions from diesel engines would poison the catalyst. Automobile and truck manufacturers are intensively investigating possible technologies that would reduce emissions from diesel-fueled autos and trucks.

In addition to the aforementioned criteria pollutants, one finds in the air a host of other gaseous and particulate pollutants, generally designated as hazardous air pollutants (HAP), or simply *air toxics.* The EPA has identified 189 HAPs. Of course, not all HAPs are related to fossil fuel usage. Examples of fossil fuel HAPs are products of incomplete combustion (PIC), volatile organic compounds (VOC), polycyclic aromatic hydrocarbons (PAH), toxic metals (e.g., mercury, cadmium, selenium, arsenic, vanadium, etc.) Many of the fossil fuel–related HAPs are found as condensed matter on particles emitted by stationary sources (e.g., fly ash from power plants) or mobile sources (e.g., exhaust smoke from trucks). While HAPs may be more harmful to our health than the criteria pollutants (some of them are carcinogens), it is difficult to establish a dose–response relationship. Therefore, instead of setting HAP emission standards,

TABLE 3 U.S. Federal Vehicle Emission Standards

	Light-duty Vehicles (Auto)				Light-duty Trucks (Gasoline)			
Model Year	HC (g/km)	CO (g/km)	NO (g/km)	PM (g/km)	HC (g/km)	CO (g/km)	NOx (g/km)	PM (g/km)
1968	2.00	20.50						
1971[a]	2.90	29.20	2.49					
1974	2.11	24.20	1.86					
1977	0.93	9.32	1.24					
1978	0.93	9.32	1.24		1.24	12.40	1.93	
1979	0.93	9.32	1.24		1.06	11.20	1.43	
1980	0.25	4.35	1.24		1.06	11.20	1.43	
1981	0.25	2.11	0.62		1.06	11.20	1.43	
1982	0.25	2.11	0.62	0.37	1.06	11.20	1.43	
1985	0.25	2.11	0.62	0.37	0.50	6.21	1.43	0.99
1987	0.25	2.11	0.62	0.12	0.50	6.21	1.43	1.62
1988	0.25	2.11	0.62	0.37	0.50	6.21	0.75	1.62
1994	0.25	2.11	0.25	0.05	0.50	3.42	0.60	0.06

[a] Test method changed in 1971.

the EPA mandates that specific control technologies be installed on major emitting sources. These are called maximum achievable control technologies (MACT). For example, for toxic volatile gases, the most often used control technologies are physical adsorption on porous adsorbents (usually activated carbon), or chemical absorption in solvents, including water, that have a large absorption capacity for these gases. When the concentration of toxic gases in the effluent is high, secondary incineration of the effluent may be warranted. For detailed descriptions of MACTs, the reader is also referred to the appropriate handbooks.[1,2]

Pollutant Transport and Dispersion

When air pollutants exit a smoke stack or exhaust pipe (called the *sources*), they are transported by winds and dispersed by turbulent diffusion. Winds blow from high pressure toward low-pressure cells at speeds that depend on the pressure gradient. Because of the Coriolis force, wind trajectories are curvilinear in reference to fixed earth coordinates, although within a relatively short (few to tens of km) distance, wind trajectories can be approximated as linear. Winds have a horizontal and vertical component. Over flat terrain, the horizontal component predominates; in mountainous and urban areas with tall buildings, the vertical component can be significant, as well at the land/sea interface.

In the bottom layer of the atmosphere, called the troposphere, the temperature usually declines with altitude. For a dry atmosphere, the temperature gradient is −9.6°C/km. This is called the *dry adiabatic lapse rate.* In a moist atmosphere, the temperature gradient is less. Under certain conditions (e.g., nocturnal radiative cooling of the earth surface), the temperature gradient may even become positive. This is called *inversion.* The global and temporal average temperature gradient in the troposphere is −6.5°C/km. When a negative temperature gradient exists, upper parcels of the air are denser than lower ones, so they tend to descend, while lower parcels buoy upward, giving rise to eddy or turbulent mixing. The more negative the temperature gradient, the stronger the turbulence, and the faster the dispersion of a pollutant introduced into the troposphere. Wind shears also cause turbulence. A wind shear exists when, in adjacent layers of the atmosphere, winds blow in different directions and speeds.

FIGURE 1 Los Angeles smog. Note the low inversion beneath which the smog accumulates. Above the inversion, the air is relatively clear. Photo by the South Coast Air Quality Management District.

During an inversion, there is little turbulence, and a pollutant will disperse very slowly. Inversions may also occur aloft, that is, a negative temperature gradient exists at the bottom, followed by a positive gradient above. The layer up to the altitude at which the inversion occurs is called the *mixing layer* and the altitude at the inversion is called the *mixing height*. The shallower the mixing layer, the greater chances for air pollution episodes to develop, because pollutants emitted near the ground are confined to the shallow mixing layer. This often occurs in cities such as Los Angeles, Houston, Atlanta, Salt Lake City, Denver, Mexico City, Sao Paulo, Athens, Madrid, Rome, and Istanbul. Some of these cities are surrounded by mountain chains. In the basin of the mountain chain, or in the valley, the mixing layer is shallow, and the winds in the layer are usually weak, leading to poor ventilation. During the morning rush hour, pollutants are emitted into the shallow mixing layer, where they are concentrated because of the “lid” imposed by the inversion aloft. Later in the day, when solar radiation breaks up the inversion, the pollutants disperse to higher altitude, and the pollutant concentration becomes more diluted. The photo in Figure 1 shows a pollution episode in Los Angeles. The mixing height extends only to the middle of the tall building. The lower part is obscured by the smog, the upper part, which is above the mixing layer, is in relatively clear air.

Air Quality Modeling

The estimation of ambient pollutant concentrations in space and time due to emissions of single or multiple sources is called air quality modeling (AQM), or source–receptor modeling (SRM). The basic ingredients of AQM are the emission strengths of the sources, meteorological conditions, and solar irradiation. Air quality models are of the trajectory-type, where the coordinate system moves together with the plume of pollutants, or grid-type, where the coordinate system is fixed over an area, and the emission strengths and meteorological variables are inserted in each grid of the model domain. Some models consider only conservative pollutants, where the emitted pollutant does not change en route to the receptor. Other models consider chemical transformation processes and “sinks,” e.g., dry and wet deposition to the ground. Air quality models where transformation and deposition processes need to be considered are acid deposition, regional haze, and photo-oxidants.

Acid Deposition

While commonly called acid rain, acid deposition is a better term, because deposition can occur both in the wet and dry form. The ingredients of acid deposition are sulfuric and nitric acids. The primary pollutants are SO_2 and NO_x, which is the sum of NO and NO_2 molecules. Both SO_2 and NO_x result from fossil fuel combustion. Sulfur is a ubiquitous ingredient of coal and petroleum. When these fuels are burned in air, SO_2 is emitted from a smoke stack or the exhaust pipe of a vehicle. Coal and petroleum also contain nitrogen in their molecular make-up, resulting in NO_x emissions when these fuels are combusted in air. In addition, some NO_x is formed from the recombination of air oxygen and nitrogen at the high flame temperatures. So, even the combustion of natural gas, which has no nitrogen in its molecular make-up, produces some NO_x

Primary emitted SO_2 and NO_x are transformed in the atmosphere to sulfuric and nitric acids. The resulting acids can be either deposited in the dry phase on land or water, a process called dry deposition, or scavenged by falling rain drops or snow flakes, resulting in wet deposition.[3] Acid deposition modeling is successful in predicting the amount of acid deposition given the emission strength of the precursors SO_2 and NO_x.[4] From these models, it was concluded that acid deposition within a geographic domain is approximately linearly dependent on SO_2 and NO_x emission strength in that domain, so a certain percentage of precursor emission reduction results in a proportional deposition reduction of sulfuric or nitric acid. Indeed, in countries and continents where serious curtailments of precursor emissions have been made, a proportional reduction of acid deposition occurred. In the United States, as a result of reducing emissions of SO_2 by approximately one-half since the enactment of the Clean Air Act of 1990, sulfuric acid deposition has declined by approximately one-half.[5] Nitric acid deposition has not fallen appreciably, because the control of NO_x is much more difficult to accomplish than the control of SO_2, especially from dispersed sources such as commercial and residential boilers and furnaces, automobiles, and diesel trucks.

Regional Haze

Small particles (also called fine particles or aerosols), less than 1–2 μm in diameter, settle very slowly on the ground. Small particles can be either in the solid or liquid phase. For example, fly ash or smoke particles are solid; mist is liquid. Small particles can be of natural origin (e.g., volcanic dust, wind blown soil dust, forest and brush fires) or of anthropogenic origin (e.g., fly ash, diesel truck smoke). They can be emitted as primary particles or formed by transformation and condensation from primary emitted gases. They can travel hundreds to thousands of kilometers from their emitting sources. The particles can envelope vast areas, such as the northeastern or southwestern United States, southeastern Canada, western and central Europe, and southeastern Asia. Satellite photos often show continental areas covered with a blanket of haze. The haze may extend far out over the ocean. This phenomenon is called regional haze. Small particles are efficient scatterers of sunlight. Light scattering prevents distant objects from being seen. This is called visibility impairment. Figure 2 shows an encroaching haze episode on a mountain chain in Vermont. As the haze thickens, distant mountain peaks are no longer visible, and eventually neighboring peaks disappear. Increasing concentration of particles in urbanized parts of continents causes the loss of visibility of the starlit nocturnal sky. These days, small stars, less than the fifth order of magnitude, rarely can be seen from populated areas of the world.

The composition of fine particles varies from region to region, depending on the precursor emissions. In the northeastern United States, central Europe, and southeastern Asia, more than half of the composition is made up of sulfate particles, due to the combustion of high sulfur coal and oil. The rest is made up of nitrate particles, carbonaceous material (elemental and organic carbon), and crustal matter (fugitive particles from soil, clay, and rock erosion).

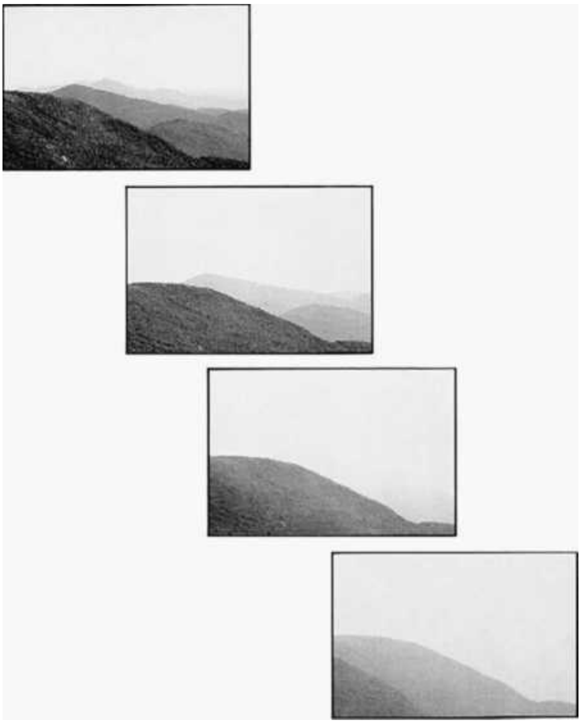

FIGURE 2 Regional haze in the Vermont green mountains. Note that as the pollution episode progresses, adjacent peaks are no longer visible. Photo by the Vermont agency of environmental conservation.

Photo-Oxidants

The family of photo-oxidants includes tropospheric ozone, O_3 (the bad ozone), ketones, aldehydes, and nitrated oxidants, such as peroxyacetylnitrate (PAN) and peroxybenzoylnitrate (PBN). The modeling of photo-oxidants is more complicated than that of acid deposition.[6] Here, the primary precursor is NO_x, which as mentioned previously, is emitted because of fossil fuel combustion. A part of NO_x is the NO_2 molecule, which splits (photo-dissociates) by solar ultraviolet and blue photons into NO and atomic oxygen. The photo-dissociation rate is dependent on solar irradiation, which, in turn, is dependent on latitude, season, time of day, and cloudiness. Atomic oxygen combines with molecular oxygen to form O_3. The NO that is formed in the photo-dissociation is quickly re-oxidized into NO_2 by peroxy radicals, RO_2, present in the polluted atmosphere. The peroxy radicals are formed from VOCs that are emitted as a consequence of incomplete combustion of fossil fuels, or from evaporation and leakage of liquid fossil fuels and solvents. The VOCs are oxidized in a complicated sequence of photo-chemical reactions to the peroxy radicals. The oxidation rates of VOCs are also dependent on solar irradiation and on the specific VOC molecule. Long-and branch-chained hydrocarbons (e.g., *n*-octane and *iso*octane) are more reactive then short-and straight-chained ones (e.g., methane and ethane); unsaturated hydrocarbons (e.g., ethene) are more reactive than saturated ones (e.g., ethane). Aromatic hydrocarbons (e.g., benzene) are more reactive than aliphatic ones (e.g., hexane), and so on.

Thus, photo-oxidants have two kinds of precursors, NO_x and VOCs, which make abatement of these secondary pollutants, as well as their modeling, so complicated. First of all, as mentioned previously, complete NO_x emission control is difficult to accomplish, because in addition to coming from large stationary sources, NO_x is emitted from a myriad of dispersed sources, such as home and commercial furnaces and boilers, automobiles, trucks, off-road vehicles, aircraft, locomotives, and ships. In principle, anthropogenic VOCs could be substantially controlled, for example, by ensuring complete combustion of the fossil fuel, or with the catalytic converter on automobiles. But, not all VOCs are of anthropogenic origin. Trees and vegetation emit copious quantities of VOCs, such as terpenes and pinenes, which are pleasant smelling, but they do participate in photo-chemical reactions that produce photo-oxidants. Even though great effort and expenses are being made in many developed countries to control precursors, photo-oxidant concentrations over urban-industrial continents have improved only slightly, if at all. In less developed countries that do not have the means of controlling photo-oxidant precursors, their concentrations are on a steady increase.

Global Warming

Of all environmental effects of fossil fuel usage, global warming, including its concomitant climate change, is the most perplexing, potentially most threatening, and arguably most intractable problem. It is caused by the ever-increasing accumulation in the atmosphere of carbon dioxide (CO_2) and other gases, such as methane (CH_4), nitrous oxide (N_2O), and chloro-fluoro-carbons (CFC), collectively called greenhouse gases (GHG). Atmospheric aerosols, natural as well as anthropogenic, also may contribute to global warming.

The term greenhouse effect is derived by analogy to a garden greenhouse. There, a glass-covered structure lets in the sun's radiation, warming the soil and plants that grow in it, while the glass cover restricts the escape of heat into the ambient surroundings by convection and radiation. Similarly, the earth atmosphere lets through most of the sun's radiation, which warms the earth surface, but the GHGs and some aerosols trap outgoing terrestrial infrared (IR) radiation, keeping the earth's surface warmer than if the GHGs and aerosols were absent from the atmosphere.

A schematic of the greenhouse effect is represented in Figure 3. To the left of the schematic is the atmospheric temperature structure, which defines the various spheres. In the troposphere, the temperature decreases on average by 6.5°C/km. This sphere is thoroughly mixed by thermal and mechanical turbulence, and this sphere contains most of the air pollutants mentioned in the previous sections. In the stratosphere, the temperature increases steadily. Because of the positive temperature gradient, this sphere is very stable with very little turbulence and mixing. At about 50–60 km height, the temperature declines again with altitude, giving rise to the mesosphere. Finally, above 90–100 km, the temperature gradient reverses itself, and becomes positive. The highest sphere is called the thermosphere. Its temperature can reach hundreds to one thousand degrees, depending on solar radiation intensity that directly heats this sphere.

The average solar radiation that impinges on the top of the atmosphere is about 343 W/m^2. This is the annual, diurnal, and spatial average irradiation. Of this irradiation, currently about 30% (103 W/m^2) is immediately reflected into space by land, ocean, icecaps, and clouds, and scattered into space by atmospheric molecules. The reflected and scattered sunlight is called albedo. The albedo may not remain constant over time. With increased melting of the ice caps, and increased cloud cover, in part due to anthropogenic influences, the albedo may change over time. The remaining 70% of solar irradiation heats the earth's surface, land, and oceans. Currently, the global average surface temperature is 288 K (about 15°C). A body (the so-called black body) that is heated to 288 K radiates 390 W/m^2. The earth's surface radiation occurs in the far IR. This is called earth shine. A part of the earth shine is reflected back to the earth's surface by clouds and aerosols; another part is first absorbed by certain gaseous molecules, and then re-radiated back to the surface. The absorption/re-radiation occurs by poly-atomic molecules, including water vapor and the GHGs: CO_2, CH_4, N_2O, O_3, CFCs, and others. The reflection and re-radiation to the earth's surface of the outgoing terrestrial IR radiation is causing the earth's surface to become warmer than it would be merely by solar irradiation. This is the greenhouse effect. With increasing concentrations of anthropogenic GHGs and aerosols, the earth's surface temperature will

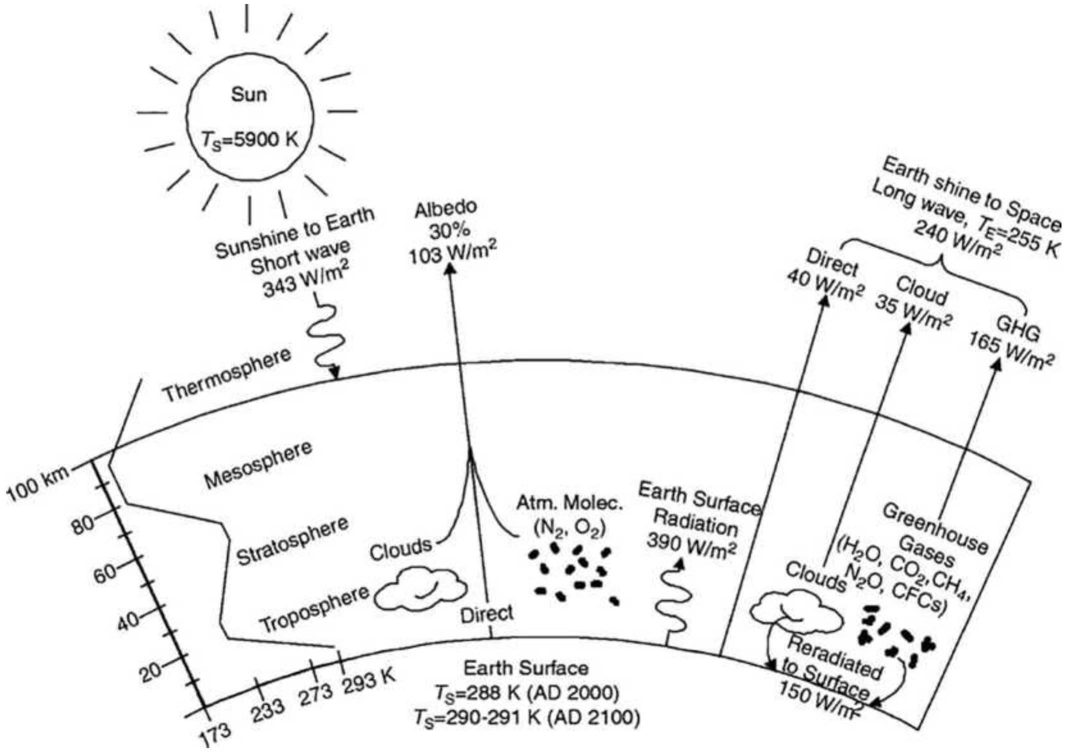

FIGURE 3 Schematic of the greenhouse effect.

increase. It should be emphasized that the greenhouse effect is not due to trapping of the incoming solar radiation, but outgoing terrestrial IR radiation. In fact, because of the trapping of earth shine by GHGs, the upper layers of the atmosphere (primarily the stratosphere) will become colder, not warmer.[7]

The extent of global warming can be predicted by radiative transfer models. These models include the radiative properties of GHGs and their distribution in the earth's atmosphere, as well as the temperature and pressure gradients in the atmosphere. There is general agreement among the models as to the extent of surface warming due to GHG absorption/re-radiation, called radiative forcing. Based on the models, it is predicted that the average earth surface temperature will increase as shown in Figure 4. The middle, "best," estimate predicts a rise of the earth's surface temperature by the end of the 21st century of about 2°C; the "optimistic" estimate predicts about 1°C, and the "pessimistic" estimate predicts about a 3°C rise. The optimistic estimate relies on the slowing of CO_2 and other GHG emissions; the pessimistic estimate relies on "business-as-usual," i.e., on the continuing rate of growth of CO_2 and other GHG emissions, and the "best" estimate is somewhere in between.[8] If the GHG concentrations increase in the atmosphere at their current rate, by the year 2100, CO_2 will contribute about 65% to global warming, CH_4 15%, N_2O 10%, and CFC about 5%–10%. (By international conventions, CFCs are being phased out entirely. But because of their very long lifetime in the atmosphere, they still will contribute to global warming by the year 2100.)

In addition to radiative forcing, global warming may be enhanced by the so-called feedback effects. For example, water vapor is a natural GHG. When the temperature of the ocean surface increases, the evaporation rate will increase. As a consequence, the average water vapor content of the atmosphere will increase. This causes more absorption of the outgoing infrared radiation and more global warming. Furthermore, increased evaporation may cause more cloud formation. Clouds and aerosols also can

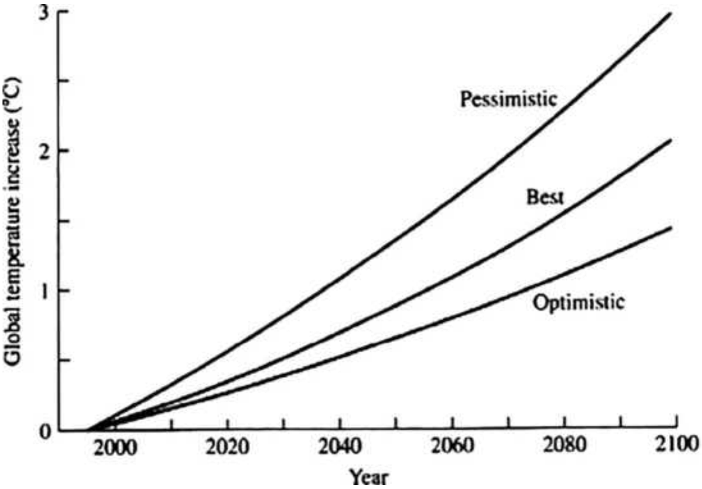

FIGURE 4 Projected trend of the earth surface temperature increase. Upper curve: pessimistic scenario with no emission curtailment; lower curve: optimistic scenario with significant emission curtailment; middle curve: in-between scenario.
Source: Cambridge University Press (see Intergovernmental Panel on Climate Change).[8]

trap outgoing terrestrial radiation, further increasing global warming. Melting ice caps and glaciers decrease the reflection of incoming solar radiation (reduced albedo), which also increases global warming. The prediction of the feedback effects is more un-certain than the prediction of radiative forcing, but generally, it is assumed that the feedback effects may double the surface temperature increases because of radiative forcing alone.

Has the surface temperature already increased due to anthropogenic activities? Figure 5 plots the global average surface temperature over the last century and a half. Even though there are large annual fluctuations, the smoothed curve through the data points indicates an upward trend of the temperature. From 1850, the start of the Industrial Revolution, to date, the global average surface temperature increased by about 0.5°C–1°C. This is in accordance with radiative models that predict such a trend, considering the increase of GHG concentrations over that period.

Other Effects of Global Warming

Because of increased GHG concentrations in the atmosphere, the earth's surface temperature may rise, as discussed in the previous section. The surface temperature rise may cause several ancillary effects on global climate and hydrogeology, which in turn will affect human habitat, welfare, and ecology.

Sea Level Rise

With increasing surface temperatures, the average sea level will rise because of three factors: melting of polar ice caps, receding of glaciers, and thermal expansion of the ocean surface waters. Combining all three factors, it is estimated that by the end of the next century, the average sea level may be 30–50 cm higher than it is today. This can seriously affect low-lying coastal areas, such as the Netherlands in Europe, Bangladesh in Asia, and low-lying islands in the Pacific and other oceans.[8]

Climate Changes

Predicting global and regional climatic changes because of average surface temperature rise is extremely difficult and fraught with uncertainties. It is expected that regional temperatures, prevailing winds, and storm and precipitation patterns will change, but where and when, and to what extent changes will occur, is a subject of intensive investigation and modeling on the largest available computers, the so-called supercomputers. Climate is not only influenced by surface temperature changes, but also by biological and hydrological processes, and by the response of ocean circulation, which are all coupled to temperature changes. It is expected that temperate climates will extend to higher latitudes, probably enabling the cultivation of grain crops further toward the north than at present. But crops need water. On the average, the global evaporation and precipitation balance will not change much, although at any instant, more water vapor (humidity) may be locked up in the atmosphere. However, precipitation patterns may alter, and the amount of rainfall in any episode may be larger than it is now. Consequently, the runoff (and soil erosion) may be enhanced, and areas of flooded watersheds may increase. Hurricanes and typhoons spawn in waters that are warmer than 27°C, in a band from 5 to 20° north and south latitude. As the surface waters become warmer, and the latitude band expands, it is very likely that the frequency and intensity of tropical storms will increase.

The sea level and climatic changes may cause a redistribution of agricultural and forestry resources, a considerable shift in population centers, and incalculable investments in habitat and property protection.

Greenhouse Gas Concentrations Trends

Currently, about 6.8 Gt/y of carbon (25 Gt/y CO_2) are emitted into the atmosphere by fossil fuel combustion. Another 1.5 ± 1 Gt/y are emitted due to deforestation and land use changes, mainly artificial burning of rain forests in the tropics, and logging of mature trees, which disrupts photosynthesis. Figure 6 plots the trend of atmospheric concentrations of CO_2, measured consistently at Mauna Loa, Hawaii since 1958 to date. At present, the average CO_2 concentration is about 375 parts per million by volume (ppmv). The plot shows seasonal variations due mainly to assimilation/respiration of CO_2 by plants, but there is a steady increase of the average concentration at a rate of approximately 0.4%/y. If that rate were to continue into the future, a doubling of the current CO_2 concentration would occur in about 175 years. However, if no measures are taken to reduce CO_2 emissions, then due to the population increase, and the concomitant enhancement of fossil fuel use, the rate of growth of CO_2 concentration will increase more than 0.4%/y, and the doubling time will be achieved sooner.

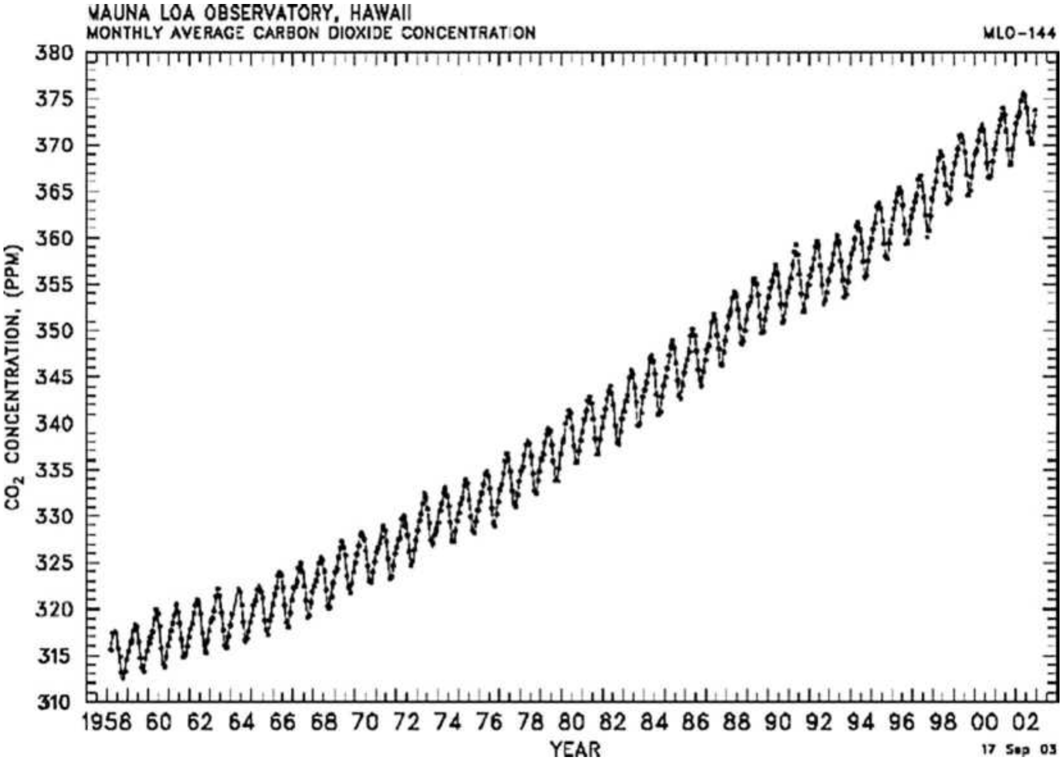

FIGURE 6 Carbon dioxide concentration trend 1958–2002.
Source: Oak Ridge National Laboratory (see CO_2 Information Center).[9]

Methane emissions are in part due to fossil energy usage, because CH_4 leaks from gas pipes, storage tanks, tankers, and coal mine shafts. Anthropogenic emissions of CH_4 from fossil fuel usage amount to about 100 Mt/y. However, CH_4 is also emitted from municipal waste landfills, sewage treatment, biomass burning, cultivated rice paddies, enteric fermentation of cattle, and other anthropogenic activities, so that the total amount of CH_4 emissions is about 400 Mt/y. Currently, the average atmospheric concentration of CH_4 is about 1.7 ppmv, growing at about 0.6%/y. Nitrous oxide (N_2O) is a minor product of combustion of fossil fuels. Currently, the concentration of N_2O is about 0.3 ppmv, growing by about 0.25%/y. CFCs are not directly associated with fossil fuel usage; however, they are emitted inadvertently from energy using devices, such as refrigerators, air conditioners, chillers, and heat pumps. Current concentrations of the various CFCs are about 0.5 parts per billion by volume (ppbv), and their concentrations are slowly declining due to the phase-out of production of CFCs.

What Can Be Done about Global Warming

Global warming could be lessened by reducing significantly the emissions of GHGs into the atmosphere. Most GHG emissions are a consequence of fossil fuel use. While it is important to reduce the emissions of all GHGs, the greatest preventative measure would come from reducing CO_2 emissions. CO_2 emission reductions can be accomplished by a combination of several of the following approaches.

Demand-Side Conservation and Efficiency Improvements

This includes less space heating and better insulation, less air conditioning, use of more fluorescent instead of incandescent lighting, more energy efficient appliances, process modification in industry, and very importantly, more fuel efficient automobiles. Some measures may even incur a negative cost, i.e., consumer savings by using less energy, or at least a rapid payback period for the investment in energy saving devices.

Supply-Side Efficiency Measures

Here we mean primarily increasing the efficiency of electricity production. Natural gas combined cycle power plants (NGCC) emit less CO_2 than single cycle coal fired power plants. First, because NG emits about one-half the amount of CO_2 per fuel heating value than coal, and second, because the thermal efficiency of combined cycle power plants is in the 45%–50% range vs. the 35%–38% range of single cycle plants. In the future, integrated coal gasification combined cycle power plants (IGCC) may come on-line with a thermal efficiency in the 40%–45% range reckoned on the basis of the coal heating value. Furthermore, IGCC may enable the capture of CO_2 at the gasification stage, with subsequent sequestration of the captured CO_2 in geologic and deep ocean repositories.

Shift to Non-Fossil Energy Sources

The choices here are agonizing, because the largest impact could be made by shifting to nuclear and hydro electricity, both presently very unpopular and fraught with environmental and health hazards. The shift to solar, wind, geothermal, and ocean energy is popular, but because of their limited availability and intermittency, and because of their larger cost compared to fossil energy, a substantial shift to these energy sources cannot be expected in the near future.

None of these options can prevent global warming by itself. They have to be taken in combination and on an incremental basis, starting with the least expensive ones and progressing to the more expensive ones. Even if the predictions of global climate change were to turn out exaggerated, the fact that fossil fuel usage entails many other environmental and health effects, and the certainty that fossil fuel resources are finite, makes it imperative that we curtail fossil energy usage as much as possible.

Summary and Conclusions

The use of fossil fuels to supply energy for the use of the world's population has resulted in the release to the atmosphere of troublesome chemical byproducts that present harm to humans and other natural species. These effects can be localized (near the emission source), can extend to large regional areas (involving sub-continents), and can even cover the globe, from pole to pole. A large portion of the human population is exposed to one or more of these environmental effects. The scientific understanding of how fossil fuel use causes these effects is well advanced, providing quantitative means for explaining what is currently observed and predicting what changes will occur in the future from projected future fuel consumption. These projections provide a basis for modifying the amount and character of future energy supply so as to lessen harmful environmental consequences. The technological systems that employ fossil fuel energy have been developed to lessen the amounts of harmful emissions, albeit at significant energy and economic cost. Further improvements can be expected, but at increasing marginal cost. The most severe emission control problem, in terms of economic and energy cost, is CO_2, a major contributor to global warming. The implementation of policies by national governments and international bodies to curtail the use of fossil energy and the concomitant emissions of CO_2 will become a growing task for humankind in this century.

Geothermal Energy Resources

Ibrahim Dincer
and Arif Hepbasli

Introduction

With increasing awareness of the detrimental effects of the burning of fossil fuels on the environment, there has been an increasing interest worldwide in the use of clean and renewable energy sources. Although geothermal energy is categorized in international energy tables as one of the "new renewables," it is not a new energy source at all. People have used hot springs for bathing and washing clothes since the dawn of civilization in many parts of the world.[1] Heat is a form of energy, and *geothermal energy* is, literally, the heat contained within the Earth that generates geological phenomena on a planetary scale. "Geothermal energy" is often used nowadays, however, to indicate that part of the Earth's heat that can, or could, be recovered and exploited by man, and it is in this sense that we will use the term from now on.[2] Geothermal energy utilization is basically divided into two categories, i.e., electric energy production and direct uses. Direct use of geothermal energy is one of the oldest, most versatile, and also the most common form of utilization of geothermal energy.[3] The early history of geothermal direct use has been well documented for over 25 countries in the *Stories from a Heat Earth—Our Geothermal Heritage*[4] that documents geothermal use for over 2000 years.[5]

Geothermal energy has until recently had a considerable economic potential only in areas where thermal water or steam is found concentrated at depths less than 3 km in restricted volumes, analogous to oil in commercial oil reservoirs. The use of ground-source heat pumps has changed this. In this case, the earth is the heat source for the heating and/or the heat sink for cooling, depending on the season. This has made it possible for people in all countries to use the heat of the earth for heating and/or cooling, as appropriate. It should be stressed that the heat pumps can be used basically everywhere.[1]

Based on country update papers submitted for the World Geothermal Congress 2010 (WGC-2010), covering the period 2005 to 2009, an estimate of the installed thermal power for direct utilization at the end of 2009 is 50,583 MW_t, almost a 79% increase over the 2005 data, growing at a compound rate of 12.3% annually with a capacity factor of 0.27. The thermal energy used is 438,071 TJ/yr (121,696 GWh/yr), about a 60% increase over 2005, growing at a compound rate of 9.9% annually. The distribution of thermal energy used by category is approximately 49.0% for ground-source heat pumps, 24.9% for bathing and swimming (including balneology), 14.4% for space heating (of which 85% is for district heating), 5.3% for greenhouses and open ground heating, 2.7% for industrial process heating, 2.6% for aquaculture pond and raceway heating, 0.4% for agricultural drying, 0.5% for snow melting and cooling, and 0.2% for other uses. Energy savings amounted to 307.8 million barrels (46.2 million tons) of equivalent oil annually, preventing 46.6 million tons of carbon and 148.2 million tons of CO_2[5] being released to the atmosphere, which includes savings in geothermal heat pump cooling (compared to using fuel oil to generate electricity).

The main objective of this entry is to provide a comprehensive picture about geothermal energy resources and their use for various purposes, ranging from power production to hydrogen production. It first gives a brief historical development of geothermal energy resources and geothermal energy applications. The following sections delve the nature of geothermal resources, classification of geothermal resources by energy and exergy, Lindal diagram, and some energetic and exergetic parameters for practical applications.

Historical Background

Early humans probably used geothermal water that occurred in natural pools and hot springs for cooking, bathing, and hot water and heating purposes. Archeological evidence indicates that the Indians of the Americas occupied sites around these geothermal resources for over 10,000 years to recuperate from battle and take refuge. Many of their oral legends describe these places and other volcanic phenomena. Recorded history shows uses by Romans, Japanese, Turks, Icelanders, Central Europeans, and the Maori of New Zealand for bathing, cooking, hot water, and space heating. Baths in the Roman Empire, the middle kingdom of the Chinese, and the Turkish baths of the Ottomans were some of the early uses of balneology, where body health, hygiene, and discussions were the social custom of the day. This custom has been extended to geothermal spas in Japan, Germany, Iceland, and countries of the former Austro-Hungarian Empire, the Americas, and New Zealand. Early industrial applications include chemical extraction from the natural manifestations of steam, pools, and mineral deposits in the Larderello region of Italy, with boric acid being extracted commercially starting in the early 1800s. At Chaudes-Aigues in the heart of France, the world's first geothermal district heating system was started in the 14th century and is still in use. The oldest geothermal district heating project in the United States is on Warm Springs Avenue in Boise, Idaho, which came on line in 1892 and continues to provide space heating for up to 450 homes.[2,4]

As outlined in various literature (e.g., Dickson and Fanelli[2] and Cataldi[4]), a brief summary is given as follows. The first use of geothermal energy for electric power production was carried out in Italy with some experimental tests by Prince Gionori Conti between 1904 and 1905. The first commercial power plant with a capacity of 250 kW_e was commissioned in 1913 at Larderello, Italy. An experimental plant was installed in the Geysers in 1932 to power a local resort. Such initiatives were followed in Wairakei (New Zealand) in 1958, with an experimental plant in Pathe (Mexico) in 1959, and the first commercial plant at The Geysers in the United States in 1960. Japan followed with a capacity of 23 MW_e in Matsukawa in 1966. All of these early plants utilized steam directly from the earth (mainly dry steam fields), except the one in New Zealand, which was considered the first to use flashed or separated steam for running the turbines. The former USSR produced power from the first true binary power plant with a capacity of 680 kW_e using 81°C water in Paratunka on the Kamchatka Peninsula—the lowest temperature at that time. Iceland first produced power at Namafjall in the Northern part of the country by using a 3 MWe non-condensing turbine. These were later followed by various plants in El Salvador, China, Indonesia, Kenya, Turkey, Philippines, Portugal (Azores), Greece, and Nicaragua in the 1970s and 1980s. Some recent plants have been installed in Thailand, Argentina, Taiwan, Australia, Costa Rica, Austria, Guatemala, and Ethiopia, with the latest installations in Germany and Papua New Guinea.

More recently, renewable energy resources have received increasing interest for sustainable hydrogen production. In this regard, Balta et al.[6,7] have recently studied on geothermal based hydrogen production methods comprehensively and defined various potential methods using thermochemical and hybrid cycles driven essentially by heat, as considered appropriate for geothermal sources. This has further widened the scope of geothermal energy resources. Geothermal based hydrogen production offers potential advantages over other sources for a growing hydrogen economy. These advantages do not ensure that geothermal based hydrogen will be the only option, but it will compete with other hydrogen production options. In some countries, geothermal energy is considered a primary energy source of producing hydrogen since it provides reliable energy supply in an environmentally benign manner. Hydrogen can be produced from geothermal energy using five potential methods such as 1) direct production of hydrogen from geothermal steam; 2) water electrolysis using the electricity generated from a power plant; 3) high- temperature steam electrolysis; 4) thermochemical cycles driven by geothermal heat; and 5) hybrid cycles driven by geothermal heat and electricity. A comprehensive discussion of these methods is available elsewhere.[6,7]

Nature of Geothermal Resources

The *geothermal gradient* expresses the increase in temperature with depth in the Earth's crust. Down to the depths accessible by drilling with modern technology, i.e., over 10,000 m, the average geothermal gradient is about 2.5–3°C/100 m. For example, if the temperature within the first few meters below ground level, which on average corresponds to the mean annual temperature of the external air, is 15°C, then we can reasonably assume that the temperature becomes about 65–75°C at 2000 m depth, 90–105°C at 3000 m, and so on for a further few thousand meters. There are, however, vast areas in which the geothermal gradient is far from the average value. In areas in which the deep rock basement has undergone rapid sinking, and the basin is filled with geologically "very young" sediments, the geothermal gradient may be lower than 1°C/100 m. On the other hand, in some "geothermal areas," the gradient is more than 10 times the average value (further details are given in Dickson and Fanelli[2]).

Geothermal energy essentially comes from the natural heat of the earth as a result of the decay of the naturally radioactive isotopes of uranium, thorium, and potassium. Because of the internal heat, the Earth's surface heat flow averages 82 mW/m^2 with an equivalent total heat loss rate (the mean terrestrial heat flow of continents and oceans is 65 and 101 mW/m^2) of about 42 million MW.[2,8,9] The estimated total thermal energy above mean surface temperature to a depth of 10 km is 1.3×10^{27} J, which is equivalent to burning 3.0×10^{17} barrels of oil. Since the global energy consumptions for all types of energy are equivalent to use of about 100 million barrels of oil per day, the Earth's energy to a depth of 10 km could theoretically supply all of mankind's energy needs for about 6 million years (as further discussed in Wright[8] and Lund[9]).

A geothermal system essentially consists of three elements, namely, 1) a heat source; 2) a reservoir; and 3) a heat-carrying fluid (geothermal liquid) as illustrated in Figure 1. The heat source can be either at very high temperature greater than 600°C with magmatic intrusion at relatively shallow depths (5–10 km) or at relatively low temperatures. As mentioned above, the Earth's temperature increases with depth. The reservoir is a volume of hot permeable rocks from which the circulating fluids extract heat and connected to a surfacial recharge area through which the meteoric waters can replace or partly replace the fluids that escape from the reservoir through springs or are extracted by boreholes. The geothermal fluid is water (in the majority of cases, meteoric water) either in liquid or in vapor phase,

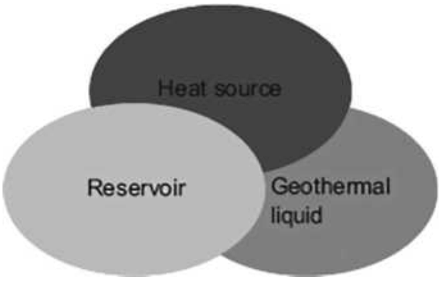

FIGURE 1 Geothermal system.

depending on its temperature and pressure. The geothermal water often carries with it some chemicals and gases such as CO_2 and H_2S.

Geothermal Energy and Environmental Impact

Problems with energy supply and use are related not only to global warming but also to such environmental concerns as air pollution to climate change, forest destruction, and emission of radioactive substances. These issues must be taken into consideration simultaneously if humanity is to achieve a bright energy future with minimal environmental impacts. Much evidence exists, which suggests that the future will be negatively impacted if humans keep degrading the environment.

One solution to both energy and environmental problems is to make much more use of renewable energy resources, particularly geothermal. This cause is sometimes espoused with a fervor that leads to extravagant and impossible claims being made. Engineering practicality, reliability, applicability, economy, scarcity of supply, and public acceptability should all be considered accordingly.

In order to achieve the energetic, economic, and environmental benefits that geothermal offers, the following integrated set of activities should be acted accordingly:

- *Research and Development:* Research and development priorities should be set in close consultation with industry to reflect their needs. Most research is conducted through cost-shared agreements and falls within the short-to- medium term. Partners in these activities should include a variety of stakeholders in the energy industry, such as private-sector firms, utilities across the country, provincial governments, and other federal departments.
- *Technology Assessment:* Appropriate technical data should be gathered in the laboratory and through field trials on factors such as cost benefit, reliability, environmental impact, safety, and opportunities for improvement. These data should also assist the preparation of technology status overviews and strategic plans for further research and development.
- *Standards Development:* The development of technical and safety standards is needed to encourage the acceptance of proven technologies in the marketplace. Standards development should be conducted in cooperation with national and international standards writing organizations, as well as other national and provincial regulatory bodies.
- *Technology Transfer:* Research and development results should be transferred through sponsorship of technical workshops, seminars, and conferences, as well as through the development of training manuals and design tools, Web tools, and the publication of technical reports.

Such activities will also encourage potential users to consider the benefits of adopting geothermal energy technologies. In support of developing near-term markets, a key technology transfer area is to accelerate the use of geothermal energy technologies, particularly for district heating applications and power generation.

Geothermal Energy and Sustainability

Sustainable development requires a sustainable supply of clean and affordable energy resources that do not cause negative societal impacts. Supplies of such energy resources as fossil fuels and uranium are finite. Energy resources such as geothermal are generally considered renewable and therefore sustainable over the relatively long term.

Sustainability often leads local and national authorities to incorporate environmental considerations into energy planning. The need to satisfy basic human needs and aspirations, combined with increasing world population, will make the need for successful implementation of sustainable development increasingly apparent. Various criteria that are essential to achieving sustainable development in a society follow:[10,11]

- Information about and public awareness of the benefits of sustainability investments
- Environmental education and training
- Appropriate energy and exergy strategies
- The availability of renewable energy sources and cleaner technologies
- A reasonable supply of financing
- Monitoring and evaluation tools

Geothermal as a renewable energy has an important role to play in meeting future energy needs in both rural and urban areas. The development and utilization of geothermal energy applications should be given a high priority, especially in the light of increased awareness of the adverse environmental impacts of fossil-based generation. The need for sustainable energy development is increasing rapidly in the world. Widespread use of geothermal energy is important for achieving sustainability in the energy sectors in both developing and industrialized countries.

Geothermal energy can be a key component for sustainable development for three main reasons:

1. They generally cause less environmental impact than other energy resources. The variety of geothermal energy applications provides a flexible array of options for their use.
2. They cannot be depleted. If used carefully in appropriate applications, renewable energy resources can provide a reliable and sustainable supply of energy almost indefinitely. In contrast, fossil fuel and uranium resources are diminished by extraction and consumption.
3. They favor both system centralization and decentralization and local solutions that are somewhat independent of the national network, thus enhancing the flexibility of the system and providing economic benefits to small isolated populations. Also, the small scale of the equipment often reduces the time required from initial design to operation, providing greater adaptability in responding to unpredictable growth and/or changes in energy demand.

Not all renewable energy resources are inherently clean in that they cause no burden on the environment in terms of waste emissions, resource extraction, or other environmental disruptions. Nevertheless, use of geothermal almost certainly can provide a cleaner and more sustainable energy system than increased controls on conventional energy systems.

To seize the opportunities, it is essential to establish a geothermal energy market and gradually build up the experience with the cutting-edge technologies. The barriers and constraints to the diffusion of geothermal energy use should be removed. The legal, administrative, and financing infrastructure should be established to facilitate planning and application of geothermal energy projects. Government could/should play a useful role in promoting geothermal energy technologies through fundings and incentives to encourage research and development as well as commercialization and implementation in both urban and rural areas.

Classification of Geothermal Resources

There is no standard international terminology in use throughout the geothermal community, which is unfortunate, as this would facilitate mutual comprehension.[2] In the following, some of the most common classifications in this discipline are presented in terms of energetic and exergetic aspects.

Classification of Geothermal Resources by Energy

The most common classification of geothermal resources is done based on the enthalpy values of the geothermal fluids, acting as the energy carrier for transporting the heat from deep hot rocks to the Earth's surface. In this regard, enthalpy and temperature levels are accordingly considered as given in Table 1. The temperatures of these geothermal resources range from the mean annual temperature of around 20°C to over 300°C. In general, resources above 150°C are used for electric power generation, although power has recently been generated at Chena Hot Springs Resort in Alaska using a 74°C geothermal resource.[12] Resources below 150°C are usually used in direct-use projects for individual and district heating and cooling applications. Furthermore, the ambient temperatures in the range of 5–30°C can be used with geothermal (ground source) heat pumps to provide both heating and cooling. The resources may also be categorized into three enthalpy levels (low, medium, and high) according to criteria that are generally based on the energy content of the fluids and their potential forms of utilization. Furthermore, Table 2 presents a summary of the types of geothermal resources, reservoirs temperatures, reservoirs fluids, applications, and systems.

Although numerous criteria can be utilized for classification, the reservoir temperature still remains as the primary criterion. Table 3 lists a possible scheme in which geothermal resources are classified into

TABLE 1 Geothermal Resource Types and Temperature Ranges

Resource Type		Temperature Range (°C)
Convective hydrothermal resources	Vapor dominated	≈240
	Hot water dominated	20–350
Other hydrothermal resources	Sedimentary basin	20–150
	Geopressured	90–200
	Radiogenic	30–150
Hot rock resources	Solidified (hot dry rock)	90–650
	Part still molten magma	>600

TABLE 2 Geothermal Resource Types, Applications, and System Types

Reservoir Temperature	Reservoir Fluid	Applications	Systems
High temperature (>220°C)	Water or steam	Power generation Direct use	• Flash steam • Combined (flash and binary) cycle • Direct fluid use • Heat exchangers • Heat pumps
Medium temperature (100–220°C)	Water	Power generation Direct use	• Binary cycle • Direct fluid use • Heat exchangers • Heat pumps
Low temperature (50–150°C)	Water	Direct use	• Direct fluid use • Heat exchangers • Heat pumps

TABLE 3 Classification of Different Schemes for Geothermal Resources

Class of Resource	Reservoir Temperature (°C)	Mobile Fluid Phase in Reservoir	Production Mechanism	Fluid State at Well Head	Well Productivity and Controlling Factors Other than Temperature	Applicable Power Conversion Technology	Unusual Development or Operational Problems
1. Non-electrical	<100	Liquid water	Artesian self-flowing wells; pumped wells	Liquid water	Well productivity dependent on reservoir flow capacity and static water level	Direct use	
2. Very low temperature	100 to <150	Liquid water	Pumped wells	Liquid water (for pumped wells); steam–water mixture (for self-flowing wells)	Typical well capacity 2 to 4 MW_e; dependent on reservoir flow capacity and gas content in water; well productivity often limited by pump capacity	Binary	
3. Low temperature	150 to <190	Liquid water	Pumped wells; self-flowing wells (only at the higher temperature end of the range)	Liquid water (for pumped wells); steam–water mixture (for self-flowing wells)	Typical well capacity 3 to 5 MW_e; dependent on reservoir pressures, reservoir flow capacity and gas content in water; productivity of pumped wells typically limited by pump capacity and pump parasitic power need; productivity of self-flowing wells strongly dependent on reservoir flow capacity	Binary; two-stage flash; hybrid	Calcite scaling in production wells and stibnite scaling in binary plant are occasional problems
4. Moderate temperature	190 to <230	Liquid water	Self-flowing wells	Steam–water mixture (enthalpy equal to that of saturated liquid at reservoir temperature)	Well productivity highly variable (3 to 12 MW_e); strongly dependent on reservoir flow capacity	Single-stage flash; two-stage flash; hybrid	Calcite scaling in production wells occasional problem; alumino-silicate scale in injection system a rare problem

TABLE 3 (*Continued*) Classification of Different Schemes for Geothermal Resources

Class of Resource	Reservoir Temperature (°C)	Mobile Fluid Phase in Reservoir	Production Mechanism	Fluid State at Well Head	Well Productivity and Controlling Factors Other than Temperature	Applicable Power Conversion Technology	Unusual Development or Operational Problems
5. High temperature	230 to <300	Liquid water; liquid-dominated two-phase	Self-flowing wells	Steam–water mixture (enthalpy equal to or higher than that of saturated liquid at reservoir temperature); saturated steam	Well productivity highly variable (up to 25 MW_e); dependent on reservoir flow capacity and steam saturation		
6. Ultrahigh temperature	300+	Liquid-dominated two-phase	Self-flowing wells	Steam–water mixture (enthalpy equal to or higher than that of saturated liquid at reservoir condition); saturated steam; superheated steam	Well productivity extremely variable (up to 50 MW_e); dependent on reservoir flow capacity and steam saturation		
7. Steam field	240 (33.5 bar-a pressure; 2800 kJ/kg enthalpy)	Steam	Self-flowing wells	Saturated or superheated steam	Well productivity extremely variable (up to 50 MW_e); dependent on reservoir flow capacity		

Source: Adapted from Sanyal.[15]

seven categories based on temperature, while they are explained in more detail in Sanyal.[15] This classification includes non-electrical grade (<100°C), very low temperature (100°C to <150°C), low temperature (150°C to 190°C), moderate temperature (190°C to <230°C), high temperature (230°C to <300°C), ultrahigh temperature (>300°C), and steam fields (approximately 240°C with steam as the only mobile phase).[16] In the first four classes of reservoirs, liquid water is the mobile phase; in the "high" and "ultrahigh" temperature reservoirs, the mobile fluid phase is either liquid or a liquid–vapor mixture. Thus, this makes steam fraction a second criterion. Unfortunately, there is no readily available procedure to classify enhanced geothermal systems or hot dry rock resources other than perhaps considering temperature-based classification as discussed above.

Classification of Geothermal Resources by Exergy

Although many agree on the classification of geothermal resources based on temperature and enthalpy levels as part of the energy aspects under the first law of thermodynamics, there are still some ambiguities with respect to their quality that address the second law of thermodynamics through exergy. Therefore, geothermal resources should be classified by their exergy, a measure of their ability to do work[17,18]).

Lee[17] proposed a new parameter, the so-called specific exergy index (SExI) for better classification and evaluation as follows:

$$\text{SExI} = \frac{h_{\text{brine}} - 273.16\ S_{\text{brine}}}{1192} \tag{1}$$

which is a straight line on an $h\!-\!s$ plot of the Mollier diagram. Straight lines of SExI = 0.5 and SExI = 0.05 can therefore be drawn in this diagram and used as a map for classifying geothermal resources by taking into account the following criteria:

- SExI < 0.05 for low-quality geothermal resources
- 0.05 ≤ SExI < 0.5 for medium-quality geothermal resources
- SExI ≥ 0.5 for high-quality geothermal resources

Here, the demarcation limits for these indexes are exergies of saturated water and dry saturated steam at 1 bar absolute.

In order to map any geothermal field on the Mollier diagram as well as to determine the energy and exergy values of the geothermal brine, the average values for the enthalpy and entropy are then calculated from the following equations:[18]

$$h_{\text{brine}} = \frac{\sum_{i}^{n} \dot{m}_{w,i} h_{w,i}}{\sum_{i}^{n} \dot{m}_{w,i}} \tag{2}$$

$$S_{\text{brine}} = \frac{\sum_{i}^{n} \dot{m}_{w,i} S_{w,i}}{\sum_{i}^{n} \dot{m}_{w,i}} \tag{3}$$

The above-given exergetic classification has been used by some investigators in their studies. From these, Quijano[19] performed an exergy analysis of the Ahuachapán and Berlin geothermal fields. After plotting the thermodynamic states of both fields on the Mollier diagram and calculating the values of SExI, he classified these geothermal fields as the medium high exergy zone. Ozgener et al.[20] and Baba et al.[21] utilized this index (SExI) for the Balcova geothermal field located in the western part of Turkey, endowed with considerably rich geothermal resources. The number of the operating wells in this field varies depending on the heating days and operating strategies. Taking into account the eight operating wells and using Eqs. 1–3, the SExI is found to be 0.07 since it falls into the medium-quality geothermal resources according to the classification of Lee.[17] However, given the classification of the Balcova geothermal field with respect to its average reservoir as 113.9°C, the Balcova geothermal field becomes an intermediate-enthalpy resource. This clearly indicates that the classification with respect to the SExI is more meaningful as there is no need for a temperature range classification. Ozgener et al.[22,23] also determined the SExI values for the Gonen and Salihli geothermal fields in Turkey as 0.025 and 0.049, respectively. They concluded that both these fields fall into the low-quality geothermal resources according to the classification of Lee. Etemoglu and Can[24] studied geothermal resources in Turkey based on SExI. In their analysis, the triple point of water was selected as the dead-state conditions since the enthalpy and entropy values were zero. Geothermal resources with SExI values of 0.56 were classified as high-exergy resources; those whose values were <0.05 were low-exergy resources, and those whose values are between these two were medium-exergy resources.

The Lindal Diagram

There is another way of classifying the geothermal fields developed by Lindal[25] as illustrated in Figure 2. This diagram has frequently appeared in books, reports, and articles on direct uses of geothermal energy and shows the temperature required for both current and potential applications of geothermal energy. In other words, the minimum production temperatures in a geothermal field are generally required for the different types of use as shown in the diagram. This is now widely used by the geothermal community to depict temperature as the yardstick of direct applications. The boundaries, however, serve only as guidelines. Conventional electric power production is limited to fluid temperatures about 150°C, but considerably lower temperatures can be used with the application of binary fluids (outlet temperatures commonly at 100°C, while there are also some applications up to 74°C). The ideal inlet temperature into houses for space heating using radiators is about 80°C, but by using radiators of floor heating, or by applying heat pumps or auxiliary boilers, thermal waters with temperatures only a few degrees above the ambient can be used beneficially. It is a common misconception that direct use of geothermal is confined to low-temperature resources. High-temperature resources can, of course, also be used for heating and drying purposes even if the process is at a very low temperature. Refrigeration is, in fact, only possible with temperatures above about 120°C.[26]

Some Energetic and Exergetic Parameters

Coskun et al.[27] have introduced some geothermal energy systems-related parameters, namely, energetic renewability ratio, exergetic renewability ratio, energetic reinjection ratio, and exergetic reinjection ratio:

- *Energetic renewability ratio:* This is defined as the ratio of useful renewable energy obtained from the system to the total energy input (all renewable and non-renewable together) to the system.

$$R_{\mathrm{Ren}_E} = \frac{\dot{E}_{\mathrm{usf}}}{\dot{E}_{\mathrm{total}}} \tag{4}$$

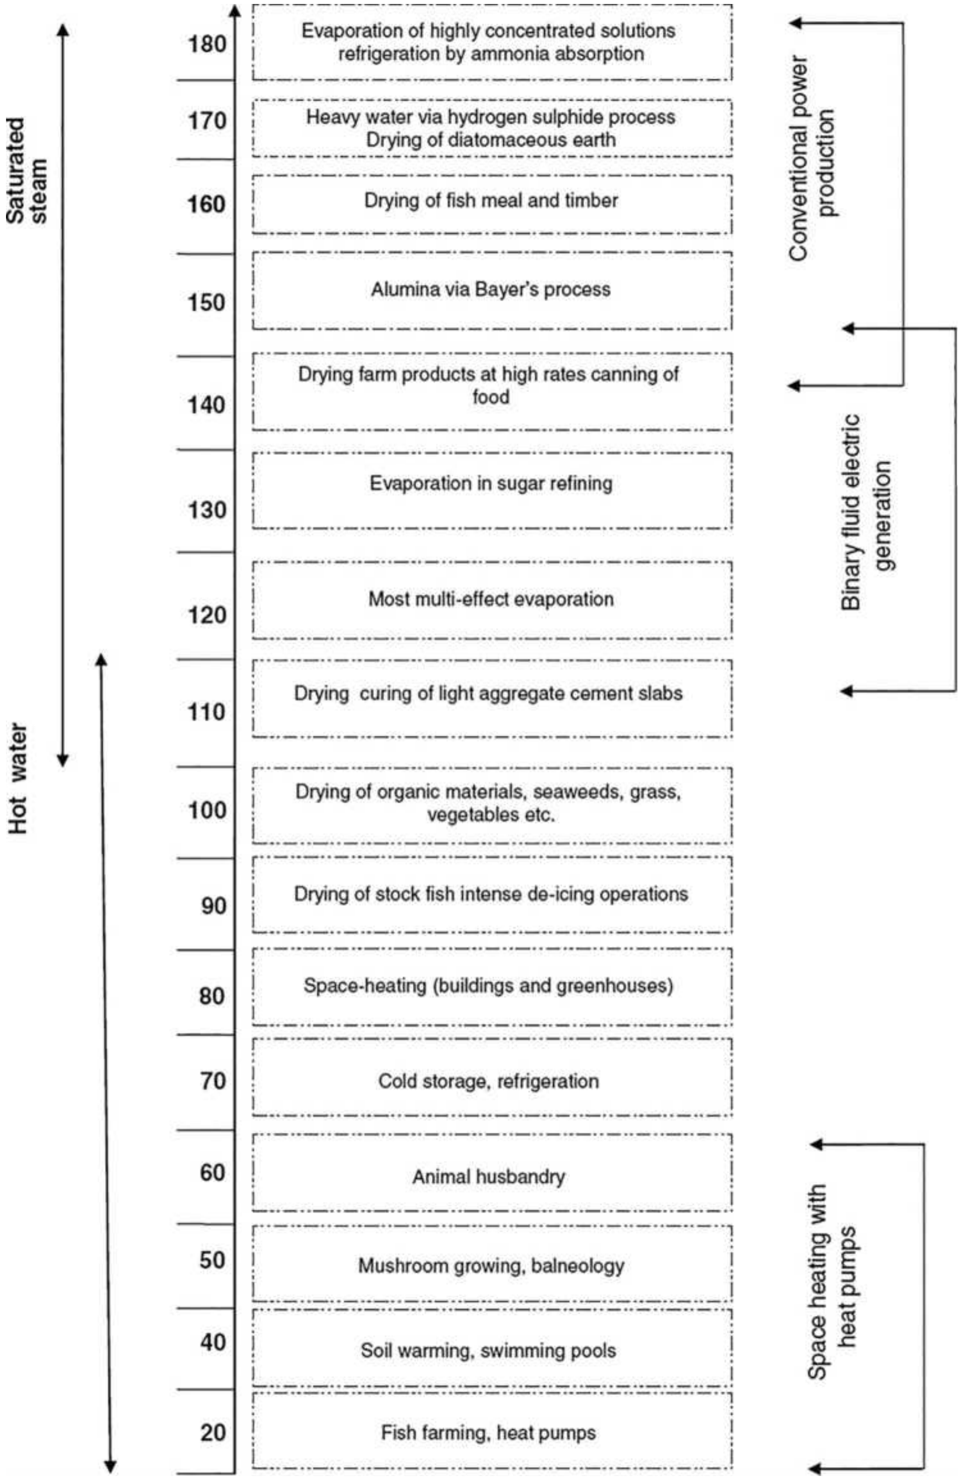

FIGURE 2 Lindal diagram indicating the applications for geothermal resources depending on the temperature. **Source:** Adapted from Hepbasli.[28]

- *Exergetic renewability ratio:* This is defined as the ratio of useful renewable exergy obtained from the system to the total exergy input (all renewable and non-renewable together) to the system:

$$R_{\mathrm{Re\ in}_{\mathrm{Ex}}} = \frac{\dot{E}x_{\mathrm{usf}}}{\dot{E}x_{\mathrm{total}}} \tag{5}$$

Here, total energy and exergy input terms include the wellhead geothermal water energy only in energy and exergy efficiencies. However, in the above equations for energetic and exergetic renewability ratios, all renewable and non-renewable energy and exergy inputs are considered for input.

- *Energetic reinjection ratio:* This is defined as the ratio of renewable energy discharged to environment or reinjected to the well from the system to the total geothermal energy supplied to the system:

$$R_{\mathrm{Re\ in}_{\mathrm{E}}} = \frac{\dot{E}_{\mathrm{nd}}}{\dot{E}_{\mathrm{gw}}} \tag{6}$$

- *Exergetic reinjection ratio:* This is defined as the ratio of renewable exergy discharged to environment or reinjected to the well from the system to the total geothermal exergy supplied to the system:

$$R_{\mathrm{Re\ in}_{\mathrm{Ex}}} = \frac{\dot{E}x_{\mathrm{nd}}}{\dot{E}x_{\mathrm{gw}}} \tag{7}$$

Here, the monthly variations of the above-listed parameters as studied by Coskun et al.[27] for the Edremit Geothermal District Heating System (GDHS) are illustrated in Figure 3. As seen in Figure 3a and b, both energetic and exergetic renewability ratios decrease with increasing temperature in the summer season. Here, one can extract the following:

- The energetic renewability ratio varies between 0.32 and 0.33 for the Edremit system during summer when heating is not required.
- The exergetic renewability ratio varies between 0.25 and 0.35 for the Edremit system during the summer when heating is not required.

It was observed that the outdoor reference ambient temperatures do not have a direct effect on both mass flow rate and energy/exergy losses as a result of no heating requirement for the summer season. Domestic hot water requirement is one important parameter for the summer season. Domestic hot water requirement increases for hot days. Because of the increase in domestic hot water requirement, pump energy consumption in total energy input increases. Moreover, calculations show that total exergy loss/destruction tended to increase in the summer season. For instant, pump exergy destruction increases in the summer season as a result of the increase in the required domestic mass flow rate. In the heating season, total "winter" heat demand is the sum of the domestic hot water+heating proper. The mass flow rates for the network water and geothermal water vary during the season dependent on the average useful energy demand. The demand is the highest in January, declines until May, and begins increasing until the end of December. It is obvious that based on the demand, the mass flow rates proportionally change. The energetic and exergetic renewability ratios become the lowest in January, increasing until May, and begin decreasing until the end of December. We have understood from these results that heat demand and renewability ratio values are opposite characteristic properties. The renewability values are given for the heating season as below:

- The energetic renewability ratio varies between 0.33 and 0.34 for the Edremit system.
- The exergetic renewability ratio varies between 0.53 and 0.63 for the Edremit system.

In addition, both energetic and exergetic reinjection ratios are calculated using Eqs. 6 and 7 for the Edremit GDHS annually as given in Figure 3c and d, respectively. These figures can be explained for summer and winter seasons as follows. The energetic reinjection ratio increases in higher temperatures with the effect of pump energy consumption. They vary between 0.59 and 0.62 for the Edremit system during the summer season when heating is not required (Figure 3c). Variation of the exergetic reinjection ratio depends on outdoor temperature and has similar characteristic with average annual temperature (see Figure 3d). Used geothermal water exergy rate decreases as a result of increase in reference ambient temperature in the summer season. Used geothermal exergy rate decreases through the middle of summer, at the highest temperature. The exergetic reinjection ratio varies between 0.10 and 0.20 for the Edremit system during the summer season (see Figure 3d).

Furthermore, Hepbasli[28] has recently proposed the following new exergetic parameters, based on the system given in Ozgener et al.[29] while their energetic approaches may be also considered using their exergetic relations:

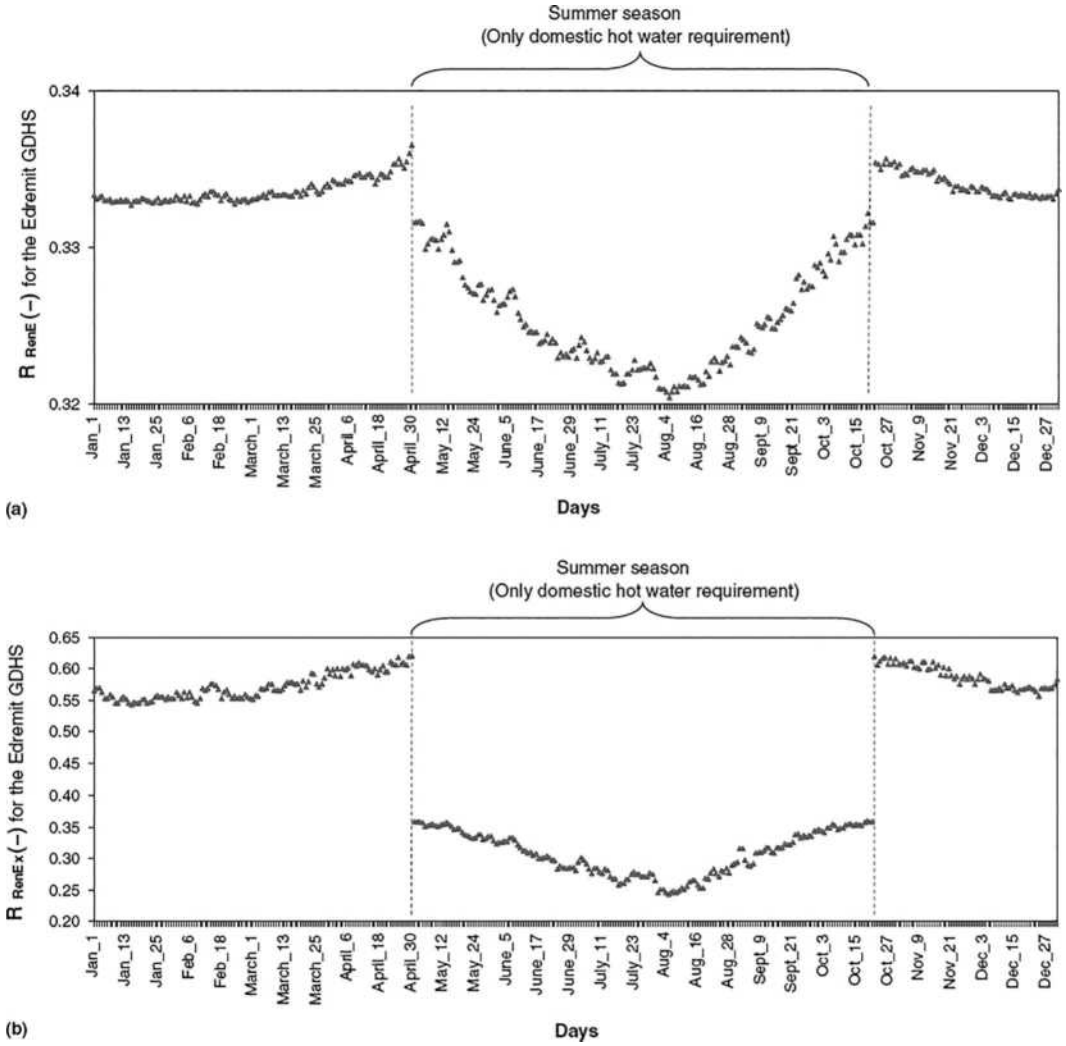

FIGURE 3 (a) Change of energetic renewability ratio for the Edremit GDHS annually. (b) Change of exergetic renewability ratio for the Edremit GDHS annually (modified from Coskun et al.[27]).

(*Continued*)

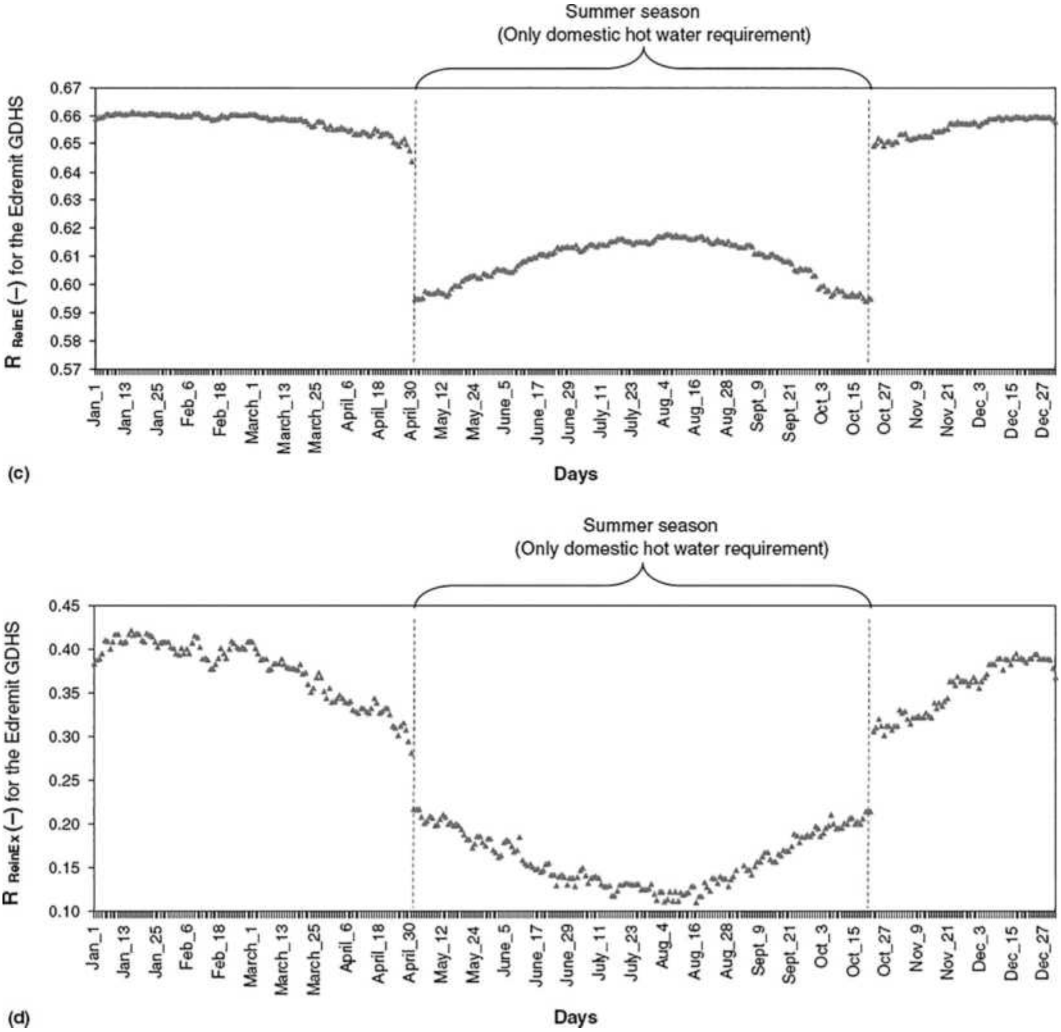

FIGURE 3 (CONTINUED) (c) Change of energetic reinjection ratio for Edremit GDHS annually. (d) Change of exergetic reinjection ratio for Edremit GDHS annually (modified from Coskun et al.[27])**S**

1. *Distribution cycle exergetic ratio* (R_{DCEx}): This is defined as the ratio of the exergetic capacity of the district heating water circulating through the district heating distribution network (MW) to the exergetic capacity of the geothermal reservoir in the field considered (MW):

$$R_{\mathrm{DCEx}} = \frac{\dot{E}x_{\mathrm{dhw}}}{\dot{E}x_{\mathrm{gr}}} \tag{8}$$

2. *Energy consumptions circuit exergetic ratio* (R_{ECCEx}): This is defined as the ratio of the exergetic capacity of the fluid circulating through the energy consumptions circuit (building substations) district heating distribution network (MW) to the exergetic capacity of the geothermal reservoir in the field considered (MW):

$$R_{\mathrm{ECCEx}} = \frac{\dot{E}x_{\mathrm{dhw}}}{\dot{E}x_{\mathrm{gr}}} \tag{9}$$

The average values for the enthalpy and entropy to be used in the calculations may be calculated from Eqs. 2 and 3.

3. *Reservoir specific exergy utilization index* (RSExUI): This is defined as the ratio of the exergetic capacity of the geothermal reservoir in the field considered (MJ) to the total heating surface area of all the buildings (m^2) and given by

$$\mathrm{RSExUI}\left(\mathrm{MJ}/m^2\right) = \frac{\dot{E}x_{gr}\,(\mathrm{MJ})}{A_{\mathrm{building}}\left(m^2\right)} \tag{10}$$

4. *Geothermal brine specific exergy utilization index* (GBSExUI): This is defined as the ratio of the geothermal brine exergy input value (MJ) to the total heating surface area of all the buildings (m^2) and given by

$$\mathrm{GBSxUI}\left(\mathrm{MJ}/m^2\right) = \frac{\dot{E}x_{gb}\,(\mathrm{MJ})}{A_{\mathrm{building}}\left(m^2\right)} \tag{11}$$

Some more details on the use of exergy for design and analysis of geothermal district heating systems are available elsewhere.[30]

Performance Evaluation

From the thermodynamics point of view, exergy is defined as the maximum amount of work that can be produced by a system or a flow of matter or energy as it comes to equilibrium with a reference environment. Exergy is a measure of the potential of the system or flow to cause change, as a consequence of not being completely in stable equilibrium relative to the reference environment. Unlike energy, exergy is not subject to a conservation law (except for ideal, or reversible, processes). Rather, exergy is consumed or destroyed, due to irreversibilities in any real process. The exergy consumption during a process is proportional to the entropy created due to irreversibilities associated with the process.

Exergy analysis is a technique that uses the conservation of mass and conservation of energy principles together with the second law of thermodynamics for the analysis, design, and improvement of geothermal energy systems as well as others. It is also useful for improving the efficiency of energy-resource use, for it quantifies the locations, types, and magnitudes of wastes and losses. In general, more meaningful efficiencies are evaluated with exergy analysis rather than energy analysis, since exergy efficiencies are always a measure of how nearly the efficiency of a process approaches the ideal. Therefore, exergy analysis identifies accurately the margin available to design more efficient energy systems by reducing inefficiencies. We can suggest that thermodynamic performance is best evaluated using exergy analysis because it provides more insights and is more useful in efficiency-improvement efforts than energy analysis. For exergy analysis, the characteristics of a reference environment must be specified. This is commonly done by specifying the temperature, pressure, and chemical composition of the reference environment. The results of exergy analyses, consequently, are relative to the specified reference environment, which, in most applications, is modeled after the actual local environment. The exergy of a system is zero when it is in equilibrium with the reference environment.

Energy and exergy balances for an unsteady-flow process in a system during a finite time interval can be written as:

$$\text{Energy input} - \text{Energy output} = \text{Energy accumulation} \tag{12}$$

$$\text{Exergy input} - \text{Exergy output} - \text{Exergy consumption} = \text{Energy accumulation} \tag{13}$$

For a general steady-state, steady-flow process, it is assumed that the accumulation terms in the above equations become zero. Therefore, input terms become equal to output terms.

For a steady-state, steady-flow process, the mass balance equation can be expressed as

$$\sum_{\dot{m}_{\text{in}}} = \sum_{\dot{m}_{\text{out}}} \tag{14}$$

For a general steady-state, steady-flow process, the general energy and exergy balance equations can also be written more explicitly as

$$\dot{Q} + \sum_{\dot{m}_{\text{in}}} h_{\text{in}} = \dot{W} + \sum_{\dot{m}_{\text{out}}} h_{\text{out}} \tag{15}$$

And

$$\sum \left(1 - \frac{T_0}{T_s}\right)\dot{Q}_s + \sum \dot{m}_{\text{in}}\left(h_{\text{in}} - T_0 s_{\text{in}}\right) - \dot{E}x_d \tag{16}$$

$$= \dot{W} + \sum m_{\text{out}}\left(h_{\text{out}} - T_0 s_{\text{out}}\right)$$

We can generally define the energy and exergy efficiencies as follows:

$$\eta = \frac{\dot{E}_{\text{net}}}{\dot{E}_{\text{tot}}} \tag{17}$$

And

$$\psi = \frac{\dot{E}x_{\text{net}}}{\dot{E}x_{\text{tot}}} \tag{18}$$

For further details of both energy and exergy analyses and applications to various energy systems, see Dincer and Rosen.[31]

Note that in the calculations, the temperature T_0 and pressure P_0 of the environment are often taken as standard-state values, such as 1 atm and 25°C. However, these properties may be specified differently depending on the application. T_0 and P_0 might be taken as the average ambient temperature and pressure, respectively, for the location at which the system under consideration operates. Or, if the system uses atmospheric air, T_0 might be specified as the average air temperature. If both air and water from the natural surroundings are used, T_0 would be specified as the lower of the average temperatures for air and water.

Detailed energy and exergy as well as exergoeconomic analysis methodologies for geothermal energy systems are given elsewhere.[22,23]

Case Study

Here, we present a case study analysis of the Salihli Geothermal District Heating System (SGDHS), which has a maximal yield of 87 L/s at an average reservoir temperature of 95°C, with a minimal capacity of 838 MW.[30] The SGDHS was originally designed for 20,000 residences equivalence. Of these, 2400 residences equivalence are heated by geothermal energy as of February 2004. The outdoor and indoor

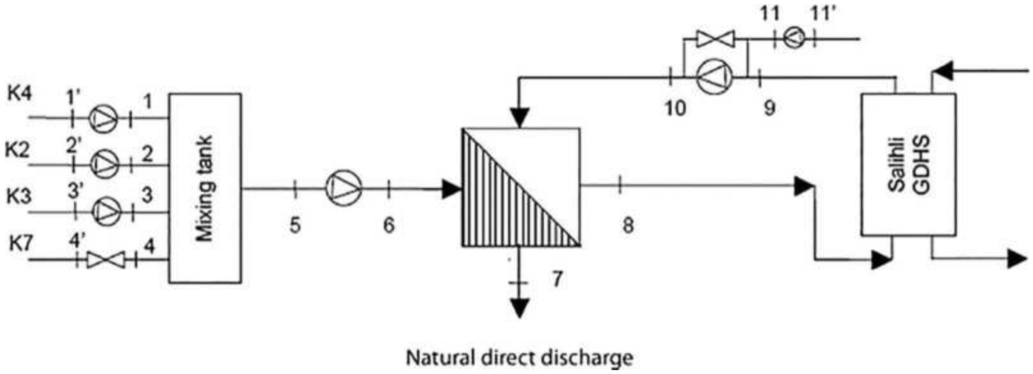

FIGURE 4 A schematic of the SGDHS.
Source: Adapted from Dincer et al.[30]

design temperatures for the system are 4°C and 22°C, respectively. Figure 4 illustrates a schematic of the SGDHS where two hospitals and official buildings heated by geothermal energy were also included. The SGDHS consists mainly of three cycles, such as 1) energy production cycle (geothermal well loop and geothermal heating center loop); 2) energy distribution cycle (district heating distribution network); and 3) energy consumption cycle (building substations). At the beginning of 2004, there were seven wells ranging in depth from 70 to 262 m in the SGDHS. Of these, five wells were in operation at the date studied and two wells (K5 and K6) were out of operation. Four wells (designated as K2, K3, K4, and K7) and one well (K1) are production and balneology wells, respectively. The well head temperatures of the production wells vary from 56°C to 115°C, while the volumetric flow rates of the wells range from 2 to 20 L/s. The geothermal fluid is basically sent to two primary plate-type heat exchangers and is cooled to about 45°C, as its heat is transferred to secondary fluid. The geothermal fluid[30] is discharged via natural direct discharge, with no recharge to Salihli geothermal field production, but reinjection studies are expected to be completed in the near future. The temperatures obtained during the operation of the SGDHS are, on average, 98°C/45°C for the district heating distribution network and 62°C/42°C for the building circuit. By using the control valves for flow rate and temperature at the building main station, the needed amount of water is sent to each housing unit and the heat balance of the system is achieved. Geothermal fluid, collected from the four production wells at an average well heat temperature of 95.5°C, is pumped to the inlet of the heat exchanger mixing tank later through a main collector (from four production wells) with a total mass flow rate of about 47.62 kg/s. Geothermal fluid of intermingling molecules of different species through molecular diffusion was neglected in this study. As a result, not only irreversibility of the mixing tank was assumed equal to zero but also heat losses from the tank and main collector pipeline through the mixing process were neglected. In the SGDHS investigated, the thermal data on pressures, temperatures, and flow rates of the fluids were measured using a number of devices and employed in the models.[22,23]

Results and Discussion

The thermodynamic data used in the case study are based on the actual data taken from the SGDHS on February 1, 2004. The number of the wells in operation in the Salihli geothermal field may normally vary depending on the heating days as well as operating strategy. Taking into account the four productive wells when this study was conducted, the specific exergy index (SExI) is found to be 0.049, which is very close to the limit of the medium-quality geothermal resources. This shows

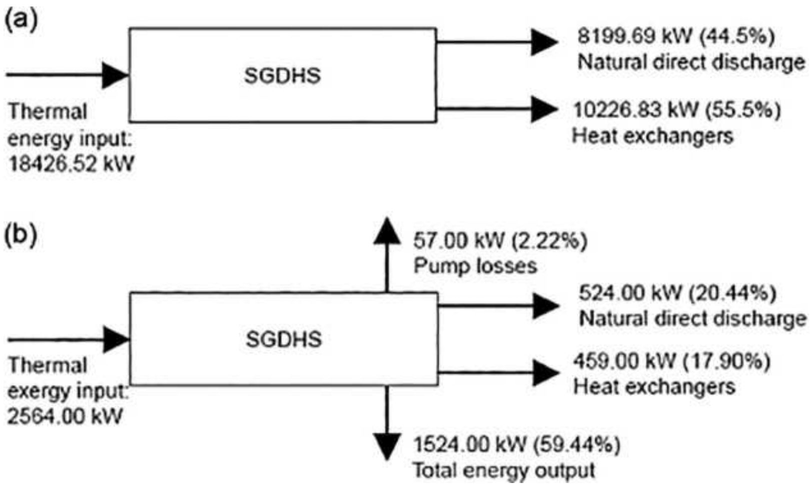

FIGURE 5 System flow diagrams for (a) energy and (b) exergy.
(**Source:** Adapted from Dincer et al.[30])

that the Salihli geothermal field falls into the low-quality geothermal resources according to the classification of Lee.[18]

The total mass flow rates of the geothermal fluid at the inlet of the heat exchanger (the total mass flow rate of the production wells) were measured to be 47.62 kg/s at an average temperature of 44.2°C on February 1, 2004. If hot water losses measured in the district heating distribution network are above 5 m^3/h, the water is generally added via a pump (using pressurized water tanks) to the network in order to cover the leaks taking place. However, the hot water losses were neglected in this study as these losses were below 5 m^3/h on the day of the study.

We present our calculation results, based on the actual data taken, given elsewhere.[30] These include all energetic and exergetic as well as other thermodynamic parameters along with the efficiencies. The energy and exergy efficiencies of the SGDHS are determined to be 55.5% and 59.4%, respectively. Here, the exergy efficiency is higher due to the recirculation and heat recovery processes.

We also present our energy and exergy flow diagrams in Figure 5. As illustrated in Figure 5a, the natural direct discharge of the system accounts for 44.5% of the total energy input. An investigation of the exergy flow diagram given in Figure 5b shows that 40.56% (accounting for about 1040 kW) of the exergy entering the system is lost, while the remaining 59.44% is utilized. The highest exergy loss of 20.44% occurs from the natural direct discharge in this study. The second largest exergy destruction occurs from the heat exchanger with 17.90% (about 459 kW) of the total exergy input. This is followed by the total exergy destruction associated with the pumps amounting to some 57 kW, which accounts for 2.22% of the exergy input to the system.

Conclusions

This entry has presented some historical background on geothermal energy resources and geothermal energy applications and classified geothermal resources by energy and exergy in detail along with some practical cases studies. It has discussed energetic, environmental, and sustainability aspects of geothermal energy and systems and proposed some energetic and exergetic parameters. Also, a procedure for performance assessment of geothermal energy systems is presented. A case study on how both energy and exergy analyses are necessary for better performance of the systems is likewise presented.

Nomenclature

$\dot{E}$	energy rate (kW)
$\dot{E}x$	exergy rate (kW)
$\dot{F}$	exergy rate of the fuel (kW)
h	specific enthalpy (kJ/kg)
IP	improvement potential rate (kW)
$\dot{m}$	mass flow rate (kg/s)
$\dot{P}$	product exergy rate (kW)
$\dot{Q}$	heat transfer rate (kW)
S	specific entropy (kJ/kg/K)
SExI	specific exergy index (dimensionless)
T	temperature (°C or K)
$\dot{W}$	work rate, power (kW)

Greek letters

β	exergetic factor (%)
η	energy efficiency (%)
ψ	exergy efficiency (%)
δ	fuel depletion rate (%)
ξ	productivity lack (%)
χ	relative irreversibility (%)

Subscripts

0	reference environment, dead state
d	natural direct discharge; destruction
HE	heat exchanger
in	inlet
s	source
out	outlet
tot	total

Green Energy

Ibrahim Dincer
and Adnan Midili

Introduction

Green energy can be considered a catalyst for energy security, sustainable development, and social, technological, industrial, and governmental innovations in a country. An increase in the green energy consumption of a country provides a positive impact on the economic as well as the social development of the country. Moreover, the supply and utilization of low-priced green fuel are particularly significant for global stability and peace because energy plays a vital role in industrial and technological developments around the world.

Critical energy issues in the 21st century will likely include energy security for almost 7 billion people, the expected global population by the middle of the 21st century, and global warming, mainly caused by CO_{2s} emissions generated from the combustion of fossil fuels.[1,2] Fossil fuels have caused some major problems for human health and human welfare due to their extensive use in various industrial and nonindustrial sectors. In reality, the main source of these problems is the extensive use of fossil-based technologies and strategies used by humans to govern throughout the centuries. In recent decades, the world has struggled with shortages of fossil fuels, pollution, and increased global energy requirements due to fast population growth, fast technological developments, and higher living standards. These factors have led to world population transition, migration, hunger, environmental (especially air and water pollution) problems, deteriorating health and disease, terrorism, energy and natural resources concerns, and wars. Also, problems with energy supply and use are related not only to global unrest, but also to such environmental concerns as air pollution, acid precipitation, ozone depletion, forest destruction, and the emission of radioactive substances. These issues must be taken into consideration simultaneously if humanity is to achieve a bright energy future with minimal environmental impact.

Other environmental considerations have been given increasing attention by energy industries and the public. The concept that consumers share responsibility for pollution and its cost has been increasingly accepted. In some jurisdictions, the prices of many energy resources have increased over the last one to two decades, in part to account for environmental costs. Global demand for energy services is expected to increase by as much as an order of magnitude by 2050, while primary-energy demands are expected to increase by 1.5 ± 0.3 times.[2] Accordingly, humans have reached energy shortage and pollution levels that are not tolerable anymore. The urgent need in this regard is to develop green energy–based permanent solutions for a sustainable future without any negative environmental and societal impacts. As a consequence, investigations for green energy should be encouraged particularly for green energy–based sustainability and future world stability.

In this book contribution, the authors present key information on green energy–based sustainability and global stability in accordance with major considerations that are presented in the following subtitles. In addition, this presents some key parameters like the green energy impact ratio and the green energy–based sustainability ratio. Moreover, anticipated patterns of future energy use and consequent environmental impacts (focusing on acid precipitation, stratospheric ozone depletion, and the greenhouse effect) are comprehensively discussed. Also, potential solutions to current environmental problems are identified along with green energy technologies. The relationships between green energy and sustainable development are described. Throughout the entry, several issues relating to green energy, the environment, and sustainable development are examined from both current and future perspectives. The specific objectives of this entry can be enumerated as follows:

- To help understand the main concepts and issues about green energy use and sustainability aspects
- To develop relationships between green energy use and sustainability development
- To encourage the strategic use and conservation of green energy sources
- To provide methods for energy security, implementation, and development
- To increase motivation on the implementation of green energy strategies for better energy supply
- To provide solutions to reduce negative environmental impacts by considering the possible green energy strategies
- To discuss possible green energy strategies for sectoral use

Green Energy

The most important property of green energy sources is environmental compatibility. In line with this characteristic, green energy sources will likely become the most attractive energy sources in the near future and will be the most promising energy sources for the technological and environmental perspectives of the 21st century, particularly in the context of sustainable development for the future. Green energy is one of the main factors that must be considered in discussions of sustainable development and future world stability. Several definitions of sustainable development have been put forth, including the following common one: "development that meets the needs of the present without compromising the ability of future generations to meet their own needs."[3,4] There are many factors that can contribute to achieving sustainable development. One of them is the requirement for a supply of energy resources that is fully sustainable. A secure supply of green energy resources is generally agreed to be a necessary but not sufficient requirement for development within a society.

Furthermore, sustainable development within a society demands a sustainable supply of green energy sources and an effective and efficient utilization of green energy technologies. Green energy can be defined as an energy source that has zero or minimum environmental impact, is more environmentally benign and more sustainable, and is produced from solar, hydro, biomass, wind, and geothermal, etc., energies. These types of green energy reduce the negative effects of fossil energy resources and the overall emissions from electricity generation and decrease greenhouse gases. They give an opportunity to take an active role in improving the environment and meet clean energy demand for both industrial and nonindustrial applications. Considering the benefits of green energy, it can be said that the sustainability of green energy supply and progress is assumed to be a key element in the interactions between nature and society. In addition, sustainable development requires a supply of energy resources that is sustainably available at reasonable cost and causes no or minimal negative societal impacts. Clearly, energy resources such as fossil fuels are finite and thus lack the characteristics needed for sustainability while others such as green energy sources are sustainable over the relatively long term.[5] Particularly, low-priced green energy is the most essential means for increasing the sustainable technological development and industrial productivity as well as people's living standards in a society. Therefore, achieving solutions to the energy shortages and environmental problems presented today requires long-term potential actions for sustainable development. In this regard, green energy sources and technologies appear to be the one of the most efficient and effective solutions. It can be said that one solution to the impending energy shortage and environmental problems is to make much more use of green energy sources and technologies. Another important solution is to develop permanent and effective sustainable green energy strategies for the increase of sustainable global stability.[1,6] For these purposes, engineering practicality, reliability, applicability, economy, scarcity of supply, and public acceptability should also be considered.

Green Energy and Environmental Consequences

Some of the global problems affecting world stability are presented in Figure 1. Fossil fuel utilization effects such as global climate change, world energy conflicts, and energy source shortages have increasingly threatened world stability. These negative effects may be observed locally, regionally, and globally.

This concern arises due to world population growth, fast technological development, and increasing energy demand. In the past, fossil energy sources could be used to solve world energy problems. However, in this century, fossil fuels cannot continue indefinitely as the principal energy sources due to the rapid increase of world energy demand and energy consumption. Due to world population growth and the advance of technologies that depend on fossil fuels, the reserves of fossil fuels eventually will

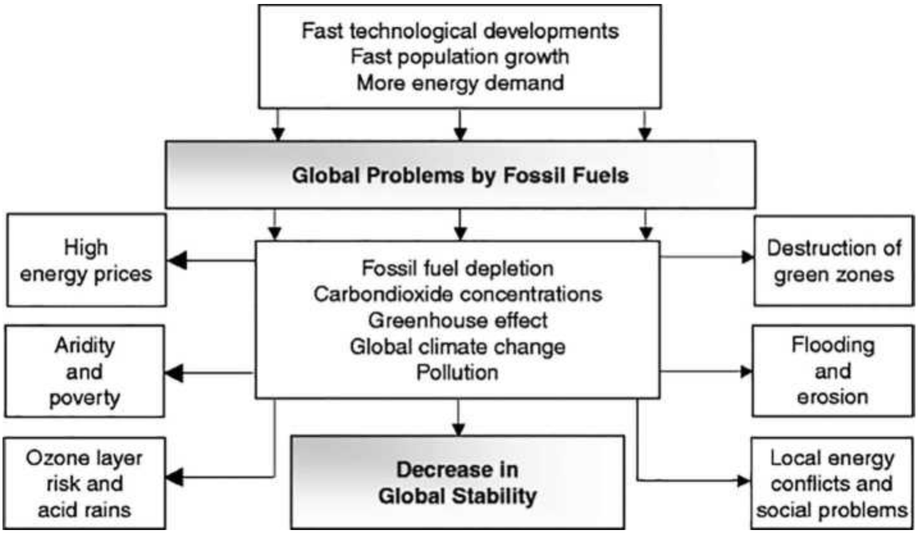

FIGURE 1 Problems affecting global stability.

not be able to meet world energy demand. Energy experts point out the fact that reserves account for less than 40 years for petroleum, 60 years for natural gas, and 250 years for coal.[1] The increase of the energy consumption and energy demand indicates our dependence on the fossil fuels. If the increase of fossil fuel utilization continues in this manner, it is likely that the world will be affected by many negative problems due to fossil fuels. As one outcome, global stability will probably decrease. This effect is presented as flow chart in Figure 2. For instance, shortages of fossil fuel reserves and global environmental problems will likely lead to global unrest throughout the world. As a result, local, regional, and world conflicts may appear across the world.

To further support these arguments, the observed and predicted consumptions of world primary energy, fossil fuels, and green energy from 1965 to 2050 are displayed in Figure 3 based on the data taken from literature.[7,8]

According to Figure 3, the quantities of world primary energy consumption are expected to reach 16502 Mtoe (Million tons of oil equivalent) by the year 2050. World population is now over 6 billion, double the population of 40 years ago, and it is likely to double again by the middle of the 21st century. The world's population is expected to rise to about 7.0 billion by 2010. Even if birth rates fall so that the world population becomes stable by 2050, the population will still be about 10 billion. Because the population is expected to increase drastically, conventional energy resource shortages are likely due to insufficient fossil fuel resource supplies. In the near future, therefore, green energy will become increasingly important to compensate for shortages of conventional resources. The correlations that have been applied here are as follows:

For world primary energy consumption:

$$\mathrm{WPEC} = 143.57 \times Y - 277808 \left(R^2 = 0.9902\right) \tag{1}$$

For world fossil fuel consumption:

$$\mathrm{WPEC} = 113.61 \times Y - 219092 \left(R^2 = 0.9968\right) \tag{2}$$

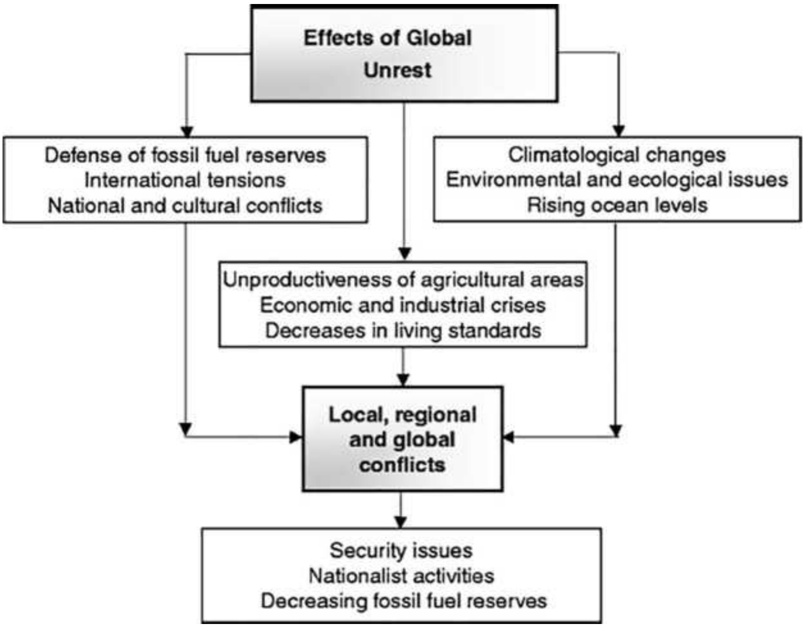

FIGURE 2 Some possible effects and results of the global unrest.

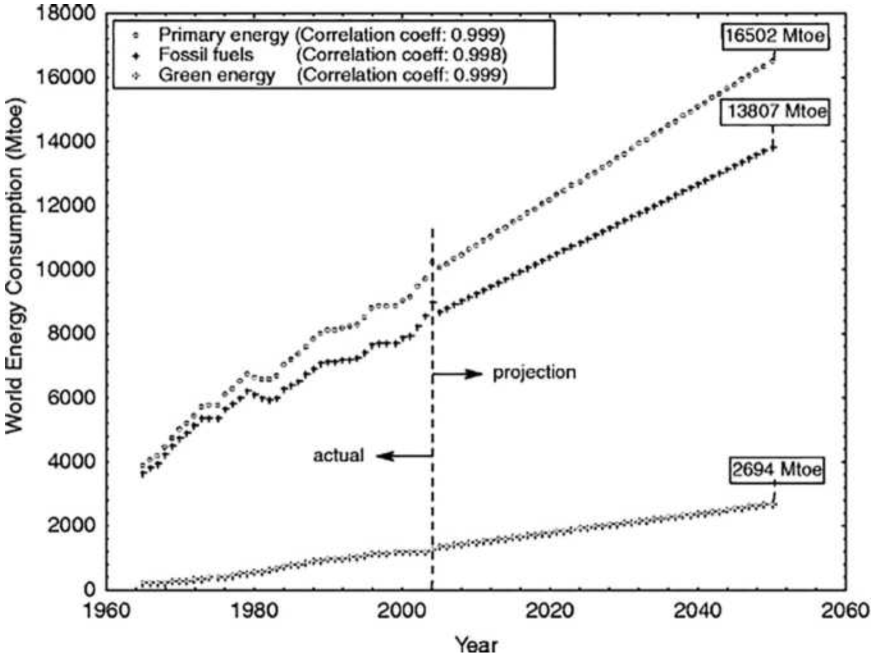

FIGURE 3 Observed and projected quantities of world primary energy, fossil fuels, and green energy consumptions (Mtoe: million tons of oil equivalent).

For world green energy consumption:

$$\text{WPEC} = 29.956 \times Y - 58715 \left(R^2 = 0.9985\right) \tag{3}$$

Here, WPEC is world primary energy consumption (Mtoe); WFFC, world fossil fuel consumption (Mtoe); WGEC, world green energy consumption; *Y* is time (years); and *R* is the correlation coefficient.

Energy shortages will accelerate the fluctuations of energy prices and economic recessions and decrease living standards and increase the unrest among countries. Decreased available fossil fuel reserves and increased fuel costs since the middle to late 1900s have led to variations in lifestyles and standards of life. These effects have, in some regions, decreased living standards of entire societies. Countries that need more energy resources have been purchasing cheaper energy sources. Countries that look after the future welfare of their societies have received the attention of countries that possess fossil fuel supplies, posing the potential for world conflict. Problems are often attributed to decreases in fossil fuel energy reserves. Those who seek a clean world must find appropriate alternatives to fossil fuels. Why not green energy? Green energy that is abundantly available all over the world can help:

- Reduce or stop conflicts among countries regarding energy reserves
- Facilitate or necessitate the development of new technologies
- Reduce air, water, and land pollution and the loss of forests
- Reduce illnesses and deaths caused by direct or indirect use of energy

Therefore, green energy and related technologies are needed to improve global stability by reducing the harmful effects of fossil-based energy consumption. Thus, the importance of green energy in reducing world problems and achieving a sustainable energy system should be emphasized and a transition to the green economy should be encouraged.

Energy, Environment, and Sustainability

Environmental concerns are an important factor in sustainable development. For a variety of reasons, activities that continually degrade the environment are not sustainable over time, e.g., the cumulative impact on the environment of such activities often leads over time to a variety of health, ecological, and other problems. A large portion of the environmental impact in a society is associated with its utilization of energy resources. Ideally, a society seeking sustainable development utilizes only energy resources that release no or minimal emissions to the environment and thus cause no or little environmental impact. However, because all energy resources lead to some environmental impact, it is reasonable to suggest that some (not all) of the concerns regarding the limitations imposed on sustainable development by environmental emissions and their negative impacts can be in part overcome through increased energy efficiency. Clearly, a strong relation exists between energy efficiency and environmental impact because for the same services or products less resource utilization and pollution is normally associated with increased energy efficiency. While not all green energy resources are inherently clean, there is such a diversity of choices that a shift to renewables carried out in the context of sustainable development could provide a far cleaner system than would be feasible by tightening controls on conventional energy.[9] Furthermore, being by nature site-specific, they favor power system decentralization and locally applicable solutions more or less independent of the national network. It enables citizens to perceive positive and negative externalities of energy consumption. Consequently, the small scale of the equipment often makes the time required from initial design to operation short, providing greater adaptability in responding to unpredictable growth and changes in energy demand. In this regard, sustainability often leads local and national authorities to incorporate environmental considerations into energy planning. The need to satisfy basic human needs and aspirations combined with the increasing world population will make the need for successful implementation of sustainable development increasingly apparent. Various criteria that are essential to achieving sustainable development in a society are as follows:[3,4,10]

- Information about and public awareness of the benefits of sustainability investments, environmental education, and training
- Appropriate energy strategies
- The availability of green energy resources and technologies
- A reasonable supply of financing
- Monitoring and evaluation tools

Environmental concerns are significantly linked to sustainable development. Activities which continually degrade the environment are not sustainable. For example, the cumulative impact on the environment of such activities often leads over time to a variety of health, ecological, and other problems. Clearly, a strong relation exists between efficiency and environmental impact because for the same services or products, less resource utilization and pollution is normally associated with increased efficiency.[3] Improved energy efficiency leads to reduced energy losses. Most efficiency improvements produce direct environmental benefits in two ways. First, operating energy input requirements are reduced per unit of output and pollutants generated are correspondingly reduced. Second, consideration of the entire life cycle for energy resources and technologies suggests that improved efficiency reduces environmental impact during most stages of the life cycle. In recent years, the increased acknowledgment of humankind's interdependence with the environment has been embraced in the concept of sustainable development. With energy constituting a basic necessity for maintaining and improving standards of living throughout the world, the widespread use of fossil fuels may have impacted the planet in ways far more significant than first thought. In addition to the manageable impacts of mining and drilling for fossil fuels and discharging wastes from processing and refining operations, the greenhouse gases created by burning these fuels is regarded as a major contributor to a global warming threat.

Global warming and large-scale climate change have implications for food chain disruption, flooding, and severe weather events.

Therefore, use of green energy sources can help reduce environmental damage and achieve sustainability. The attributes of green energy technologies (e.g., modularity, flexibility, low operating costs) differ considerably from those for traditional, fossil-fuel-based energy technologies (e.g., large capital investments, long implementation lead times, operating cost uncertainties regarding future fuel costs). Green energy technologies can provide cost-effective and environmentally beneficial alternatives to conventional energy systems. Some of the benefits of the green energy- based systems are as follow:[3,10]

- They are relatively independent of the cost of oil and other fossil fuels, which are projected to rise significantly over time. Thus, cost estimates can be made reliably for green energy systems and they can help reduce the depletion of the world's nongreen energy resources.
- Implementation is relatively straightforward.
- They normally cause minimum environmental degradation and so they can help resolve major environmental problems. Widespread use of green energy systems would certainly reduce pollution levels.
- They are often advantageous in developing countries. In fact, the market demand for renewable energy technologies in developing nations will likely grow as they seek a better standard of living.

Under these considerations, green energy resources have some characteristics that lead to problematic but often solvable technical and economic challenges:

- Generally diffuse
- Not fully accessible
- Sometimes intermittent
- Regionally variable

The overall benefits of green energy technologies are often not well understood, leading to such technologies often being assessed as less cost-effective than traditional technologies. For green energy technologies to be assessed comprehensively, all of their benefits must be considered. For example, many green energy technologies can provide, with short lead times, small incremental capacity additions to existing energy systems. Such power generation units usually provide more flexibility in incremental supply than large devices like nuclear power stations.

Green Energy and Sustainable Development

Sustainability has been called a key to the solution of current ecological, economic, and developmental problems by Dincer and Rosen[10] A secure supply of energy resources is generally agreed to be a necessary but not sufficient requirement for development within a society. Furthermore, sustainable development demands a sustainable supply of energy resources that, in the long term, is readily and sustainably available at reasonable cost and can be utilized for all required tasks without causing negative societal impacts. Supplies of such energy resources as fossil fuels (coal, oil, and natural gas) and uranium are generally acknowledged to be finite; other energy sources such as sunlight, wind and falling water are generally considered renewable and therefore sustainable over the relatively long term. Wastes (convertible to useful energy forms through, for example, waste-to-energy incineration facilities) and biomass fuels are also usually viewed as sustainable energy sources.

In general, the implications of these statements are numerous and depend on how sustainable is defined.[3] For sustainable development, green energy can play an important role for meeting energy requirements in both industrial and local applications. Therefore, development and utilization of green energy sources and technologies should be given a high priority for sustainable development in a country. The need for sustainable energy development is increasing rapidly in the world. Widespread use of green energy sources and technologies is important for achieving sustainability in the energy sectors in both developing and industrialized countries. Thus, green energy resources and technologies are a key component of sustainable development for three main reasons:

- They generally cause less environmental impact than other energy sources. The variety of green energy resources provides a flexible array of options for their use.
- They cannot be depleted. If used carefully in appropriate applications, green energy resources can provide a reliable and sustainable supply of energy almost indefinitely.
- They favor system decentralization and local solutions that are somewhat independent of the national network, thus enhancing the flexibility of the system and providing economic benefits to small isolated populations. Also, the small scale of the equipment often reduces the time required from initial design to operation, providing greater adaptability in responding to unpredictable growth and changes in energy demand.
- Major considerations involved in the development of green energy technologies for sustainable development as modified from[10] are presented in Figure 4.

As a consequence, it can be said that green energy and technologies are definitely needed for sustainable development that ensures a minimization of global unrest. The relation between green energy and sustainability is of great significance to the developed countries as well as developing or less developed countries. Moreover, examining the relations between green energy sources and sustainability makes it clear that green technology is directly related to sustainable development. Therefore, attaining

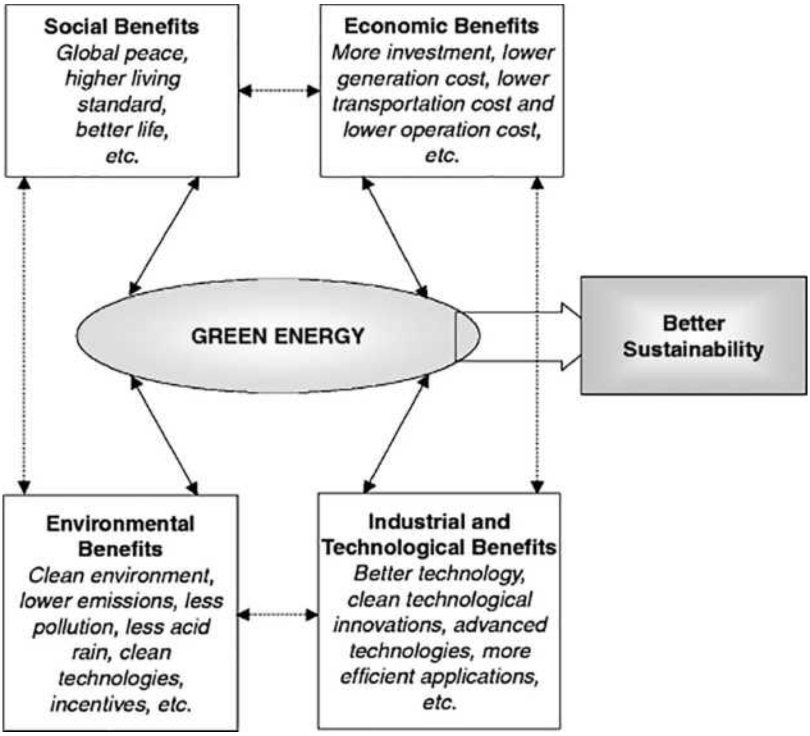

FIGURE 4 Major considerations involved in the development of green energy technologies for sustainable development.

sustainable development requires that green energy resources be also used, and is assisted if resources are used efficiently.[4,10] Thus, if sustainable green energy technologies are effectively put into practice, the countries may maximize the benefits from the green energy sources and technologies while minimizing the global unrest[1] associated with the use of fossil fuel energy sources. It is expected that this initiative can contribute to development over a longer period of time, i.e., to make development more sustainable.

Green Energy Resources and Technologies

Since the oil crises in the early 1970s, there has been active worldwide research and development in the field of green energy resources and technologies. During this time, energy conversion systems that were based on green energy technologies appeared to be most attractive because of facts such as the projected high cost of oil and the cost effectiveness estimates and easy implementation of green energy technologies. Furthermore, in more recent times, it has been realized that green energy sources and technologies can have a beneficial impact on essential technical, environmental, economic, and political issues of the world. As pointed out by Hartley,[3,9] green energy technologies produce marketable energy by converting natural phenomena into useful energy forms. These technologies use the energy inherent in sunlight and its direct and indirect impacts on the earth (photons, wind, falling water, heating effects, and plant growth), gravitational forces (the tides), and the heat of the earth's core (geothermal) as the resources from which they produce energy. These resources represent a massive energy potential which dwarfs that of equivalent fossil resources. Therefore, the magnitude of these is not a key constraint on energy production.

However, they are generally diffused and not fully accessible, some are intermittent, and all have distinct regional variabilities. Such aspects of their nature give rise to difficult, but solvable, technical, institutional, and economical challenges inherent in development and the use of green energy resources. Despite having such difficulties and challenges, the research and development on green energy resources and technologies has been expanded during the past two decades because of the facts listed above. Recently, significant progress has been made by (1) improving the collection and conversion efficiencies, (2) lowering the initial and maintenance costs, (3) increasing the reliability and applicability, and (4) understanding the phenomena of green energy technologies.

Green energy technologies become important as environmental concerns increase, utility (hydro) costs climb, and labor costs escalate.[3,9] The uncertain global economy is an additional factor. The situation may be turned around with an increase in research and development in the advanced technologies fields, some of which are closely associated with green energy technologies. This may lead to innovative products and job creation supported by the governments. The progress in other technologies, especially in advanced technologies, has induced some innovative ideas in green energy system designs. The ubiquitous computer has provided means for optimizing system performance, costs/benefits, and environmental impacts even before the engineering design was off the drawing board. The operating and financial attributes of green energy technologies, which include modularity and flexibility and low operating costs (suggesting relative cost certainty) are considerably different than those for traditional, fossil-based technologies, whose attributes include large capital investments, long implementation lead times, and operating cost uncertainties regarding future fuel costs. The overall benefits of green energy technologies are often not well understood and consequently they are often evaluated to be not as cost effective as traditional technologies. In order to comprehensively assess green energy technologies, however, some of their benefits that are often not considered must be accounted for. Green energy technologies, in general, are sometimes seen as direct substitutes for existing technologies so that their benefits and costs are conceived in terms of assessment methods developed for the existing technologies. Many government organizations and universities recognize the opportunity and support the efforts to exploit some commercial potential by:

- Analyzing opportunities for green energy and working in consultation with industry to identify research, development, and market strategies to meet technological goals.
- Conducting research and development in cooperation with industry to develop and commercialize technologies.
- Encouraging the application of green energy technologies to potential users, including utilities.
- Providing technical support and advice to industry associations and government programs that are encouraging the increased use of green energy. In order to realize the energy and the economic and environmental benefits that green energy sources offer, the following integrated set of activities should be acted on accordingly.[3,9,10]
- Conducting research and development. The priorities should be set in close consultation with industry to reflect their needs. Most research is conducted through cost- shared agreements and falls within the short-to-medium term. Partners in research and development should include a variety of stakeholders in the energy industry such as private sector firms, utilities across the country, provincial governments, and other federal departments.
- Assessing technology. Data should be gathered in the lab and through field trials on factors such as cost benefit, reliability, environmental impact, safety, and opportunities for improvement. This data should also assist the preparation of technology status overviews and strategic plans for research and development.
- Developing standards. The development of technical and safety standards is needed to encourage the acceptance of proven technologies in the marketplace. Standards development should be conducted in cooperation with national and international standards writing organizations as well as other national and provincial regulatory bodies.
- Transferring technology. Research and development results should be transferred through the sponsorship of technical workshops, seminars, and conferences, as well as through the development of training manuals and design tools and the publication of technical reports. Such activities will also encourage potential users to consider the benefits of adopting green energy technologies. In support of developing near-term markets, a key technology transfer area is to accelerate the use of green energy technologies in a country's remote communities.

Such activities will also encourage potential users to consider the benefits of adopting renewable energy technologies. In support of developing near-term markets, a key technology transfer area is to accelerate the use of green energy technologies in a country's remote communities.

Essential Factors for Sustainable Green Energy Technologies

There are various essential parameters, as outlined and detailed in Figure 5. These factors can help in identifying and achieving required green energy strategies and technologies for sustainable development. As shown in Figure 5, green energy technologies are largely shaped by broad and powerful trends that are rooted in basic human needs. In conjunction with this, the increasing world population requires the definition and successful implementation of green energy technologies. Briefly, the important parameters and their interrelations, as outlined in Figure 5, are definitely required to carry out the best green energy program and to select the most appropriate green energy technologies for sustainable development.

Exergetic Aspects of Green Energy Technologies

The impact of energy resource utilization on the environment and the achievement of increased resource-utilization efficiency are best addressed by considering exergy. The exergy of an energy form or a substance is a measure of its usefulness, quality, or potential to cause change and provide the basis for an effective measure of the potential of a substance or energy form to impact the environment. In practice,

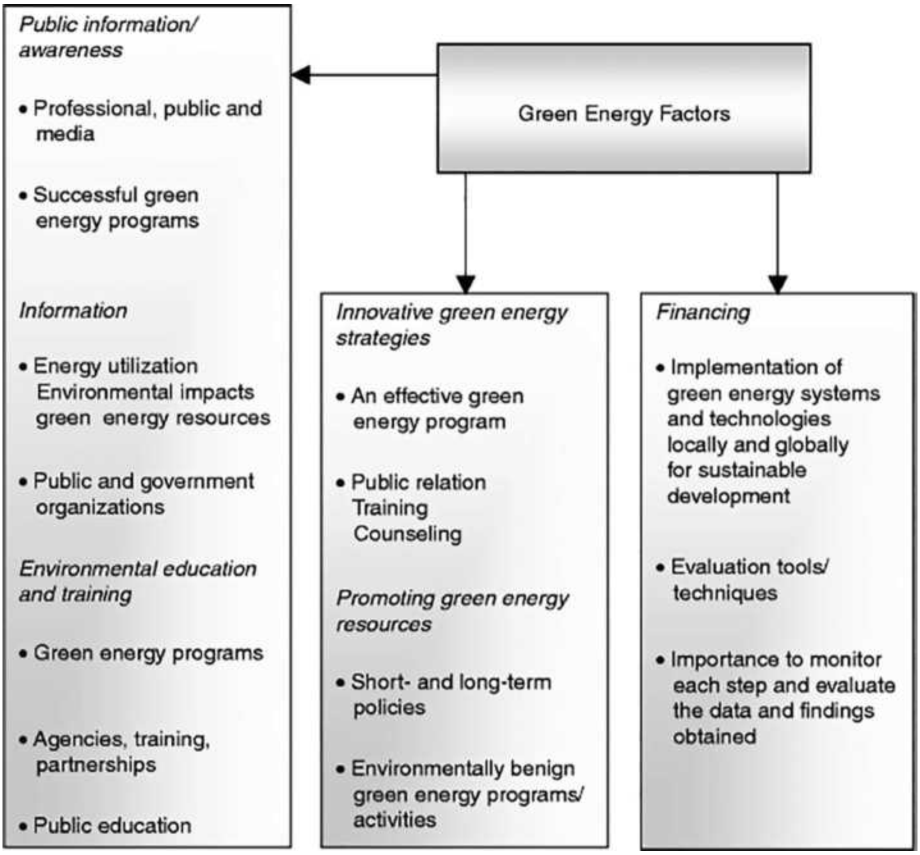

FIGURE 5 Essential factors for green energy technologies.

a thorough understanding of exergy and the insights it can provide into the efficiency, environmental impact, and sustainability of green energy technologies are helpful if not required for the engineer or scientist working in the area of green energy–based environmental systems.[4,11] For green energy technologies, applications of exergy methods can have numerous broad and comprehensive benefits:

- A better knowledge of the efficiencies and losses for the technologies and systems and how they behave and perform
- A clearer appreciation of the environmental impacts of green energy technologies as well as the mitigation of environmental that they can facilitate
- Better identification of the ways green energy technologies can contribute to sustainable development

Green Energy Applications

Green energy technologies are expected to play a key role in sustainable energy scenarios for the future. The foremost factor that will determine the specific role of green energy and technologies will likely be energy demand. Therefore, in order to compensate the energy requirement, it will be possible to produce green energy from renewable energy sources such as hydraulic, solar, wind, geothermal, wave and biomass, etc. If so, the green energy and technologies can be utilized for many application fields as shown in Figure 6.

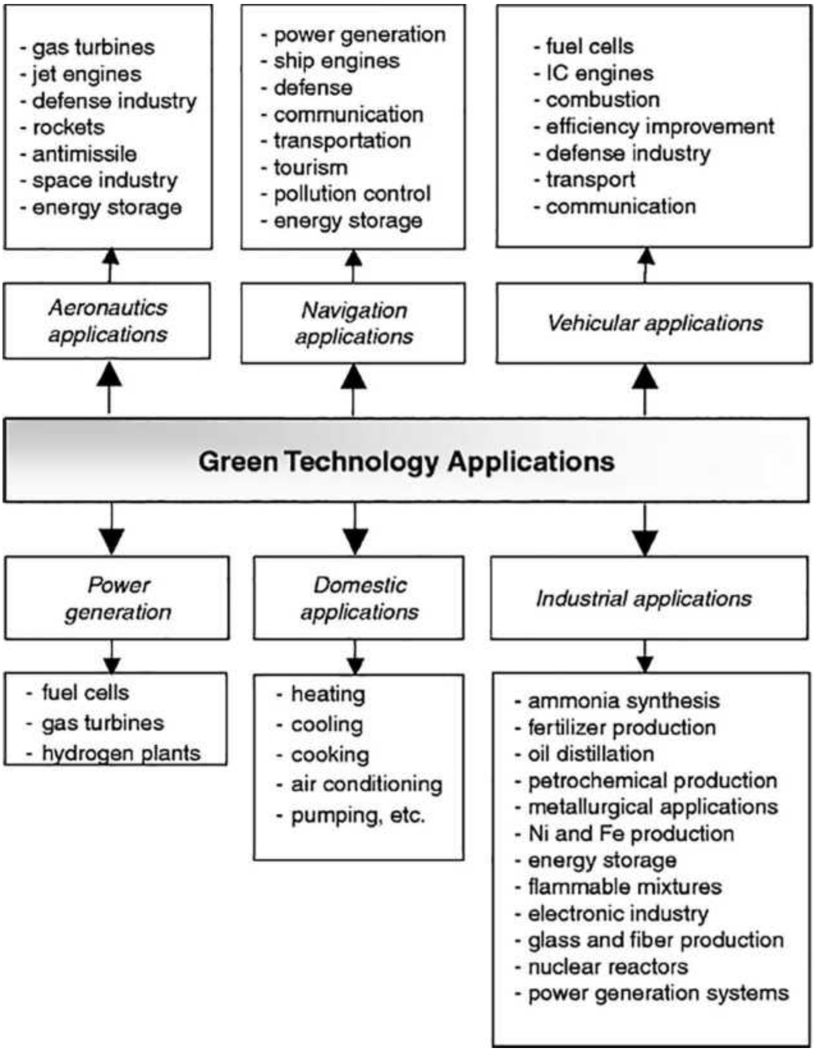

FIGURE 6 Possible application fields of green energy and technologies for sustainable

Thus, it can be said that green energy and technologies, which are abundantly available, can help:

- Provide more environmentally benign and more sustainable future
- Increase energy security
- Facilitate or necessitate the development of new, clean technologies
- Reduce air, water, and soil pollution and the loss of forests
- Reduce energy-related illnesses and deaths
- Reduce or stop conflicts among countries regarding energy reserves

Therefore, green energy and related technologies are needed to ensure global stability by reducing the harmful effects of fossil-based energy consumption. Thus, the importance of green energy in reducing the world problems and achieving a sustainable energy system should be emphasized considering the sustainable green energy strategies; and a transition to green energy economy should be encouraged and developed countries in particular should increase investments in green energy and technologies.

Green Energy Analysis

In light of the above major considerations, in order to accelerate the use of green energy sources and technologies and the implementation of green energy strategies, and in this regard, to describe the relationship between the global stability and sustainable development, some key steps are presented as follows:

- Key strategies
- Green energy based sustainability ratio
- Global unrest and peace

Green Energy-Based Sustainable Development Ratio

In order to discuss the key role of green energy for sustainable development and global stability, the general algebraic form of the equation that is the green energy-based sustainable development ratio should be presented based on the above strategies. For this purpose, the works that were early presented by Midilli et al.[1,2,6,12] and Dincer[3,10] were taken as the reference basis. The following important parameters, which are sectoral, technological, and practical application impact ratios, are taken into consideration to estimate the green-energy-based sustainable development ratio. The detailed derivations of these parameters are presented in the literature.[2] Briefly, the green energy–based sustainable development ratio is mainly based on the following parameters:

- *Sectoral impact ratio,* (R_{si}) (ranging from 1 to 1/3), is based on the provided financial support ($C_{p,\ si}$) of public, private, and media sectors for transition to green energy–based technologies, and depending on the total green energy financial budget (C_{geb}), as a reference parameter.[2]
- *Technological impact ratio,* (R_{ti}) (ranging from 1 to 1/3), is based on the provided financial support ($C_{p,\ ti}$) for research and development, security, and analysis of green energy–based technologies, and also depending on the total green energy financial budget (C_{geb}) as a reference parameter.[2]
- *Practical application impact ratio,* (R_{pai}) (ranging from 1 to 1/3), is based on the provided financial support ($C_{p,\ pai}$) for projection, production, conversion, marketing, distribution, management, and consumption of green fuel from green energy sources, and also depending on the total green energy financial budget (C_{geb}), as a reference parameter.[2] Here, it should be emphasized that these parameters can be defined as the ratio of the provided financial support to the total green energy financial budget in a country. In addition, it should be always remembered that it is assumed that the financial share of each parameter is equal to one-third of the total green energy financial budget in a country. The utilization ratio of green energy depends on the green energy utilization and the world primary energy quantity. Green energy–based global stability is a function of utilization ratios of coal, petroleum, and natural gas, and utilization ratios of green energy at certain utilization ratios of these fuels, and utilization ratio of green energy. Therefore, the green-energy-based sustainable development ratio is written in algebraic form as follows:[2]

$$R_{ges} = R_{gei} \times R_{geu} \tag{4}$$

where

$R_{gei} = \left(R_{si} + R_{ti} + R_{pai}\right)$ green energy impact ratio; $R_{si} = C_{p,\,si}/C_{geb}$ sectoral impact ratio, which is estimated based on the provided financial support of the public, private, and media sectors for transition to green energy ($C_{p,\ si}$) and also the green energy budget allocation of a country:(C_{geb});

$R_{ti} = C_{p,\,ti}/C_{geb}$ technological impact ratio, which is estimated based on the provided financial supports for research and development, security, and analysis of green- energy-based technologies ($C_{p,\ ti}$) and also the green energy budget allocation of a country (C_{geb});

$R_{\text{pai}} = C_{\text{p, pai}}/C_{\text{geb}}$ practical application impact ratio, which is estimated based on the provided financial supports for projection, production, conversion, marketing, distribution, management, and consumption of green fuel from green energy sources, and also the green energy budget allocation of a country (C_{geb});

$R_{\text{geu}} = 1 - Q_{\text{wffc}}/Q_{\text{wpec}}$ green energy utilization ratio, which is also defined as a function of fossil fuel utilization ratio (R_{ffu}).

Here Q_{wffc} explains world fossil fuel consumption (M) and Q_{wpec} world primary energy consumption (M).

Global Unrest and Peace

Fossil fuels such as petroleum, coal, and natural gas, which have been extensively utilized in industrial and domestic applications for a long time, have often been the cause of global destabilization and unrest. This problem is likely to increase in significance in the future and suggests the need for investigations of, among other factors, the role of hydrogen energy relative to future global unrest and global peace. In general, the global unrest arising from the use of fossil fuels is considered as a function of the usage ratios of these fossil fuels.[12] In order to estimate the level of global unrest, it is important to select a proper reference value. Therefore, it is assumed that the lowest value of global unrest and the highest value of global peace are equal to 1, which is a reference point to evaluate the interactions between global unrest and global peace.[12] Consequently, the general algebraic case form of global unrest expression is as follows[12]:

$$\text{GU} = \left\{ 1 - \left[\left(\frac{q_p}{q_{\text{wpec}}} + \frac{q_c}{q_{\text{wpec}}} + \frac{q_{\text{ng}}}{q_{\text{wpec}}} \right) - \left(r_{H_2-p} + r_{H_2-c} + r_{H_2-ng} \right) \right] \right\}^{-1} \tag{5}$$

where q_{p}, q_{c} and q_{ng} define the consumption quantities of petroleum, coal, and natural gas, respectively; q_{wpec} defines the quantity of world primary energy consumption; r_{H_2-p} is the utilization ratio of hydrogen from nonfossil fuels at a certain utilization ratio of petroleum; r_{H_2-c} is the utilization of hydrogen from nonfossil fuels at a certain utilization ratio of coal; $r_{H_2-\text{ng}}$ is the utilization of hydrogen from nonfossil fuels at a certain utilization ratio of natural gas. The values of q_{p}, q_{c}, q_{ng}, and q_{wpec} can be taken from the literature.[8] The values for r_{H_2-p}, r_{H_2-c}, and $r_{H_2-\text{ng}}$ can be taken depending on the utilization ratios of the petroleum, coal, and natural gas presented in the literature.

In order to estimate the level of global peace quantitatively, it is assumed that the highest value of global peace is equal to 1, which is a reference point to evaluate the interactions between global unrest and global peace.[12] Thus, the relationship between global unrest and global peace can be written as a function of the utilization ratio of hydrogen from nonfossil fuels. The general algebraic case form of global peace expression proposed is as follows:

$$\text{GP} = \frac{U_{H_2}}{Q_{\text{wpec}}} \times \frac{1}{(\text{GU})} \tag{6}$$

where U_{H_2} defines the utilization of hydrogen from non-fossil fuels, which can be taken from the literature.

Case Study

The first case study is given to determine the green-energy- based sustainability ratio depending on the three subcases that are carried out based on the sectoral impact ratio, the technological impact ratio, and the practical application impact ratio by using actual data from the literature.[8] All cases are presented in Table 1. The results of the first case study are presented in Figures. 7 and 8a–c.

TABLE 1 The Cases Depending on Green Energy Impact Ratio for the Green Energy–Based Sustainability Ratio

Effect of Variable Parameters (entity)			10%	30%	50%	70%	90%
Cases		Percent of Total Financial Budget for Green Energy	Green Energy Impact Ratio (Rgei)				
I	2 constant parameters	n/3	0.699	0.766	0.833	0.899	0.966
	1 variable parameter	k ×(1/3)×∈					
II	1 constant parameter	n/3	0.400	0.533	0.666	0.800	0.933
	2 variable parameters	k ×(1/3)× ∈					
III	3 variable parameters	k×(1/3)×∈	0.100	0.300	0.500	0.700	0.900

Here, n defines the number of constant parameters; k, the number of variable parameters.

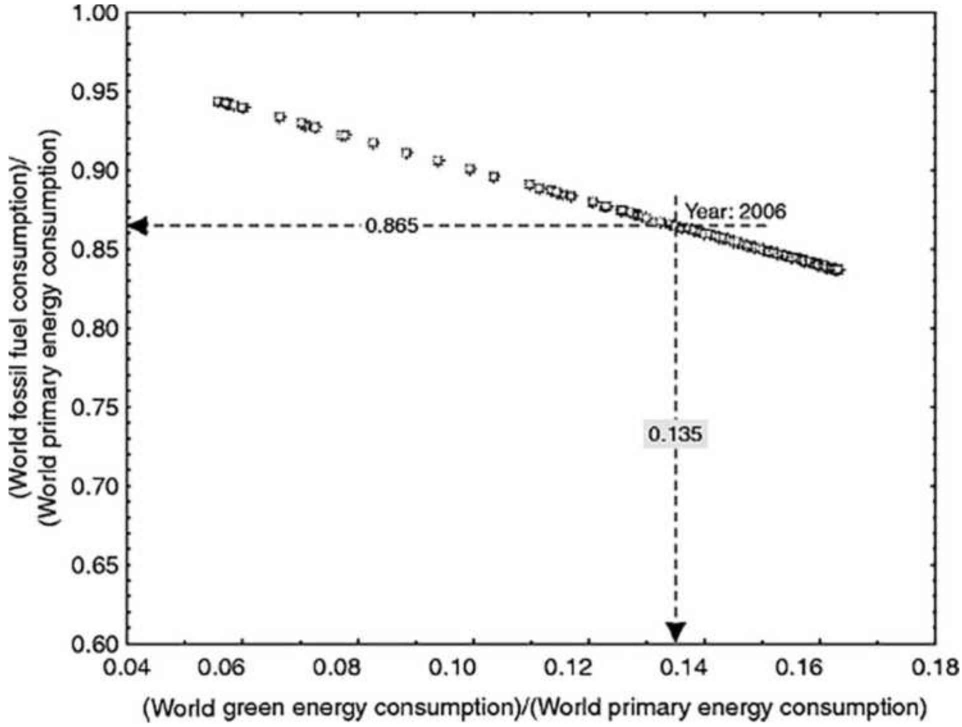

FIGURE 7 World fossil fuel consumption ratio as a function of green energy consumption ratio.

The second case study is performed to determine the global unrest and global peace level based on the predicted utilization ratios of hydrogen from nonfossil fuels. In this regard, two important empirical relations that describe the effects of fossil fuels on world peace and global unrest are taken into consideration for this case study. The results of this case study are presented in Figure 9.

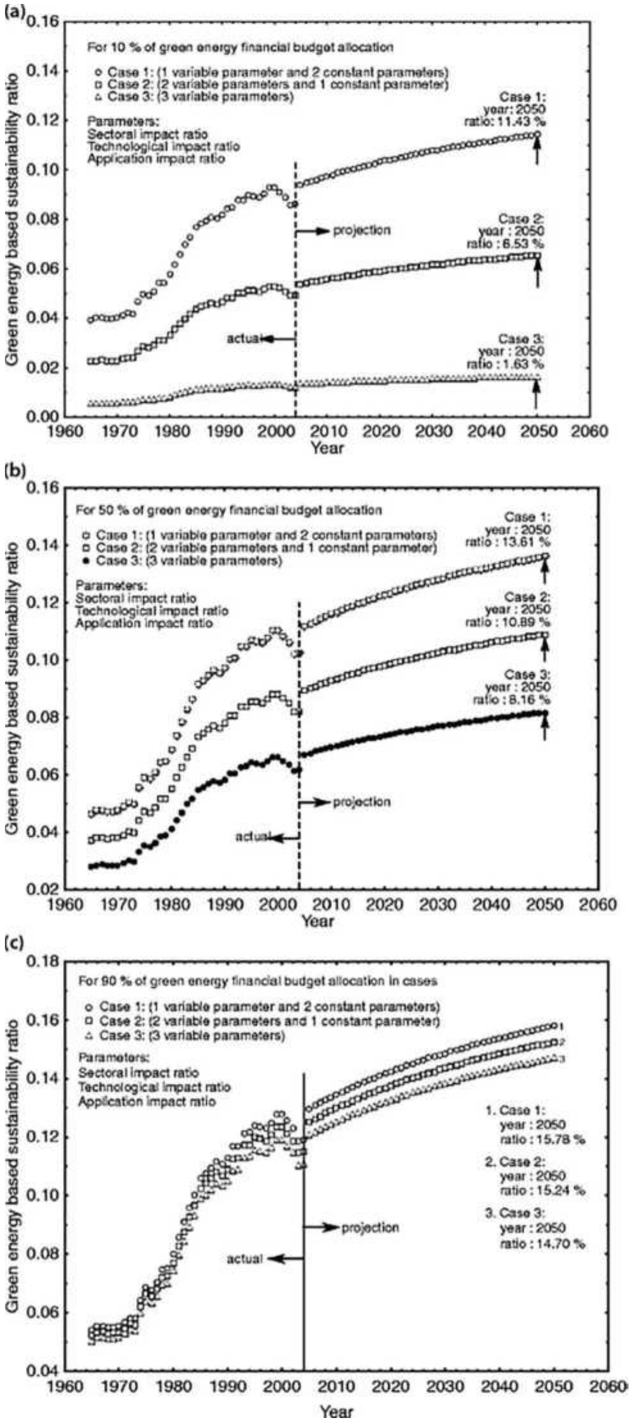

FIGURE 8 (a) Green energy–based sustainability ratio versus time depending on the actual and projected green energy consumption data for 10% of green energy financial budget allocation. (b) Green energy–based sustainability ratio versus time depending on the actual and projected green energy consumption data for 50% of green energy financial budget allocation. (c) Green energy–based sustainability ratio versus time depending on the actual and projected green energy consumption data for 90% of green energy financial budget allocation.

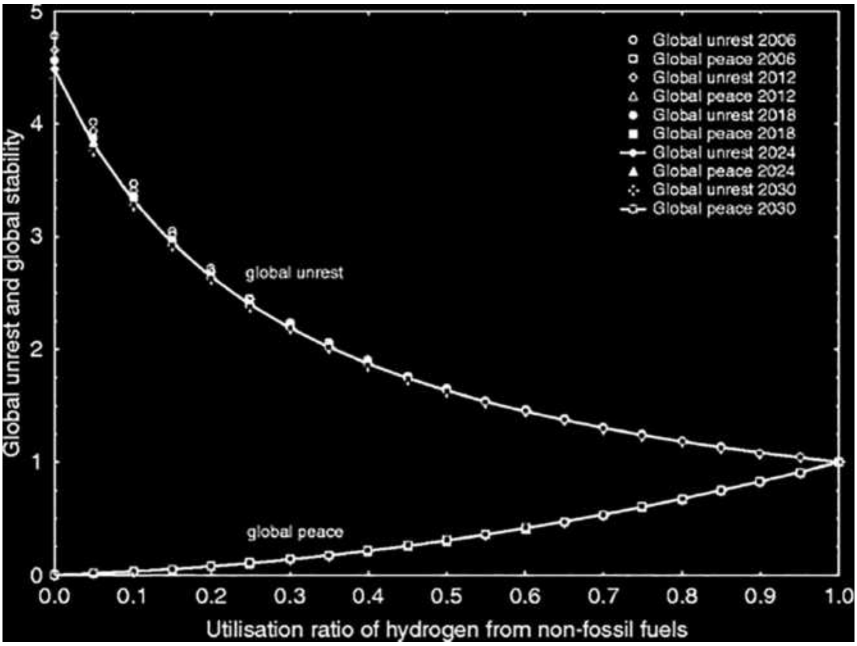

FIGURE 9 Comparison of levels of global unrest and global stability as a function of hydrogen utilization ratios from non-fossil fuels.

Results and Discussion

In accordance with the objective of this entry, the projection data is obtained using actual data of primary energy, fossil fuel, and green energy consumptions. Considering the technological impact ratio (max. value=1/3 of the green energy financial budget), the sectoral impact ratio (max. value=1/3 of the green energy financial budget allocation), and the practical application impact ratio (max. value=1/3 of the green energy financial budget allocation), three cases are analyzed and discussed in detail in this part.

Figure 7 shows the variations of the fossil fuel utilization ratio (world fossil fuel consumption/world primary energy consumption) as a function of the green energy utilization ratio (world green energy consumption/world primary energy consumption). It is found out from this figure that the fossil fuel utilization ratio decreases depending on the rise of the year while green energy utilization ratio increases. For example, the green energy utilization ratio was 5.71% in 1970, 8.25% in 1980, 11.67% in 1990, and 13.27% in 2000 while the fossil fuel utilization ratio was 94.29% in 1970, 91.75% in 1980, 88.32% in 1990, and 86.77% in 2000, based upon the actual data. However, it is observed that the green energy utilization ratio increased and reached 12.31% while fossil fuel utilization ratio decreased to 87.69% in 2004. Based on the projected data, it expected that green energy utilization ratio will reach almost 13.52% in 2006, 14.09% in 2012, 14.58% in 2018, 15.01% in 2024, and 15.38% in 2030. However, it is expected that the fossil fuel utilization ratio will decrease to almost 86.48% in 2006, 85.91% in 2012, 85.42% in 2018, 85.99% in 2024, and 84.62% in 2030. Thus, in order to increase the green energy utilization ratio and to reduce the harmful effects resulting from the fossil fuel consumption, the investments on green energy should be encouraged and the green energy strategies should be put into practice for sustainable development.

First, it should be stated that one or two of the parameters that are sectoral, technological, and practical application impact ratios can be selected as constant parameters. As shown in Table 1, a variable and two constant parameters are considered in Case 1, two variables and one constant parameter are considered in Case 2, and three variable parameters are considered in Case 3. When Case 1 is applied for green energy supply and progress, it is found that the green energy impact ratio changes between 0.699 and 0.966 depending on the percentages of the variable parameter. In the application of Case 2 it is obtained that the green energy impact ratio varies between 0.40 and 0.933 depending on the percentages of two variable parameters. In the application of Case 3, it is calculated that the green energy impact ratio changes from 0.1 to 0.9 depending on the percentages of three variable parameters. When the three Cases are compared to each other, it can be said that the highest values of green energy impact ratio are found by applying Case 1, and also that Case 3 gives the lowest green energy impact ratios. Thus, Case 1 should be selected to increase the green energy impact ratio and the green-energy-based sustainability ratio.

Figure 8a–c show a variation of the green energy–based sustainability ratio (R_{ges}) as a function of year by depending on the percentages of the green energy financial budget as 10%, 50%, and 90%, or the effect of the parameters in the Cases, respectively. The values of green-energy-based sustainability ratios were calculated using Figure 4.

As shown in these figures, the values of R_{ges} increase with time based on the cases. The highest values of R_{ges} are obtained when Case 1 is applied, as shown in Figure 8a–c. For example, the green-energy-based sustainability ratios are estimated to be 9.46% in 2006, 9.86% in 2012, 10.21% in 2018, 10.50% in 2024, and 10.76% in 2030 in case of 10% of green energy financial budget; 13.06% in 2006, 13.62% in 2012, 14.09% in 2018, 14.51% in 2024, and 14.86% in 2030 in case of 90% of green energy financial budget.

It is important to implement green energy strategies through green energy systems and applications for sustainable future. If so, the green energy–based sustainability ratio increases and green energy is more easily supplied, thus its technologies are more preferred and applied. Hence, as long as sustainable green energy strategies are increasingly applied and the green technologies are more utilized and encouraged, the negative effects stemming from the fossil fuel utilization will decrease and the green-energy-based sustainability ratio will increase.

Figure 9 compares the levels of global unrest and global peace as a function of the predicted utilization ratio of hydrogen from non-fossil fuels. Figure 4 indicates that there is an inversely proportional relationship between global peace and global unrest, depending on the utilization ratio of hydrogen from non-fossil fuels.

To better appreciate this figure, some of the key energy- related reasons for global unrest need to be understood. They include:

- Increases in fossil fuel prices
- Environmental effects of energy use, including pollution due to emissions, stratospheric ozone layer depletion, and global warming
- Decreases in the amount of fossil fuel available per capita and the associated decrease in living standards
- Increases in energy demand due to technological developments attributable to and based on fossil fuels
- Depletion of fossil fuel reserves
- Increases in conflicts for fossil fuel reserves throughout the world
- The lack of affordable and practical alternative energy sources to fossil fuels

It is found out from Figure 9 that an increase in hydrogen utilization accordingly decreases the reasons for global unrest, allowing the benefits of global peace to be realized over time; and the lowest levels of global unrest occur when hydrogen from non-fossil fuels is substituted completely for fossil fuels. In general, the level of global unrest is higher than 1 and the problems causing global unrest can be reduced by using hydrogen energy from non-fossil sources instead of fossil fuels. Figure 5 suggests that the utilization of hydrogen from non-fossil fuels at certain ratios of petroleum, coal, and natural gas decreases the amount of fossil fuel consumption and thus reduces the level of global unrest closer to 1. As shown in Figure 9, it is expected that, depending on the actual and projected fossil fuel consumption data, the levels of global unrest will be approximately 4.78 in 2006, 4.66 in 2012, 4.56 in 2018, 4.48 in 2024, and 4.41 in 2030 when the utilization ratio of hydrogen is zero. If the utilization ratio of hydrogen from non-fossil fuels is lower than 100%, the level of global peace is less than 1 and the reasons for global unrest increase. Therefore, it is beneficial to encourage the utilization of hydrogen from non-fossil fuels in place of fossil fuels. The highest level of global peace is attained when 100% of hydrogen from non-fossil fuels is used in place of fossil fuels. Some advantages of having the highest level of global peace are:

- Lifetimes of fossil fuel reserves are extended and real fossil fuel prices, consequently, can be held constant or reduced relative to present prices.
- Environmental effects from using fossil fuels are reduced or prevented because of the utilization of hydrogen from renewable energy sources and technologies.
- Technological developments based on hydrogen from nonfossil fuels increase and the requirement of technologies based on fossil fuels decrease.
- Living standards are probably higher than at present due in part to the increased consumption of the technologies related to hydrogen from sustainable green energy sources.
- Pressures to discover energy sources reduce because hydrogen can be abundantly produced and conflicts for energy supplies subside.

To increase global peace, the relationship of hydrogen to renewable energy sources needs to be understood, as does the importance of producing hydrogen from renewable energy sources.

Figure 10 describes routes using sustainable green energy sources for green power production. It is expected that the utilization of sustainable green energy sources will reduce the negative energy-related environmental effects such as global climate change and emissions of CO, CO_2, NO_x, SO_x, non-methane hydrocarbons, and particulate matter. In this regard, some potential solutions to decreasing the global unrest associated with the harmful pollutant emissions have evolved, including:[3]

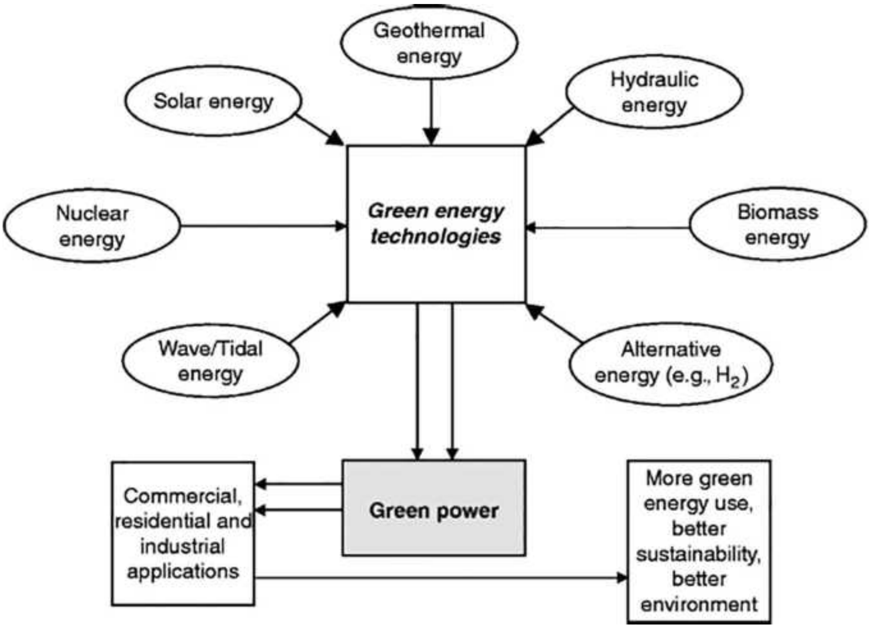

FIGURE 10 Routes for green power production from sustainable green energy sources.

- Education and training for a sustainable future
- Renewable energy technologies
- Energy conservation (efficient energy utilization)
- Cogeneration and district heating
- Energy storage technologies
- Alternative energy dimensions for transport
- Energy source switching from fossil fuels to environmentally benign energy forms
- Coal cleaning technologies
- Optimum monitoring and evaluation of energy indicators
- Policy integration
- Recycling
- Process change and sectoral shiftment
- Acceleration of forestation
- Carbon or fuel taxes
- Greener materials substitution
- Promoting public transport
- Changing life styles
- Increasing public awareness

Considering the above explanations, the following important remarks can be extracted. Fossil fuel consumption and green energy consumption are expected to reach 13807.2 and 2694.9 M, respectively, by the year 2050. This increase indicates that humans will still be dependent on fossil fuels. Based on the projected data, the green energy consumption ratio expects that the green energy utilization ratio will reach almost 16.33% and the fossil fuel utilization ratio will decrease to almost 83.67% in 2050. If the increase of fossil fuel consumption continues in this manner, it is likely that the world will be affected by many negative problems due to fossil fuels. More utilization of fossil fuels will harm world stability and increase local and global environmental problems, resulting in increasing global unrest. It is thus suggested that the utilization of fossil fuels should be reduced, and fossil-based technologies should be gradually converted to green-energy-based technologies.

Case 1 gives better results than Case 2 and Case 3. Therefore, for a higher green energy impact ratio in practice, Case 1 should be applied to increase the green energy sustainability ratio depending on the green energy strategies. Moreover, Case 1 gives the best results of the green energy–based sustainability ratio depending on the green energy impact ratio and the green energy utilization ratio.

The approximate quantified measures developed for level of global peace (ranging between 0 and 1) and level of global unrest (ranging between 1 and ∞)expressions can help understand and measure levels of global unrest and global peace. The highest level of global peace occurs when $GP=1$ and correspondingly, the lowest level of global unrest when $GU=1$, and efforts to increase global peace and stability should cause the values of GP and GU to shift towards these limiting cases. Hydrogen from non-fossil fuels can replace oil, coal, and natural gas to reduce the level of global unrest.

Sustainable green energy strategies are definitely required to ensure the global stability by reducing the harmful effects of fossil-based energy consumption. So, it is suggested that the importance of green energy and technologies that probably reduce world problems and achieve a sustainable energy system should be emphasized with consideration of the sustainable energy strategies. Moreover, a transition to a green energy–based economy should be encouraged and developed countries in particular should increase investments in green energy and technologies. Progress of green energy and technologies is based on sustainable green energy strategies for future green energy scenarios. The foremost factor that will determine the specific role of green energy and technologies will likely be energy demand. In order to balance the energy demand now and in the future, it is suggested that sustainable green energy sources and technologies be taken into consideration to increase the sustainable development in a country.

Conclusion

Green energy for sustainable development has been discussed and some key parameters to increase green energy–based sustainability and the global peace level have been presented. The effects of technological, sectoral, and practical application impact ratios on the green energy impact ratio and the green energy-based sustainability ratio are examined thoroughly. In addition, the key role of hydrogen—one of the most green energy carriers for the future—is discussed in terms of global unrest and peace. Accordingly, sustainable green energy and technologies are definitely required to ensure global stability by reducing the harmful effects of fossil-based energy consumption. The most important scenario that encourages the transition to green energy and technologies and promotes green energy–based technologies is to supply the required incentives and interactions among the countries, scientists, researchers, societies, and all. Therefore, the investments in green energy supply should be, for the future of world nations, encouraged by governments and other authoritative bodies who, for strategic reasons, wish to have a green alternative to fossil fuels.

Ozone Layer

Luisa T. Molina

Introduction

The Earth's ozone layer shields all life from the sun's harmful ultraviolet (UV) radiation. It is mainly located in the lower stratosphere, between 12 and 30 km above Earth's surface. Ozone is a gas that is present naturally in the Earth's atmosphere; it is continuously being made by the action of solar radiation on molecular oxygen, predominantly in the upper stratosphere and at low latitudes; it is also continuously being destroyed throughout the atmosphere by a variety of chemical processes. The ozone abundances in the atmosphere are therefore determined by the balance between chemical production and destruction processes.

The average concentration of ozone in the atmosphere is about 300 parts per billion by volume (ppbv); most of it (~90%) is contained in the stratosphere. Even though it occurs in such small quantities, ozone plays a vital role in sustaining life on Earth by absorbing most of the biologically damaging UV sunlight. However, the fragile ozone layer is being depleted since the late 1970s as a consequence of the emission of human-made chemicals, chlorofluorocarbons (CFCs), to the atmosphere. The CFCs are industrial chemicals that have been used in the past as coolants for refrigerators and air conditioners, propellants for aerosol spray cans, foaming agents for plastics, and cleaning solvents for electronic components, among other uses. They are thought of as "miracle" compounds because they are non-flammable, noncorrosive, and unreactive with most other substances. Ironically, it is their chemical inertness that creates a global scale problem by enabling them to reach the stratosphere, where they decompose, releasing chlorine atoms that deplete the ozone layer.

Observations of the ozone layer itself showed that depletion was indeed occurring; the most dramatic loss was discovered over Antarctica—far from the emitted sources. In response to the likelihood of increasing depletion of ozone in the stratosphere, an international agreement, the Montreal Protocol on Substances that Protect the Ozone Layer, was signed by most national governments of the world calling for an orderly phase out of all ozone-depleting substances (ODSs). Thus, ozone, a trace constituent in the atmosphere, has become an issue of global prominence and the model for international cooperation to protect the environment from unintended consequences of human activities.

While the Montreal Protocol has made great strides in phasing out ODSs, new challenges are emerging. Changes in climate are expected to have an increasing influence on stratospheric ozone in the coming decades. International efforts to protect the ozone layer would require improved understanding of the complex linkages between stratospheric ozone and climate change. Moreover, some new ODSs replacements are extremely powerful global warming gases and represent a potential focal area within the overall climate change challenge. This entry describes the discovery of the ozone depletion phenomenon, the chemicals that cause ozone depletion in the stratosphere, polar ozone destruction processes, impacts of ozone depletion on human health and on ecosystems, international treaties that regulate the ODSs, and the linkage between stratospheric ozone and climate change.

Atmospheric Ozone

Ozone was discovered by the German chemist Christian Schoenbein in 1840 while observing an electrical discharge; he noted its distinctively pungent odor and named it "ozone, " which means "smell" in Greek. An ozone (O_3) molecule is made of three oxygen atoms, instead of two of the normal oxygen molecule (O_2), which makes up 21% of the air we breathe. Ozone is found mainly in two regions of the Earth's atmosphere (Figure 1):

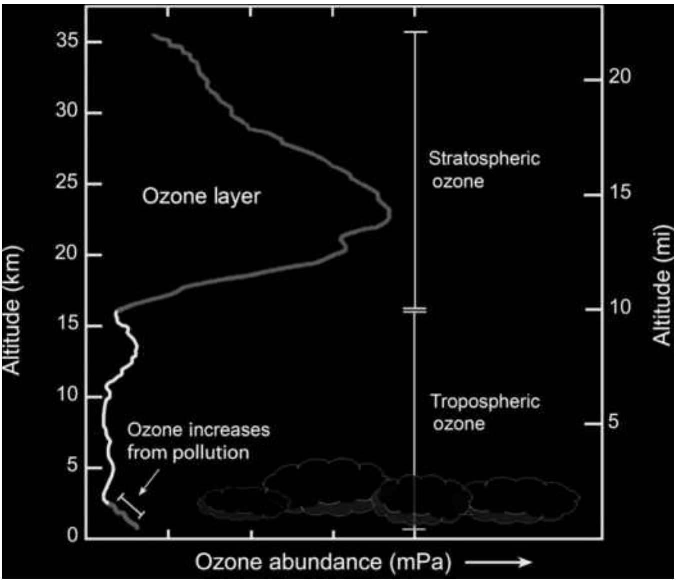

FIGURE 1 Typical atmospheric ozone profile. Ozone abundances are shown here as the pressure of ozone at each altitude using the unit "milli-Pascals" (mPa) (100 million mPa = atmospheric sea-level pressure).

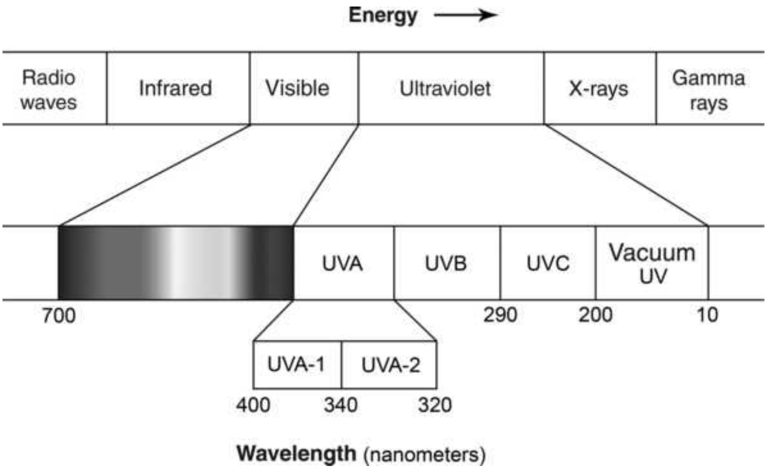

FIGURE 2 Spectrum of electromagnetic radiation.

1. Stratosphere, from about 10–16 km above Earth's surface up to 50 km. The ozone in this region is commonly known as the ozone layer.
2. Troposphere, the lowest region of the atmosphere, between Earth's surface and the stratosphere. Some of the tropospheric ozone is generated by atmospheric photochemical reactions (smog), and some is transported from the stratosphere.

The ozone molecules in the stratosphere and the troposphere are chemically identical; however, they have very different roles in the atmosphere and very different effects on humans and the biosphere. Stratospheric ozone—sometimes referred to as "good ozone"—plays a beneficial role by absorbing most of the biologically damaging UV sunlight (UV-B), allowing only a small amount to reach the Earth's surface (Figure 2). At the Earth's surface, ozone is a key component of urban smog and is harmful to human health, agriculture, and ecosystems; hence, it is often referred as "bad ozone." Furthermore, because ozone is a powerful greenhouse gas, increase in tropospheric ozone contributes to global warming.[1] Thus, depending on where ozone resides, it can have positive or negative impacts on human well-being and the environment.[2]

Origin of Ozone

The fundamental ozone formation–destruction mechanism consists of the following reactions, suggested initially by the British physicist Sidney Chapman[3] in the 1930s:

$$O_2 + \text{UV light} \rightarrow O + O \tag{1}$$

$$O + O_2 + M \rightarrow O_3 + M \tag{2}$$

$$O_3 + \text{UV light} \rightarrow O + O_2 \tag{3}$$

$$O + O_3 \rightarrow O_2 + O_2 \tag{4}$$

Molecular oxygen absorbs solar radiation at ~200 nm and releases oxygen atoms (Reaction 1), which rapidly combine with oxygen molecules to form ozone (Reaction 2). Ozone absorbs solar radiation very efficiently at wavelengths ~200 to 300 nm.[4] This absorption process leads to the decomposition of ozone, producing oxygen atoms (Reaction 3), which in turn regenerate the ozone molecule by Reaction 2. Thus, the net effect of Reactions 2 and 3 is the conversion of solar energy into heat, without the net loss of ozone. This process leads to an increase of temperature with altitude, which is the feature that gives rise to the stratosphere; the inverted temperature profile is responsible for its large stability toward vertical movements (Figure 3). In contrast, the troposphere is characterized by decreasing temperature with altitude because of the heating effects from the absorption of the sun's energy at the Earth's surface. Because hot air rises, this causes rapid vertical mixing so that chemical substances emitted on the ground can rise to the tropopause (transition zone between troposphere and stratosphere) in a matter of days; they are also dispersed horizontally throughout the troposphere on the time scale of weeks to months by winds and convection. However, once they reach the stratosphere, the transport time scales in the stratosphere are much slower and mixing in the stratosphere can take months to years. Movement of air between the troposphere and stratosphere is very slow compared to the movement of air within the troposphere itself. However, this small air exchange is an important source of ozone from the stratosphere to the troposphere.

Most of the time, oxygen atoms react with molecular oxygen to make ozone (Reaction 2), but occasionally they destroy ozone (Reaction 4). The overall amount of ozone is determined by a balance between the production and the removal processes. Models based only on the Chapman's mechanism were found to overpredict stratospheric ozone levels; thus, there are other reactions that contribute to the destruction of ozone.

In the early 1970s, Crutzen[5] suggested that trace amounts of nitrogen oxides ($NO_x = NO + NO_2$) formed in the stratosphere through the decomposition of nitrous oxide (N_2O), which originates from soil-borne microorganisms, control the ozone abundance through the following catalytic cycle:

$$NO + O_3 \rightarrow NO_2 + O_2 \tag{5}$$

$$NO_2 + O \rightarrow NO + O_2 \tag{6}$$

$$\frac{O_3 + \text{UV light} \rightarrow O + O_2 \left(\text{for Reaction 3}\right)}{\text{Net: } 2\,O_3 \rightarrow 3\,O_2}$$

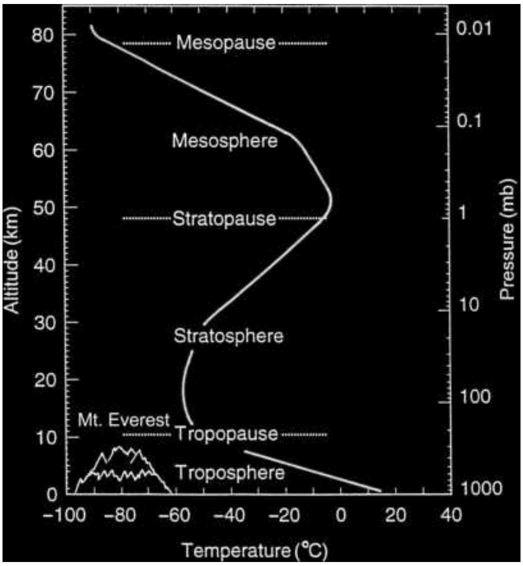

FIGURE 3 Typical variation of atmospheric temperatures and pressures with altitude.

The term “catalyst” refers to a compound that reacts with one or more reactants to form intermediates that subsequently give the final reaction product, in the process regenerating the catalyst. In the above cycle, the species NO (nitric oxide) and NO_2 (nitrogen dioxide) are still present after these three reactions have occurred, but two molecules of ozone have been destroyed. These species have an odd number of electrons; they are free radicals and are chemically very reactive. Although the concentration of NO and NO_2 is small (several ppbv), each radical pair can destroy thousands of ozone molecules before being temporarily removed, mainly by reaction with hydroxyl (OH) radical to form nitric acid:

$$OH + NO_2 \rightarrow HNO_3 \tag{7}$$

Independently, Johnston[6] suggested that the NO_x chain reaction can be initiated by the direct release of NO_x in the exhaust of supersonic transport (SST) aircraft and could disturb the delicate natural balance between ozone formation and destruction.

In the troposphere, NO_x, together with volatile organic compounds in the presence of sunlight, are the ingredients for the photochemical formation of ground-level ozone. Thus, NO_X plays a dual role, destroying or generating O_3 depending on the altitude.

Other free radicals that destroy stratospheric ozone are OH and HO_2, derived from the water molecule:

$$OH + O_3 \rightarrow HO_2 + O_2 \tag{8}$$

$$\begin{array}{l} HO_2 + O_3 \rightarrow OH + 2O_2 \\ \hline \text{Net: } 2\,O_3 \rightarrow 3\,O_2 \end{array} \tag{9}$$

Chlorine atoms are also very efficient catalysts for ozone destruction and may proceed in a similar cycle[7–9] as will be discussed below. Small amounts of chlorine compounds of natural origin exist in the stratosphere; the most important source is methyl chloride (CH_3Cl), which is emitted mainly from oceanic and terrestrial ecosystems. Most of the CH_3Cl is destroyed in the troposphere, but a few percent reaches the stratosphere. There are also large natural sources of inorganic chlorine compounds at the Earth’s surface, e.g., NaCl and HCl from the oceans; however, they are water soluble and are removed efficiently from the atmosphere by clouds and rainfall.

Measurements and Distribution of Stratospheric Ozone

In the 1920s, the British meteorologist G.M.B. Dobson developed the Dobson spectrophotometer that measures sunlight at two UV wavelengths: one that is strongly absorbed by ozone and one that is weakly absorbed. The difference in light intensity at the two wavelengths provides the total ozone above the location of the instrument.[10] In 1957, a global network of ground-based, total ozone observing stations was established as part of the International Geophysical Year; currently, there are about 100 sites distributed throughout the world. Ozone concentrations are also being routinely measured by a variety of instruments on balloons, aircraft, and satellites. One of the most commonly used units for measuring ozone concentration is called “Dobson unit” (DU), which is a measure of how much ozone is contained in a vertical column of air. The average amount of ozone in the atmosphere is about 300 DU, equivalent to a layer 3 mm thick. By comparison, if all of the air in a vertical column that extends from the ground up to space were collected and squeezed together at 0°C and 1 atm pressure, that column would be 8 km thick.

As shown in Figure 4, the distribution of total ozone over the globe varies with latitude, longitude, and season.[11] The variations are caused by large-scale movements of stratospheric air and the chemical production and destruction of ozone. In general, the total ozone is highest in the polar regions and lowest at the equator. In the Northern Hemisphere, the ozone layer is thicker during spring and thinner during autumn.

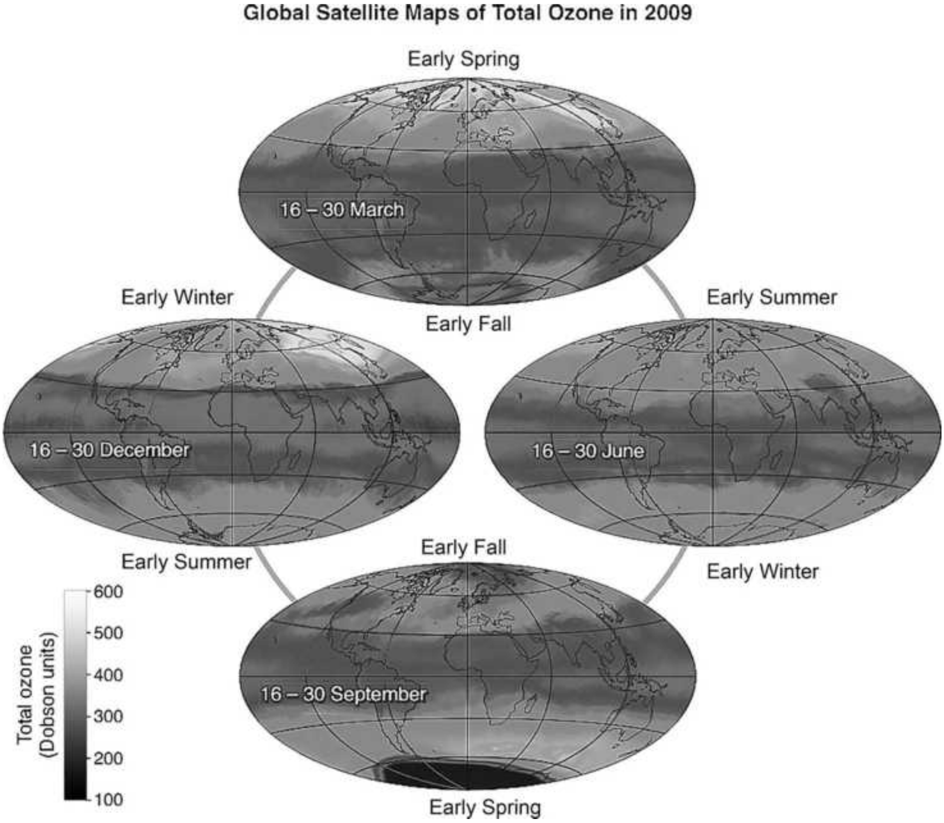

FIGURE 4 Global satellite maps of total ozone in 2009 showing the variation with latitude, longitude, and season. The variations are demonstrated here with 2-week averages of total ozone in 2009 as measured with a satellite instrument. Total ozone shows little variation in the tropics (20°N–20°S latitudes) over all seasons. Total ozone outside the tropics varies more strongly with time on a daily to seasonal basis as ozone-rich air is moved from the tropics and accumulates at higher latitudes. The low total ozone values over Antarctica in September constitute the "ozone hole" in 2009. Since the 1980s, the ozone hole in late winter and early spring represents the lowest values of total ozone that occur over all seasons and latitudes.

CFCS and the Ozone Layer

CFCs: The Miracle Compounds

In the 1930s, American mechanical engineer and chemist Thomas Midgley[12,13] invented the CFCs during a search for nontoxic and non-flammable substances that could be used as coolants in home refrigerators and air conditioners. The CFCs are compounds that contain only chlorine, fluorine, and carbon; they are also known under trademarks such as Freon (DuPont) and Genetron (Allied Signal).

The two important properties that make the CFCs commercially valuable are their volatility (they can be readily converted from a liquid to a vapor and vice versa) and their chemical inertness (they are stable, nontoxic, and nonflammable). The CFCs were thought of as miracle compounds and soon replaced the toxic ammonia and sulfur dioxide as the standard cooling fluids. Subsequently, the CFCs found uses as propellants for aerosol sprays, blowing agents for plastic foam, and cleaning agents for electronic components. All of these activities doubled the worldwide use of CFCs every 6 to 7 years and eventually reached over 700,000 metric tons annually by the early 1970s.

CFCs and the Destruction of Stratospheric Ozone

In the early 1970s, James Lovelock showed that trichlorofluoromethane (CCl_3F or CFC-11) was present in the air over Ireland using a newly developed electron capture detector.[14] Subsequently, Lovelock and co-workers[15] detected measurable levels of CCl_3F in the atmosphere over the South and North Atlantic and concluded that the CFCs were carried over by large-scale wind motions. Their interest in CFCs lies in the potential use of these compounds as inert tracers; they did not expect the CFCs to present any conceivable harm to the environment.

In 1973, Molina and Rowland[7,8,16–18] decided to investigate the ultimate fate of these new miracle compounds upon their release to the atmosphere. After carrying out a systematic search of chemical and physical processes that might destroy the CFCs in the lower atmosphere, they concluded that these compounds would break up in the middle stratosphere (~25–30 km) by solar UV radiation.

Because the CFCs are chemically inert and practically insoluble in water, they are not removed by the common cleansing mechanisms that operate in the lower atmosphere. Furthermore, the CFC molecules are transparent from 230 nm through the visible wavelengths; they are effectively protected below 25 km by the stratospheric ozone layer that shields the Earth's surface from UV light. Instead, they rise into the stratosphere, where they are eventually destroyed by the short-wavelength (~200 nm) solar UV radiation to yield radicals that can destroy stratospheric ozone through a catalytic process.[7] Because transport into the stratosphere is very slow, the atmospheric lifetime for the CFCs is about 50 to 100 years.

The destruction of CFCs by high-energy solar radiation leads to the release of chlorine atoms, as shown in Reaction 12 for CCl_3F:

$$CCI_3F + \text{UV light} \rightarrow CI + CCI_2F \tag{10}$$

The chlorine atoms attack ozone within a few seconds and are regenerated on a time scale of minutes; the net result is the conversion of one ozone molecule and one oxygen atom to two oxygen molecules.

$$CI + O_3 \rightarrow CIO + O_2 \tag{11}$$

$$\begin{array}{c} CIO + O \rightarrow CI + O_2 \\ \hline \text{Net: } O + O_3 \rightarrow O_2 + O_2 \end{array} \tag{12}$$

In the above cycle, chlorine acts as a catalyst for ozone destruction because Cl and ClO react and are reformed, and ozone is simply removed. Oxygen atoms are formed when solar UV radiation reacts with ozone and oxygen molecule (Reactions 1 and 3). It is estimated that one Cl atom can convert 100,000 molecules of ozone into oxygen molecules before that chlorine becomes part of a less reactive compound, e.g., by reaction of ClO with HO_2 or NO_2 to produce hypochlorous acid (HOCl) or chlorine nitrate ($ClONO_2$), respectively, or by reaction of the Cl atom with methane (CH_4) to produce the relatively stable hydrogen chloride (HCl):

$$CIO + HO_2 \rightarrow HOCI + O_2 \tag{13}$$

$$CIO + NO_2 \rightarrow CINO_2 \tag{14}$$

$$CI + CH_4 \rightarrow HCI + CH_3 \tag{15}$$

The chlorine-containing product species HCl, $ClONO_2$, and HOCl function as temporary inert reservoirs: they are not directly involved in ozone depletion, but they are eventually broken down by reaction with other free radicals or by absorption of solar radiation, thus returning chlorine to its catalytically active free radical form. At low latitudes and in the upper stratosphere, where the

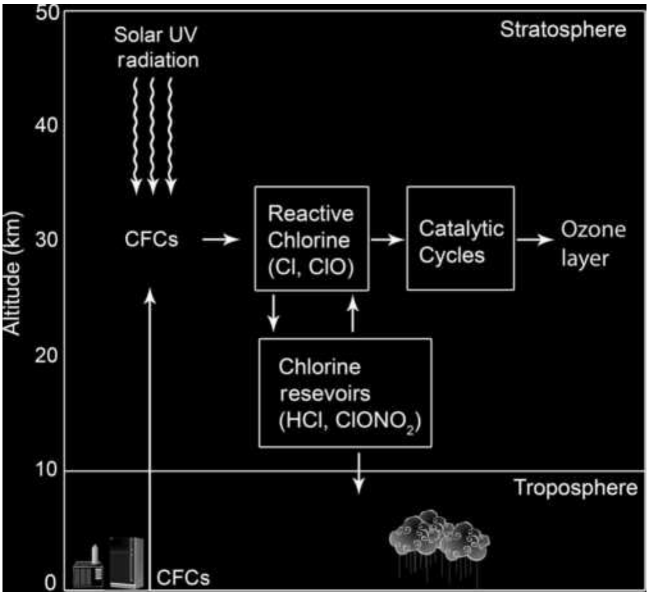

FIGURE 5 Schematic representation of the CFC-ozone depletion hypothesis.

formation of ozone is fastest, a few percent of the chlorine is in this active form; most of the chlorine is in the inert reservoir form, with HCl being the most abundant species. The temporary chlorine reservoirs remain in the stratosphere for several years before returning to the troposphere, where they are rapidly removed by rain or clouds. A schematic representation of these processes is presented in Figure 5.

Other ODSs

Besides CFCs, there are other chlorine substances from human activities that destroy ozone in the stratosphere. Carbon tetrachloride and methyl chloroform are important ODSs that are used as fire extinguisher, cleaning agents, and solvents.

Another category of ODSs contains bromine. There are industrial sources of brominated ODSs as well as natural ones; the most important are the halons and methyl bromide (CH_3Br). Halons are halocarbon gases containing carbon, bromine, fluorine, and (in some cases) chlorine; they are produced industrially as fire extinguishers. Methyl bromide is both natural and human-made; it is used as an agricultural fumigant. These sources release bromine to the stratosphere at pptv levels, compared with ppbv for chlorine. On the other hand, bromine atoms are about 60 times more efficient than chlorine atoms for ozone destruction on an atom-per-atom basis;[19–21] a large fraction of the bromine compounds is present as free radicals because the temporary reservoirs are less stable and are formed at considerably slower rates than the corresponding chlorine reservoirs.

Many of the ODSs contain fluorine atoms in addition to chlorine and bromine. However, in contrast to chlorine and bromine, fluorine atoms abstract hydrogen atoms very rapidly from methane and from water vapor, forming the stable hydrogen fluoride (HF), which serves as a permanent inert fluorine reservoir. Hence, fluorine free radicals are extremely scarce and the effect of fluorine on stratospheric ozone is negligible. Halogen source gases that contain fluorine and no other halogens are not classified as ODSs. An important category is the hydrofluorocarbons (HFCs) discussed in the "International Response: Montreal Protocol" section.

The publication of the 1974 Molina–Rowland article[7] stimulated numerous scientific studies, including laboratory studies, computer modeling, and field measurements, to understand the impacts of chlorine and bromine on stratospheric ozone.[20,21] The U.S. National Academy of Sciences issued two reports in 1976, verifying the Molina-Rowland findings.[22,23]

Stratospheric Ozone Depletion

Discovery of the Antarctic Ozone Hole

In 1985, Joseph Farman and coworkers[24] reported that the ozone concentrations recorded at the Halley Bay Observatory in Antarctica has dropped dramatically in the spring months starting in the early 1980s, compared to the data obtained since 1957, when the British Antarctic Survey began ozone measurements using a Dobson Spectrometer. The 1984 October monthly ozone averaged less than 200 DU, about 35% lower than the 300 DU levels recorded in 1957–1958 and on through the 1960s. Farman et al.'s findings were subsequently confirmed by satellite observation from the total ozone mapping spectrometer (TOMS).[25] Furthermore, satellite measurements confirmed that the bulk of the chlorine in the stratosphere is of human origin.[26] Additional measurements from ground-based Dobson instruments[27] and from satellites indicate that the extent of ozone depletion over Antarctica in the spring months continued to increase after 1985, with concentrations as low as 85 to 95 DU reported from some of the polar stations.

Measurements show that ozone was also being depleted in the Northern Hemisphere, particularly at high latitudes and in the winter and spring months. Examination of the ozone records shows that significant changes have also occurred in the lower stratosphere at mid- latitudes.[20,21] Figure 6 shows an acute drop in total atmospheric ozone during October in the early and mid-1980s measured by instruments from the ground and from a satellite.[28]

The discovery of the depletion of ozone over Antarctica—the ozone hole—was not predicted by the atmospheric scientists (see Figure 7). The large magnitude of the depletion suggests that the stratospheric

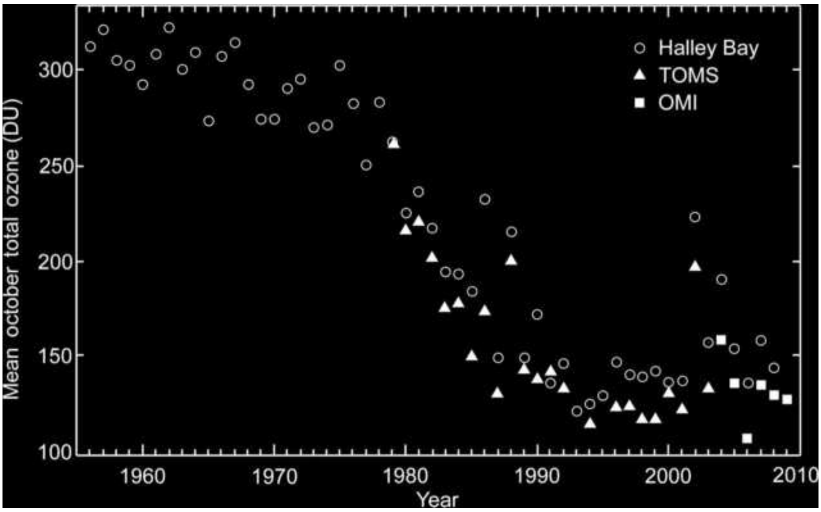

FIGURE 6 Average total amount of ozone measured in October over Antarctica. Instruments on the ground (at Halley Bay) and high above Antarctica (the TOMS and ozone monitoring instrument [OMI] measured an acute drop in total atmospheric ozone during October in the early and middle 1980s).

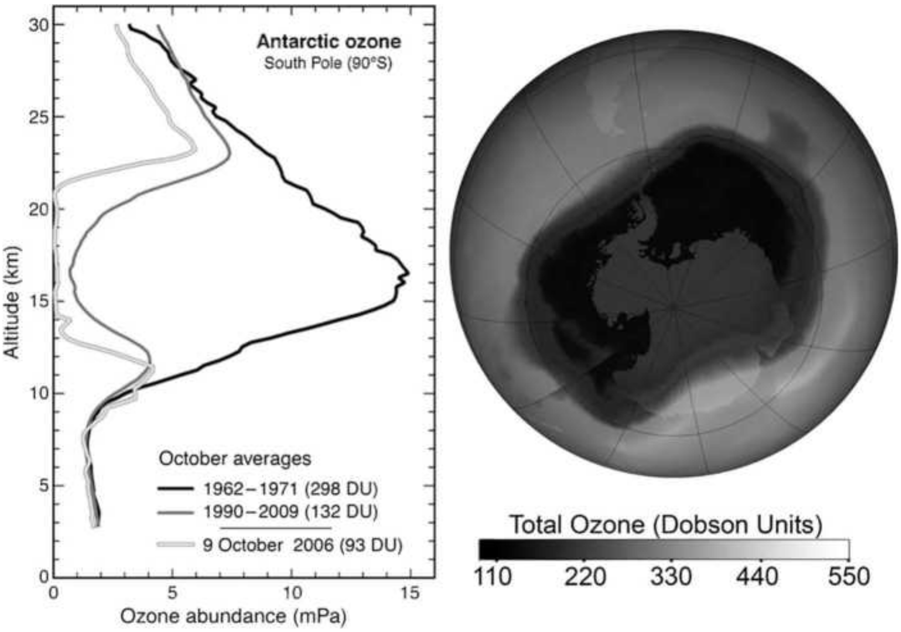

FIGURE 7 Antarctic ozone hole. Left panel: Vertical distributions of Antarctic ozone. A normal ozone layer was observed to be present between 1962 and 1971. In more recent years, as shown here for October 9, 2006, ozone is almost completely destroyed between 14 and 21 km in the Antarctic in spring (Source: Adapted from Fahey and Hegglin[11]). Right panel: The darker shaded regions over the Antarctic continent show the severe ozone depletion or ozone hole on October 9, 2006, measured by satellite instrument. The hole reached 26.2 million km^2, the greatest extent recorded in the Antarctic.
Source: NASA Ozone Hole Watch.[28]

ozone is influenced by processes that had not been considered previously. Researchers all over the world raced to develop plausible explanation; the cause of this depletion soon became very clear. Laboratory experiments, field measurements over Antarctica, and model calculations showed unambiguously that the ozone hole over Antarctica can indeed be traced to the industrial CFCs.[20,21]

Polar Ozone Chemistry

Characteristics of the Polar Regions

ODSs emitted at Earth's surface are transported over great distances to the stratosphere by atmospheric air motions and are present throughout the stratospheric ozone layer. Yet, the most dramatic ozone depletion was over Antarctica—the ozone hole—far from the emitted sources. A major reason why an Antarctic ozone hole of the observed extent could happen is because of the unique atmospheric and chemical conditions that exist there. The very low winter temperatures in the Antarctic stratosphere cause polar stratospheric clouds (PSCs) to form. Special reactions that occur on PSCs, combined with the relative isolation of polar stratospheric air, allow chlorine and bromine reactions to produce the ozone hole in the Antarctica when the sunlight returns in the springtime.

Both polar regions of the earth are cold, primarily because they receive far less solar radiation than the tropics and mid-latitudes do. Moreover, most of the sunlight that does shine on the polar regions is reflected by the bright white surface. Winter temperatures at the North Pole can range from about −45°C to −25°C and summer temperatures can average around the freezing point (0°C).

In comparison, the annual mean temperature at the South Pole is about −60°C in the winter and −28°C in the summer.

What makes the South Pole so much colder than the North Pole is that it sits on top of a very thick ice sheet, which itself sits on the continent of Antarctica. The surface of the ice sheet at the South Pole is more than 2700 m (9000 ft) above sea level; Antarctica is by far the highest continent on the earth. In contrast, the North Pole is at sea level in the middle of the Arctic Ocean, which also acts as an effective heat reservoir.

Stratospheric air in the polar regions is relatively isolated from other stratospheric regions for long periods in the winter months. The isolation comes about because of strong winds that encircle the poles, forming a polar vortex (or polar cyclone), which prevents substantial air masses into or out of the polar stratosphere. This cyclonic circulation strengthens in winter as stratospheric temperatures decrease.[11] All through the long, dark winter, chemical changes occur in polar regions from reactions on PSCs inside the vortex; the isolation preserves those changes until the spring sunlight strikes the stratosphere above the frozen continent in late August. The result is massive ozone destruction inside the vortex forming an ozone hole, as described below. The polar vortex diminishes when the continent and the air above it begin to warm up and ozone-rich air from outside the vortex flows in, replacing much of the ozone that was destroyed.

The Antarctic polar vortex is more pronounced and persistent than its Arctic counterpart with the result that the isolation of air inside the vortex is much more effective in the Antarctic than in the Arctic. In addition to being significantly warmer, the Northern Hemisphere also has numerous mountain ranges and a more active tropospheric meteorology, giving rise to enhanced planetary wave and a less stable Arctic vortex.

Polar Stratospheric Clouds

The conditions in the polar stratosphere are unique in several ways. Firstly, ozone is not generated there because the high-energy solar radiation that is absorbed by molecular oxygen is scarce over the poles. Secondly, the total ozone column abundance at high latitudes is large because ozone is transported toward the poles from higher altitudes and lower latitudes. Thirdly, the prevailing temperatures over the stratosphere above the poles in the winter and spring months are the lowest throughout the atmosphere, particularly over Antarctica. Typically, average daily minimum values are as low as −90°C in July and August over Antarctica and near −80°C in late December and January over the Arctic (Figure 8). Ozone is expected to be rather stable over the poles if one considers only gas-phase chemical and photochemical processes, because regeneration of ozone-destroying free radicals from the reservoir species would occur very slowly at those temperatures. However, another unique feature of the polar stratosphere is the seasonal presence of PSCs (Fig. 9). Different types of liquid and solid PSC particles form when stratospheric temperatures fall below −78°C. As a result, PSCs are often found over large areas of the winter polar regions and over significant altitude ranges. With a temperature threshold of −78°C, PSCs exist in larger areas and longer periods in the Antarctica than in the Arctic.

The stratosphere is normally very dry; water is present only at a level of a few ppmv, comparable to that of ozone itself. Over the poles, a somewhat larger amount of water is present, resulting from the oxidation of methane. Furthermore, the temperature can drop below −85°C over Antarctica in the winter and spring months, leading to the formation of ice clouds. The presence of trace amounts of nitric and sulfuric acids enables the formation of PSCs a few degrees above the frost point (the temperature at which ice can condense from the gas phase); these acids can form cloud particles consisting of crystalline hydrates.

Solomon et al.[29] first suggested that PSCs could play a major role in ozone depletion over Antarctica by promoting the release of photolytically active chlorine from its reservoir species (HCl, $ClONO_2$, and HOCl). This occurs mainly by the following reaction:

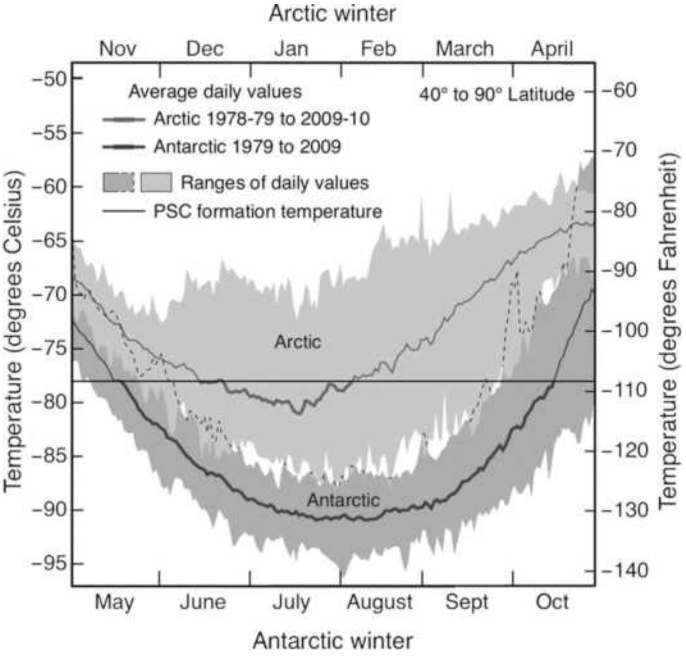

FIGURE 8 Arctic and Antarctic temperatures. Air temperatures in both polar regions reach minimum values in the lower stratosphere in the winter season. Typically, average daily minimum values are as low as −90°C in July and August in the Antarctic and near −80°C in late December and January in the Arctic. PSCs are formed in the polar ozone layer when winter minimum temperatures fall below the formation temperature of about −78°C. Note that the dashed black lines denote the upper limits of the Antarctic temperature range where they overlap with the Arctic temperature range.
Source: Fahey and Hegglin.[11]

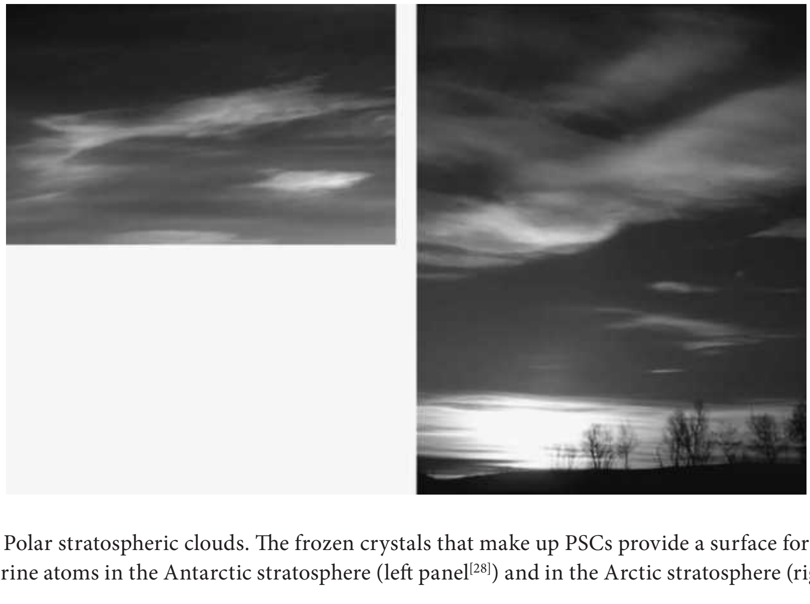

FIGURE 9 Polar stratospheric clouds. The frozen crystals that make up PSCs provide a surface for the reactions that free chlorine atoms in the Antarctic stratosphere (left panel[28]) and in the Arctic stratosphere (right panel[11]).

$$\mathrm{HCI + CIONO_2 \rightarrow CI_2 + HNO_3} \tag{16}$$

$$\mathrm{CI_2} + \text{sunlight} \rightarrow \mathrm{CI + CI} \tag{17}$$

Indeed, laboratory studies have shown that this reaction occurs very slowly in the gas phase;[30] however, it proceeds with remarkable efficiency in the presence of ice surfaces.[31] The product, Cl_2, is immediately released to the gas phase while the other product, HNO_3, remains in the condensed phase. Cl_2 decomposes readily to Cl atoms even with the faint amount of sunlight present over Antarctica in the early spring:

When average temperatures begin increasing by late winter, PSCs form less frequently and their surface conversion reactions produce less ClO. Without continued ClO production, ClO amounts decrease and other chemical reactions re-form the reactive reservoirs, $ClONO_2$ and HCl. The most intense period of ozone depletion will end when PSC temperatures no longer occur.

An important feature for Reaction 16 in the presence of PSCs is the removal of NO_x from the gas phase; the source for these free radicals in the polar stratosphere is nitric acid, which condenses in the cloud particles. NO_x normally interfere with the catalytic ozone loss reactions by scavenging ClO to form chlorine nitrate (Reaction 14). In the absence of NO_x, the fraction of chlorine compounds in the form of free radical is larger and makes it possible for the ozone depletion reaction to occur. These experimental results have been corroborated by other studies.[32] Further laboratory studies[33,34] and theoretical calculations[35] indicate that HCl solvates readily on the ice surface, forming hydrochloric acid. Therefore, chlorine activation reactions on the surfaces of ice crystals proceed through ionic mechanisms analogous to those in aqueous solutions.

Another natural source of ozone depletion is the sulfate aerosols that come from volcanic eruptions. The most recent large eruption was that of Mt. Pinatubo in 1991, which ejected large amounts of sulfur dioxide into the stratosphere, resulting in up to a 10-fold increase in the number of particles available for surface reactions. These particles increased the global ozone depletion by 1%–2% for several years following the eruption.[11]

Polar Ozone Destruction

While the presence of the PSCs explains how chlorine can be released from the inactive reservoir chemicals, it remains unanswered how a catalytic cycle might be maintained to account for the large ozone destruction observed. The ClO_x cycles such as Reactions 11 and 12 are not efficient in the polar stratosphere because they require the presence of free oxygen atoms, which are scarce at high latitudes.

Several catalytic cycles have been suggested as occurring over Antarctica during winter and spring. One of the dominant cycles involving ClO dimer or chlorine peroxide (ClOOCl) was proposed by Molina and Molina.[36] The cycle is initiated by the combination of two ClO radicals forming ClOOCl, which then photolyzes to release molecular oxygen and free chlorine atoms:

$$\mathrm{C1O + C1O + M \rightarrow C1OOC1 + M} \tag{18}$$

$$\mathrm{C1OOC1} + \text{sunlight} \rightarrow \mathrm{C1 + C1OO} \tag{19}$$

$$\mathrm{C1OO + M \rightarrow C1 + O_2 + M} \tag{20}$$

$$\frac{2\left[\mathrm{C1 + O_3 \rightarrow C1O + O_2}\right]\ (\text{for Reaction 11})}{\text{Net: } 2\ \mathrm{O_3} \rightarrow 3\ \mathrm{O_2}}$$

No free oxygen atoms are involved in this cycle. Visible sunlight is required to complete and maintain the cycle; thus, this cycle can occur only in late winter/early spring when sunlight returns to the polar region. Laboratory studies have shown that the photolysis products of ClOOCl are indeed Cl atoms.[37,38]

Another important cycle operating in the polar stratosphere involves the reaction of bromine monoxide (BrO) with ClO suggested by McElroy et al.:[39]

$$\mathrm{BrO+C1O+sunlight \rightarrow C1+Br+O_2} \tag{21}$$

$$\mathrm{Br+O_3 \rightarrow BrO+O_2} \tag{22}$$

$$\underline{\mathrm{C1+O_3 \rightarrow C1O+O_2}\ (\text{for Reaction } 11)}$$
$$\text{Net: } 2\ \mathrm{O_3} \rightarrow 3\ \mathrm{O_2}$$

Field Measurements of Atmospheric Trace Species

Ground-based and aircraft expeditions were launched in the years following the ozone hole discovery to measure trace species in the stratosphere over Antarctica.[40] The results provided strong evidence for the crucial role played by industrial chlorine in the ozone depletion. One of the most convincing evidence was provided by the NASA ER-2 aircraft measurements in 1987, which flew into the Antarctic vortex. The flight data (Figure 10) showed an anticorrelation between ClO measured by Anderson et al.[41] with in situ ozone measurements monitored by Proffitt et al.[42] The results show that the ClO + ClO cycle accounts for about three-quarters of the observed ozone loss, with the BrO + ClO cycle accounting for the rest. Furthermore, NO*x* levels were found to be very low and nitric acid was shown to be present in the cloud particles, as expected from the laboratory studies.

Recent laboratory measurements of the dissociation cross section of ClO dimer[43] and analyses of observation from aircraft and satellites have reaffirmed that polar springtime ozone depletion is caused primarily by the ClO + ClO catalytic ozone destruction cycle, with substantial contributions from the BrO + ClO cycle.[44]

Field measurements have also been conducted in the Arctic stratosphere,[45] indicating that a large fraction of the chlorine is also activated there. Nevertheless, ozone depletion is less severe over the Arctic and is not as localized because the atmosphere above the Arctic is warmer than above the Antarctic; the active chlorine does not remain in contact with ozone long enough and at low enough temperatures to destroy it before the stratospheric air over the Arctic mixes with warmer air from lower latitudes. This warmer air also contains NO_2, which deactivates the chlorine. On the other hand, cold winters can lead to significant ozone depletion—30% or more—over large areas, as described below.[46]

Depletion of the Global Ozone Layer

Global total ozone levels are influenced not only by the concentrations of ODSs but also by atmospheric transport (winds), incoming solar radiation, aerosols (fine particles suspended in the air), and other natural compounds. Global total ozone has decreased beginning in the 1980s, reaching a maximum of about 5% in the early 1990s (Figure 11a). The lowest global total ozone values occurred in the years following the eruption of Mt. Pinatubo in 1991, which resulted in up to a 10-fold increase in the number of sulfuric-acid-containing particles available for surface reaction in the stratosphere, thereby increased global ozone depletion for several years before they were removed from the stratosphere by natural processes. The depletion has lessened since then; the average global ozone for 2005–2009 is about 3.5% below the 1964–1980 average.

Observed total ozone loss varies significantly with latitude on the globe. Figure 11b shows how the 2005–2009 ozone depletion varies with latitude. The ozone loss is very small near the equator and increases with latitude towards the poles. The largest decreases have occurred at high latitudes in both

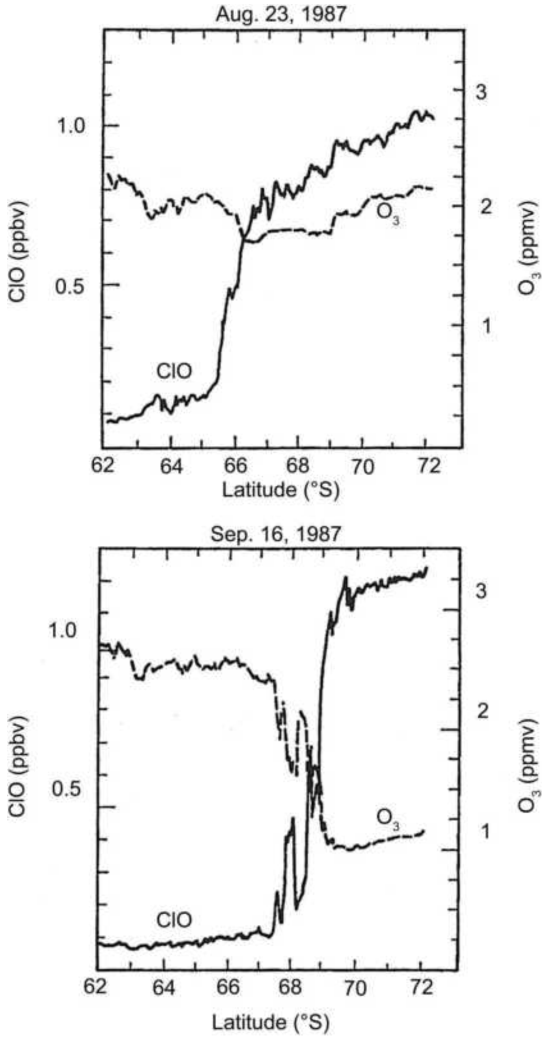

FIGURE 10 Aircraft measurements conducted on August 23 and September 16, 1987, of chlorine monoxide (ClO) by Anderson et al.[41] and of ozone (O_3) by Proffitt et al.[42]
Source: Adapted from Anderson.[41]

hemispheres because of the large winter/spring depletion in the polar regions; the losses are greater in the Southern Hemisphere because of the Antarctic ozone hole. Since the 1980s, Antarctic ozone loss in the springtime has been quite large, covering nearly the entire continent with virtually all of the ozone destroyed between 15 and 20 km. Ozone loss over the Arctic is smaller than its Antarctic counterpart; it is modulated strongly by variability in atmospheric dynamics, transport, and temperature. The degree of spring Arctic depletion is highly variable from year to year, but large Arctic depletion has also been observed recently with the most dramatic occurring in the spring of 2011. Observations over the Arctic region as well as from satellites show an unprecedented ozone column loss comparable to some Antarctic ozone holes. The formation of the "Arctic ozone hole" in 2011 was driven by an anomalously strong stratospheric polar vortex and an unusually long cold period, leading to persistent enhancement of active chlorine and severe ozone loss that exceeded 80% over 18–20 km altitude. This result raises the possibility of yet more severe depletion as lower stratospheric temperatures decrease. More acute Arctic

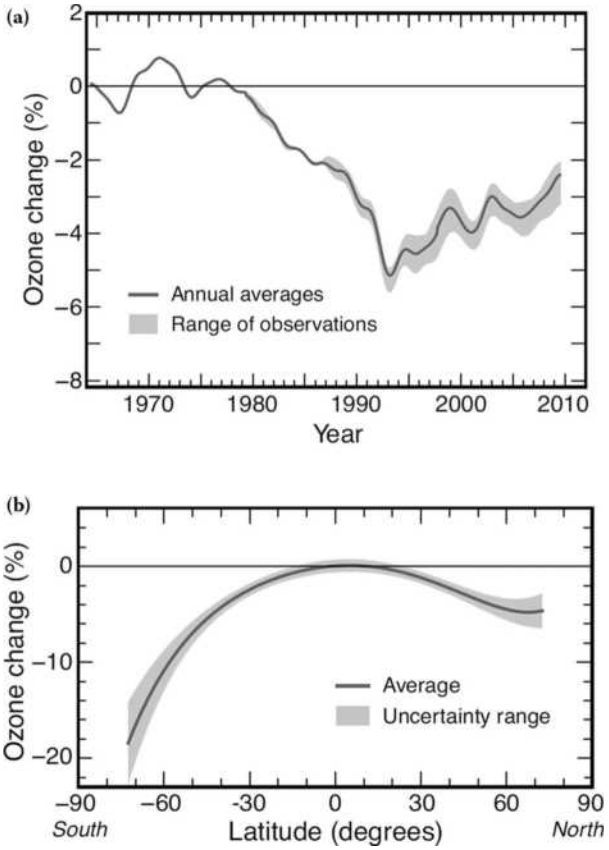

FIGURE 11 Global total ozone changes. Satellite observations show depletion of global total ozone beginning in the 1980s. Panel (a) compares annual averages of global ozone with the average from the period 1964 to 1980 before the ozone hole appeared. Seasonal and solar effects have been removed from the observational data set. On average, global ozone decreased each year between 1980 and 1990. The depletion worsened for a few years after 1991 following Mt. Pinatubo eruption. Panel (b) shows variation of the 2005–2009 depletion with latitude over the globe. The largest decreases have occurred at high latitudes in both hemispheres because of the large winter/spring depletion in polar regions; the losses are greater in the Southern Hemisphere because of the Antarctic ozone hole.

Source: Fahey and Hegglin.[11]

ozone loss could exacerbate biological risks from exposure to increased UV radiation, especially if the vortex shifted over densely populated mid-latitudes, as it did in April 2011.[46]

Ozone depletion is also observed at the mid-latitudes between equatorial and polar latitudes. Total ozone averaged for 2005–2009 is about 3.5% lower in northern mid-latitudes (35°N–60°N) and about 6% lower at southern mid-latitudes (35°S–60°S) compared with the 1964–1980 average (Figure 11b). Chemical destruction processes occurring at midlatitudes contributes to observed depletion in these regions, although it is much smaller than in the polar regions because the amounts of reactive halogen gases are lower and a seasonal increase of the most reactive halogen gases in Antarctic late winter does not occur in mid-latitude regions. Changes in mid-latitude ozone are also affected by changes occurring in the polar regions when the ozone-depleted air over both polar regions is dispersed away from the poles following the vortex breakdown, thus reducing average ozone concentrations at nonpolar latitudes.

Ozone Depletion and Biological Effects

Because ozone absorbs UV radiation from the sun, depletion of the stratospheric ozone layer is expected to lead to increases in the amount of solar UV radiation reaching the Earth's surface, predominantly in the wavelength range of 290 to 320 nanometers (UV-B radiation). UV-B radiation is also partially shielded by clouds, dust, and air pollutants. Large ozone losses in the Antarctica have produced a clear increase in surface UV radiation. Ground-based measurements show that the average spring erythemal (sunburning) irradiance for 1990–2006 is up to 85% greater than the modeled irradiance for 1963–1980, depending on site. The Antarctic spring erythemal irradiance is approximately twice that measured in the Arctic for the same season.

Analyses based on surface and satellite measurements show that erythemal UV irradiance over mid-latitudes has increased since the late 1970.[44] This is in qualitative agreement with the observed decrease in column ozone, although other factors (mainly clouds and aerosols) have influenced long-term changes in erythemal irradiance. Clear-sky UV observations from unpolluted sites in midlatitudes show that since the late 1990s, UV irradiance levels have been approximately constant, consistent with ozone column observations over this period.

The environmental and health effects of stratospheric ozone depletion have been summarized in several assessment reports.[47–49] UV-B radiation can induce acute skin damage in humans, such as sunburn, as well as eye diseases and infectious diseases.[50,51] Human epidemiological studies and animal experiments have established that UV-B radiation is a key risk factor for development of skin cancer, both melanoma and non-melanoma, especially in light-skinned population. Non-melanoma (squamous cell carcinoma and basal cell carcinoma) is the more common form of skin cancer and can be readily treated and is rarely fatal,[51] whereas melanoma is the most dangerous and the leading cause of death from skin cancer. Absorption of strong UV radiation damages the DNA molecule, eventually leading to faulty replication and mutation.[52] Numerous experiments have shown that the cornea and lens of the eye can also be damaged by UV-B radiation, and that chronic exposure to this radiation increased the likelihood of certain cataracts.[49] Studies in human subjects show that exposure to UV-B radiation can suppress proper functioning of the body's immune system. Animal experiments indicate that overexposure to UV-B radiation decreases the immune response to skin cancers and some infectious agents.[53,54]

Terrestrial plants can also be affected by UV-B radiation, although the response varies to a large extent among different species. In addition to plant growth, the changes induced by UV radiation can be indirect, for example, by affecting the timing of developmental phases or the allocation of biomass to the different parts of the plant.[55] Aquatic ecosystems can also be damaged by UV-B radiation; for example, there is evidence for impaired larval development and decreased reproductive capacity in some amphibians, shrimp, and fish.[56] There is also direct evidence of UV-B effects under the ozone hole on the productivity of natural phytoplankton communities in Antarctic waters.[57]

International Response: Montreal Protocol

Following the publication of the Molina–Rowland article,[7] the U.S. National Academy of Sciences issued two reports in 1976 stating that the atmospheric sequence outlined by Molina and Rowland was essentially correct.[22,23] The United States, Canada, Norway, and Sweden responded in late 1970s by banning the sale of aerosol spray cans containing CFCs; this caused a temporary halt in the growing demands for CFCs. However, worldwide use of the chemicals continued and the production rate began to rise again.

The discovery of the massive ozone losses in Antarctica in 1985 spurred a rush of scientific research activities, leading to improved understanding of stratospheric chemistry and the evolution of the ozone layer. These new scientific developments have provided the foundation for the critical policy decisions that followed.

In 1985, under the auspices of the United Nations Environment Programme (UNEP), 20 nations signed the Vienna Convention for the Protection of the Ozone Layer.[58] In September 1987, the recognition that CFC use was increasing and the mounting scientific evidence that this increase would cause large ozone depletions led to an international agreement limiting the production of CFCs.[58] This agreement, the Montreal Protocol on Substances that Deplete the Ozone Layer, initially called for a reduction of only 50% in the manufacture of CFCs by the end of the century. In view of the scientific evidence that emerged in the following years, the initial provisions were strengthened through the London (1990), Copenhagen (1992), Montreal (1997), and Beijing (1999) amendments as well as several adjustments by both controlling additional ODSs and by moving up the date by which already controlled substances must be phased out. At the 19th Meeting of the Parties to the Montreal Protocol in 2007, the Parties agreed to adjust their commitments related to the phase out of HCFCs.[58] Fig. 12 shows the projected abundance of ODSs in the stratosphere according to the provisions of the Montreal Protocol and subsequent amendments.[44]

The Montreal Protocol is now more than 20 years old and has been ratified by 196 countries, although not all the parties have ratified the subsequent amendments. It is widely regarded as one of the most effective multilateral environmental agreements in existence. The production of CFCs in industrialized countries was phased out at the end of 1995, and other compounds such as the halons, methyl bromide, carbon tetrachloride, and methyl chloroform (CH_3CCl_3) were also regulated. Developing countries were allowed to continue CFC production until 2010, to facilitate their transition to the newer CFC-free technologies. An important feature of the Montreal Protocol was the establishment of a funding mechanism to help these countries meet the costs of complying with the protocol and with its subsequent amendments.[58]

A significant fraction of the former CFC usage is being dealt with by conservation and recycling. Some of the former use of CFCs is being temporarily replaced by hydrochlorofluorocarbons (HCFCs)—compounds that have similar physical properties to the CFCs, but their molecules contain hydrogen atoms and are less stable in the atmosphere. A large fraction of the HCFCs released industrially reacts

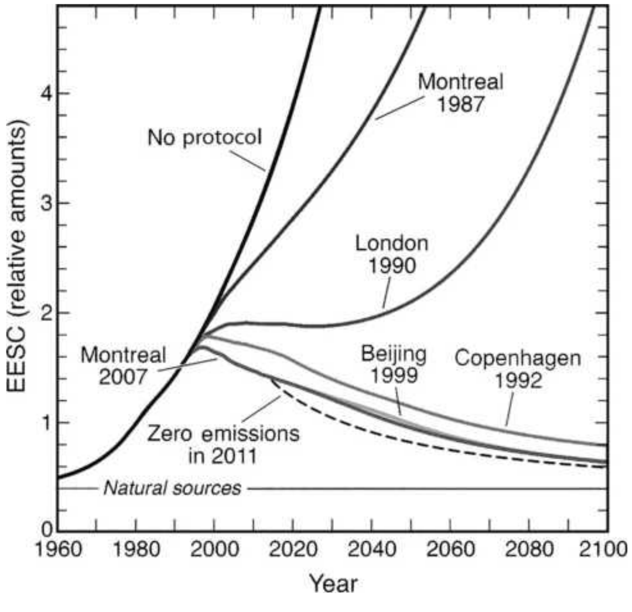

FIGURE 12 Measured and projected chlorine concentrations in the stratosphere according to the provisions of the Montreal Protocol and subsequent amendments. EESC is the equivalent effective stratospheric chlorine.
Source: Fahey and Hegglin.[11]

in the lower atmosphere with the OH radical before reaching the stratosphere, forming water and an organic free radical that rapidly photo-oxidizes to yield water-soluble products, which are then removed from the atmosphere mainly by rainfall. Although HCFCs are more ozone friendly than CFCs, they still destroy some ozone. They are now also regulated under the Montreal Protocol; the concentrations of HCFCs are projected to grow for another two decades before decreasing.

Some HFCs, which do not contain chlorine atoms, are now being used as CFC replacements; they are ozone friendly because fluorine forms stable compounds in the stratosphere. However, they have the potential to contribute to global warming. HFCs are now regulated under the Kyoto Protocol, an agreement under the United Nations Framework Convention on Climate Change.

About half of the CFC usage has been replaced by not-in-kind alternatives; for example, CFC-113—used extensively as a solvent to clean electronic components—has been phased out by CFC-free cleaning technologies such as soap and water or terpene-based solvents; there are also new technologies to manufacture clean electronic boards. Other examples include the use of stick or spray pump deodorants to replace CFC-12 aerosol deodorants and the use of mineral wool to replace CFC, HFC, or HCFC insulating foam.

Overall, the provisions of the Montreal Protocol have been successfully enforced. Atmospheric measurements indicate that the abundance of chlorine contained in the CFCs and other halocarbons has declined in response to the Montreal Protocol regulations.[44] On the other hand, because of the long lifetime of the CFCs in the atmosphere, relatively high chlorine levels in the stratosphere—with the consequent ozone depletion—are expected to continue well into the 21st century.

The total tropospheric abundance of chlorine from ODSs and methyl chloride had declined in 2008 to 3.4 parts per billion (ppb) from its peak of 3.7 ppb between 1992 and 1994. However, the rate of decline in total tropospheric chlorine was only two-thirds as fast as was expected because of the increase in the HCFC abundances. The rapid HCFC increases are coincident with increased production in the developing countries, particularly in East Asia. The rate of decline of total tropospheric bromine from controlled ODSs was close to that expected and was driven by changes in methyl bromide.[44]

By the middle of the 21st century, the amounts of halogens in the stratosphere are expected to be similar to those present in 1980 prior to the onset of the ozone hole. However, the influence of climate change could accelerate or delay ozone recovery.[44]

Stratospheric Ozone and Climate Change Linkage

Greenhouse Gases and Climate Change

The Earth absorbs energy from the Sun, and also radiates energy back into space. However, much of this energy going back to space is absorbed by greenhouse gases occurring naturally in the atmosphere, such as CO_2, CH_4, water vapor, N_2O, and ozone. Because the atmosphere then radiates most of this energy back to the Earth's surface, our planet is warmer than it would be if the atmosphere did not contain these gases. This is the natural "greenhouse effect," which maintains the surface of the Earth at a temperature that is suitable for life as we know it today. However, this natural greenhouse effect has intensified since the start of the industrial era as human activities emit more greenhouse gases to the atmosphere, including industrial compounds such as CFCs, HFCs, perfluorocarbons (PFCs), and sulfur hexafluoride (SF_6), resulting in a shift in the radiative balance of the Earth's atmosphere.

According to the Intergovernmental Panel on Climate Change, there is now visible and unequivocal evidence of climate change impacts, and there is a consensus that greenhouse gas emissions from human activities are the main drivers of change. The Earth's average temperature has been recorded to have increased by approximately 0.74°C over the past century.[1] Climate change is now recognized as a major global challenge that will have significant and long-lasting impacts on human well-being and development.[59]

One way of quantifying the contribution of greenhouse gases to climate change is through the standard metric known as radiative forcing, which is defined as positive if it results in a gain of energy for the Earth system (warming) and negative if it results in a loss (cooling).[1] The largest radiative forcing comes from CO_2, followed by CH_4, tropospheric ozone, halocarbons, and N_2O. All of these gases absorb infrared radiation emitted from the Earth's surface and re-emit it at a lower temperature, thus decreasing the outgoing radiation flux and producing a positive forcing, leading to warming. In contrast, stratospheric ozone depletion represents a small negative forcing, which leads to cooling of Earth's surface (Fig. 13); however, this contribution is expected to decrease as ODSs are gradually removed from the atmosphere.

Halocarbons and Climate Change

The understanding of the interaction between ozone depletion and climate change has been strengthened in recent years.[44,49] Stratospheric ozone and tropospheric ozone both absorb infrared radiation emitted by Earth's surface. Stratospheric ozone also significantly absorbs solar radiation. Therefore, changes in the stratospheric ozone and tropospheric ozone are directly linked to climate change. Stratospheric ozone and climate change are also indirectly linked because both ODSs and their replacements are greenhouse gases and represent an important contribution to the radiative forcing (see Fig. 13).

One approach of comparing the influence of individual halocarbons on ozone depletion and climate change is to use ozone depletion potentials (ODPs) and global warming potentials (GWPs). The ODP and GWP of a gas quantify its effectiveness in causing ozone depletion and climate forcing, respectively. GWP is defined as the total forcing attributed to a mass of emitted pollutant during a specified time after emissions (typically 100 years) as compared to the same mass of CO_2. ODP is the relative value that indicates the potential of a substance to destroy ozone as compared with the potential of CFC-11, which is assigned a reference value of 1.

Table 1 lists the atmospheric lifetime, global emissions, ODP, and GWP of some halogen source gases and the HFC replacement gases.[11,44] All ODSs and their substitutes shown here have a non-zero GWP,

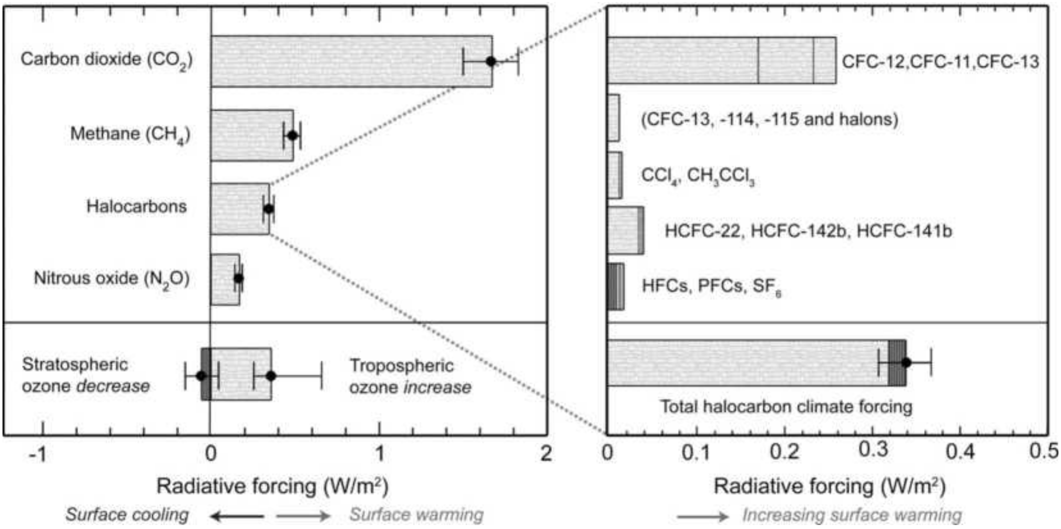

FIGURE 13 Radiative forcing of climate change. Left panel: radiative forcing of major greenhouse gases. Right panel: radiative forcing of halocarbons (darker shading designates Kyoto Protocol gases).

TABLE 1 Atmospheric Lifetimes, Global Emissions, ODPs, and GWPs of Some Halogen Source Gases and HFC-Substituted Gases

Gas	Atmospheric Lifetime	Global Emissions (2008) (kt/yr)[a]	ODP	GWPb
Halogen source gases				
Chlorine gases				
CFC-11	45	52–91	1	4,750
CFC-12	100	41–99	0.82	10,900
CFC-113	85	3–8	0.85	6130
Carbon tetrachloride (CClq)	26	40–80	0.82	1400
HCFCs	1–17	385–481	0.01–0.12	77–2220
Methyl chloroform (CH_3CCl_3)	5	<10	0.16	146
Methyl chloride (CH_3Cl)	1	3600–4600	0.02	13
Bromine gases				
Halon-1301	65	1–3	15.9	7140
Halon-1211	16	4–7	7.9	1890
Methyl bromide (CH_3Br)	0.8	110–150	0.66	5
Very short-lived gases (e.g., $CHBr_3$)	<0.5	c	Very low[c]	Very low[c]
HFCs				
HFC-134	13.4	149±27	0	1370
HFC-23	222	12	0	14,200
HFC-143^a	47.1	17	0	4180
HFC-125	28.2	22	0	3420
HFC-152^a	1.5	50	0	133
HFC-32	5.2	8.9	0	716

[a] Includes both human activities (production and banks) and natural sources. Units are in kilotons per year.
[b] One-hundred-year GWPs. Values are calculated for emissions of an equal mass of each gas.
[c] Estimates are very uncertain for most species.

with values spanning the wide range of 4 to 14,000; they are far more effective than equivalent amount of CO_2 in causing climate forcing. Therefore, the future selection of specific HFCs as replacement for ODS will have important consequences for climate change.

The CFCs, halons, and HCFCs are ODSs; they are controlled under the Montreal Protocol. Thus, the Montreal Protocol has provided collateral benefit of reducing the contributions of ODSs to climate change. In 2010, the decrease of annual ODS emissions under the Montreal Protocol is estimated to be about 10 gigatons of avoided CO_2-equivalent emissions per year, which is about 5 times larger than the annual emissions reduction target for the first commitment period (2008–2012) of the Kyoto Protocol.[44]

The HFCs, used as ODSs substitutes, do not destroy ozone (ODPs equal zero) and are considered ozone safe and have become the major replacement for CFCs and HCFCs. However, like the ODSs they replace, many HFCs have high GWP. HFCs, together with CO_2, CH_4, N_2O, PFCs, and SF_6, are controlled under the Kyoto Protocol. According to a new UNEP report, emissions of HFCs are growing at a rate of 8% per year due to growing demand in emerging economies and increasing populations. Without intervention, the increase in HFCs emissions is projected to offset much of the climate benefit achieved by the earlier reduction in ODS emissions. It is therefore important to select HFCs with low GWP potential and short lifetimes to minimize the climate impact while protecting the ozone layer.[60] This is one of the focal areas for the newly launched Climate and Clean Air Coalition on Short-lived Climate Pollutants.[61]

Impact of Climate Change on Ozone

The ODSs have declined as a result of the Montreal Protocol and its subsequent amendments; it is expected that this will lead to the recovery in the stratospheric ozone abundances. However, it is difficult to attribute ozone increases to the decreases in ODSs alone during the next few years because of natural variability, observational uncertainty, and confounding factors, such as changes in stratospheric temperature or water vapor. In contrast to the diminishing role of ODSs, changes in climate are expected to have an increasing influence on the recovery of ozone layer from the effects of ODSs.

Stratospheric ozone is influenced by changes in temperatures and winds in the stratosphere. For example, lower temperatures and stronger polar winds could both increase the extent and severity of winter polar ozone depletion. Observations show that the global-mean lower stratosphere has cooled by 1–2°C and the upper stratosphere cooled by 4–6°C between 1980 and 1995. There have been no significant long-term trends in global-mean lower stratospheric temperatures since about 1995. The two main reasons for the cooling of the stratosphere are depletion of stratospheric ozone and increase in atmospheric greenhouse gases. Ozone absorbs solar UV radiation, which heats the surrounding air in the stratosphere. Loss of ozone means that less UV light gets absorbed, resulting in cooling of the stratosphere. A significant portion of the observed stratospheric cooling is also due to human-emitted greenhouse gases. While the Earth's surface is expected to continue warming in response to the net positive radiative forcing from greenhouse gas increases, the stratosphere is expected to continue cooling.

A cooler stratosphere would extend the time period over which PSCs are present in winter and early spring, leading to increased polar ozone depletion. In the upper stratosphere at altitudes above PSC formation regions, a cooler stratosphere is expected to increase ozone amounts because lower temperatures decrease the effectiveness of ozone loss reactions.

Climate change may also affect the stratospheric circulation, which will significantly alter the distribution of ozone in the stratosphere. These changes tend to decrease total ozone in the tropics and increase total ozone at mid- and high latitudes. Changes in circulation induced by changes in ozone can also affect patterns of surface wind and rainfall. The projected changes in ozone and clouds may lead to large decreases in UV at high latitudes, where UV is already low, and to small increases at low latitudes, where it is already high. This could have important implications for human and ecosystem health. However, these projections depend strongly on changes in cloud cover, air pollutants, and aerosols, all of which are influenced by climate change. It is therefore important to improve our understanding of the processes involved and to continue monitoring ozone and surface UV spectral irradiances both from the surface and from satellites.[62]

Conclusions

The depletion of the stratospheric ozone layer exemplifies the global environmental challenges human face: it is an unintended consequence of human activity. Strong involvement and cooperation of stakeholders at all levels (scientists, technologists, economic and legal experts, environmentalists, and policy makers); strengthening of human and institutional capacities, coupled with suitable mechanisms for facilitating technological and financial flows; and changes in human behavior have been critical to the success in phasing out the ODSs.

The 1987 Montreal Protocol on Substances that Deplete the Ozone Layer is a landmark agreement that has successfully reduced the global production, consumption, and emissions of ODSs. By protecting the ozone layer from much higher levels of depletion, it has provided direct benefits to human health and agriculture, which in turn provide economic benefits by decreasing health costs and increasing crop production. Furthermore, because many ODSs are also potent greenhouse gases, the Montreal Protocol has provided substantial co-benefits to climate change.

On the other hand, demand for replacement substances such as HFCs has increased. Many of these substances are Kyoto gases. Additional climate benefits could be achieved by managing the emissions of replacement fluorocarbon gases and by implementing alternative gases with lower GWPs, as well as designing buildings that avoid the need for air conditioning.

Assuming full Montreal Protocol compliance, midlatitude ozone is expected to return to 1980 levels before mid-century. The recovery rate will be slower at high latitudes. Springtime ozone depletion is expected to continue to occur at polar latitudes, especially in Antarctica, in the next few decades. It is estimated that the ozone layer over the Antarctica will recover to pre-1980 levels between 2060 and 2075, and probably one or two decades earlier in the Arctic. However, effective control mechanisms for new chemicals threatening the ozone layer are essential; continued monitoring of the ozone layer is crucial to maintain momentum on recovering the ozone layer while simultaneously minimizing the influence on climate.

Changes in climate are expected to have an increasing influence on stratospheric ozone in the coming decades. An important scientific challenge is to project future ozone abundance based on an improved understanding of the complex linkages between stratospheric ozone and climate change.

Human activities will continue to change the composition of the atmosphere and new challenges that require international cooperation and collaboration will emerge. The ozone-hole phenomenon demonstrates the importance of long-term atmospheric monitoring and research, without which depletion of the ozone layer might not have been detected until more serious damage was evident. It is important for national and international agencies to continue their coordinated efforts on atmospheric monitoring, research, and assessment activities to provide sound scientific data needed to understand environmental changes on both regional and global scales.

Thermodynamics

Ronald L. Klaus

Introduction

Thermodynamics is concerned with the interaction between matter and energy on a macroscopic level. It is therefore the basic science that underlies the engineering of the use of energy in all its forms. It is governed by two basic laws with far-reaching implications. The first concerns the conservation of energy, and the second puts limits on the amount of energy that can be converted into work over and above what the first law might be thought to imply.

The actual performance of practical process equipment can be predicted by application of these two laws. That, in turn, depends on the ability to estimate the thermodynamic properties of the streams that enter and leave this equipment. The exact equations needed to calculate these properties can be derived from the formalism of thermodynamics. Certain simplifications, such as the ideal gas law or the assumption of an equation of state, are usually required to make numerical estimates of these properties.

First Law of Thermodynamics

Formulation

The first law of thermodynamics is a statement of the principle of conservation of energy for a closed system—namely, one in which there is no transfer of mass across the system boundaries.

$$\Delta U = Q - W_{\text{total}} \tag{1}$$

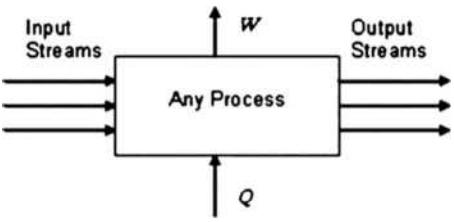

FIGURE 1 Schematic representation of any thermodynamic process.

This equation ignores certain effects such as differences in fluid velocities, which become important only at very high velocities, and differences in fluid elevations, which become important only when there are greatly varying elevations. U is a thermodynamic property called internal energy. It accounts for energy due to the motion of molecules in a fluid and the exchanges of energy between them. The Δs refer to differences in the property value between the final and initial states of the system. U, Q, and W all have units of energy. However, this equation can also have another interpretation for open flow systems at steady state. Such systems have input and outlet streams, and possibly an exchange of heat or work with the surroundings (Figure 1). However, the stream flows and property values throughout the system are all considered constant over time. In this case, the first law is a rate equation. ΔU is the difference between the sum of U times the mass flow rate for all the output streams minus that same sum for all the inlet streams. Q and W are rates of energy transfer. The arrows in Figure 1 indicate the direction of the flow of work, W, and heat, Q, when these quantities are positive.

When applying Eq. 1 to a flow process, W_{total} includes the work done in moving fluids into and out of the process. To eliminate these effects, another thermodynamic property, namely enthalpy, H, is defined,

$$H = U + PV \tag{2}$$

where P is pressure and V is volume.

For a flow process at steady state, this changes the first law to

$$\Delta H = Q - W \tag{3}$$

In Eq. 3, W is the work produced by the process apart from that involved in moving fluids into and out of the process. It is often called the shaft work.

In these equations, it is important to make a distinction between intrinsic and extrinsic properties. The former are properties per unit mass or per mole, whereas the latter are total values of the property for the mass flow of the given process stream. These and other thermodynamic relationships can be applied to either, provided that they are applied consistently.

U, H, P, and V are examples of thermodynamic state functions—that is, their intrinsic values depend only on the state of the fluid (usually its temperature, pressure, and composition) and not on the process used to bring the fluid to that state. On the other hand, quantities like Q and W are not state functions. When a fluid makes a transition from one state to another, the values of Q and W associated with that transition are dependent on the "path" over which that transition was made.

Enthalpies of Formation and Reaction

Enthalpy cannot be calculated in an absolute sense. It requires the definition of a reference state, at which it is taken to be zero. Enthalpies in all other states are referenced to this state. The most rigorous definition of a reference state is to take it as comprising the constituent atomic species in their normal molecular configurations at some temperature and pressure—typically 25°C and 1 atm. Normal molecular configuration means the normal configuration the atomic molecules take in nature, such as O_2, H_2, N_2, etc. Thus, these molecules would be taken to have zero enthalpy at 25°C and 1 atm. The phases of these elemental species also have to be stated. They are generally taken to be the normal phase of the element at the stated conditions. The reference states for gases are usually taken to be in their "ideal gas state" (ig). (The ideal gas state is difficult to describe briefly. It is a fluid with the same heat capacity as the real fluid's heat capacity at very low pressure. However, unlike the real fluid, it obeys the ideal gas law. For low-pressure calculations, the difference between the ideal gas state and the real fluid at low pressure is not important.)

With these ideas as a starting point, the enthalpies of compounds can be built up by considering real or imaginary reactions through which they are formed from their constituent elements. For example, the enthalpy of formation of methane would be the enthalpy change associated with the following reaction:

$$\mathrm{C(s)+2H_2(ig)=CH_4(ig)} \quad (25°\mathrm{C}, 1\ \mathrm{atm})$$

where s indicates solid and ig indicates the ideal gas state. Such chemical reactions are usually accompanied by the absorption or release of a certain amount of heat. If the reaction is carried out at constant temperature and pressure, and if no work is done, according to the first law, this heat is the enthalpy difference of the reaction and defines the standard enthalpy (or heat) of formation of the resulting compound.

Standard enthalpies of formation are widely tabulated. An excellent source is the collection by the National Institute of Standards and Technology (NIST).[1] Enthalpies of formation for some common species are given in Table 1. They are given both in the units that appear in the NIST collection and in nondimensionalized form. The latter permits their use in any system of units simply by multiplying by RT_0 in the desired units. To is taken to be 0°C (= 273.15°K=459.67°*R*), and *R* is the Universal Gas Constant. Note that °*R* represents degrees Rankine and °K represents degrees Kelvin.

Many different units are used in energy calculations. The values of some useful conversion factors and the values of the universal gas constant appear in Table 2.

These enthalpies of formation can be combined to produce enthalpy changes for any chemical reaction whose species have known enthalpies of formation. For example, in the combustion reaction

$$\mathrm{CH_4+2O_2=CO_2+2H_2O}$$

the enthalpy change may be calculated as follows:

$$\Delta H=\Delta H_\mathrm{f}(\mathrm{CO_2})+2\Delta H_\mathrm{f}(\mathrm{H_2O})-\Delta H_\mathrm{f}(\mathrm{CH_4})-2\Delta H_\mathrm{f}(\mathrm{O_2})$$
$$=(-393.51)+2(-285.830)-(-74.84)-0=-890.3\mathrm{kj/gmole}$$

TABLE 1 Enthalpies of Formation of Some Common Compounds

Chemical Specie	Formula	State	MW	ΔH_f (T=298.15°C)	ΔH_f (Non dim.)
Methane	CH_4	IG	16.04	−74.87	−32.968
Ethane	C_2H_6	IG	30.08	−83.8	−36.901
Propane	C_3H_8	IG	44.10	−104.7	−46.104
n-Octane	C_8H_{18}	IG	114.23	−208.4	−91.767
n-Octane	C_8H_{18}	L	114.23	−250.3	−110.217
Carbon dioxide	CO_2	IG	44.01	−393.51	−173.278
Carbon monoxide	CO	IG	28.01	−110.53	−48.671
Water	H_2O	IG	18.02	−241.826	−106.486
Water	H_2O	L	18.02	−285.830	−125.863

Note: Units of ΔH_f= kJ/gmole; Non-dimensionalization, $\Delta H_f/RT_0$ where T_0= 273.15°K.

TABLE 2 Some Useful Conversion Factors and Constants

Type	Value	Conversion
Length	1 m	3.28084 ft
		39.3701 in.
Mass	1 kg	2.20462 lbm
Force	1 N	1 kg m/s^2
		0.224809 lbf
Pressure	1 bar	10^5 N/m^2
		10^5 Pa
		0.986923 atm
		14.5038 psia
Pressure	1 atm	14.6960 psia
Volume	1 m^3	35.3147 ft^3
Density	1 g/cm^3	62.4278 lbm/ft^3
Energy	1 J	1 N m
		1 m^3 Pa
		10^{-5} m^3 bar
		10^{-3} kW s
		9.86923 cm^3 atm
		0.239006 cal
		5.12197×10^{-3} ft^3 psia
		0.737562 ft lbf
		9.47831×10^{-4} Btu
Power	1 kW	10^3 J/s
		239.006 cal/s
		737.562 ft lbf/s
		0.94783 Btu/s 1.34102 hp

Note: Values of the universal gas constant, R
8.314 J/gmole K = 8.314 m^3 Pa/(gmol K) = 83.14 cm^3 bar/(gmole K) 82.06 cm^3 atm/(gmole K)
1.987 cal/(gmole K) = 1.986 Btu/(lbmole R)
0.7302 ft^3 atm/(lbmole R) = 10.73 ft^3 psia/(lbmole R)
1545 ft lbf/(lbmole R)

If ΔH is positive, the reaction is called endothermic, whereas if it is negative, it is called exothermic. Because this particular reaction is a combustion reaction, the absolute value of its enthalpy change is also called the enthalpy change (or heat) of combustion.

Application to Combustion

The goal of a power cycle is to convert the chemical energy of a fuel into usable mechanical energy that can produce useful shaft work or drive a generator to produce electricity (Figure 2). What one hopes to do is to convert as much of the fuel's chemical energy into useful work. The hope for this ideal is reflected in what is called the heating value of the fuel. It is taken to be the negative of the enthalpy change of the combustion reaction through which a fuel is completely oxidized at the so-called ISO (International Organization for Standardization) conditions—namely, 15°C and 1 atm pressure. (ISO conditions for air also include a relative humidity of 60%.) Thus, it is the negative of the enthalpy change of the following kind of reaction:

$$\text{Fuel} + aO_2(\text{ig}) \rightarrow bCO_2(\text{ig}) + cH_2O(\text{ig or 1}) + \text{Any other products}(51°\text{C}, 1\text{ atm})$$

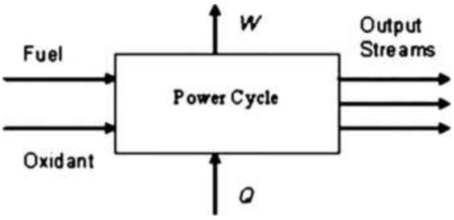

FIGURE 2 Schematic representation of a power cycle.

TABLE 3 Heating Values of Some Common Fuels

	HHV		LHV		LHV/
Fuel	Btu/lbm	Btu/gal	Btu/lbm	Btu/gal	HHV
No. 2 oil	19,580	142,031	18,421	133,623	0.9408
No. 4 oil	18,890	146,476	17,804	138,055	0.9425
No. 6 oil	18,270	150,808	17,312	142,901	0.9476
Diesel fuel	19,733		18,487		0.9368

where *a, b,* and *c* are coefficients that depend on the particular fuel.

It is unfortunate that ISO conditions differ from the reference state at which enthalpies of formation are usually tabulated. Nevertheless, the latter can be adjusted to ISO conditions, and values for some common fuels appear in Table 3.

Heating Values, Heat Rates, and Power Cycle Efficiency

One area of confusion about heating values comes because of the choice of the phase of the water produced as a combustion product. If the product water is considered to be a liquid, its enthalpy will be lower than that if it is considered to be a vapor. The former choice leads to a higher heating value (HHV), whereas the latter leads to a lower heating value (LHV). If the chemical composition of the fuel is known, the heating value is the mole fraction average of the heating values of the individual constituents divided by the average molecular weight of the fuel. Where the composition of the fuel is not known, accurate heating values are determined experimentally.

The heat rate is one often-tabulated measure that is used to describe the effectiveness of a machine—such as an internal combustion engine or a gas turbine—used to convert the chemical energy of a fuel into usable mechanical or electrical energy. Several definitions go into it.

$$\text{Heat Energy Input(Btu/s)}$$

$$= \text{First Law Available Chemical Energy}$$

$$= \text{Heating value of a Fuel } (\text{Btu/lb}) \times \text{Fuel flow rate } (\text{lb/s})$$

Heat Rate (Btu/kWh)

$$= \text{Heat Energy Input } (\text{Btu/s}) \times 3600 (\text{Btu/s}) / \text{Power Produced } (\text{kW})$$

The heat rate is based on a particular choice of either HHV or LHV of the fuel. The higher the heat rate, the more fuel is being used per kW of power produced and therefore the less efficient the machine. The heat rate is directly related to the efficiency.

$$\text{Efficiency} = \frac{\text{Power Output}(\text{kW}) \times 9.47831 \times 10^{-4}\,\text{Btu/J}}{\text{Heat Energy Input } (\text{Btu/s})}$$

Comparison with the previous equations yields Efficiency

$$\text{Efficiency} = \text{Conversion Factor } (\text{Btu/kWh}) / \text{ Heat Rate} (\text{Btu/kWh})$$

The conversion factor's role is strictly to convert the units. In the units shown it is equal to

$$\text{Conversion Factor} = 9.47831 \times 10^{-4}\,\text{Btu/J} \times 1000\text{J/kW} - \text{s} \times 3600\text{s/h} = 3412.19\text{Btu/kWh}$$

When the power-generating equipment is used to produce electricity, the efficiency is often called the electrical efficiency.

The efficiency calculated by the above equations is based on the hope of converting the entire heating value of the fuel into useful work. It is unfortunate that this has come to be the standard because there is a further limitation imposed by the second law of thermodynamics. It tells us that nature will not allow conversion of this much chemical energy into useful work, even if the power cycle were constructed as perfectly as possible under the most ideal conditions.

The Second Law of Thermodynamics

Reversibility

Before stating the second law specifically, it is necessary to introduce the concept of reversibility. Most processes produce changes in the substances on which they operate. Reversibility has to do with how easy it would be to undo the changes that are produced in a substance through some process. Specifically, reversibility means that a change that a process makes on a substance could theoretically be undone (reversed) with only an infinitesimal change in the conditions in the process.

For example, suppose that heat is exchanged by allowing heat to flow from a hotter substance to a cooler one. For this change to be reversible, temperatures at every point where heat transfer takes place must differ only infinitesimally. Thus, if we raised the temperature profile of the cooler substance by just an infinitesimal amount, the heat could be transferred back to the hotter substance.

As another example, suppose that a gas is compressed in a cylinder by moving a piston in such a way that it reduces its volume. For the change to be reversible, the pressure the piston exerts must be only differentially greater than the pressure of the gas. In this case, if the piston pressure were reduced only infinitesimally, the gas could be expanded back to its original state, and all the work of compression would be recovered. On the other hand, if a pressure were applied that differed substantially from that of the gas in the piston, the change brought about would be irreversible, because a differential change in the applied pressure could not reverse the effects of the compression.

Formulation

The second law of thermodynamics has a certain mystique to it because unlike most physical laws, it is not a conservation law (e.g., conservation of mass, energy, momentum, etc.). Instead, it puts certain limits on what nature allows in spite of the great conservation laws. It is also not as intuitive as the other great laws. Therefore, much has been written to try to explain it. However, it can be applied rigorously based on the following three-part formulation. This formulation refers to a given substance of constant mass that experiences changes from an initial to a final state through the possible exchange of heat and work with its surroundings.

Part 1: There is a thermodynamic state function, called entropy, S, which is defined by the following equation:

$$\mathrm{d}S = \frac{\mathrm{d}Q_{\mathrm{rev}}}{T} \tag{4}$$

where $\mathrm{d}S$ is the differential change in entropy and $\mathrm{d}Q_{\mathrm{rev}}$ refers to a differential amount of heat transferred to or from a substance in a reversible manner. That is, to calculate finite entropy differences, this equation needs to be integrated along a reversible path.

Stating that entropy is a state function is not a trivial claim. What it means is that no matter what reversible path is chosen, the net change in entropy will be the same, provided that the initial and final states are the same.

Part 2: No matter how a change of state is brought about in a given substance

$$\Delta S_{\mathrm{substance}} + \Delta S_{\mathrm{surrounding}} \geq 0 \tag{5}$$

The differences implied by the Δs are differences between the end state and the initial state of both the substance and surroundings. Notice that there is such a thing as a change in the entropy of the surroundings as well as the substance. It too can be calculated by Eq. 4.

Part 3: The inequality in the previous equation becomes an equality if, and only if, the process used to bring about the change is completely internally reversible and if the process also exchanges heat with the surroundings in a completely reversible manner.

Thus, this third part becomes a criterion of reversibility for a process or piece of equipment. Furthermore, the greater the inequality, the greater the irreversibility.

In general, the surroundings are considered to be at a constant ambient temperature, T_0. Thus,

$$\Delta S_{\mathrm{surroundings}} = \frac{Q_{\mathrm{surroundings}}}{T_0} = \frac{Q_{\mathrm{substance}}}{T_0} \tag{6}$$

where the two Qs are heat transfers to the surroundings and substance, respectively, which are the same in magnitude but opposite in sign. This equation can be combined with Eq. 5 to give

$$Q \leq T_0 \Delta S \tag{7}$$

Along with the first law for flow processes, this gives

$$W \leq T_0 \Delta S - \Delta H \tag{8}$$

In these equations, the subscripts have been dropped and all quantities refer to the substance, not the surroundings. Furthermore, although these equations were derived for changes in a substance of constant mass (closed system), as with the first law, they can also be applied to a steady flow system. In this case, the Δs refer to differences in the fluxes of the thermodynamic properties between the output and inlet streams.

The implications of these two equations are very significant. They mean that in a flow process, if the inlet and outlet conditions of the various streams are fixed, there are an upper bound to the amount of heat that can be transferred to the process and an upper bound on the amount of work it can produce. The latter claim has an impact on power generation systems because it imposes a limit on the amount of power that can be produced from a given amount of fuel, regardless of its energy content. Furthermore, because the entropy change of such processes is usually negative, another implication of Eq. 7 is that a certain amount of heat must be rejected to the surroundings regardless of how well the process is designed internally.

Carnot Engine

Some of the implications of the second law can be illustrated through the so-called Carnot engine. This is an imaginary reversible engine in which heat, Q_H, is transferred from a high-temperature source at T_H into a reversible engine, which produces work, W, and discards heat, Q_C, into a cold sink—possibly the environment—at T_C (Figure 3). From the first law,

$$W = Q_H - Q_C$$

From the second law,

$$\frac{Q_C}{T_C} - \frac{Q_H}{T_H} \geq 0$$

If the Carnot efficiency is defined as the amount of work that can be produced from the high-temperature heat (i.e., W/Q_H),

$$\frac{W}{Q_H} = \frac{Q_H - Q_C}{Q_H} = \frac{T_H - T_C}{T_H} \tag{9}$$

The last term on the right is of particular interest. It means that the Carnot efficiency depends on only the temperatures of the two heat reservoirs. All the heat in a high-temperature source can never be converted to work, even if the apparatus is perfectly reversible. The higher the temperature of the hot source relative to the cold sink, the higher the Carnot efficiency.

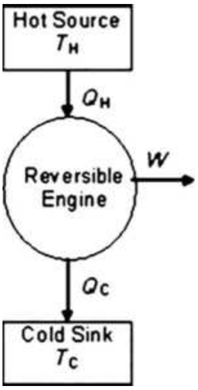

FIGURE 3 The Carnot engine.

Ideal Work, Lost Work

The second law gives a means to measure the irreversibility of a process or piece of equipment. That, in turn, is a measure of its departure from an ideal design—one which makes changes to substances in a way that most preserves their work-producing potential. This analysis begins by imagining a perfectly reversible process and defining W_{ideal} and Q_{ideal} to be the limiting values defined by Eqs. 7 and 8 (see Figure 4).

$$W_{\text{ideal}} = T_0\Delta S - \Delta H \tag{10}$$

$$Q_{\text{ideal}} = T_0\Delta S \tag{11}$$

These ideal values can be determined from the enthalpies and entropies of the various streams entering and leaving the process alone, without reference to any of the internal details of the process.

The level of irreversibility in a real process or in some part of it can be quantified through what is called lost work.[5] Because the actual work that can be obtained from any real process is always less than that what would have resulted from a completely reversible process, this leads to the following definition:

$$W_{\text{lost}} = W_{\text{ideal}} - W \tag{12}$$

By combining this with Eqs. 10 and 3, this becomes

$$W_{\text{lost}} = T_0\Delta S - Q \tag{13}$$

A real process—or any subprocess—can be represented as shown in Figure 5. The W_{lost} stream is not an actual work output. However, showing it in this manner is a reminder that in any real process a certain amount of the potential to do work has been lost due to the irreversibilities of the process. Furthermore, the lost work of all the subprocesses within the overall process sum up to the lost work of the process as a whole,

$$W_{\text{ideal}} = W + \sum W_{\text{lost}} \tag{14}$$

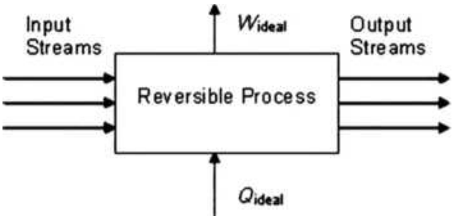

FIGURE 4 Schematic representation of a reversible thermodynamic process.

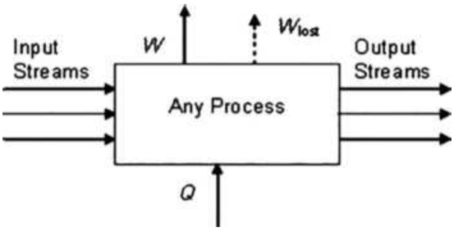

FIGURE 5 Schematic representation of any process showing lost work.

where the summation is carried out over each of the subprocesses. When analyzing a process, Eq. 13 can be applied to each piece of equipment. Then the W_{lost} for each of these can be summed according to Eq. 14. Such an analysis brings out where the greatest irreversibilities occur and therefore shows where the greatest opportunities are for improvement.

Exergy

Lost work is related to the modern concept of exergy. Lost work gives a quantitative measure of the irreversibility of a process or subprocesses within it. Furthermore, the term "lost work" seems quite descriptive. However, it is also possible to assign values—perhaps even monetary values—to streams as well as equipment. This can be done through the concept of exergy.

The exergy of a stream is the maximum amount of work that could theoretically be extracted from that stream if its temperature and pressure were reduced to that of the environment and if the concentrations of its chemical species were brought to that of the environment. It should be clear that from a power-production point of view, the economic value of a stream is related to its exergy because the production of work is usually more valuable than the production of heat alone.

Exergy analysis is based on the idea that it costs something in terms of equipment, power, adding costly streams, etc., to raise a stream's exergy—and hence its value. If what it costs to raise the value of a given stream is less than the increased value of the stream, it is a desirable thing to do.

Exergy is generally divided into four parts: physical, chemical, kinetic (having to do with the velocity of the fluid), and potential (having to do with its height above some datum level). The first two of these parts are of primary interest here. Physical exergy is the negative of the ideal amount of work that could be extracted from a stream if its temperature and pressure were reduced to ambient conditions. That is,

$$e^{\text{Ph}} = \Delta H - T_0 \Delta S \tag{15}$$

In Eq. 15 and the following equations, the Δs refer to differences between the present state of the fluid and its state at ambient conditions.

Chemical exergy, e^{Ch}, also has to be added because the exergy, say, of a fuel at ambient conditions ought to be higher than that of its eventual combustion products at those conditions because it has the potential of producing work in being transformed into its products. This can be accounted for in an equation similar to the one above, but this time involving properties of formation at ambient conditions.

$$e^{\text{Ch}} = \Delta H_{\text{f}} - T_0 \Delta S_{\text{f}} \tag{16}$$

Exergy is not quite a thermodynamic state function because it depends on environmental temperature. Also, unlike enthalpy or internal energy, it is not conserved in a process. Nevertheless, it is a useful measure of the power-producing value of a process stream. In any real processes, every process step results in a net loss of exergy.

The relationship between exergy and lost work is very straightforward—namely,

$$\text{Lost Work} = \sum \text{Exergies of incoming streams} - \sum \text{Exergies of outgoing streams} \tag{17}$$

where the summations are carried out over all incoming and outgoing streams, respectively.

Reversibility Revisited

The preceding analysis shows how the second law can be used to provide a measure of the irreversibility of a process or part of a process. Every irreversibility causes a loss in the potential to convert energy into work. In this era of diminishing supplies of cheap fuels and increasing demands for electric power, this is an important consideration. Furthermore, irreversibilities in one part of a process reduce the amount of work that can be produced—or else increase the amount of work that is needed—in the rest of the process, even though the source of the irreversibility may be far removed from the place in the process where work is produced or consumed.

The following is a list of some process steps that introduce irreversibility into processes, including power cycles:

- Heat transfer across a nonzero temperature difference
- Mixing of fluids of differing pressures, temperatures, or compositions
- Pressure drops that do not recover work
- Chemical reactions that do not take place at equilibrium conditions
- Flashing of liquids when pressure is reduced
- Two-phase contact and mass transfer between fluids whose various species have concentrations that differ from their equilibrium values
- Temperature and pressure shocks when fluids enter equipment at different temperatures or pressures from those that are present within the equipment

The most thermodynamically efficient designs—those that most preserve the work-producing potential of the fluids in the process—are those that strive for the greatest reversibilities in the various pieces of process equipment. However, there is another side to this question. The more reversible a piece of equipment is, the greater its capital cost is apt to be. Thus, in the practical design of equipment there is often a trade-off between reversibility and capital cost. Processes need to be evaluated not only for their thermodynamic efficiency, but also for their thermoeconomic effectiveness.

Calculation of Thermodynamic Properties

Rigorous Equations

Process equipment cannot be designed or evaluated apart from the ability to estimate the thermodynamic properties of the entering and exiting streams. The following are rigorous equations for the calculation of some of the important thermodynamic properties of pure or constant-composition substances (The equations can be found in many thermodynamics text books. A concise useful summary is found in Van Ness and Abott.)[6]:

$$dH = C_p dT + \left[V - T\left(\frac{\partial V}{\partial T_p} \right) \right] dP \tag{18}$$

$$dS = \left(\frac{C_P}{T} \right) dT - \left(\frac{\partial V}{\partial T} \right)_P dP \tag{19}$$

$$G = H - TS \tag{20}$$

C_p is the heat capacity at constant pressure, defined by

$$C_P = \left(\frac{\partial H}{\partial T} \right)_P \tag{21}$$

G is called the Gibbs free energy or Gibbs function and has importance in equilibrium calculations. Eq. 20 can be considered its definition. By differentiation and comparison with the other two, it can be shown that

$$dG = VdP - SdT \tag{22}$$

These are differential equations that emphasize that these properties need reference values from which differences can be calculated. To obtain values for the property differences for real substances, the pressure–volume–temperature (PVT) behavior of the fluid needs to be inserted into the equations, which would then be integrated to produce the final results.

Ideal Gas

One way of inserting PVT behavior is through equations of state. One of the simplest models for gases is that of the ideal gas, whose equation of state on a molar basis is

$$\mathrm{PV} = \mathrm{RT} \tag{23}$$

This equation reflects the fact that the molecules in the gas do not interact in any way, although they may have very complex energy interactions within a given molecule.

When this equation is inserted into the rigorous equations, one obtains

$$\mathrm{d}H^* = C_p^* \mathrm{d}T \tag{24}$$

$$\mathrm{d}S^* = \left(\frac{C_p^*}{T}\right)\mathrm{d}T + \left(\frac{R}{P}\right)\mathrm{d}P \tag{25}$$

$$\mathrm{d}G^* = RT\mathrm{d}\,\mathrm{In}\,P - S^*\mathrm{d}T \tag{26}$$

where the asterisk designates the properties as those of an ideal gas.

The integrated forms of Eqs. 24 and 25 are

$$\Delta H^*(P2,T2;P1,T1) = \int_{T1}^{T2} C_p^* \mathrm{d}T \tag{27}$$

$$\Delta S^*(P2,T2;P1,T1) = \int_{T1}^{T2} \left(\frac{C_p^*}{T}\right)\mathrm{d}T + R\ \mathrm{In}\left(\frac{P2}{P1}\right) \tag{28}$$

The heat capacity has been left behind the integral sign because even for most ideal gases, it varies with temperature. However, neither ideal gas heat capacities nor enthalpies vary with pressure, but ideal gas entropies do. Ideal gas heat capacity data is often presented in the form of an analytical equation. One common form used by NIST[7] is

$$C_p^* = A + BT + CT^2 + DT^2 + DT^3 + \frac{E}{T^2} \tag{29}$$

NIST tabulates the constants (*A*, *B*, etc.), for many compounds.

Real Fluids

Real fluids may be represented by the following general equation of state:

$$\mathrm{V} = \mathrm{Z}(\mathrm{P},\mathrm{T})\mathrm{RT}/\mathrm{P} \tag{30}$$

where *Z* is the compressibility factor, which can be a function of both *P* and *T*. It is common to report PVT data in the form of the compressibility factor. For an ideal gas, *Z*=1. Thus, the compressibility factor is a measure of the deviation from ideal gas behavior.

When Eq. 30 is substituted in Eqs. 18 and 19, one obtains

$$\mathrm{d}H = C_{\mathrm{P}}\mathrm{d}T - \left[\frac{RT^2}{P}\left(\frac{\partial Z}{\partial T}\right)_{\mathrm{P}}\right]\mathrm{d}P \tag{31}$$

$$\mathrm{dS} = \left(\frac{C_{\mathrm{P}}}{T}\right)\mathrm{d}T - R\left(Z + T\frac{\partial Z}{\partial T}\right)\frac{\mathrm{d}P}{P} \tag{32}$$

One consequence of these equations is that thermodynamic properties of real fluids can be calculated from their ideal gas–heat capacity (as a function of temperature) and their PVT behavior. This follows from the fact that to get from one state to another, these equations can first be integrated to zero pressure (which requires only PVT data), then integrated at zero pressure to the final temperature (which requires only ideal gas heat capacity data), and then integrated back to the end-point pressure.

Several approaches have been used to apply these equations for practical calculations. A first approach is to take known ideal gas-heat capacity and PVT data, and use them directly in these equations. Such data are not often available, and even when they are, this is a tedious process. Nevertheless, it has been done for a number of well-studied chemical species, most notably water. This is the basis of the steam tables, which have been put into analytical form for easy computer calculations.[8]

A second approach is through generalized correlations. An early attempt to describe the PVT behavior of many fluids was begun by Pitzer[9] through the use of his so- called acentric factor. His correlations have been extended so that they can be used to predict the more important thermodynamic properties of real no-polar fluids in both vapor and liquid phases.[10]

A third approach is to insert an equation of state into Eqs. 31 and 32 so that they may be integrated analytically. One excellent equation of state for low-density gases is the virial equation

$$Z = 1 + \frac{B(T)}{V} + \frac{C(T)}{V^2} + \frac{D(T)}{V^3} + \cdots \tag{33}$$

where B, C, D, etc., are functions of temperature only and are called the second, third, fourth, etc., virial coefficients. There is a great deal of data for the second virial coefficients.[11] Where data are not available, correlations have been developed to estimate them.[12,13] Third virial coefficients are usually not available, but prediction methods have been proposed.[14] Very little information is available for higher-order coefficients. Other equations of state have also enjoyed success in predicting properties of real fluids, both in the vapor and liquid phases. Among the more successful are the Soave–Redlich–Kwong[15] and Peng–Robinson[16] equations.

Solutions

The properties of solutions—whether they are gas or liquid mixtures—are not merely the mole fraction averages of the properties of the pure components. For any thermodynamic property, M, the exact equation for the properties of mixtures is

$$(P,T,\bar{x}) = \sum_i x_i \overline{M_i}(P,T,\bar{x}) \tag{34}$$

where $\overline{M}_i$ is called the "partial molal property of i" and $\bar{x}$ is a vector containing all of the compositions of the various constituents of the solution. The summation is carried out over all constituents. $\overline{M_i}$ is the property of constituent i at pressure, P, and temperature, T, as it exists in solution of composition $\bar{x}$. In general, this is different from its value as a pure substance.

The most general equation through which partial molal properties may be evaluated is

$$\overline{M_i} = \left(\frac{\partial (nM)}{\partial_{ni}} \right)_{P,T,\mathrm{nj}} \tag{35}$$

where n is the total number of moles and n_i is the number of moles of specie "i".

The partial derivative implies that the extensive property, *nM*, is differentiated with respect to the particular specie of interest, *i*, with pressure, temperature, and all of the other constituent amounts held constant. If properties of the various possible mixtures are known or can be approximated analytically, this equation provides a means to calculate their partial molal properties.

An important approximation for solutions is that of so- called "ideal solutions," whose properties are calculated as follows,

$$V^{\mathrm{id}} = \sum_i x^i V^i \tag{36}$$

$$H^{\mathrm{id}} = \sum_i x_i H_i \tag{37}$$

$$S^{\mathrm{id}} = \sum_i x_i S_i - R \sum_i x_i \operatorname{In} x_i \tag{38}$$

$$G^{\mathrm{id}} = \sum_i x_i G_i + RT \sum_i x_i \operatorname{In} x_i \tag{39}$$

where the superscript, "id," designates these as the properties for ideal solutions. All ideal gases are ideal solutions. The ideal-solution approximation is useful in some situations, but most liquids depart from it significantly. Notice also that properties involving entropy have a mixing effect (second terms on the right side of Eqs. 38 and 39) even if they are ideal solutions. This reflects the fact that the entropy of a solution is always higher than the combined entropies of its constituents.

The true properties of solutions can be calculated from their PVT behavior. For humid air, for example, the mixing effect is often neglected. However, one recent study done by M. Conde Company[17] includes virial coefficient information, including information for mixtures, sufficient to produce very accurate psychrometric properties of air-water mixtures.

Phase Equilibrium

Phase equilibrium can also be predicted from thermodynamic properties. The way this is done goes beyond the scope of this entry. However, several ideas can be stated here. One aspect of phase equilibria—namely pure-component vapor pressures—has been widely measured and can be used as a starting point for multicomponent phase equilibrium estimates. Vapor pressure data is often correlated by the Antoine equation,

$$\log_{10}\left(P^V\right) = A - \left(\frac{B}{T+C} \right) \tag{40}$$

where *A*, *B*, and *C* are constants. Such constants for many compounds also appear in the NIST collection.[18]

One calculations is the two-phase equilibrium between (1) pure special case of interest in energy liquid water and (2) a vapor phase one of whose components is water vapor. If the vapor phase is considered to be an ideal gas (and thus an ideal mixture), and if certain other assumptions are made, the composition of water in the vapor phase can be estimated by

$$yH_2O = \frac{P^V}{P} \tag{41}$$

where the vapor pressure can be calculated from the Antoine equation. This is a useful approximation that can be refined if PVT data for the vapor mixture are available.

Conclusions

This entry attempts to give an introduction to some of the basic principles of thermodynamics and how they relate to various energy engineering applications. The two main laws of thermodynamics govern the performance of any energy-conversion process. Their application requires the ability to estimate the thermodynamic properties of the various process streams. Such estimates are also based on the formalism that thermodynamics provides. Thus, thermodynamics provides the basic framework within which the design and evaluation of all energy-conversion equipment and processes must be performed.

Support for this work by VAST Power Systems, Elkhart, Indiana, is gratefully acknowledged.

Nomenclature

All thermodynamic properties have the units of energy or energy per unit time except where otherwise specified.

C_p	Heat capacity at constant pressure (energy/temperature)
e^{Ch}	Chemical exergy
e^{Ph}	Physical exergy
G	Gibbs free energy, or Gibbs function
H	Enthalpy
M	General thermodynamic property
M_i	Partial molal property of specie "i"
n	total number of moles
n_i	number of moles of specie "i"
P	Pressure (force/area)
P^V	Vapor pressure (force/area)
Q	Heat or heat flux added to a process (energy or energy per unit time)
Q_{ideal}	Heat or heat flux added to a completely reversible process (energy or energy per unit time)
R	Universal gas constant (energy/temperature)
S	Entropy (energy/temperature)
T	Temperature
T_0	Reference temperature or temperature of the surroundings
U	Internal energy
V	Volume (length^3)
W	Work or power produced by a process. Usually does not include work done by or on fluids entering or leaving the process (energy or energy per unit time)
W_{ideal}	Work or power produced by a perfectly reversible process (energy or energy per unit time)
W_{lost}	Lost work or power (energy or energy per unit time)
W_{total}	Total work or power produced by the process (energy or energy per unit time)
X_i	mole fraction of specie "i"
x	vector containing all mole fractions

yH_2O	Mole fraction of water vapor in a vapor phase
Z	Compressibility factor
Δ	Difference in the value between two states or differences between the properties of outlet and input streams
ΔH_f	Enthalpy of formation
ΔS_f	Entropy of formation (energy/temperature)

Subscripts

f	Formation
o	Base or reference state
C	Cold sink
H	Hot source
rev	Reversible

Superscripts

*	Ideal gas or ideal gas state
id	Ideal solution

Energy Conversion: Coal, Animal Waste, and Biomass Fuel

Kalyan Annamalai,
Soyuz Priyadarsan,
Senthil Arumugam,
and John M.
Sweeten

Introduction and Objectives

The overall objective of this entry is to provide the basics of energy conversion processes and to present thermochemical data for coal and biomass fuels. Energy represents the capacity for doing work. It can be converted from one form to another as long as the total energy remains the same. Common fuels like natural gas, gasoline, and coal possess energy as chemical energy (or bond energy) between atoms in molecules. In a reaction of the carbon and hydrogen in the fuel with oxygen, called an oxidation reaction (or more commonly called combustion), carbon dioxide (CO_2) and water (H_2O) are produced, releasing energy as heat measured in units of kJ or Btu (see Table 1 for energy units). Combustion processes are used to deliver (i) work, using external combustion (EC) systems by generating hot gases and producing steam to drive electric generators as in coal fired power plans, or internal combustion (IC) engines by using the hot gases directly as in automobiles or gas turbines; and (ii) thermal energy, for applications to manufacturing processes in metallurgical and chemical industries or agricultural product processing.

TABLE 1 Energy Units and Terminology

The section on energy Units and Conversion factors in Energy is condensed from Chapter 01 of Combustion Engineering by Annamalai and Puri [2005] and Tables.

Energy Units

1 Btu (British thermal unit) = 778.14 ft lbf = 1.0551 kJ, 1 kJ = 0.94782 Btu = 25,037 $lbmft/s^2$

1 mBtu = 1k Btu = 1000 Btu, 1 mmBtu = 1000 k Btu = 106 Btu, 1 trillion Btu = 109 Btu or 1 giga Btu

1 quad = 1015 Btu or 1.05 × 1015 kJ or 2.93 × 10n kW h

1 Peta J = 1015 J = 1012 kJ»0.00095 Quads

1 kilowatt-hour of electricity = 3,412 BTU = 3.6 Mj

1 cal: 4.1868 J, One (food) calorie = 1000 cal or 1 Cal

1 kJ/kg = 0.43 Btu/lb, 1 Btu/lb = 2.326 kJ/kg

1 kg/GJ = 1 g/MJ = 2.326 lb/mmBtu; 1 lb/mmBtu = 0.430 kg/GJ = 0.430 g/MJ

1 Btu/SCF = 37 kJ/m^3

1 Therm = 105 Btu = 1.055 × 105 kJ

1 m^3/GJ = 37.2596 ft^3/mmBTU

1 hp = 0.7064 Btu/s = 0.7457 kW = 745.7 W = 550 lbf ft/s = 42.41 Btu/min

1 boiler HP = 33475 Btu/h, 1 Btu/h = 1.0551 kJ/h

1 barrel (42 gal) of crude oil = 5,800,000 Btu = 6120 MJ

1 gal of gasoline = 124,000 Btu = 131 MJ

1 gal of heating oil = 139,000 Btu = 146.7 MJ, 1 gal of diesel fuel = 139,000 Btu = 146.7 MJ

1 barrel of residual fuel oil = 6,287,000 Btu = 6633 MJ

1 cubic foot of natural gas = 1,026 Btu = 1.082 MJ, 1 Ton of Trash = 150 kWh

1 gal of propane = 91,000 Btu = 96 MJ, 1 short ton of coal = 20,681,000 Btu = 21821 MJ

Emission reporting for pollutants: (i) parts per million (ppm), (ii) normalized ppm, (iii) emission Index (EI) in g/kg fuel, (iv) g/GJ, v) mg/ m^3 of flue gas:

Conversions in emissions reporting: (ii) normalized ppm = ppm × (21-O_2% std)/(21-O_2% measured); (iii) EI of species k: C % by mass in fuel × mol Wt of k × ppm of species k × 10–3/{12.01(CO_2% + CO%)}, (iv) g/GJ = EI/ {HHV in GJ/kg}; (v) mg/m^3 = ppm of species k × Mol Wt of k/24.5

Volume of 1 kmol (SI) and 1 lb mole (English) of an ideal gas at STP conditions defined below: Pressure at 101.3 kPa (1 atm, 14.7 psia, 29.92 in.Hg, 760 Torr) fixed; T changes depending upon type of standard adopted

Scientific (or SATP, standard ambient T and P)	US standard (1976) or ISA (International standard atmosphere)	NTP (gas industry reference	Chemists-standard-atmosphere (CSA)
25°C (77°F)	15°C (60°F)	20°C(68°F), 101.3 kPa	0°C (32°F),
24.5 m^3/kmol (392 ft^3/lb mole); $\rho_{air,SATP} = 1.188$ kg/m^3 = 0.0698 lbm/ft^3	23.7 m^3/kmol (375.6 ft^3/lb mole); $\rho_{air,ISA} = 1.229$ kg/m^3 = 0.0767 lbm/ft^3	24.06 m^3/kmole or 385 ft^3/lb mole; $\rho_{air,NTP} = 1.208$ kg/m^3 = 0.0754 lbm/ft^3	22.4 m^3/kmol (359.2 ft^3/lb mole), $\rho_{air,CSA} = 1.297$ kg/m^3 = 0.0810 lbm/ft^3

Fuels can be naturally occurring (e.g., fossil fuels such as coal, oil, and gas, which are residues of ancient plant or animal deposits) or synthesized (e.g., synthetic fuels). Fuels are classified according to the phase or state in which they exist: as gaseous (e.g., natural gas), liquid (e.g., gasoline or ethanol), or solid (e.g., coal, wood, or plant residues). Gaseous fuels are used mainly in residential applications (such as water heaters, home heating, or kitchen ranges), in industrial furnaces, and in boilers. Liquid fuels are used in gas turbines, automotive engines, and oil burners. Solid fuels are used mainly in boilers and steelmaking furnaces.

During combustion of fossil fuels, nitrogen or sulfur in the fuel is released as NO, NO_2 (termed generally as NO_x) and SO_2 or SO_3 (termed as SO_x). They lead to acid rain (when SO_x or NO_x combine with H_2O and fall as rain) and ozone depletion. In addition, greenhouse gas emissions (CO_2, CH_4, N_2O,

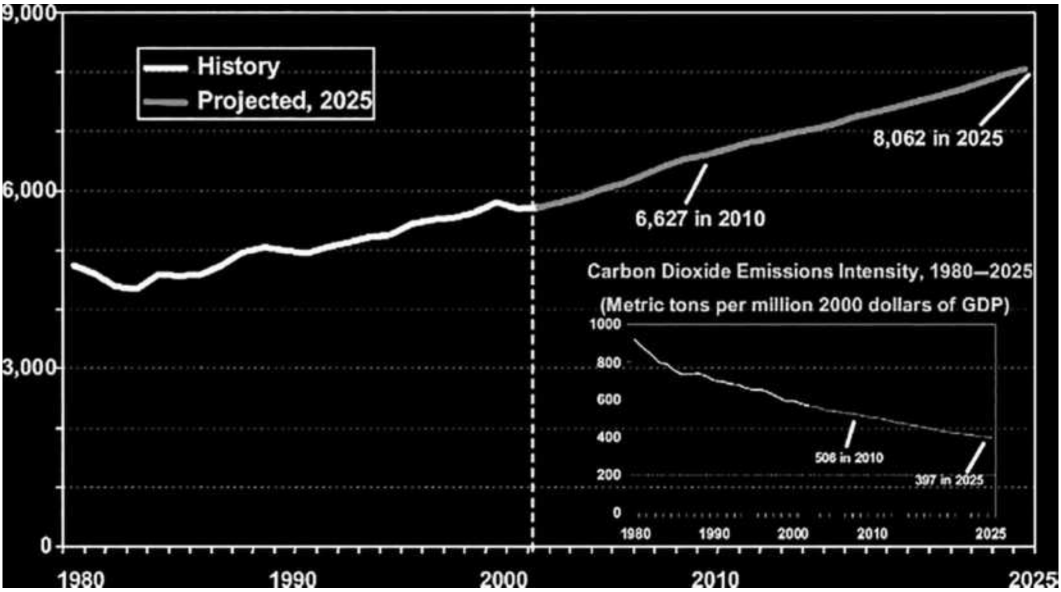

FIGURE 1 Total CO_2 emission in million metric tons per year: History and Projected 1980–2025.
Source: DOE-EIA.[1]

CFCs, SF_6, etc.,) are becoming a global concern due to warming of the atmosphere, as shown in Figure 1 for CO_2 emissions. Global surface temperature has increased by 0.6°C over the past 100 years. About 30%–40% of the world's CO_2 is from fossil fuels. The Kyoto protocol, signed by countries that account for 54% of the world's fossil based CO_2 emissions, calls for reduction of greenhouse gases by 5% from 1990 levels over the period from 2008 to 2012.

The total worldwide energy consumption is 421.5 quads of energy in 2003 and is projected to be 600 quads in 2020, while U.S. consumption in 2004 is about 100 quads and is projected to be 126 quads in 2020. The split is as follows: 40 quads for petroleum, 23 for natural gas, 23 for coal, 8 for nuclear power, and 6 for renewables (where energy is renewed or replaced using natural processes) and others sources. Currently, the United States relies on fossil fuels for 85% of its energy needs. Soon, the U.S. energy consumption rate which distributed as electrical power (40%), transportation (30%), and heat (30%), will outpace the growth in the energy production rate, increasing reliance on imported oil. The Hubbert peak theory (named after Marion King Hubbert, a geophysicist with Shell Research Lab in Houston, Texas) is based upon the rate of extraction and depletion of conventional fossil fuels, and predicts that fossil-based oil would peak at about 12.5 billion barrels per year worldwide some time around 2000. The power cost and percentage use of coal in various U.S. states varies from 10 cents (price per kWh) at 1% coal use for power generation in California to 48 cents at 94% use of coal in Utah.

Biomass is defined as "any organic material from living organisms that contains stored sunlight (solar energy) in the form of chemical energy."[1] These include agro-based materials (vegetation, trees, and plants); industrial wastes (sawdust, wood chips, and crop residues); municipal solid wastes (MSWs), which contain more than 70% biomass (including landfill gases, containing almost 50% CH_4); and animal waste. Biomass is a solid fuel in which hydrogen is locked with carbon atoms. Biomass production worldwide is 145 billion metric tons. Biomass now supplies 3% of U.S. energy, and it could be increased to as high as 20%. Renewable energy sources (RES) include biomass, wind, hydro, solar, flowing water or hydropower, anaerobic digestion, ocean thermal (20°C temperature difference), tidal energies, and geothermal (a nonsolar source of energy), and these supply 14% of the world demand. The RES constitute only 6%, while coal, petroleum, and natural gas account for 23%, 40%, and 24%, respectively. About 9%

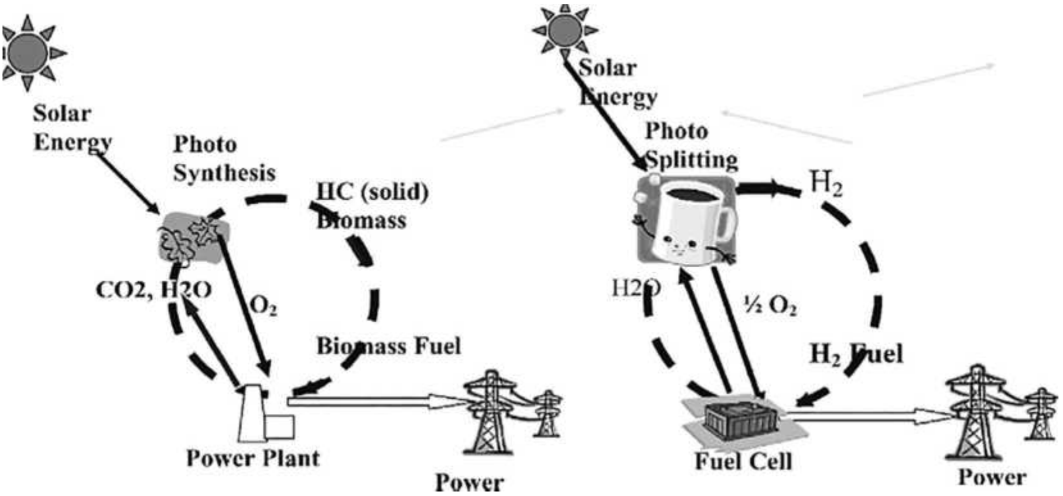

FIGURE 2 Comparison of biomass energy and H_2 energy cycles.

of the world's electricity is from RES, and 65% of the electricity contributed by biomass. About 97% of energy conversion from biomass is by combustion. Many U.S. states have encouraged the use of renewables by offering REC (Renewable Energy Credits). One REC = 1 MW/h = 3.412 mmBtu; hence the use of 1 REC is equivalent to replacing approximately 1500 lb of coal, reducing emission of NO_x and SO_x by 1.5 lb for every 1 REC, assuming that emissions of NO_x and SO_x are 0.45 lb per mmBtu generated by coal. Several emission-reporting methods and conversions are summarized in Table 1. Recently, H_2 is being promoted as a clean-burning, non-global-warming, and pollution-free fuel for both power generation and transportation.

Figure 2 shows a comparison between biomass and hydrogen energy cycles. In the biomass cycle, photosynthesis is used to split CO_2 into C and O_2, and H_2O into H_2 and O_2, producing Hydrocarbons (HC) fuel (e.g., leaves) and releasing O_2. The O_2 released is used to combust the HC and produce CO_2 and H_2O, which are returned to produce plant biomass (e.g., leaves) and O_2. On the other hand, in the hydrogen cycle, H_2O is disassociated using the photosplitting process to produce H_2 and O_2, which are then used for the combustion process. The hydrogen fuel can be used in fuel cells to obtain an efficient conversion. Photosynthesis is water intensive; most of the water supplied to plants evaporates through leaves into the atmosphere, where it re-enters the hydrology cycle.

This entry is organized in the following format: (i) coal and biosolid properties; (ii) coal and biosolid pyrolysis (a process of thermal decomposition in the absence of oxygen), combustion, and gasification; (iii) combustion by cofiring coal with biosolids; (iv) gasification of coal and biosolids (a process that includes pyrolysis, partial oxidation due to the presence of oxygen, and hydrogenation); and (v) reburn for NO_x reduction.

Fuel Properties

Fuel properties play a major role in the selection, design, and operation of energy conversion systems.

Solid Fuels

The primary solid fuel widely used in power plants is coal containing combustibles, moisture, and intrinsic mineral matter originating from dissolved salts in water. During the "coalification" process, lignite, the lowest rank of coal (low C/O ratio), is produced first from peat, followed by subbituminous (black lignite, typically low sulfur, noncaking), bituminous (soft coal that tends to stick when heated and is typically high in S), and finally anthracite (dense coal; has the highest carbon content, >90%, low volatile <15%) with a gradual increase in the coal C/O ratio. The older the coal, the higher its rank. Anthracite (almost carbon) is the highest-ranked coal, with a high heating value. To classify coals and ascertain the quality of coal, it is essential to perform proximate and ultimate analyses according to American Society of Testing Materials (ASTM) standards.

Proximate Analysis (ASTM D3172)

A solid fuel consists of combustibles, ash, and moisture. Combustibles together with ash are called the solid content of fuel. A proximate analysis provides the following information: surface moisture (SM) or dry loss (DL), i.e., moisture in air-dried coal; the inherent moisture in the coal (M); volatile matter (VM; produced by pyrolysis, a thermal decomposition process resulting in release of water, gases, oil and tar); fixed carbon (FC; skeletal matter left after release of volatiles); mineral matter (MM; inert collected with solid fuel); and heating value (HV). On combustion, the MM may be partially oxidized or reduced, and the material left after combustion of C and H in the fuel is called ash (CaO, $CaCO_3$, Fe_2O_3, FeO, etc.).

Table 2 shows comparative proximate analyses of coal, advanced feedlot biomass (FB, low-ash cattle manure; see "Coal and Bio-Solids Cofiring"), and litter biomass (LB, chicken manure).[2] Feedlot manure has higher moisture, nitrogen, chlorine, and ash content than coal. With aging or composting, the VM in manure decreases as a result of the gradual release of hydrocarbon gases or dehydrogenation, but fuel becomes more homogeneous.

Ultimate/Elemental Analysis (ASTM D3176)

Ultimate analysis is used to determine the chemical composition of fuels in terms of either the mass percent of their various elements or the number of atoms of each element. The elements of interest are C, H, N, O, S, Cl, P, and others. It can be expressed on an "as received" basis, on a dry basis (with the moisture in the solid fuel removed), or on a dry ash free (DAF) basis (also known as the moisture ash free basis MAF). Tables 3 and 4 show the ultimate analyses of various types of coal and biomass fuels.[3] While nitrogen is not normally present in natural gas, coal has 1%–1.5%; cattle manure and chicken waste contain high amounts of N (Table 2).

Heating Value (ASTM D3286)

The gross or higher heating value (HHV) of a fuel is the amount of heat released when a unit (mass or volume) of the fuel is burned. The HHV of solid fuel is determined using ASTM D3286 with an isothermal jacket bomb calorimeter. For rations fed to animals and animal waste fuels, the HHV for DAF roughly remains constant at about 19,500 kJ/kg (8400 Btu/lb),[4] irrespective of stage of decomposition of animal waste. The HHV can also be estimated using the ultimate analysis of the fuel and the following empirical relation from Boie[5]:

$$\mathrm{HHV}_{\mathrm{fuel}}\left(\mathrm{kJ/kg\ fuel}\right) = 35{,}160\ Y_c + 116{,}225\ Y_H - 11{,}090\ Y_O + 6280\ Y_N + 10465\ Y_S \tag{1}$$

$$\mathrm{HHV}_{\mathrm{fuel}}\left(\mathrm{BTU/lb\ fuel}\right) = 15{,}199\ Y_C + 49{,}965\ Y_H - 4768\ Y_O + 2700\ Y_N + 4499\ Y_S, \tag{2}$$

where Y denotes the mass fraction of an element C, H, O, N, or S in the fuel. The higher the oxygen content, the lower the HV, as seen in biomass fuels.

Annamalai et al. used the Boie equation for 62 kinds of biosolids with good agreement.[6] For most biomass fuels and alcohols, the HHV in kilojoules per unit mass of stoichiometric oxygen is constant at 14,360–14,730 kJ/kg of O_2 (6165–6320 Btu/lb of O_2).[7]

TABLE 2 Coal, Advanced Feedlot Biomass (FB) and Litter Biomass (LB)

[a] HHV based on Boie equation.

[b] Aerts et al[20]; [Adapted from Ebeling and Jenkins[3] and AnnamalaiJ[17] See foot note of Table 3.2 for conversions to English units and estimation of NO_x and SO_2 emissions.

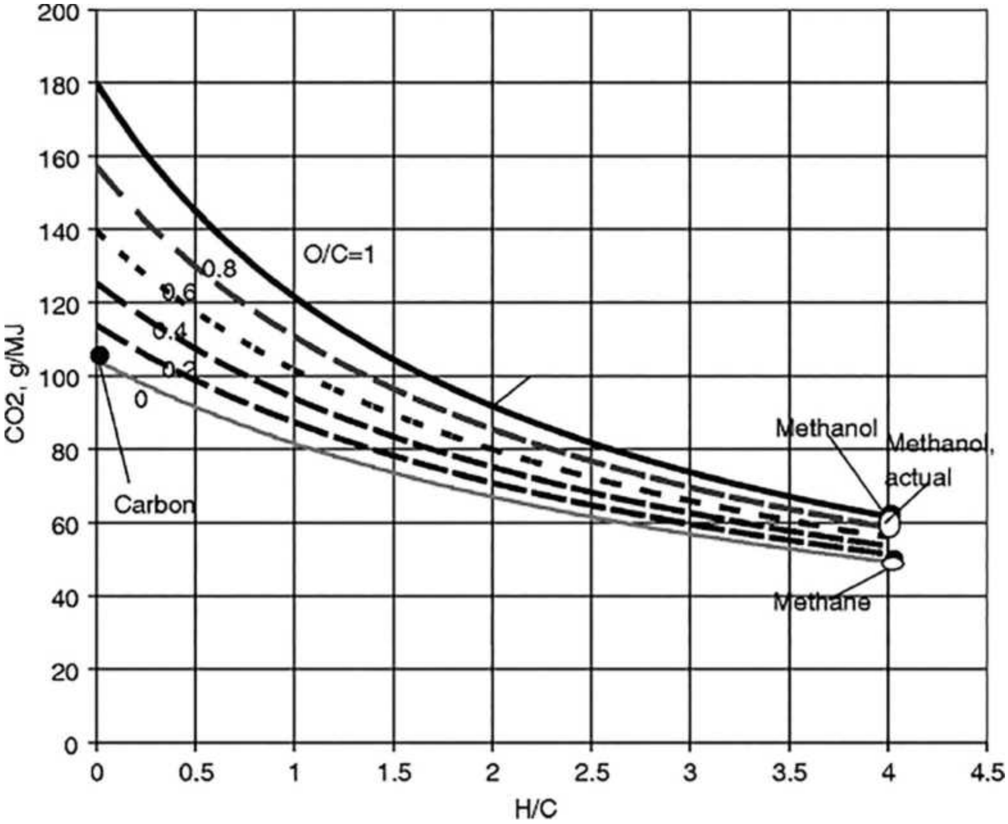

FIGURE 3 Emission of CO_2 as a function of H/C and O/C atom ratios in hydrocarbon fuels.
Source: Adapted from Annamalai and Puri.[8]

Estimate of CO_2 Emission

Using the Boie-based HVs for any fuel of known elemental composition, one can plot the CO_2 emission in g/MJ (Figure 3) as a function of H/C and O/C ratios.[8] Comparisons for selected fuels with known experimental HVs are also shown in the same figure. Coal, with H/C ratio ≈ 0.5, releases the highest CO_2, while natural gas (mainly CH_4) emits the lowest CO_2. Because the United States uses fossil fuels for 86% of its energy needs (100 quads), the estimated CO_2 emission is 6350 million ton/year, assuming that the average CO_2 emission from fossil fuels is 70 kg/GJ (methane: 50 kg/GJ vs coal: 90 kg/GJ). Figure 1 seems to confirm such estimation within a 10% error.

Flame Temperature

Figure 4 shows a plot of maximum possible flame temperature vs moisture percentage with combustion for biomass fuels. The result can be correlated as follows[4]:

$$T(\mathrm{K}) = 2290 - 1.89\mathrm{H_2O} + 5.06\ \mathrm{Ash} - 0.309\ \mathrm{H_2O}\,Ash - 0.180\ \mathrm{H_2O_2} - 0.108\ \mathrm{Ash}^2 \quad (3)$$

$$T(^{\circ}\mathrm{F}) = 3650 - 3.40\ \mathrm{H_2O} + 9.10\ \mathrm{Ash} - 0.556\ \mathrm{H_2O\ Ash} - 0.324\ \mathrm{H_2O_2} - 0.194\ \mathrm{Ash}^2 \quad (4)$$

The adiabatic flame temperature decreases if the ash and moisture contents increase.

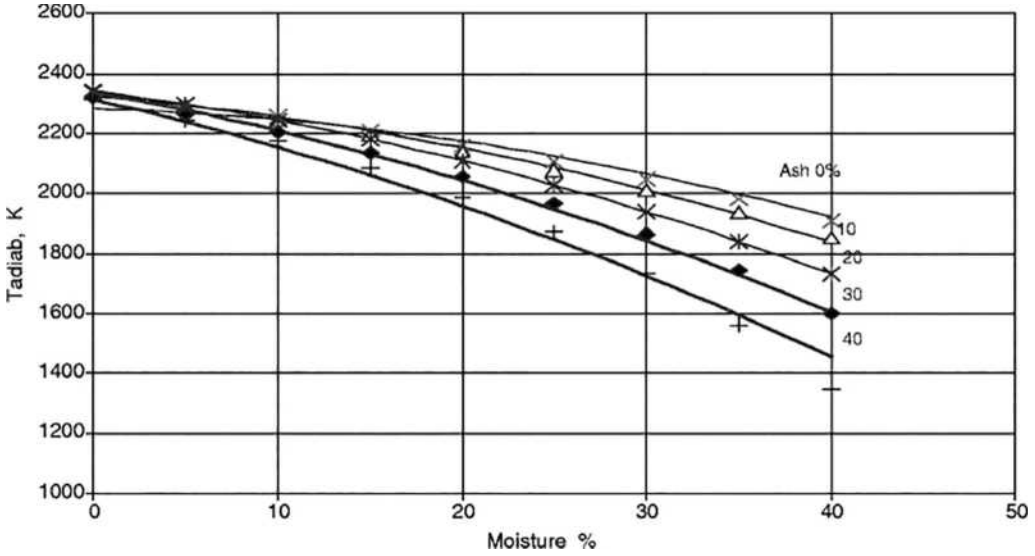

FIGURE 4 Correlation of adiabatic flame temperature with moisture and ash contents.

Flue Gas Volume

The flue gas volume for C–H–O is almost independent of O/C ratios. The fit at 6% O_2 in products gives the following empirical equation for flue gas volume (m^3/GJ) at SATP[8]:

$$\text{Flue gas}_{\text{vol}}\left(\text{m}^3/\text{GJ}\right)=4.96\left(\frac{\text{H}}{\text{C}}\right)^2-38.628\left(\frac{\text{H}}{\text{C}}\right)+389.72 \tag{5}$$

$$\text{Flue gas}_{\text{vol}}\left(\text{ft}^3/\text{mmBtu}\right)=184.68\left(\frac{\text{H}}{\text{C}}\right)^2-1439.28\left(\frac{\text{H}}{\text{C}}\right)+14520.95 \tag{6}$$

Liquid Fuels

Liquid fuels, used mainly in the transportation sector, are derived from crude oil, which occurs naturally as a free-flowing liquid with a density of $\rho \approx 780\,\text{kg/m}^3$–$1000\,\text{kg/m}^3$, containing 0.1% ash and 0.15%–0.5% nitrogen. Crude oil normally contains a mixture of hydrocarbons, and as such, the “boiling” temperature keeps increasing as the oil is distilled. Most fuel oils contain 83%–88% carbon and 6%–12% (by mass) hydrogen.

Gaseous Fuels

The gaseous fuels are cleaner-burning fuels than liquid and solid fuels. They are a mixture of HC but dominated by highly volatile CH_4 with very little S and N. Natural gas is transported as liquefied natural gas (LNG) and compressed natural gas (CNG), typically at 150–250 bars. Liquefied petroleum gas (LPG) is a byproduct of petroleum refining, and it consists mainly of 90% propane. A low-Btu gas contains 0–7400 kJ/SCM (Standard Cubic Meter, 0–200 Btu/SCF, standards defined in Table 1); a medium-Btu gas. 7400–14,800 kJ/SCM (200–400 Btu/SCF); and a high-Btu gas, above 14,800 kJ/SCM (more than 400 Btu/ SCF). Hydrogen is another gaseous fuel, with a heat value of 11,525 kJ/SCM (310 Btu/SCF). Because the fuel quality (heat value) may change when fuel is switched, the thermal output rate at a fixed gas-line pressure changes when fuels are changed.

Coal and Biomass Pyrolysis, Gasification, and Combustion

Typically, coal densities range from 1100 kg/m^3 for low-rank coals to 2330 kg/m^3 for high-density pyrolytic graphite, while for biomass, density ranges from 100 kg/ m^3 for straw to 500 kg/m^3 for forest wood.[9] The bulk density of cattle FB as harvested is 737 kg/m^3 (CF) for high ash (HA-FB) and 32 lbs/CF for low ash (LA-FB).[10] The processes during heating and combustion of coal are illustrated in Figure 5, and they are similar for biomass except for high VM. The process of release of gases from solid fuels in the absence of oxygen is called pyrolysis, while the combined process of pyrolysis and partial oxidation of fuel in the presence of oxygen is known as gasification. If all combustible gases and solid carbon are oxidized to CO_2 and H_2O, the process is known as combustion.

Pyrolysis

Solid fuels, like coal and biomass, can be pyrolyzed (thermally decomposed) in inert atmospheres to yield combustible gases or VM. While biomass typically releases about 70%–80% of its mass as VM (mainly from cellulose and hemicellulose) with the remainder being char, mainly from lignin content of biomass, coal releases 10%–50% of its mass as VM, depending upon its age or rank. Typically, a medium-rank coal consists of 40% VM and 60% FC, while a high-rank coal has about 10% VM. Bituminous coal pyrolyzes at about 700 K (with 1% mass loss for heating rates <100°C/s), as in the case of most plastics. Pyrolytic products range from lighter volatiles like CH_4, C_2H_4, C_2H_6, CO, CO_2, H_2, and H_2O to heavier molecular mass tars. Apart from volatiles, nitrogen is also evolved from the fuel during pyrolysis in the form of HCN, NH_3, and other compounds or, more generally, XN.

Sweeten et al. performed the thermogravimetric analysis (TGA) of feedlot manure.[4] The results are shown in Figure 6. In the case of manure, drying occurred between 50 and 100°C, pyrolysis was initiated around 185°C–200°C for a heating rate of 80°C/min, and the minimum ignition temperature was approximately 528°C. The gases produced during biomass pyrolysis can also be converted into transportation fuels like biodiesel, methanol, and ethanol, which may be used either alone or blended with gasoline.

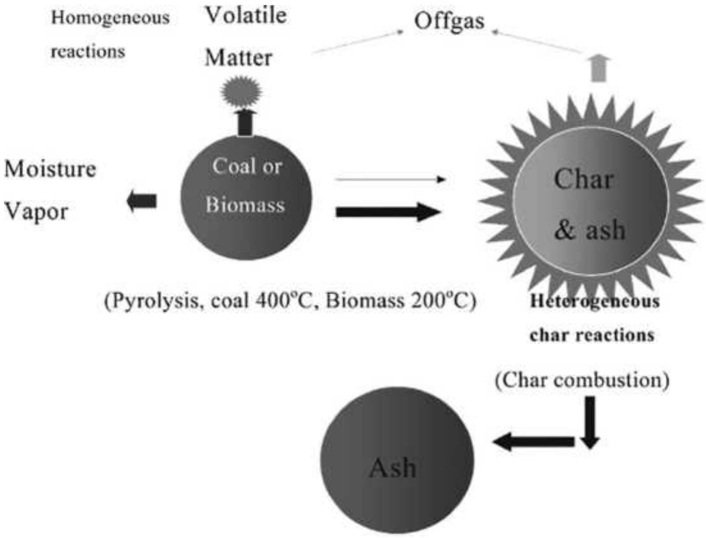

FIGURE 5 Processes during coal pyrolysis, gasification, and combustion.

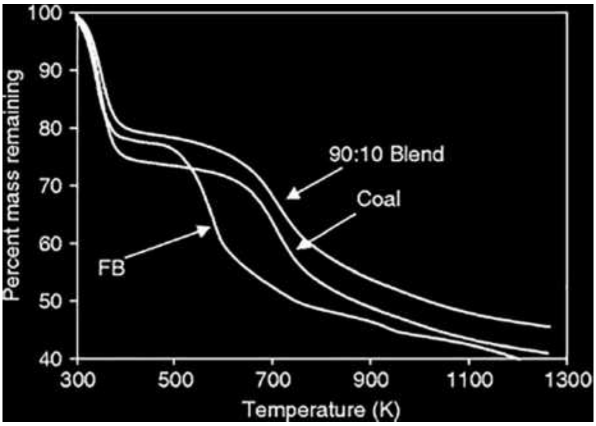

FIGURE 6 Thermo-gravimetric analyses of Feedlot Biomass (FB or cattle manure), coal, and 90:10 coal: FB blends.
Source: Sweeten et al.[4]

Volatile Oxidation

Once released, volatiles (HC, CO, H_2, etc.,) undergo oxidation within a thin gas film surrounding the solid fuel particle. The oxidation for each HC involves several steps. The enveloping flame, due to volatile combustion, acts like a shroud by preventing oxygen from reaching the particle surface for heterogeneous oxidation of char. Following Dryer,[11] the one-step global oxidation of a given species can be written as

$$\text{Fuel} + \upsilon_{CO_2} O_2 \overset{\text{oxidation}}{\rightarrow} \upsilon_{CO_2} CO_2 + \upsilon_{H_2O} H_2O \tag{7}$$

$$-\frac{d[\text{Fuel}]}{dt}, \frac{\text{kg}}{\text{m}^3\ \text{sec}} = \text{A}\ \exp\left(\frac{-E}{RT}\right)[Y_{\text{fuel}}]^a [Y_{O_2}]^b \tag{8}$$

where [ ] represents the concentration of species in kg/m^3, Y the mass fraction, A the pre-exponential factor, E the activation energy in kJ/kmole, and a and b the order of reaction; they are tabulated in Bartok and Sarofim for alkanes, ethanol, methanol, benzene and toluene.[11]

Char Reactions

The skeletal char, essentially FC, undergoes heterogeneous reactions with gaseous species. The heterogeneous combustion of carbon or char occurs primarily via one or more of the following reactions:

Reaction I. $C + \frac{1}{2} O_2 \rightarrow CO$
Reaction II. $C + O_2 \rightarrow CO_2$
Reaction III. $C + CO_2 \rightarrow 2\ CO$
Reaction IV. $C + H_2O \rightarrow CO + H_2$

Assuming a first-order reaction for scheme I, the oxygen consumption rate is given as

$$\dot{m}_{O2} \approx \pi d_P^2 B_I T^n \exp\left(-\frac{E}{R_V T_P}\right) \rho_\infty Y_{O2,w.} \tag{9}$$

The dominant oxygen transfer mechanism at high temperatures is via reaction I with an E/R (a ratio of activation energy to universal gas constant) of about 26,200 K, where $B_I = 2.3 \times 10^7$ m/s and $n = 0.5$ to 1. Reaction II has an E/R of 20,000 K, and $B_{II} = 1.6 \times 10^5$ m/s. Reaction III, the Boudouard reduction reaction, proceeds with an E/R of about 40,000 K. The reduction reactions, III and IV, may become significant, especially at high temperatures for combustion in boiler burners. Reaction with steam is found to be 50 times faster than CO_2 at temperatures up to 1800°C at 1 bar for 75–100 micron-sized Montana Rosebud char.[12] The combustible gases CO and H_2 undergo gas phase oxidation, producing CO_2 and H_2O.

Ignition and Combustion

Recently, Essenhigh et al. have reviewed the ignition of coal.[13] Volatiles from lignite are known to ignite at $T > 950$ K in fluidized beds. Coal may ignite homogeneously or heterogeneously depending upon size and volatile content.[14,15] A correlation for heterogeneous char ignition temperature is presented by Du and Annamalai, 1994.

Once ignited, the combustion of high volatile coal proceeds in two stages: combustion of VM and combustion of FC. Combustion of VM is similar to the combustion of vapors from an oil drop. The typical total combustion time of 100-micron solid coal particle is on the order of 1 s in boilers and is dominated by the time required for heterogeneous combustion of the residual char particle, while the pyrolysis time ($t_{pyr} = 10^6$ (s/m^2) d_p^2) is on the order of 1/10th–1/100th of the total burning time. Since biosolid contains 70%–80% VM (coal contains 10% VM), most of the combustion of volatiles occurs within a short time (about 0.10 s).

For liquid drops and plastics of density ρ_c, simple relations exist for evaluating the combustion rates and times. If the transfer number B is defined as

$$B = \frac{cp\{T_\infty - T_w\}}{L} + \frac{Y_{O_{2,\infty}}}{\nu_{O_2}} \frac{h_c}{L}, \tag{10}$$

where $T_w \approx$ TBP for liquid fuels; $T_w = T_g$, the temperature of gasification for plastics; L is the latent heat for liquid fuel and $L = q_g$, heat of gasification for plastics; $Y_{O_{2\infty}}$ is the stoichiometric oxygen mass per unit mass of fuel (typically 3.5 for liquid fuels); and h_c is the lower heating value of fuel; then the burn rate ($\dot{m}$) and time (t_b) for spherical condensates (liquid drops and spherical particles of diameter d_p and density ρ_c) are given by the following expressions:

$$\dot{m} \approx 2\pi \frac{\lambda}{c_p} d_p \ln(1+B) \tag{11}$$

$$t_b = \frac{d_0^2}{\alpha_c}, \tag{12}$$

Where

$$\alpha_c = 8 \frac{\lambda}{c_P} \frac{\ln(1+B)}{\rho_c} \tag{13}$$

and c_p and λ are the specific heat and thermal conductivity of gas mixture evaluated at a mean temperature (approximately 50% of the adiabatic flame temperature).

The higher the B value, the higher the mass loss rate, and the burn time will be lower. The value of B is about 1–2 for plastics (polymers), 2–3 for alcohols, and 6–8 for pentane to octane. The burn time of plastic waste particles will be about 3–4 times longer than single liquid drops of pentane to octane (≈ gasoline) of similar diameter.

Combustion in Practical Systems

The time scales for combustion are on the order of 1000, 10, and 1 ms for coal burnt in boilers and liquid fuels burnt in gas turbines and diesel engines. Coal is burnt on grates in lumped form (larger-sized particles, 2.5 cm or greater with a volumetric intensity on the order of 500 kW/m^3), medium-sized particles in fluidized beds (1 cm or less, 500 kW/m^3), or as suspensions or pulverized fuel (pf; 75 micron or less, 200 kW/m^3) in boilers.

Apart from pyrolysis, gasification, and combustion, another option for energy conversion (particularly if solid fuel is in slurry firm, such as flushed dairy manure), is the anaerobic digestion (in absence of oxygen) to CH_4 (60%) and CO_2 (40%) using psychrophilic (ambient temperature), mesophilic (95°F) and thermophilic (135°F) bacteria in digesters.[10] Typical options of energy conversion, indicated in Figure 7, include anaerobic digestion (path 1, the biological gasification process), thermal gasification with air to produce CO, HC, CO_2 (path 2A) or with steam to produce CO_2 and H_2 (path 2B), cofiring (path 3), reburn (path 4; see "Reburn with Bio-Solids"), and direct combustion (path 5).

Suspension Firing

In suspension-fired boilers, solid fuel is pulverized into smaller particles (d_p = 75 μm or less) so that more surface area per unit mass is exposed to the oxidant, resulting in improved ignition and combustion characteristics. Typical boiler burners use swirl burners for atomized oil and pulverized coal firing, while a gas turbine uses a swirl atomizer in highly swirling turbulent flow fields. A swirl burner for pf firing is shown in Figure 8. The air is divided into a primary air stream which transports the coal (10%–20% of the total air, heated to 70°C–100°C to prevent condensation of vapors and injected at about 20 m/s to prevent settling of the dust, loading dust and gas at a ratio of 1:2) and a secondary air stream (250°C at 60–80 m/s) which is sent through swirl vanes, supplying the remaining oxygen for combustion and imparting a tangential momentum to the air. In wall-fired boilers, burners are stacked above each other on the wall; while in tangential-fired boilers, the burners are mounted at the corners of rectangular furnaces.

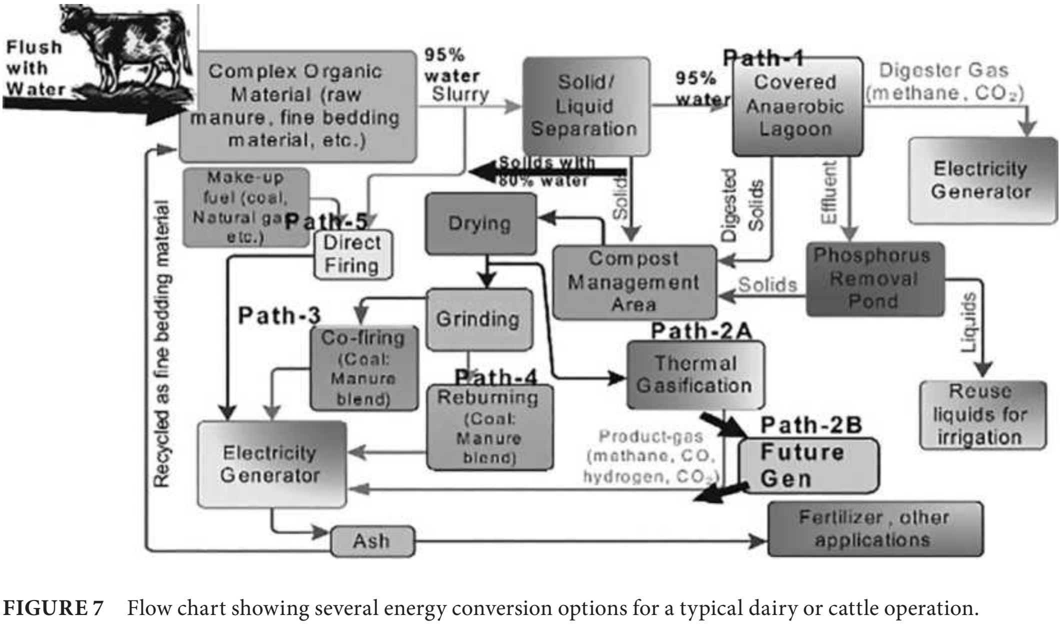

FIGURE 7 Flow chart showing several energy conversion options for a typical dairy or cattle operation.

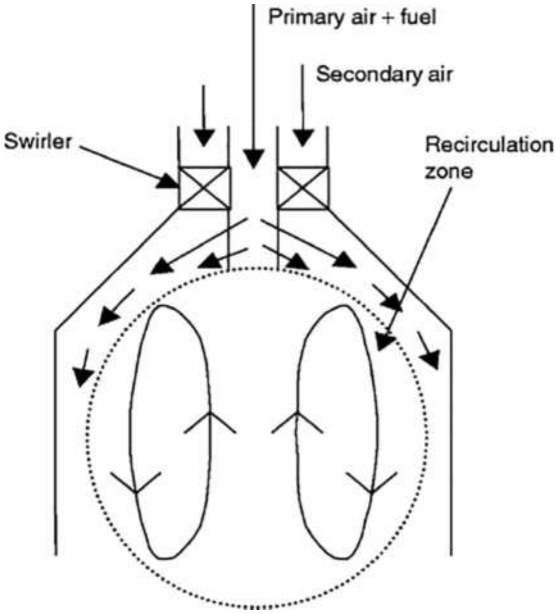

FIGURE 8 Pulverized Fuel (pf) fired swirl burner.

Stoker Firing

The uncrushed fuel [fusion temperature <1093°C (2000°F); volatile content >20%; sizes in equal proportions of 19 mm × 12.5 mm (3/4 in. × ½ in.), 6.3 mm × 3.2 mm (½ in. × ¼ in.), 3.2 mm × 3.2 mm (¼ in × ¼ in.)][16] is fed onto a traveling chain grate below to which primary air is supplied (Figure 9), which may be preheated to 177°C (350°F) if moisture exceeds 25%. The differential pressure is on the order of 5–8 mm (2–3 in.). The combustible gases are carried into an over-fire region into which secondary air (almost 35% of total air at three levels for low emissions) is fired to complete combustion. The over-fire region acts like a perfectly stirred reactor (PSR). It is apparent that solid fuels need not be ground to finer size.

Fixed Bed Combustor

The bed contains uncrushed solid fuels, inert materials (including ash), and processing materials (e.g., limestone to remove SO_2 from gases as sulfates). It is fed with air moving against gravity for complete combustion, but the velocity is low enough that materials are not entrained into the gas streams. Large solid particles can be used.

Fluidized Bed Combustor

When air velocity (V) in fixed bed combustor (FXBC) is increased gradually to a velocity called minimum fluidization velocity V_{mf}, the upward drag force is almost equal to the weight of the particle, so that solids float upward. The bed behaves like a fluid (like liquid water in a tank), i.e., it becomes fluidized. If $V > V_{mf}$, then air escapes as bubbles and is called a bubbling fluidized bed combustor (BFBC). The bed has two phases: the bubble phase, containing gases (mostly oxygen), and the emulsion phase (dense phase, oxygen deficient), containing particles and gas. Many times gas velocity is so high that gaseous combustibles produced within the bed burn above the bed (called free board region), while solids (e.g., char and carbon) burn within the bed. Fluidized Bed Combustor (FBC) is suitable for fuels which are difficult to combust in pf-fired boilers.

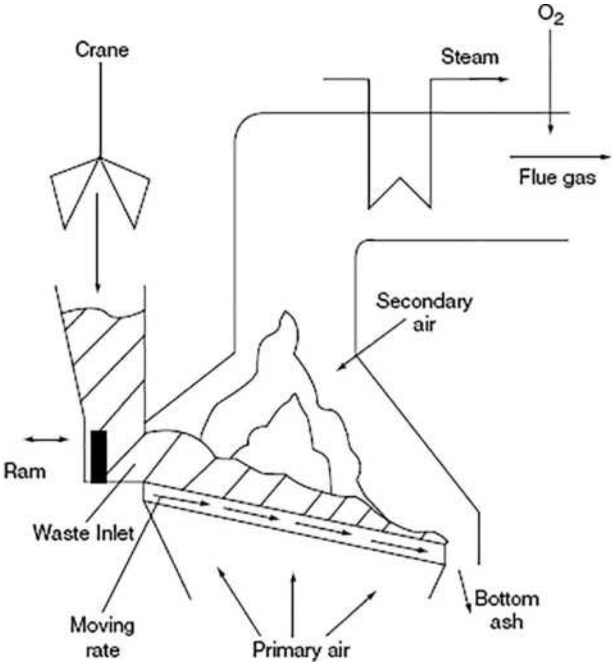

FIGURE 9 Schematic of stoker firing.
Source: Loo and Kessel.[39]

Circulating Fluidized Bed Combustor (CFBC)

When air velocity in FBC is increased at velocity $V >> V_{mf}$, particles are entrained into the gas stream. Since the residence time available to particles for combustion is shorter, unburned particles are captured using cyclones located downstream of the combustor and circulated back to the bed.

The residence time (t_{res}) varies from a low value for pf-fired burners to a long residence time for fixed-bed combustors. The reaction time (t_{reac}) should be shorter than t_{res} so that combustion is complete. The reaction time includes time to heat up to ignition temperature and combustion. The previous section on fuel properties and the homogenous (e.g., CH_4, CO oxidation) and heterogeneous (e.g., carbon oxidation) reaction kinetics can be used to predict t_{reac} or burn time t_b.

Coal and Bio-Solids Cofiring

General Schemes of Conversion

Most of the previously reviewed combustion systems typically use pure coal, oil, or gas. The same systems require redesign for use with pure biomass fuels. A few of the technologies, which utilize bio-solids as an energy source, are summarized in Annamalai et al.[17] These technologies include direct combustion (fluidized beds), circulating fluidized beds, liquefaction (mostly pyrolysis), onsite gasification for producing low to medium Btu gases, anaerobic digestion (bacterial conversion), and hydrolysis for fermentation to liquid fuels like ethanol.[18,19]

Cofiring

Although some bio-solids have been fired directly in industrial burners as sole-source fuels, limitations arose due to variable moisture and ash contents in bio-solid fuels, causing ignition and combustion problems for direct combustion technologies. To circumvent such problems, these fuels have been fired along with the primary fuels (cofiring) either by directly mixing with coal and firing (2%–15% of heat input basis) or by firing them in between coal-fired burners.[20–24]

Cofiring has the following advantages: improvement of flame stability problems, greater potential for commercialization, low capital costs, flexibility of adaptation of biomass fuels and cost effective power generation, mitigated NO_x emissions from coal-fired boilers, and reduced CO_2 emissions. However, a lower melting point of biomass ash could cause fouling and slagging problems.

Some of the bio-solid fuels used in cofiring with coal are cattle manure,[25,26] sawdust and sewage sludge,[21] switch grass,[20] wood chips,[24,27] straw,[22,28] and refuse-derived fuel (RDF).[21] See Sami et al. for a review of literature on cofiring.[7]

Coal and Agricultural Residues

Sampson et al. reported test burns of three different types of wood chips (20%, HHV from 8320 to 8420 Btu/lb) mixed with coal (10,600 Btu/lb) at a stoker (traveling grate) fired steam plant.[24] The particulate emission in grams per SCF ranged from 0.05 to 0.09. An economic study, conducted for the 125,000 lb/h steam power plant, concluded that energy derived from wood would be competitive with that from coal if more than 30,000 tons of wood chips were produced per year with hauling distances less than 60 mi. Aerts et al. carried out their experiments on cofiring switch grass with coal in a 50-MW, radiant, wall-fired, pulverized coal boiler with a capacity of 180 tons of steam at 85 bar and 510°C (Figure 10). The NO_x emissions decreased by 20%, since switchgrass contains lesser nitrogen (Table 4).[20] It is the author's hypothesis that a higher VM content of bio-solids results in a porous char, thus accelerating the char combustion process. This is validated by the data from Fahlstedt et al. on the cofiring of wood chips, olive pips and palm nut shells with coal at the ABB Carbon 1 MW Process Test Facility; they found that blend combustion has a slightly higher efficiency than coal-only combustion.[27]

Coal and RDF

Municipal solid waste includes residential, commercial, and industrial wastes which could be used as fuel for production of steam and electric power. MSW is inherently a blended fuel, and its major components are paper (43%); yard waste, including grass clippings (10%); food (10%); glass and ceramics (9%); ferrous materials (6%); and plastics and rubber (5%). Refer to Tables 5 and 6 for analyses. When

raw waste is processed to remove non-combustibles like glass and metals, it is called RDF. MSW can decompose in two ways, aerobic and anaerobic. Aerobic decomposition (or composting) occurs when O_2 is present. The composting produces CO_2 and water, but no usable energy products. The anaerobic decomposition occurs in the absence of O_2. It produces landfill gas of 55% CH_4 and 45% CO_2.

Coal and Manure

Frazzitta et al. and Annamalai et al. evaluated the performance of a small-scale pf-fired boiler burner facility (100,000 Btu/h) while using coal and premixed coal manure blends with 20% manure. Three types of feedlot manure were used: raw, partially composted, and fully composted. The burnt fraction was recorded to be 97% for both coal and coal-manure blends.[25,26]

NO_x Emissions

During combustion, the nitrogen evolved from fuel undergoes oxidation to NO_x; and this is called fuel NO_x to distinguish it from thermal NO_x, which is produced by oxidation of atmospheric nitrogen. Unlike coal, most of the agricultural biomass being burned is very low in nitrogen content (i.e., wood or crops), but manure has a higher N content than fossil fuels. A less precise correlation exists between cofiring levels on a Btu basis and percent NO reduction under cofiring. The following Eq. (valid between 3 and 22% mass basis cofiring) describes NO_x reduction as a function of cofiring level on a heat input basis:

$$NO_x \text{ Reduction}(\%) = 0.0008(\text{COF}\%)^2 + 0.0006 \text{ COF}\% + 0.0752, \tag{14}$$

where COF% is the percentage of co-firing on a heat input basis. The mechanisms used to reduce NO_x emissions by cofiring vary between cyclone firing and PC firing.

Figure 11 shows the percentage reduction in NO with percentage cofiring of low-N agricultural biomass fuels. This relationship does not apply to high-N biofuels such as animal manure.

Fouling in Cofiring

Hansen et al. investigated the ash deposition problem in a multi-circulating fluidized bed combustor (MCFBC) fired with fuel blends of coal and wood straw.[25] The Na and K lower the melting point of ash. For ash fusion characteristics see Table 7. Rasmussen and Clausen evaluated the performance of an 80-MW co-generation power plant at Grenaa, Denmark, fired with hard coal and bio-solids (surplus straw from farming). Large amounts of Na and K in straw caused superheater corrosion and

combustor fouling.[29] Annamalai et al. evaluated fouling potential when feedlot manure biomass (FB) was cofired with coal under suspension firing.[30] The 90:10 Coal:FB blend resulted in almost twice the ash output compared to coal and ash deposits on heat exchanger tubes that were more difficult to remove than baseline coal ash deposits. The increased fouling behavior with blend is probably due to the higher ash loading and ash composition of FB.

Gasification of Coal and Bio-Solids

Gasification is a thermo-chemical process in which a solid fuel is converted into a gaseous fuel (primarily consisting of HC, H_2 and CO_2) with air or pure oxygen used for partial oxidation of FCs. The main products during gasification are CO and H_2, with some CO_2, N_2, CH_4, H_2O, char particles, and tar (heavy hydrocarbons). The oxidizers used for the gasification processes are oxygen, steam, or air. However, for air, the gasification yields a low-Btu gas, primarily caused by nitrogen dilution present in the supply air. Syngas ($CO + H_2$) is produced by reaction of biomass with steam. The combustible product, gas, can be used as fuel burned directly or with a gas turbine to produce electricity; or used to make chemical feedstock (petroleum refineries). However, gas needs to be cleaned to remove tar, NH_3,

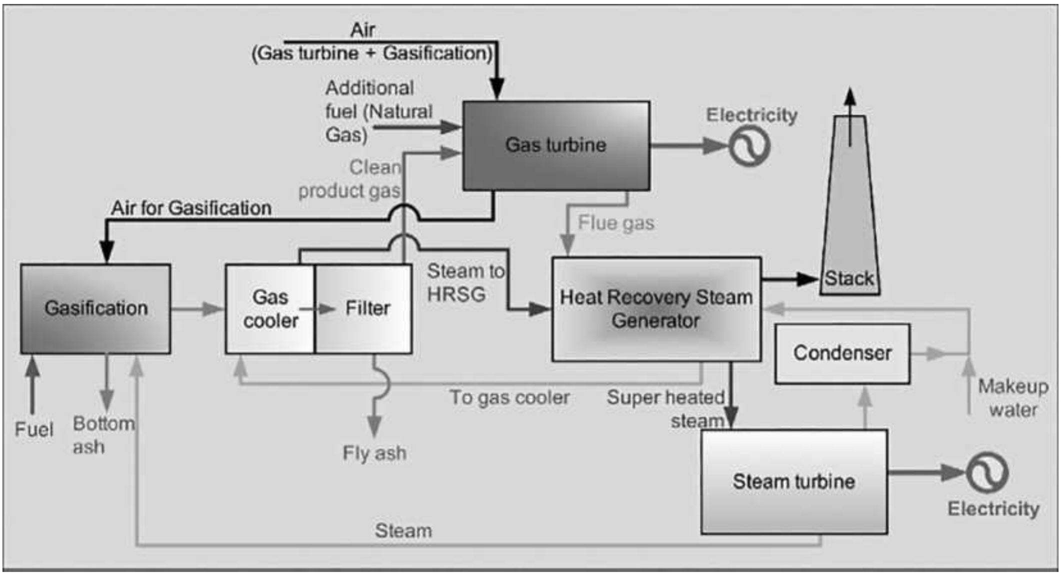

FIGURE 12 Fluidized-bed gasification for Integrated Gasification Combined Cycle (IGCC) Process.

and sulfur compounds. The integrated gasification combined cycle (IGCC) (Figure 12), for combined heat and power (CHP), and traditional boilers use combustible gases from gasifiers for generation of electric power.

Typically in combined cycles, gaseous or liquid fuel is burnt in gas turbine combustors. High-temperature products are expanded in a gas turbine for producing electrical power; a low-temperature (but still hot) exhaust is then used as heat input in a boiler to produce low-temperature steam, which then drives a steam turbine for electrical power. Therefore, one may use gas as a topping cycle medium, while steam is used as fluid for the bottoming cycle. The efficiency of a combined cycle is on the order of 60%, while a conventional gas turbine cycle has an efficiency of 42%.[31] Commercial operations include a 250-MW IGCC plant at Tampa, Florida, operating since 1996; a 340-MW plant at Negishi, Japan, since 2003; and a 1200-MW GE-Bechtel plant under construction in Ohio for American Electric Power, to start in 2010.[31]

There are three basic gasification reactor types: (i) fixed-bed gasifiers (Figure 13); (ii) fluidized-bed gasifiers, including circulating-bed (CFB) or bubbling-bed; and (iii) entrained-flow gasifiers. The principles of operation are similar to those of combustors except that the air supplied is much below stoichiometric amounts, and instead of a combination of steam, air and CO_2, air can also be used. The oxidant source could also include gases other than air, such as air combined with steam in Blasiak et al.[32]

Futuregen

FutureGen is a new U.S. initiative to build the world's first integrated CO_2 sequestration and H_2 production research power plant using coal as fuel. The technology shown in Figure 14 employs modern coal gasification technology using pure oxygen, resulting in CO, C_nH_m (a hydrocarbon), H_2, HCN, NH_3, N_2, H_2S, SO_2, and other combinations which are further reacted with steam (reforming reactions) to produce CO_2 and H_2. The bed materials capture most of the harmful N and S compounds followed by gas-cleaning systems; the CO_2 is then sequestered and H_2 is used as fuel, using either combined cycle or fuel cells for electricity generation or sold as clean transportation fuel. With partial oxidation of gasification products and char supplying heat for pyrolysis and other endothermic reactions (i.e., net zero external

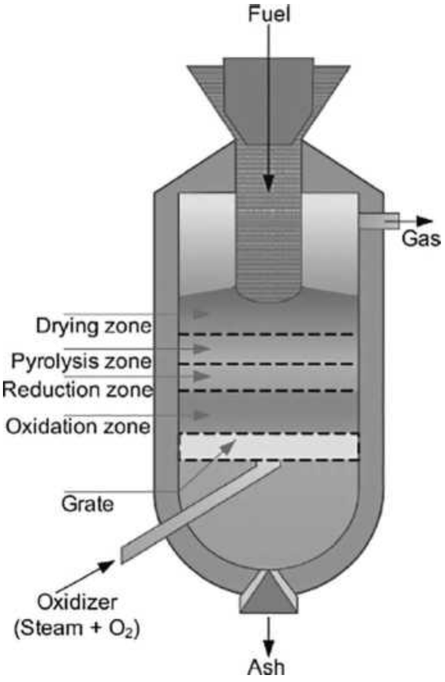

FIGURE 13 Updraft fixed-bed gasifier.

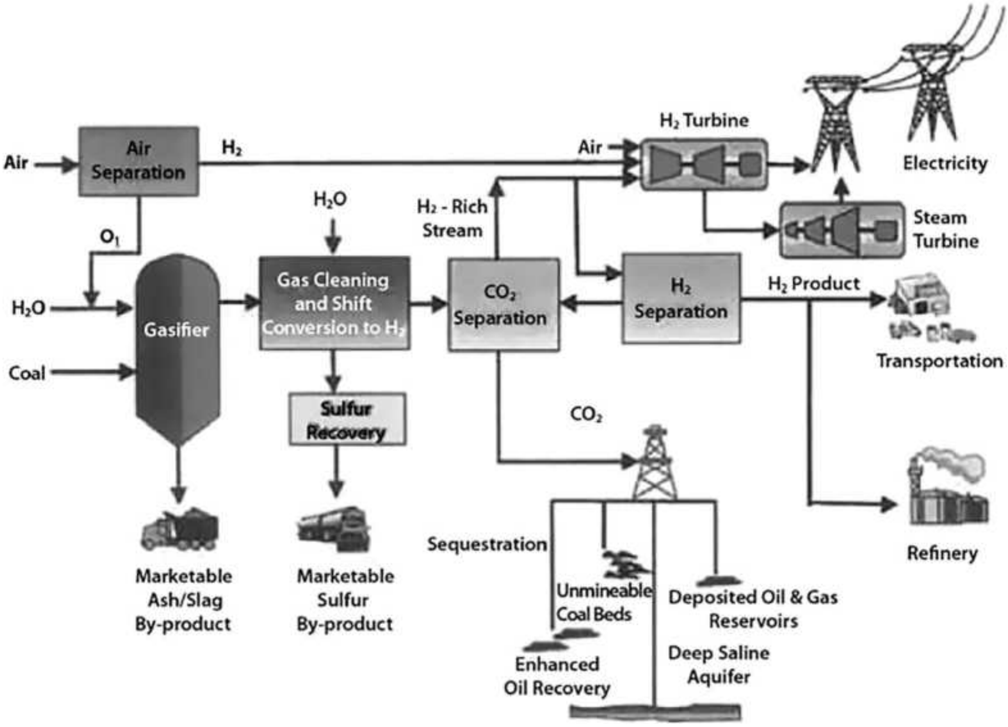

FIGURE 14 FutureGen layout. Source: http://www.fe.doe.gov.

heat supply in gasifier), the overall gasification reaction can be represented as follows for 100 kg of DAF Wyoming coal:

$$\text{Reaction V} \quad C_{6.3}H_{4.4}N_{0.0076}O_{1.15}S_{0.014} + 8.14\ H_2O(l) + 1.67\ O_2 \rightarrow 6.3\ CO_2 + 10.34\ H_2 + 0.038\ N_2 + 0.014\ SO_2$$

It is apparent that the FutureGen process results in enhanced production of H_2, using coal as an energy source to strip H_2 from water. For C–H–O fuels, it can be shown that theoretical H_2 production (N_{H2}) in moles for an empirical fuel CH_hO_o is given as $\{0.4115\,h - 0.6204\,o + 1.4776\}$ under the above conditions. For example, if glucose $C_6H_{12}O_6$ is the fuel, then empirical formulae is CH_2O; thus, with h = 2, o = 1, $N_{H_2} = 1.68$ kmol, using atom balance, $CH_2O + 0.68\ H_2O(\ell) + 0.16\ O_2\ CO_2 + 1.68\ H_2$.

Reburn with Bio-Solids

NO_x is produced when fuel is burned with air. The N in NO_x can come both from the nitrogen-containing fuel compounds (e.g., coal, biomass, plant residue, animal waste) and from the N in the air. The NO_x generated from fuel N is called fuel NO_x, and NO_x formed from the air is called thermal NO_x. Typically, 75% of NO_x in boiler burners is from fuel N. It is mandated that NO_x, a precursor of smog, be reduced to 0.40–0.46 lb/mmBtu for wall and tangentially fired units under the Clean Air Act Amendments (CAAA). The current technologies developed for reducing NO_x include combustion controls (e.g., staged combustion or low NO_x burners (LNB), reburn) and post-combustion controls (e.g., Selective Non-Catalytic Reduction, SNCR using urea).

In reburning, additional fuel (typically natural gas) is injected downstream from the primary combustion zone to create a fuel rich zone (optimum reburn stoichiometric ratio (SR), usually between SR 0.7 and 0.9), where NO_x is reduced up to 60% through reactions with hydrocarbons when reburn heat input with CH_4 is about 10%–20%. Downstream of the reburn zone, additional air is injected in the burnout zone to complete the combustion process. A diagram of the entire process with the different combustion zones is shown in Figure 15. There have been numerous studies on reburn technology found in literature, with experiments conducted, and the important results summarized elsewhere.[33] Table 8 shows the percentages of reduction and emission obtained with coal or gas reburn in coal-fired installations and demonstration units.

The low cost of biomass and its availability make it an ideal source of pyrolysis gas, which is a more effective reburn fuel than the main source fuel, which is typically coal. Recently, animal manure has been tested as a reburn fuel in laboratory scale experiments. A reduction of a maximum of 80% was achieved for pure biomass, while the coal experienced a reduction of between 10 and 40%, depending on the equivalence ratio.[34] It is believed that the greater effectiveness of the feedlot biomass is due to its greater volatile content on a DAF basis and its release of fuel nitrogen in the form of NH_3, instead of HCN.[35]

Energy Demand: From Individual Behavioral Changes to Climate Change Mitigation

Leila Niamir and
Felix Creutzig

Introduction

Decarbonization of the economy requires massive worldwide efforts and a strong involvement of regions, cities, businesses, and individuals in addition to commitments at national levels (1). Human consumption, in combination with a growing population, contributes to climate change by increasing the rate of green house gas (GHG) emissions (2,3). Over the last decade, instigated by the Paris Agreement, the efforts to limit global warming have been expanding. However, significant attention is being devoted to new energy technologies on both the production and consumption sides, while changes in individual behavior and management practices as part of the mitigation strategy are often neglected (4–8).

Although demand-side solutions are promising, they are not given the same level of attention as technological supply-side solutions in assessments, like the IPCC's AR5, and in integrated assessment models (IAMs) in general, or in the popular media, as mirrored in the observation that directed innovation perversely privileges energy-supply technologies over efficient end-use technologies (10). This potentially has two main reasons: (a) demand-side solutions are often embedded in a complex network of social institutions and practices (11), and thus less prone to quantitative analysis and clear-cut implementation; (b) demand-side solutions also often involve explicit normative positions, or values, making those solutions subject to value-laden discourses (12). Specifically, as demand-side solutions presuppose modified behavior, they are less compatible with the revealed-preference framework prevalent in economics. Both reasons apply less to supply-side solutions: people consume electricity via plug-in, and the original supply of energy for electricity is irrelevant for actual consumption.

Table 1 shows the potential contribution to climate change mitigation from three sectors: buildings, transport, and food under two main perspectives: (a) hard infrastructures, such as the built environment, and (b) soft infrastructures, such as habits and norms. On the one hand, hard infrastructures, epitomized by the urban built infrastructure, provide a physical setting for shaping preferences, practices, and opportunity spaces. On the other hand, changing norms, practices, and nudges modify the opportunity space and can induce direct behavioral change (13).

In building sector, the behavioral change potential can be as high as 50% over long periods of time (Table 1). There is a range in the energy savings achievable in buildings due to behavioral changes, depending on the type of end use. For example, savings from heating loads of 10–30% are possible for changes in the thermostat setting. Similarly, cooling savings of 50–67% are recorded with measures such as substituting air-conditioning with fans in moderately hot climates with tolerable, brief heat exposures. Meanwhile, subsequent literature has provided quantitative estimates of the importance of urban transport and behavioral options (14). Overall, behavioral and infrastructural measures in cities can potentially reduce GHG emissions from urban passenger transport by 20–50% until 2050 (15). This may be achieved via three routes, technological change, modal shift, and reduced travel demand, and

TABLE 1 Climate Mitigation Options and Their Quantitative Reduction Potential

End-User Sector	Mitigation Option	Reduction Potential	Reference(s)
Urban areas and spatial planning	Modifying the emerging urbanization	20–25% reduction of future urban energy use until 2050	(17)
Transportation	Optimal pricing	15–20% reduction in automobile transport	(17)
	Compactness	United States: 10% reduction in distance traveled	(18)
		Europe: 5% reduction in distance traveled	(19)
	Behavioral measures (marketing, information provision, and tailored services)	10% reduction in transport demand	(20,21)
Tourism	Transport modal shifts and increases in average length of stay	44% emission reductions worldwide until 2035	(22)
Buildings	Developed context: short-term behavioral change potential	>20%	(2)
	Developed context: long-term behavioral change potential	50%	(23,24)
	Developing context: behavioral change potential	Relevant but lower potential	(25,26)
	Heating: adjusting thermostat setting	10–30%	(27)
	Cooling: using substitutes for air-conditioning, increasing thermostat setting, changing dress codes	50–67%	(27,28)
	Clothes washing and drying behavior (e.g., by operation at full load versus one-third to one-half load)	10–100%	(29)
	Water-heating and cooking energy savings (e.g., by shorter showers, using different cooking practices)	50%	(29)
	Lighting energy savings (e.g., by turning off unneeded lights)	70%	(29)
	Refrigerator energy savings (e.g., by smaller refrigerators)	30–50%	(29)
	Dishwasher energy savings (e.g., by full-load operation)	75%	(29)
Agriculture and other land use	Technical potential of demand-side options for 2050	70%	(30,31)
	Healthy diet: meat, fish, and egg consumption of 90 g/(person/day)	36% greenhouse gas savings	(32)

Source: Ref. (13).

information technology plays a key role in all three areas of innovation (16). Behavioral options could be fostered by information campaigns that facilitate social learning, active choice, and frame alternative mobility choices.

Reshaping urban forms and the urban environment provides ample opportunity to make private car travel obsolete and save high amounts of energy in buildings. Both transport and buildings also offer significant opportunities for reduced energy demand by soft measures, such as providing targeted information on sustainable mobility for specific groups of people. In agriculture, demand-side action, in particular, dietary shift, could reduce emissions by more than 70% compared to the trend in 2055, thereby surpassing the potential of technological options.

Demand-Side Solutions

Demand-side solutions for mitigating climate change include strategies targeting technology choices, consumption, behavior, lifestyles, coupled production–consumption infrastructures and systems, service provision, and associated sociotechnical transitions. Disciplines vary in their approaches and in the research questions that they ask on demand-side issues (4). For example, psychologists and behavioral economists focus on emotional factors and cognitive biases in the decision-making process (33); economists elaborate on how, under rational decision-making, carbon pricing and other fiscal instruments can trigger change in demand (34); sociologists emphasize everyday practices, structural issues, and socioeconomic inequality (35); anthropologists address the role of culture in energy consumption (36); and studies in technological innovation consider sociotechnical transitions and the norms, rules, and pace of adoption that support dominant technologies (37).

Figure 1 proposed a demand-side assessment framework and discuss key topics that need to be addressed: the characterization of demand; policy instruments and how they would affect demand; techno-economic evaluation; implications for well-being; mitigation pathways; and the sustainable development context.

The starting point for a demand-side assessment seeks to characterize patterns of demand for energy, mobility, food and shelter, and the associated GHG emissions. Hence, the first question to ask is: what norms, values, preferences, and structural factors shape energy demand and GHG emissions (Figure 1a)? Policy instruments can spur demand-side solutions, in ways that depend on the specific energy service and socioeconomic context. Different disciplines have provided important pieces of this big jigsaw, but much remain to be done to put the assessment of policy instruments together in a truly interdisciplinary effort and address the questions posed (Figure 1b).

Beyond specific technologies, research should take a wider scope and ask for the efficient and reliable provision of end-use services, rather than efficient technology design alone (Figure 1c). Technological studies contribute to an understanding of dynamic systems, describing cost reductions and strategies to overcome barriers on the path from research and development of a technology to market-scale deployment and uptake. Another question is: how do demand-side mitigation measures affect well-being (Figure 1d)? Reducing energy use or GHG emissions need to be balanced with the goal of enhancing human well-being (39).

Sketched approaches such as transition theory, study of behavioral tipping points and social norms, and political economy insights into policy sequencing have the potential for laying out short-term and action-oriented mitigation pathways. Such approaches, together with bottom-up assessments from technological studies, can be soft-coupled and combined with IAMs and similar economic models that assess system-wide potentials, reflecting the interaction between sectors and mitigation options (Figure 1e). The linkage between sustainable development and climate change is also articulated in the 'nationally determined' language of the Paris Agreement, which promotes climate mitigation that coincides with nationally determined development outcomes. A demand-side assessment should also be able to inform sustainable development pathways (Figure 1f).

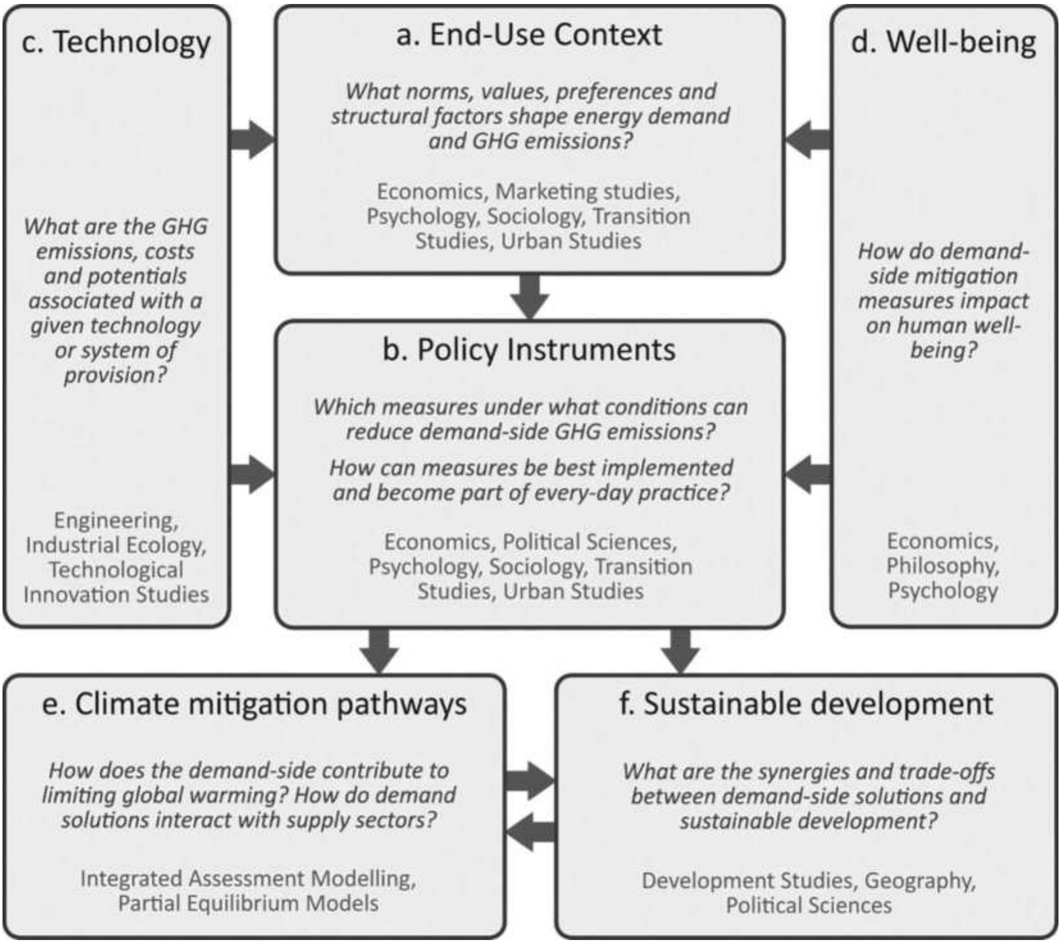

FIGURE 1 Key research questions and contributing disciplines for assessing demand-side solutions. (From Ref. 38.)

Modeling Individuals Energy Behavioral Changes

The understanding of how bottom-up processes can impact climate mitigation guides us to effective development and implementation of policies (9,40). In the last decade, a variety of macroeconomic models and assessment tools emerged (41–43) and were predominately used to support climate-energy policy decisions (44) range from the assessment of macroeconomic and cross-sectoral impacts (45–47), to detailed micro-simulation models for a specific technology (5,47,48). Much can be done to make the assumptions in macroeconomic and integrated assessment models more realistic concerning the scale and nature of damage (5). These models usually assume that economic agents form a representative group(s), have perfect access to information and adapt instantly and rationally to new situations, maximizing their long-run personal advantage (49–52).

Unlike other approaches, agent-based model (ABM) is not limited to perfectly rational agents or to abstract microdetails in aggregate system-level equations. Instead, ABM can represent the behavior of energy consumers – such as individual households – using a range of behavioral theories (9,50,53). In addition, ABM has the ability to examine how interactions of heterogeneous agents at micro-level give rise to the emergence of macro-outcomes, including those relevant for climate mitigation such as an adoption of low-carbon behavioral strategies and technologies over space and time (54). The ABM approach simulates complex and nonlinear behavior that is intractable in equilibrium models (52).

Individual energy behavior, especially when amplified through social context, shapes energy demand and, consequently, carbon emissions. By changing their behaviors, individuals can play an essential role in the transformation process towards a low-carbon society and global emissions reduction (9). However, explaining and affecting human behavior is a difficult task since human nature is complex and heterogeneous. As a result, quantitative tools to assess cumulative household emissions, given the diversity of behavior and a variety of psychological and social factors influencing it beyond purely economic considerations, are scarce (6,40,55).

BENCH Agent-Based Model

To assess the impact of individual behavior on carbon emissions, we went beyond classical economic models and the stylized representation of a perfectly informed optimizer. An agent-based simulation model was designed and developed to quantify the cumulative impacts of individual behavioral changes on regional dynamics of saved energy and CO_2 emissions (40). The BENCH (Behavioral change in ENergy Consumption of Households) model[1] builds up on the advances in agent-based modeling applied in the energy domain, and adds theoretically and empirically grounded individual behavioral rules that drive households' energy-related choices (40,52).

Driven by the empirical evidence from environmental behavioral studies (56–61), the *BENCH* model assumes that a decision regarding energy action is driven by psychological and social factors in addition to the standard economic drivers such as prices relative to incomes (40,52,55). Behavioral factors including personal norms and awareness may either amplify the economic logic behind a decision-making or impede it, serving either as a trigger or a barrier (Figure 2).

Household agents in *BENCH* are heterogeneous in socioeconomic characteristics, preferences, and awareness of environment and climate change, so they can pursue various energy choices and actions. Figure 3 illustrates our conceptual framework that represents household energy behavioral change as a dynamic process unfolding in stages. Knowledge and awareness can have an important role in triggering individual behavior change (4,15,62–67). If individuals have enough knowledge and awareness about climate, environment, and energy issues, a feeling of guilt develops and activates motivational factors, which may lead to energy-related behavior change. Motivation is enhanced by personal and social norms (58,67), which can lead to a feeling of responsibility and provoke an individual to change their behavior. When intentions for the latter are high, individuals do a formal feasibility assessment according their income, dwelling conditions, and own perceived behavioral control. Individuals compare their current energy-use habits with alternatives, and if things can be improved, the intention to pursue an alternative rises and may lead to a behavior change. This conceptual framework combines some behavioral constructs that are common between TPB (in red) and NAT (in green).

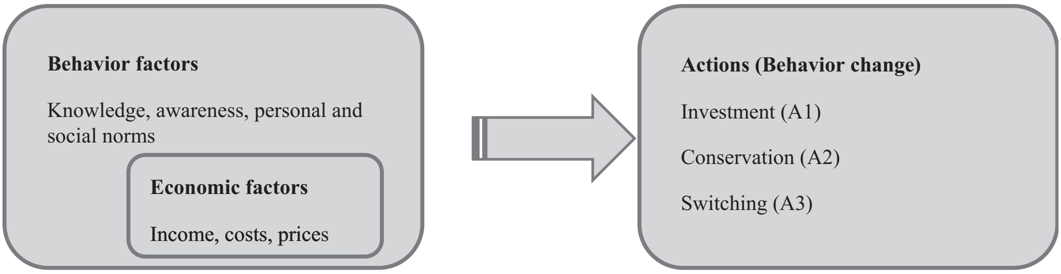

FIGURE 2 Factors affecting household decision-making regarding their energy use. (From Ref. 52.)

---

[1] **B**ehavioral change in **EN**ergy **C**onsumption of **H**ouseholds Model.

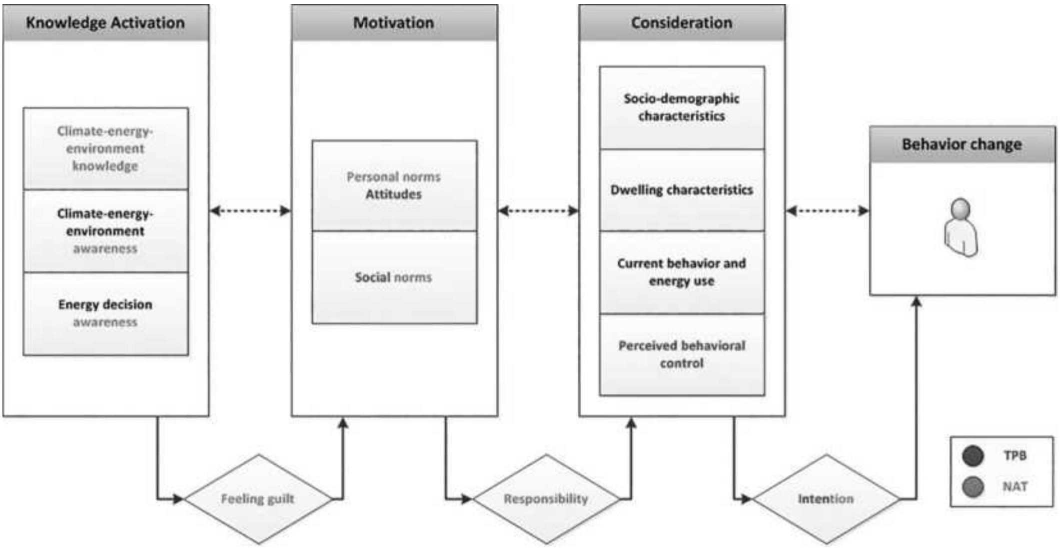

FIGURE 3 conceptual representation of multi-stage household behavioral change. (From Ref. 68.)

Empirical Data

Household agents in *BENCH* are heterogeneous in socioeconomic characteristics, preferences, and awareness of environment and climate change, so they can pursue various energy choices and actions. In order to quantify which factors – socioeconomic (e.g., income, age), behavioral (e.g., personal and social norms, knowledge and awareness about the environment, social influence), and structural (e.g., size and type of house) – trigger or attenuate a transition to a lower and greener energy footprint at the household level, the comprehensive survey (*N*=1,790 households) was designed and conducted in two provinces in Europe.

Our data analysis demonstrates that awareness and personal and social norms are equally as important as monetary factors when it comes to individual energy actions. Education and structural dwelling factors, e.g., size and type of dwelling appear to be very significant in bottom-up actions contributing to the reduction of the regional CO_2 footprint from the residential sector (68) (Figure 4).

End-User Scenarios

The *BENCH* calculated changes in electricity consumption annually and implied carbon emissions based on the primary source of energy by simulating individuals' behavior under different end-user behavioral and climate scenarios. The results indicate that accounting for demand-side heterogeneity provides a better insight into possible transition pathways to a low-carbon economy and climate change mitigation. Namely, the model including household heterogeneity, as represented by socio-demographic, dwelling, and behavioral factors, shows rich dynamics and provides a more realistic image of socioeconomics by simulating the economy through the social interactions of heterogeneous households.

Four end-user scenarios are designed and analyzed, which varied from the baseline scenario through the introduction of agent heterogeneity, the intensity of social interactions among households (slow or fast), and the lack or presence of carbon price (52). By comparing end-user scenarios, the relative impact of bottom-up drivers (social dynamics and learning on the diffusion of information) and top-down market policies (carbon price) on carbon emission reduction are estimated (Figure 5).

The impact of household attribute heterogeneity and social dynamics brought about a 5–9% CO_2 emission reduction by 2030. Adding carbon price cuts CO_2 emission down to 55% compared to the baseline scenario, which mimics the traditional economic setup of a representative rational, fully informed household making the optimal decision.

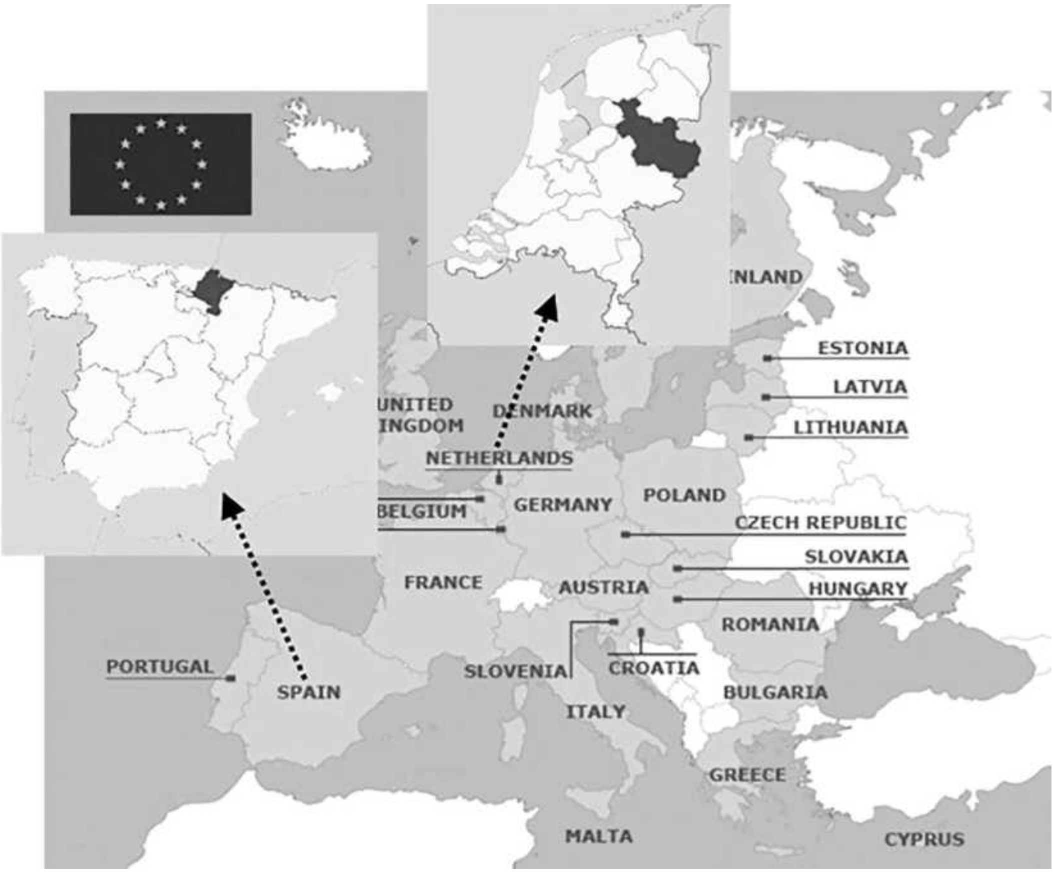

FIGURE 4 Survey case studies: the Overijssel province in the Netherlands and the Navarre province in Spain. (From Ref. 68.)

These insights have also implications for more standard policymaking. As preferences are malleable, and change with infrastructures and policy environments (13,69), policies themselves need to consider social norms and malleable preferences to avoid inefficiencies, or to even crowd out desirable outcomes (70,71).

Conclusion

Avoiding and shifting consumption plays a key role to achieve Sustainable Development Goals (SDGs) and for climate change mitigation. We can achieve the environmental targets (e.g., SDGs) through controlled consumption. Demand-side management should hence be better represented in energy systems scenarios. Demand-side management covers a broad range from technology interventions and diffusion to energy efficiency solutions and behavioral changes. Designing energy systems scenario requires an urgent understanding of which human activities are more culpable, what causes them, and how we can effectively change them. Since the nature of human is complex and heterogeneous, explaining and affecting human behavior is a difficult task. Therefore, this requires quantitative tools to assess cumulative individual emissions, given the diversity of behavior and variety of psychological and social factors influencing it beyond purely economics considerations.

The potential of individual behavioral changes in reducing carbon emissions attracts considerable attention as one of the climate change mitigation strategies (13,52). The theoretically and empirically

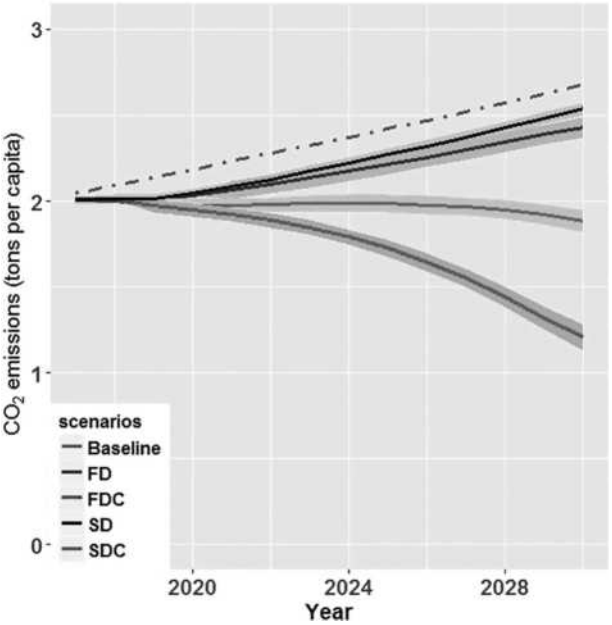

FIGURE 5 Macroimpact of heterogeneous households behavioral change combing (bottom-up) strategy and carbon price pressure (top-down) strategy on CO_2 emissions over time. Combining behavioral-climate scenarios: combination of carbon price and slow and fast social dynamics (SDC, FDC) (2017–2030). The shaded bounds around the curves indicate the uncertainty intervals across 100 runs. (From Ref. 52.)

grounded modeling tools such as the BENCH model can serve as useful instruments to quantify regional impacts of qualitative and untraceable individual behavioral aspects. The model can serve as a simulation platform to support the engagement of stakeholders. The results of this novel model indicate that accounting for the demand-side heterogeneity provides better insights into possible transition pathways to a low-carbon economy and into potential of behavioral changes as a climate change mitigation strategy (72). In order to facilitate this transition, the broader view on the social environment, cultural practices, public knowledge, producers technologies and services, and the facilities used by consumers are needed to design implementable and politically feasible policy options. It offers policymakers ways to explore various policy mixes combining price instruments (subsidies and taxes) with various targeted information policies to amplify the positive effect of individual behavioral changes regarding energy use. The reflected consideration have important implications for management practices and professionals. They point to the importance of seeing avoid and shift measures as part of management in business, administrations, and among professions.

The key message is the individuals are more than just consumers in climate change mitigation. Therefore, climate mitigation policies should go beyond economic cost-benefit incentives (e.g., subsidies and taxes). First, the social environment, cultural practices, public knowledge, producer technologies and services, and facilities used by consumers – all should be considered when designing implementable and politically feasible policy options. Second, various financial, social, and other instruments in the policy mix should be designed as a coherent set to reinforce each other, optimizing the joint effectiveness. In particular, policies such as the provision of targeted information, social advertisements, and power of celebrities for the broader public in combination with education can be used to create more knowledge and awareness in the longer run and could accompany and reinforce the effectiveness of other stimuli such as subsidies. These types of policies (soft policies) may prove to be more effective in promoting green energy solutions implemented by households compared to fiscal policy measures alone.

Wind Farms: Noise

Daniel Shepherd,
Chris Hanning,
and Bob Thorne

Introduction

Planning authorities, environmental agencies, and policy makers in many parts of the world are seeking information on possible links between wind turbine noise and health in order to legislate permissible noise levels or setback distances. Concurrently, larger and noisier wind turbines are emerging, and consent is being sought for progressively larger windfarms to be placed even closer to human habitats. While noise standards can effectively and fairly facilitate decision-making processes if developed properly, the current standards on offer suffer severe conceptual difficulties. Specifically, noise metrics considered by many in the industry as best practice may in fact relate little to health outcome variables such as annoyance or sleep disruption. In this entry, we describe the physical characteristics of wind turbine noise, review the impact of such noise on humans, and critique current approaches to mitigation.

Industrial Wind Turbines

Industrial wind turbines transform kinetic energy from the wind into electricity, a practice dating back over 100 years. Structurally, wind turbines can be decomposed into three key components (Figure 1). First, wind turbines possess a rotor, consisting of one or more blades designed to rotate when exposed to wind. The rotor can be thought of as a type of sail, catching wind in order to induce movement. Depending on the axis of blade rotation, wind turbines can be categorized as either horizontal-axis (the most common) or vertical-axis turbines. The second major component is the generator or "dynamo." The generator component includes a gearbox to regulate the speed of the dynamo and components to change blade pitch and plane of rotation with respect to wind direction. The dynamo can be used as a motor to maintain rotation at very low wind speeds. Third, there is a tower supporting the rotor and, typically, the generator. The size of a wind turbine can be specified either as a dimension (e.g., tower

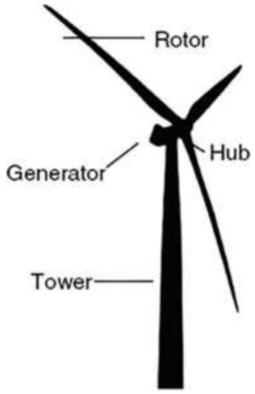

FIGURE 1 Components of a typical horizontal-axis wind turbine.

height measured from the ground to the top of a blade at its highest point) or as an electrical output (e.g., watts). Currently, turbines range from approximately 2 to 200 m high and from approximately 50 W to 6 MW.

Wind turbines can be erected in isolation or in sets and be located either onshore (i.e., terrestrial) or offshore (i.e., marine), though the latter is associated with higher construction costs. Industrial-scale wind energy generation, involving the saturation of an optimum number of wind turbines in a fixed area of land, gives rise to the concept of the "windfarm" or "wind park." Wind energy developers seek areas that have good consistent wind flow and close access to energy grids. The proliferation in the number of windfarms established globally in the past decade has been largely driven by environmental concerns such as climate change, renewableness and sustainability, and strategic energy considerations relating to the depletion of fossil fuels.[1] However, in the absence of large-scale electricity storage devices (i.e., batteries), the contribution of wind energy to a nation's electricity needs is likely to be peripheral. Another barrier is social acceptance, with reviewed social surveys indicating citizens supporting renewable energy in principle but opposed to having windfarms in their immediate vicinity due to visual impacts on the landscape, shadow flicker from the blades, and fears of noise-induced annoyance and sleep disruption.

Acoustic Profile of Wind Turbine Noise

The sound generated from a windfarm is qualitatively different from any sound source commonly met in the environment, can rapidly switch from being stationary to nonstationary, and can vary by as much as 20 dB within a single minute. When it interferes with human activities, wind turbine sound becomes a type of noise. Analysis of windfarm noise poses distinct challenges, including the identification of acoustic energy that can be directly attributed to the turbines and the detection of special audible characteristics, including distinct tonal complexes and modulation effects. Windfarm noise is often a broadband low-amplitude noise constantly shifting in character ("waves on beach," "rumble-thump," "plane never landing." etc.). In this respect, windfarm noise is not like, for example, traffic noise or the continuous hum from plant and machinery. When assessed, wind turbine noise is often related to either wind speed (m/s) or electrical output (watts) and typically increases with both.

When the wind reaches a blade, it flows both over and under the blade. The part of the airflow with momentum great enough to break away forms trailing vortexes and turbulence behind the blade, producing a set of sound sources. The power of each sound source depends on the strength of the turbulence, which in turn depends on the speed of airflow; the compressibility and viscosity of the air; the design and surface texture (roughness) of the blade; the wind speed; and the velocity of the blade at that point. The faster the blade rotates, the earlier the breakup in the boundary vortexes and the greater the interaction between the vortexes emanating by adjacent wind turbines. An amplification of potential noise occurs when two or more turbines are, or nearly are, synchronous, such that the blade passing pulses coincide and then go out of phase again.[2] With exact synchronicity, there is a fixed interference pattern; with near synchronicity, concurrent arrival of pulses will change over time and place.

Noise emissions from modern wind turbines are primarily due to turbulent flow and trailing edge sound, blade characteristics, blade/tower interaction, and to a lesser degree, mechanical processes. The most commonly used description of wind turbine noise is the A-weighted sound pressure level, which is expressed in decibels (notated dBA). The most commonly used noise compliance assessment methods for windfarms involve the "time average" sound level L_{Aeq} or the background sound level L_{A90}. These levels are quite different as the time-averaged ambient sound level includes all noises from near and far. The difference between these levels, and other common levels, is illustrated in Figure 2. The chart shows that sound levels change over time and that any derived sound level index is a summary of fluctuating levels in that time period. In a relatively short time period, such as 10 minutes, the unique noise events such as bangs or thuds from turbines shifting in the wind may be captured. If the time period is relatively long, for example, an hour, then evidence of unique short-term noise events is reduced because the sound energy is "averaged" over the whole hour, and the single-value A-weighted level will not represent short-term variations in sound character. If extraneous noise (e.g., insect noise) is included in the wind turbine measurement, its contribution to the overall level must be determined, though how this is undertaken remains a challenge.[3]

The A-frequency–weighted sound pressure level or "sound level" is the most common sound descriptor and is reputedly analogous to our hearing at medium sound levels. This is not strictly true, and the A-weighting has a significant restriction in that it does not permit measurement or assessment of low-frequency sound (i.e., 20 to 250 Hz). For more complex situations where dominant tonal components are significant (i.e., special audible characteristics), a procedure for determining tonal adjustment requiring one-third octave band frequency or narrow-band analysis is needed. These assessment procedures require the "C" weighting for low frequency or the unweighted (also known as "Z") response to measure both low-frequency and infrasonic sound. Whereas the dBC metric is able to include low-frequency sounds such as the audible rumble and thump from wind turbines, the dBZ response is more

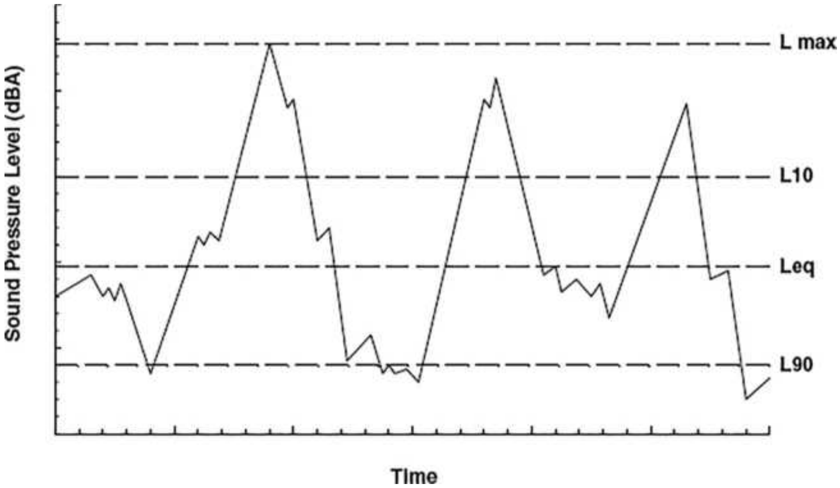

FIGURE 2 Chart illustrating different noise descriptors. L10 is the level exceeded 10% of the time, while L90 is the level exceeded 90% of the time. The time-average (equivalent continuous) sound pressure level, Leq, represents the average acoustic energy across a defined measurement epoch.

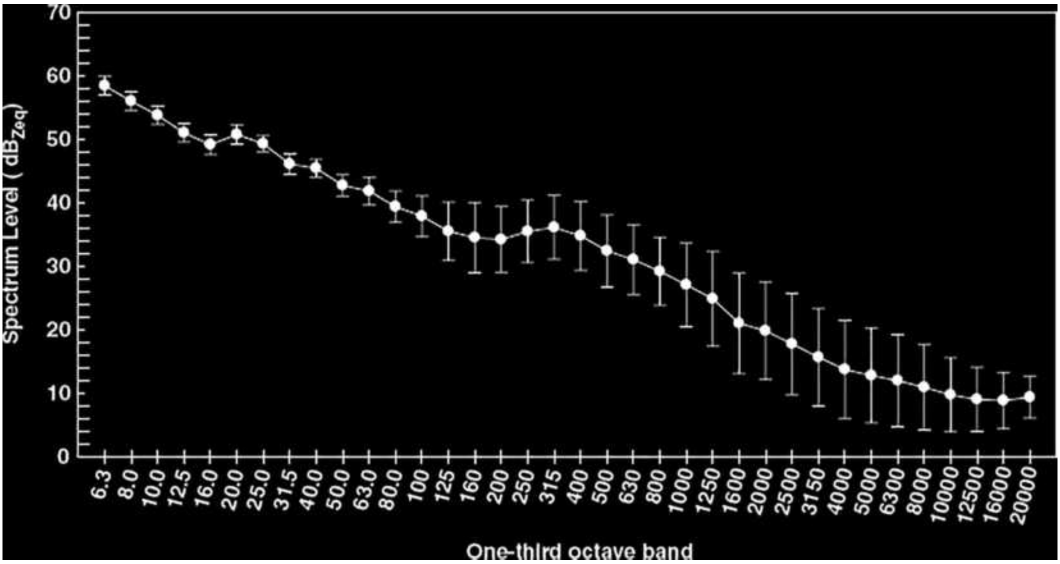

FIGURE 3 One-third octave band analysis of time-average unweighted sound pressure level (dB$_{Zeq}$) for wind turbine sound measured from 7:00 p.m. to 1:00 a.m. outside of a residence.

suitable for infrasound measurements (i.e., typically inaudible energy below 20 Hz). Figure 3 presents a third octave band analysis of outdoor wind turbine noise recorded over a 6-hr period. Other measures include assessments for tonality or low- frequency sound referenced to third octave bands and the "G" weighting for infrasound. Aside from physical measures of amplitude (e.g., dBA), wind turbine noise can be quantified with a variety of other acoustical and objective psychoacoustic measures, including amplitude modulation (for example, 100 msec samples of peak, time-average, or fast response), sound quality (including audibility, dissonance, roughness, fluctuation strength, sharpness, tonality), loudness (for steady, time-varying, and impulsive sounds), and unbiased annoyance.[4]

Certification of wind turbine noise is undertaken in accordance with the International Standard IEC 61400-11:2002.[5] Emission levels are to be reported as A- weighted time-averaged (L_{Aeq}) sound levels in one-third octave bands. Audibility is calculated by reference to tones. An informative entry in IEC 61400-11 states the following: "In addition to those characteristics of wind turbine noise described in the main text, this emission may also possess some, or all of the following: infrasound; low-frequency noise; impulsivity; low-frequency modulation of broad band or tonal noise; other, such as a whine, hiss, screech, or hum, etc., distinct pulses in the noise, such as bangs, clatters, clicks or thumps, etc." Unfortunately, many of these parameters are not reported by the turbine manufacturer and cannot be predicted with the simple calculation methods currently available. The prediction of windfarm sound levels is most often referenced to national or international standards that have been based on ISO 9613-2.[6] The propagation method is calculated with the receivers being downwind from the noise source(s). All prediction models have uncertainty to their accuracy of prediction. Table 5 of the ISO 9613-2 standard gives an estimated accuracy for broadband noise of ±3 dB at between 100 and 1000 m. This is due to the inherent nature of the calculation algorithms that go into the design of the model, the assumptions made in the implementation of the model, and the availability of good source sound power data. The ISO 9613-2 method holds for wind speeds of between approximately 1 and 5 m/s, measured at a height of 3 to 11 m above the ground. However, wind turbines are sound sources that operate at higher wind speeds than allowed for under the standard, and an accuracy of ±7 dB can be expected. [3] Ultimately, the received noise levels at residences will vary subject to varying meteorological conditions in the locality (e.g., wind speed and direction, wind shear, temperature, humidity, inversions),

TABLE 1 Factors Affecting the Prediction of Wind Farm Noise Levels at a Receiver[a]

- The true sound power level of the turbine(s) at the specified wind speed
- The reduction in sound level due to ground effects
- The increase or reduction in sound level due to atmospheric (meteorological) variations and wind direction
- The variation due to modulation effects from wind velocity gradient
- Increase and reduction in sound levels due to wake and turbulence modulation effects due to turbine placement and wind direction
- Increased sound levels due to synchronicity effects of turbines in phase due to turbine placement and wind direction
- Building resonance effects for residents inside a dwelling

[a] A conservative set of noise predictions should take all factors into account.

among other factors (see Table 1), all of which must be accounted for when measuring or modeling wind turbine noise levels.

Human Impacts of Wind Turbine Noise

A Psychological Description of Wind Turbine Noise

At the psychological level of description, wind turbine noise is most frequently characterized as a swishing or lashing sound or less commonly as thump/throb, low- frequency rumble, or a rustling sound.[7,8] Wind turbines produce noise with an impulsive character[9] and while the actual cause of the swishing or thumping has not yet been fully elucidated, it has been demonstrated that the swishing or thumping pattern is common with larger turbines[10] and may result from a fluctuating angle of attack between the trailing edge of the rotor blade and wind, or wind speed inequalities across the area being swept by the rotor blades.[11] It is thought that the swishing sound may be linked to activity in the 2000 to 4000 Hz band, with the pace of the rotor blades determining the degree of amplitude modulation.[12] Unfortunately, such amplitude-modulated sounds are generally attenuated poorly by background noise, especially so in rural areas.[13] Further, because human sensory systems behave as contrast analyzers, fluctuations in the incoming stimulus field tend to direct attention and so are more easily detected. Thus, amplitude-modulated sounds such as wind turbine noise are readily perceived and difficult to filter out, making them especially intrusive.[14] The loudness of a wind turbine depends on a number of factors, including wind speed, sound-attenuating materials between the turbines and the receiver, other masking sounds, the season, and time of day. The loudness of a modern 2 to 3 MW wind turbine can be compared to a car on a motorway, autobahn, or freeway,[15] with a sound power level of 94 to 104 dBA at a windspeed of 8 m/s.[16] Wind turbine noise is perceived louder at night and during the summer months and when the wind is blowing from the direction of the turbines toward the receiver.[7,8]

Quantifying the Health Impacts of Wind Turbine Noise

Elucidating a causal mechanism between an environmental event and health is a complicated undertaking, and noise effects are commonly “indirect” as opposed to “direct.” According to the biomedical model of health (Figure 4a), a direct health effect implies a direct pathological relationship between an environmental parameter (e.g., noise level) and a target organ. An alternative approach (Figure 4b) distinguishes between direct health effects and psychosomatic illness, the latter indicting that any physiological illness coinciding with the onset of wind turbine noise is caused by a negative psychological response to the noise and not the noise *per se.* Thus, anxiety or anger in the presence of wind turbine noise induces stress and strain that, if maintained, can eventually lead to adverse health effects. A counter argument to this approach is that some individuals are simply more susceptible to noise

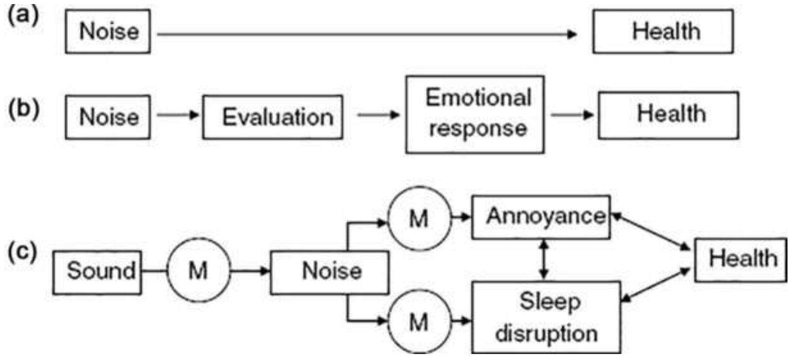

FIGURE 4 Three models representing the relationship between noise and health: the biomedical model (a) stipulating a direct causal relationship and indirect models (b and c) containing moderators and mediators.

than other individuals, which fits with the general concept of biological and physical variation. In the field of epidemiology, the differential susceptibilities of individuals are known as risk factors or vulnerabilities, with noise sensitivity being one risk factor related to negative responses to intrusive noise. A second challenge to the psychosomatic approach comes from documented instances of individuals who initially welcomed wind turbines into the community but who later campaigned to have them removed due to undesirable noise exposure.[17] Lastly, the veracity of psychosomatic arguments lessens in the face of feasible biological mechanisms describing the relationship between health and noise.[18]

An alternative and more accepted approach would be to adopt the World Health Organization's (WHO's) definition of health:[19] "A state of complete physical, mental and social well-being and not merely the absence of disease or infirmity." The forerunner of the biopsychosocial model, the WHO's definition states that optimal human functioning is determined by the interplay of biological, environmental, psychological, and social factors. Figure 4c displays a model consistent with the WHO's approach, in which the impact of noise is moderated by environmental, psychological, and social factors. A context-relevant model proposed by van den Berg and colleagues,[8] based on previous wind turbine literature, takes a similar shape to that presented in Figure 4c. They dichotomize moderators (denoted "M" in Figure 4c) into environmental moderators (e.g., degree of urbanization, house type, and ambient sound level) or psychological and demographic moderators (e.g., age, gender, education, employment status, attitudes to wind energy, noise sensitivity, and whether the individual receives a monetary return from the turbines). Other models linking wind turbine sound and health have been proposed[20] but can be considered extensions of that presented in Figure 4c.

As a new source of noise, the impact of wind turbine noise is understandably understudied relative to aviation and road traffic noise. Consequently, little data exist with which to assess the impacts of wind turbine noise on health, a state of affairs compounded by rapid development of wind turbine technology, in which data collected for smaller and less powerful turbines are not generalizable to larger, more modern turbines.[9,21] As of 2011, there have been two approaches to collecting wind turbine noise impact data, either epidemiological studies relying on masked surveys or direct clinical case studies.[22] Both approaches typically focus on the emotional impacts of noise (i.e., annoyance), upon sleep disruption, and/or the degradation of well-being and increases in stress that arise from sleep disturbance and annoyance. Irrespective of approach, however, case studies,[23–25] and epidemiological studies[7,8,20] have provided evidence that, like road traffic and aviation noise, wind turbine noise can be associated with negative health outcomes.

Wind Turbine Noise and Annoyance

People generally respond more negatively to man-made noise than to natural sounds,[26] and this generalization holds true for wind turbine noise.[16] From a psychological perspective, chronic exposure to community noise can impact health through information overload, overarousal, loss of coping strategies, loss of privacy, and loss of perceived control. These mechanisms give rise to a number of subjective responses to noise, of which the most common is annoyance. As a psychological stressor,[27] noise annoyance can express itself through malaise, fear, threat, uncertainty, restricted liberty, excitability, or defenseless- ness.[28] Furthermore, annoyance may be accompanied by intense anger, especially if one believes that they are being harmed unnecessarily. Thus, the term "annoyance" is often misinterpreted by the layperson as a feeling brought about by the presence of a minor irritant. The medical usage, in contrast, exists as a precise technical term and defines annoyance as a mental state capable of degrading health and well-being,[29,30] and it is classified as an adverse health effect by the WHO.[31]

There have been few studies estimating the health impacts of windfarms, with a series of studies undertaken in Scandinavia contributing the most to current knowledge. A seminal Swedish study undertaken by Pedersen and Persson Waye[7] sought to document the prevalence of wind turbine–induced annoyance and, further, to generate dose–response relationships between the two. Respondents were located between 150 and 1200 meters from the nearest wind turbine and were classified into noise exposure categories (see Figure 5). A significant relationship between dose (dBA) and annoyance was reported, but the variability in annoyance scores explained by noise level was small (adjusted $R^2 = 0.13$). Those reporting annoyance indicated a daily or nearly-everyday intrusion of windfarm noise. Those describing the noise as "swishing" were more likely to report noise annoyance, a finding replicated in a subsequent study reporting a high correlation (r = 0.664) between the swishing sound and annoyance.[14] Among those who noticed the noise, 11.2% reported being annoyed when indoors. A small but significant correlation was found between noise annoyance and noise sensitivity, with approximately 50% of the rural-dwelling respondents describing themselves as noise sensitive. Those making negative appraisals of the wind turbines, for example, as visually incongruent with the landscape, were at higher risk of an annoyance response. On the basis of their data, the authors undertook follow-up studies[14–16,22] supporting their conclusion that wind turbine noise maybe more potent than other categories of environmental noise (e.g., road or aviation) and appealed for further studies to determine why this might be. In a later report, Pedersen[22] suggests that coping strategy may moderate the relationship between wind turbine noise and stress.

Van den Berg et al.[8] analyzed data from 725 Dutch nationals residing within 2.1 km of a wind turbine and who were exposed to calculated outdoor noise levels between 24 and 54 dB(A). Approximately 60% of the sample could hear the turbines outdoors, while 33% reported that they could hear the wind turbines indoors. Of the 45% (n = 231) who noticed the sound of the rotor blades, 24.7% were not annoyed, 25.8% were slightly annoyed, 19.5% were rather annoyed, and 29.9% were very annoyed. The sound level explained approximately 25% of the variability in annoyance scores, and those who compared the noise to an amplitude modulation (i.e., swishing or lashing) were more likely to be annoyed, though this is not a novel finding.[14,32,33] Figure 5 plots the data from van den Berg et al., presenting proportions of detection and elicited annoyance as a function of noise level, for their entire dataset (Figure 5, circles) and for those receiving no economic benefit (Figure 5, squares). Note that, for those receiving no economic benefit, a monotonic relationship is evident, while a nonmonotonic function occurs when individuals benefiting financially from the turbines are included. Van den Berg[8] reports that this depreciation in annoyance of those benefiting economically can be explained by the control they have over the wind turbines, such that they can impede their operation if noise levels increase. Finally, it was reported that annoyance was positively correlated with stress scores, though a causal relationship could not be inferred.

It is accepted that both the physical parameters of the noise and the psychological characteristics of the listener combine to produce noise annoyance.[34] On the physical side, the relatively high annoyance

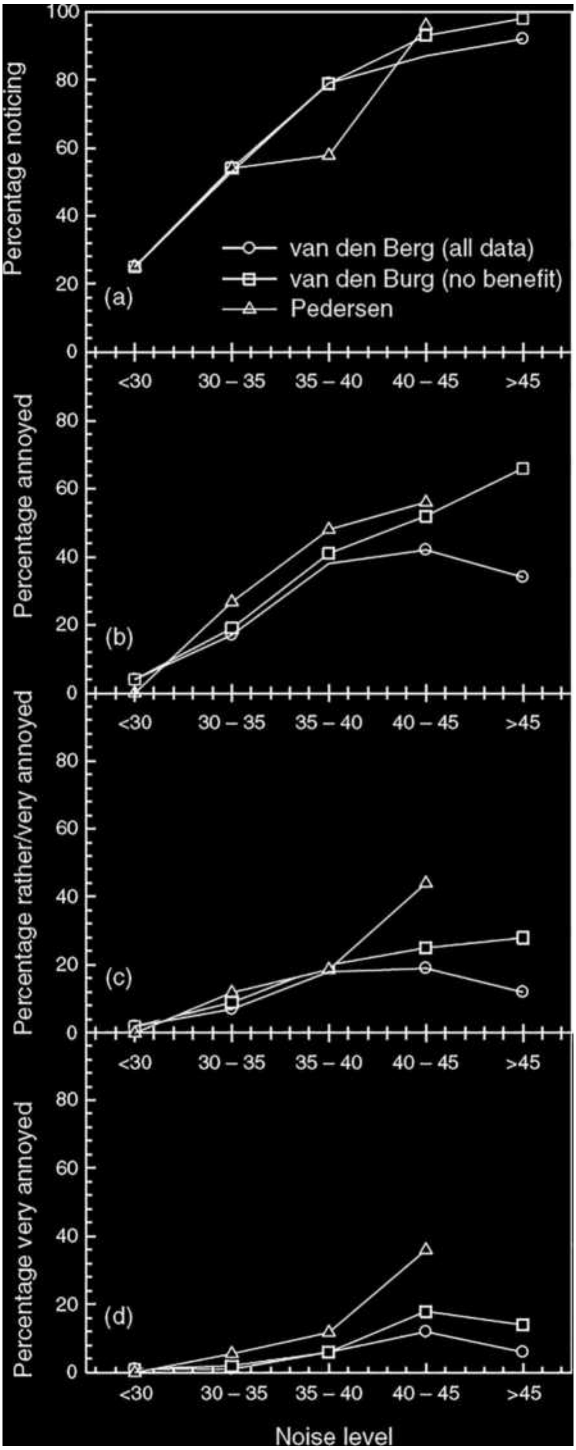

FIGURE 5 Perception of wind turbine noise as a function of noise level for three sets of data: Tables 7.25 (complete data set) and 7.26 (no economic benefit of turbines) from van den Berg et al.[8] and Pedersen and Persson Waye's[7] Table V. Plot (a) is percentage noticing the noise, while plots (b) to (d) are for annoyance. Plot (b) includes data from plots (c) and (d), and plot (c) includes data from plot (d).

levels elicited by wind turbine noises (e.g., swishing or thumping) may be explained by the increased fluctuation of the sound, up to 4 to 6 dB for a single turbine operating in a stable atmosphere.[11] Individuals are also highly sensitive to changes in frequency modulation variations of approximately 4 Hz or greater.[4] Noting that amplitude-modulated sound is known to be more annoying than unmodulated sound, Lee et al.,[34] in a laboratory setting, demonstrated that amplitude-modulated wind turbine noise was consistently judged to be more annoying than its unmodulated counterpart. Thus, the dominant acoustic driver of annoyance is likely to be noise dynamics rather than noise level. Other physical parameters linked to annoyance include terrain complexity, with rural terrain associated with greater annoyance than urban areas, possibility due to more complicated terrain exhibiting various focusing or defocusing effects and greater ground reflection.

While there is a strong correlation between the sound pressure level (i.e., amplitude) of a sound wave and the perceived loudness of a sound, there is no one-to-one mapping between sound pressure level and the psychological responses that individuals have to a sound.[35] Many non-acoustical factors determine how annoyed one will become toward a source of noise.[36–38] Thus, the response of the individual to the sound is just as important as the parameters of the acoustic wave, and the "people" side of noise should not be omitted from acoustical reports. Table 2 lists, in no particular order, non-acoustical factors found to influence levels of noise annoyance.[39] In relation to windfarms, the personal factors listed in Table 2 have been found to strongly influence how exposed individuals perceive the noise.[16] In addition, perceptions of amenity, individuals seeking refuge from urban noise, or the lower ambient sound levels typical of the rural environment may explain why annoyance responses are higher in rural as opposed to urban settings.[13,16]

When considering wind turbine noise and annoyance data emerging from the literature, a number of risk factors are evident, including an effect of age and educational status but not gender.[8] Employment status was also linked to wind turbine noise–induced annoyance in one study, possibly due to impeded restoration,[16] but to date, there are no data meaningfully comparing ethnicity or national groups (but see Pedersen et al.[40]). The general public view wind turbines as necessary but ugly,[14] and it is possible that the visual impact of a windfarm can interact with noise level to cause moderate annoyance. This amplification of annoyance is possibly due to a violation of the landscape soundscape continuum constructed by those who choose to live in areas that later contain windfarms,[41] or alternatively, multisensory engagement may enhance detection and identification of wind turbine noise.[42] The degree of influence of the visual aspects of windfarms has yet to be determined, with laboratory studies suggesting that it is wind turbine noise and not the visual impact that underlies the annoyance response,[41] while epidemiological studies suggest that the visual effects are nontrivial. [40]

TABLE 2 Non-Acoustical Factors Influencing the Degree of Annoyance to Noise

- Perceived predictability of the noise level changing
- Perceived control, either by the individual or others
- Trust and recognition of those managing the noise source
- Voice, the extent to which concerns are listened to
- General attitudes, fear of accidents, and awareness of benefits
- Personal benefits, how one benefits from the noise source
- Compensation, how one is compensated due to noise exposure
- Noise sensitivity
- Home ownership, concern about plummeting house values
- Accessibility to information relating to the noise source

Wind Turbine Noise and Sleep

The deleterious effects of noise on sleep and the consequences of sleep loss are well documented and are a major concern for governments.[43] In comparison with road, rail, and aircraft noise, there is little research on the effects of wind turbine noise on sleep. However, there is no doubt that wind turbine noise can and does disturb the sleep of those living nearby. Sleep disruption is the predominant symptom in the thousands of anecdotal cases reported in the press and on the Internet and is confirmed by more structured surveys.[25] The quantity, consistency, and ubiquity of complaints has been taken as *prima facie* epidemiological evidence of a causal link between wind turbine noise, sleep disruption, and ill health.[44]

Early investigations into wind turbine noise and sleep are difficult to interpret as researchers used imprecise outcome measures, generally relying on recalled sleep disturbances such as difficulty in initiating or returning to sleep, which tends to underestimate the magnitude of the noise impact and its consequences.[45] One of the earliest studies ($n = 128$) reported that approximately 16% of respondents living at calculated outdoor turbine noise exposures exceeding 35 dB L_{Aeq} stated that wind turbine noise disturbed their sleep.[7] A New Zealand study of 604 households within 3.5 km of a windfarm found that 42 reported occasional and 26 frequent sleep disturbance.[46] The largest wind turbine noise study to date, "Project WINDFARM- perception,"[8] concluded that turbine noise was more of an annoyance at night and that interrupted sleep and difficulty in returning to sleep increased with both indoor and outdoor calculated noise levels. Even at the lowest noise levels, 20% of 725 respondents reported disturbed sleep at least one night per month. In a meta-analysis[40,47] of three European datasets ($n = 1764$),[7,8,16] there was a clear increase in levels of sleep disturbance with dB L_{Aeq} in two of the three studies. In one study, an increment in self-report sleep disturbance occurred between 35 and 40 dBA, while in the other, it occurred between 40 and 45 dBA.

More recent research into wind turbine noise and sleep includes two studies reported by Nissenbaum, Aramini, and Hanning.[48] In the first, a pilot study, a structured questionnaire was administered to 22 subjects living 370 to 1100 m from 28 1.5 mW turbines and a control group ($n = 28$) living at least 4.5 km from the nearest turbine. The study group had clinically and statistically worse sleep disturbance, headache, vestibular symptoms, and psychiatric symptomatology. The second study, using validated questionnaires, administered the Pittsburgh Sleep Quality Index (PSQI), Epworth Sleepiness Score (ESS), and Short- form health survey (SF36) to 79 subjects living between 375 and 6600 m from two windfarms. Those living within 375–1400 m reported worse sleep, were sleepier, and had worse SF36 mental summary scores than those between 3 and 6.6 km from a turbine. Psychiatric symptom scores (irritability, stress, anger, hopelessness, and anxiety) were significantly greater, as was a composite mental health score. They were also more likely to report headaches, nausea (31.6% vs. 12.2%), and a willingness to move away. Modeled dose–response curves of both sleep and health scores against distance from nearest turbine (Figs. 6–8) were significantly related after controlling for gender, age, and household clustering. There was a sharp increase in effects between 1 and 2 km. This study is the first to use appropriate sleep outcome measures[45] and to use a control group. While the sample size is modest ($n = 78$), it is convincing evidence that wind turbine noise adversely affects sleep and health for those living within 1.5 km of turbines.

Mechanisms explaining the effects of wind turbine noise on sleep have been considered, but would benefit from further empirical support.[45] Noise of any description can interfere with sleep by preventing the onset of sleep either at sleep initiation or at the return to sleep after a spontaneous or induced awakening. The amplitude, character, and associations of the noise are all important as is the noise sensitivity of the individual and the psychological response to the noise. In this respect, wind turbine noise seems to be particularly annoying, possessing an impulsive nature with short bursts of low-frequency sound, making it audible 10–15 dBA below background level.[38,49] Nocturnal atmospheric stability ensures that wind turbine noise is maintained while ground level ambient noise diminishes. Indoor noise levels for most noise sources can be reduced by closing windows; however, the low-frequency

content of wind turbine noise means that it may be more audible indoors than outdoors. Additionally, during warmer months, windows are more likely to stay open to control thermal parameters, whence the inability to control or modify wind turbine noise will contribute to the annoyance and, presumably, the effect on sleep onset.[16]

Noise may also cause awakenings and arousals. Arousal is a brief lightening of sleep that is not recalled. Sleep becomes fragmented and, if enough arousals occur, induces the same consequences as reduction of total sleep time. Awakenings are arousals of sufficient degree for wakefulness to be reached and long enough (greater than 10 sec) to be recalled. Arousals are more likely than awakenings, and thus, relying on reported awakenings underestimates the magnitude of the noise effects. The likelihood of an arousal depends upon the volume, character, and duration of the noise as well as the sleep stage and individual propensity (i.e., noise sensitivity). In an investigation into hospital noise, dose–response curves were created for different noises in different sleep stages.[50] Noises with characteristics designed to alert (e.g., telephone, alarms) were more likely to arouse. These noises tend to be impulsive in character, as does wind turbine noise. Noises that were classified as continuous broadband noises (e.g., traffic noise) were less likely to arouse. Another study[51] has shown that subjects with fewer sleep spindles (electrophysiological markers characteristic of stage II sleep) are more easily aroused by noise (Figure 9). Sleep spindles are taken as a marker of sleep stability and may provide a physiological marker of sleep quality.

To date, there are no electrophysiological studies of wind turbine noise on sleep. However, it is reasonable to expect that, in common with road, rail, and aircraft noise, it will induce arousals, fragmenting sleep, as well as preventing the onset of and return to sleep. The sleep measures used in the study by Nissenbaum, Aramini, and Hanning[48] (i.e., ESS and PSQI) are average scores, determining sleepiness and sleep quality, respectively, over a period of weeks. Thus, occasional sleep disturbance would not alter scores as the sleep loss would have been compensated quickly over one or two nights. The study results imply strongly that sleep was being disturbed to some degree on sufficient nights to prevent compensation occurring, thus leading to persistent daytime symptoms.

Wind Turbine Syndrome

Wind turbine syndrome refers to a cluster of symptoms, which Pierpont,[24] who coined the phrase, claims are associated with exposure to wind turbine noise. Using direct clinical case studies, Pierpont describes the following symptoms to be characteristic of many individuals residing in close vicinity of wind turbines: insomnia, headaches, dizziness, unsteadiness, nausea, exhaustion, anxiety, anger, irritability, depression, memory loss, eye problems, problems with concentration and learning, and tinnitus. Pierpont hypothesizes that wind turbines may affect the vestibular system, that part of the inner ear that plays an important role in the maintenance of balance and stable visual perception. Wind turbines may compromise this system in two ways: first, by the visual disturbance of the moving blades and shadows (i.e., the flicker), and second, by direct vibration of the vestibular system. Such a model would explain why some residents in the close proximity of wind turbines (i.e., less than a kilometer) complain of vertigo, dizziness with nausea, and migraines. Wind turbine syndrome awaits further validation from the medical and scientific establishments, specifically the confirmation of a cause-and-effect relationship between wind turbine noise and vestibular function.

Wind Turbine Noise and Low-Frequency/Infrasound Components

Recent enquiry has focused on the impacts of low-frequency (20–200 Hz) and infrasonic frequencies (typically taken as below 20 Hz) being emitted by wind turbines. Infrasound is characterized by fluctuating pressure sensations at the eardrum, is atonal and countable, and is of a level proportional to wind speed.[21] Low-frequency acoustic waves emitted by wind turbines may be amplified by ground reflection and originate from varying lift forces as the rotors travel through spaces differing in wind speed and density.[21] Compared with medium (i.e., 250 to 4000 Hz) and high frequencies (above 4000 Hz), low-frequency energy decays slowly with distance, is less attenuated by conventionally designed structures, causes certain building materials to vibrate, and can sometimes resonate within rooms and undergo amplification. The effect of air absorption must also be taken into account, in which higher frequencies are attenuated at a greater rate as a function of distance, resulting in a shifting of the spectrum toward lower frequencies. The relationship between low-frequency wind turbine noise and building type creates an interesting proposition in which the low-frequency sound may be louder inside a dwelling than out,[21,52] and the assumption that walls and windows attenuate sound by 15 dB may not be applicable to frequencies below 200 Hz.

Research has shown that low-frequency noise increases cortisol levels in those who are sensitive to noise[12] and disturbs rest and sleep at levels below noise otherwise free from lower-frequency components.[31] Low-frequency noise and infrasound are known disturbers of sleep; however, the contribution, if any, of the low-frequency noise emissions of wind turbines to the sleep disturbances they induce remains to be scientifically determined. Beyond infrasound, the phenomenon of vibroacoustic disease is worthy of note. Humans chronically exposed to infrasound may exhibit elevated cortisol levels and generalized cell damage: a condition known as vibroacoustic disease.[53] A number of human and animal models explaining how infrasound can lead to cardiovascular and respiratory disease have been proposed[54] and applied to wind turbine noise.[55] The phenomenon of vibroacoustic disease is supported by correlational evidence coupled with a thoroughly detailed mechanism. However, further research is required to establish the veracity of this approach to human health within and beyond the wind turbine context.

Mitigation

There are multiple ways in which to reduce the impacts of audible and inaudible wind turbine noise. The first, and often the most effective, method is to control audible noise at the sound source. Thus, mechanical solutions invite technologies designed to attenuate wind turbine noise or to shift its spectral character in order to eliminate salient tonal characteristics. To safeguard health is more difficult, however, because wind turbine noise is largely aerodynamic in origin,[7] and it is not possible to obtain solutions that completely attenuate the noise at its source. Having minimized the noise through the implementation of technology, other approaches are often required, normally involving the application of noise standards to limit exposure levels or the determination of “safe” setback distances to mitigate noise impact. Still other approaches involve the positioning of wind turbines around preexisting noise generators,[15] in remote areas away from human habitations, or using social processes to determine wind turbine location.[27,56]

Regulating Permissible Noise Level

Permissible or safe exposure levels are often set in national noise standards, which may or may not be specific to wind turbine noise. These standards may serve one of two purposes, or sometimes both, with noise compliance guidelines naturally emerging from the two. The first purpose relates to methodologies for the physical quantification of the noise. This may involve standardized procedures for measuring noise from preexisting windfarms or detailing accepted mathematical models affording noise predictions of a planned windfarm. The second purpose is to determine what exposure levels can be considered safe and to clearly state criteria to this effect. However, there are a number of flaws inherent in wind turbine noise standards, including the metrics used to represent the noise, oversimplified modeling approaches that yield unrealistically low predictions of noise levels representing “best case” conditions,[5] or stimulus-oriented approaches that fail to account for human factors.[3,57]

There exists, in respect to levels-based noise standards, disagreement as to the relevance of physical measures such as dBA to human response,[58] not only for windfarm noise[14] but also for traffic and aviation noise. Of the few parametric studies that have been published,[7,8] only marginal dose–response relationships between wind turbine noise intensity and health measures have emerged. For example, Pedersen[22] noted that stress was not related to wind turbine noise level but rather noise annoyance.

Persson Waye and Öhtrsöm[12] reported that annoyance ratings varied for five distinct recordings of wind turbine noise, even though all five had equivalent noise levels. Others note that both laboratory and field studies have consistently found that the equivalent dBA measure fails to account for the relationship between wind turbine noise and annoyance.[14]

To some degree, then, it must be accepted that there is an uncoupling between wind turbine noise level and human response. A hitherto rarely measured characteristic of wind turbine noise is amplitude modulation, whereby noise levels fluctuate periodically as a function of blade passing frequency. Lee et al.[34] recommend that standardized metrics based on the modulation depth spectrum be developed and used in conjunction with sound levels. Other approaches to measuring amplitude modulation have existed for some time[4,59] but have yet to be seriously applied to the wind turbine noise context. However, the inability to account for amplitude modulation arises primarily due to the time-averaged dBA levels applied by noise standards, and arguably, smaller sampling epochs of around 100 msec should be adopted as best practice in order to record the amplitude modulation inherent in turbine noise.[60,61] The New Zealand Standard[62] applies a penalty for amplitude modulation, but does not describe an objective assessment. Furthermore, using aggregated metrics that average noise level over long periods underestimates the effect of peak levels and crest factors, important when considering sleep disturbance.

For the most part, the acceptable noise limits recommended by noise standards are derived from WHO guide-lines.[31,63,64] However, as Figure 10 demonstrates, using recommended noise levels from guidelines based on transport data risks exposing the population to unacceptable levels of noise. It follows that the Ldn (the “day–night” level in the United States) or Lden (the “day–evening– night” level in Europe) measures, derived from the measured LAeq sound level can be used in a wind farm context, but with caution.[65] Inspection of Figure 10 suggests that, relative to transport guidelines, at least a 10 dBA penalty should be placed on wind turbine noise. The differences in annoyance ratings between wind turbine noise and transport noise maybe accounted for by amplitude modulation, the typical location

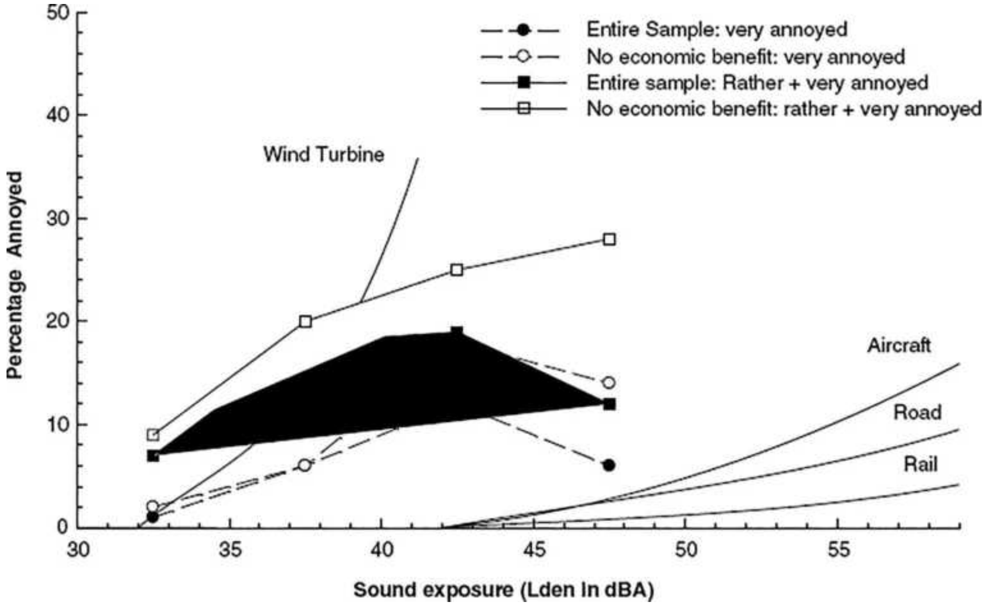

FIGURE 10 Annoyance plotted as a function of noise level for four theoretical models (rail, road, and air parameters: Miedema and Oudshoorm;[66] wind turbine parameters: Pedersen et al.;[7] and four sets of data obtained from Tables 7.24–7.26 of van den Berg et al.[8]). For the data, closed symbols are for the entire sample, while open symbols are for those who identified that they had no economic interest. Circles represent the percentage of “very annoyed” responses, while squares represent the sum of “very annoyed” and “rather annoyed” responses.

of windfarms (e.g., rural areas), or the over-representation of noise-sensitive individuals. A recent meta-analysis of three epidemiological studies revealed a consistent trend in wind turbine noise exposure and both annoyance and sleep disruption.[22] On the basis of her analysis, Pederson recommends that outdoor levels should not exceed 40 dBA, though this level could be more-or-less depending on situational factors, that is, ambient noise levels or the building's construction materials. When noise is continuous, the WHO[31] stipulates an indoor limit of 30 dBA, though for noises containing lower frequencies (e.g., wind turbine noise), a lower limit still is recommended. Thus, careful examination of the lower end of the frequency spectrum is important when judging appropriate exposure to wind turbine noise, and the use of dBC or spectral analysis in one-third octave bands or narrow bands is necessary.

In the comparison of global wind turbine noise level standards, there exist two chief methodologies, namely, sound levels not to be exceeded (usually in dBA) or a not- to-be-exceeded limit derived from the sum of the preconstruction ambient limit and a constant (e.g., L_{A90}+10 dBA). Critique of both these approaches can be found in Thorne.[3] The fact that noise limits differ between, and even within, a country is testament to the impoverished research database guiding their development or the political sensitivities around wind turbine placement. Examples of noise limits are presented in Table 3, and the variability in guidelines is evident. Based on the authors' collective experience, an interim guideline, providing a conservative noise limit capable of protecting the health of the public and susceptible individuals, would be a sound level of L_{Aeq} 35 dBA outside the residence and below the individual's threshold of hearing inside a residence. More specific guidelines are presented in Appendix A of this document.

Regulating Setback Distances

A setback distance is defined as the minimum distance between a dwelling and the closest wind turbine required to protect the health of the inhabitants. One difficulty is whether such setback distances can be standardized, as they will differ depending on a number of factors, including turbine type, terrain, and climate. Lee et al.[34] report that the perception of amplitude-modulated noise decreases with distances beyond a kilometer, though others claim that amplitude-modulated turbine noise can be heard up to 4km away from the source.[67] Setback distances maybe based on noise level, which, as

TABLE 3 A Comparison of Wind Turbine Noise Guidelines Taken from Nine Countries

Country	State	Limit (dBA)	Background Plus Constant
Australia	Victoria	LA90 35 or 40	LA90+5 dBA
	South Australia	LAeq 35 or 40	LA90+5 dBA
Australia	Queensland	LAeq 30 indoors	Health and well-being criteria
Canada	Ontario	LAeq 40 to 51	
Denmark		40	
France			Day: LA90+5 dBA Night: LA90+3 dBA
Netherlands		40	
New Zealand		LA90 35, 40	LA90+5 dBA
United Kingdom		Day: 40 Night: 43	LA90+5 dBA
United States	Illinois	Day: 50 Night: 46	
	Michigan	55	
	Oregon	35	

discussed in the preceding section, maybe an invalid approach. Instead, a better approach may be to link setbacks to turbine type. M0ller and Pedersen,[21] investigating the detection and annoyance of lower-frequency sound emitted from wind turbines, suggest that, for flat terrain, the minimum setback distance for modern turbines (2 to 3.6 MW) should be between 600 and 1200 metres. Other approaches rely on the establishment of dose–response curves relating a health outcome variable (e.g., annoyance or disturbed sleep) and distance (e.g., Figure 6). Medical professionals have proposed setback distances of 2.4 km[23,24] or 1.5 km.[45] Other research recommends a minimum of 2 km if wind turbines are sited in rough terrain.[3,20]

Conclusion

Windfarms have significant potential for sleep disruption and annoyance due to the intermittent nature and amplitude modulation of their sound emissions, even though exposure may be of low amplitude. The interactions between ambient levels, amplitude modulation, and the tonal character of windfarm noise overlaid within a soundscape are complex and difficult to measure and assess in terms of health and individual amenity. Additionally, currently employed sound level measurement and prediction approaches for complex noise sources of this nature are only partially relevant to environmental risk assessment. Aside from acoustic parameters, other factors such as noise sensitivity or amenity expectations may also predict the human response to wind turbine noise. Unfortunately then, for policymakers, there appears to be no proportional relationship between wind turbine noise levels and health, as these outcome factors will be influenced by characteristics associated with both the noise and the listener.[39]

As a relatively new source of intrusive noise, there is little research to draw upon when judging if a proposed windfarm constitutes a health threat to the exposed public. A liberal approach to assessing health impact will involve the application of previous knowledge obtained from other noise sources (e.g., road, aviation). A conservative approach, consistent with the precautionary principle, will consider wind turbine noise more potent than these other harmful noise sources. Thus, at this time, a constellation of acoustic and social metrics should be taken at preexisting wind farms in order to assess potential threat. Peak and crest noise levels, level metrics assessing low-frequency contributions (e.g., dBC), and amplitude modulation indices constitute the acoustic measures of importance. It should also be remembered that predicted levels derived from computer models represent estimates and not precise values, are constrained by numerous assumptions, contain substantial uncertainty, and as such should not constitute the sole criteria for wind turbine positioning. What form the social measures will take is yet to be elucidated, but research suggests that noise sensitivity[67] and procedural fairness[27] are the best approaches to minimize the health impacts and facilitate social acceptance of windfarms.

Acknowledgments

The authors thank Rick James of E-Coustic Solutions for sharing his acoustical expertise on the matter of wind turbine noise guidelines.

Appendix A

'Proposed Wind Turbine Siting Sound Limits', a revision by Thorne, R, of the Kamperman James criteria (2008) to include updates to ISO 1996-2 and U.K. Court of Appeal (Hulme re: Den Brook).

1. Audible Sound Limit
    a. No wind turbine or group of turbines shall be located so as to cause an exceedance of the preconstruction/operation background sound levels by more than 5 dBA. The background sound levels shall be the L_{A90} sound descriptor measured during a pre-construction noise study during the quietest time of evening or night. All data recording shall be a series of

contiguous ten (10) minute measurements. L_{A90} results are valid when L_{A10} results are no more than 15 dBA above L_{A90} for the same time period. Noise sensitive sites are to be selected based on wind development's predicted worst-case sound emissions in L_{Aeq} and L_{Ceq} which are to be provided by the developer.

- b. Test sites are to be located along the property line(s) of the receiving non-participating property(s).
- c. A 5 dB penalty is applied for tones as defined in IEC 61400-11 at the turbine and ISO1996-2 at any affected residence.
- d. A 5 dB penalty is applied for amplitude modulation as defined following. When noise from the wind farm has perceptible or audible characteristics that are perceived by the complainant as being cause for complaint, or greater than expected, the measured sound level of the source shall have a 5 dB penalty added. Audible characteristics include tonal character measured as amplitude or frequency modulation (or both); and tonality (where the tonal character/tonality of noise is described as noise with perceptible and definite pitch or tone). Amplitude modulation is the modulation of the level of broadband noise emitted by a turbine at blade passing frequency. Amplitude modulation will be deemed greater than expected if the following characteristics apply:
  - i. A change in the measured L_{Aeq}, 125 ms turbine noise level of more than 3 dB (represented as a rise and fall in sound energy levels each of more than 3 dB) occurring within a 2 second period.
  - ii. The change identified in (i) above shall not occur less than 5 times in any one minute period provided the L_{Aeq}, 1 minute turbine sound energy for that minute is not below 28 dB.
  - iii. The changes identified in (i) and (ii) above shall not occur for fewer than 6 minutes in any hour.

Noise emissions are measured outside a complainant's dwelling and shall be measured not further than 35 metres from the relevant building, and not closer than within 3.5 metres of any reflective building or surface, or within 1.2 metres of the ground.

2. Low Frequency Sound Limit
   - a. The L_{Ceq} and L_{C90} sound levels from the wind turbine at the receiving property shall not exceed the lower of either:
     - i. L_{Ceq} -L_{A90} greater than 20 dB outside any occupied structure, or
     - ii. A maximum not-to-exceed sound level of 50 dBC measured as the background sound level (L_{C90}) from the wind turbines without other ambient sounds for properties located at one mile or more from state highways or other major roads or measured as the background sound level (L_{C90}) for properties closer than one mile.
     - iii. These limits shall be assessed using the same night-time and wind/weather conditions required in 1(a). Turbine operating sound emissions (L_{Aeq} and L_{Ceq}) shall represent worst case sound emissions for stable night-time conditions with low winds at ground level and winds sufficient for full operating capacity at the hub.
3. General Clause
   - a. Sound levels from the activity of any wind turbine or combination of turbines shall not exceed L_{Aeq} 35 dB within 100 feet of any noise sensitive premises.
   - b. The monitoring shall include all the sound levels as required by these noise conditions and shall include monitoring for the characteristics described in Annex A of IEC 61400-11 including infrasound, low-frequency noise, impulsivity, low-frequency modulation of broad-band or tonal noise, and other audible characteristics. Wind speed and wind direction shall be measured at the same location as the noise monitoring location.
4. Requirements
   - a. All instruments must meet ANSI or IEC Class 1 integrating sound level meter performance specifications.
   - b. Procedures must meet ANSI S12.9, IEC61400-11 and ISO1996-2

   c. Procedures should meet ANSI, IEC and ISO standards applicable to the measurement of sound or its characteristics.
   d. Measurements must be made when ground level winds are 2m/s (4.5 mph) or less. Wind shear in the evening and night often results in low ground level wind speed and nominal operating wind speeds at wind turbine hub heights.
   e. IEC 61400-11 procedures are not suitable for enforcement of these requirements except for the presence of tones near the turbine.

5. Definitions

   ANSI S12.9 Quantities and Procedures for Description and Measurement of Environmental Sound, Parts 1 to 6.

   IEC 61400-11 Wind turbine generator systems—Part 11: Acoustic noise measurement techniques.

   ISO 1996-2 Acoustics—Description, measurement and assessment of environmental noise—Part 2: Determination of environmental noise levels.

   L_{A90}, L_{A10} Statistical measures calculated under ANSI S12.9.

   L_{Aeq}, L_{Ceq} Time average levels calculated under ANSI S12.9 or ISO 1996-2.

   Noise sensitive premises includes a residence, hotel, hostel or residential accommodation premises of any type.
